1. Tumefaction of medullary sheaths and axis-cylinders in certain bundles only, in all three divisions of the ganglion. 2. Tumefaction of axis-cylinders in a portion of the sensory root. 3. Numerous spaces in a portion of the sensory root, possibly resulting in part from degeneration of nerve-fibers. The sensory root, therefore, is not normal, and the condition in this root renders a return of the pain possible. 4. Quite intense degeneration by the Marchi method in the center and peripheral end of the ganglion and its peripheral divisions—a questionable change by this method in the sensory root.

The blood-vessels are not distinctly diseased, and no evidence is offered that the diseased condition of the nerve-fibers resulted from vascular degeneration. Neither do the nerve-cells, by the stains suitable to the method of hardening employed in this case, offer the slightest foundation for the theory of a cellular origin of tic douloureux.

MICROSCOPIC EXAMINATION OF THE SECOND GASSERIAN GANGLION REMOVED BY DR. CUSHING.

A description of this, if given in detail, would be very similar to that of the first ganglion.

First Division.—In some bundles the medullary sheaths are much swollen, and here and there a swollen axis-cylinder is found, especially in fibers cut longitudinally. An axis-cylinder may appear to be normal in one part of its course and swollen in another. The greater portion of the first division appears to be normal.

Second Division.—The condition of the second division is very similar to that of the first division. Some of the medullary sheaths and axis-cylinders are moderately swollen, but the greater number of nerve-fibers are normal. The small vessels contained within this division of the ganglion have thickened walls. The Marchi stain shows no distinct degeneration. This may partly be due to the hardening in formalin, for while this stain may be employed with formalin-hardened preparations the results are sometimes less successful than with Müller fluid preparations.

Third Division.—The third division is more altered than either of the other two; more nerve-fibers are diseased and the tumefaction of the medullary sheaths and axis-cylinders is greater. No alteration is detectable by the Marchi method.

Ganglion.—Most of the nerve-cells appear to be fully or nearly normal, but some are deeply stained and much shriveled. (Fig. 8.) The cells of the ganglion vary normally in the intensity of their coloring and size, but in the sections of this ganglion the cells which are shriveled are the ones most deeply stained by thionin. The ganglion was hardened in formalin soon after removal, and these shriveled cells can hardly be regarded as artefacts. Most of the cells extend to their capsules without leaving pericellular spaces, and the peripheral portion of the cells contains fewer chromophilic elements than the central portion, and these elements next to this clear peripheral zone are larger and more deeply stained than the others. We know, from v. Lenhossék's description of the cells of the spinal ganglion, that these cells of the Gasserian ganglion are normal. The nucleus is usually very sharply defined and central and the nucleolus deeply stained, but some nerve-cells are greatly shriveled and deeply stained, and in some the nucleus is peripheral. Some cells are also deeply pigmented.

Sensory Root.—The sensory root is normal.

So far as I know the condition of the sensory root of a ganglion removed for trifacial neuralgia has been reported in only two cases—one by Krause, and one by my-

self. Krause found the sensory root diseased and I found it normal. In Krause's case pain returned on the other side of the face. We can not say whether or not the occurrence of pain on the side from which the ganglion was not removed was caused by the diseased sensory root of the opposite side. In Dr. Cushing's first case the axis-cylinders of the sensory root were not normal. The tumefaction in these fibers was not excessive, and yet it was sufficient to lead me to believe that a recurrence of the pain in this patient is possible. I have examined the sensory root in three ganglia removed on account of prosopalgia, and only in this one case have I found this root diseased. When we remember that the sensory root of the fifth nerve passes to the sensory nucleus in the tegmentum of the pons, and that many of its fibers descend as the spinal root of the fifth nerve so low as the upper part of the spinal cord, we see that its fibers are distributed over a large area, and that when this root is diseased the diseased fibers are distributed over a considerable extent of the central nervous system. When the Gasserian ganglion is removed the cells in which this root arises are destroyed and the root probably degener-

Fig. 8. Oc. 3; Ob. 7. Atrophied nerve cells within the Gasserian Ganglion (method of v. Lenhossék).

ates throughout its length, and it probably loses the power of transmitting any form of irritation after removal of the ganglion. If the root is found diseased at the time of operation, it indicates that the degenerative process has extended centrally beyond the Gasserian ganglion, and the danger of a recurrence of pain is probably greater than when the root remains normal. It occurred to me that possibly the moderate tumefaction of the axones in the sensory root in Dr. Cushing's first case was produced by pulling on the root at the time of removal. The normal condition of the sensory root in the other two cases examined by me hardly permits such a theory. I have taken the sciatic nerve from a cat soon after death, and have forcibly pulled it apart, placed it in Müller's fluid, and examined the axis-cylinders, but I was not able to find the tumefaction of the latter. I fear, therefore, that we must regard the sensory root of Dr. Cushing's first patient as diseased.

In the second ganglion removed by Dr. Cushing the nerve-cells are diseased. This ganglion was placed in formalin and in its preparation the thionin stain of v. Lenhossék could be employed. V. Lenhossék has given

such an admirable description of the cells of the spinal ganglion in man that we know the appearance of cells of a normal Gasserian ganglion very well. Most of the cells in this second ganglion are normal, but many are intensely shriveled and deeply stained. It is difficult to believe that these cells are artefacts. The degenerated condition of these cells does not prove that the primary lesions of trifacial neuralgia are in the Gasserian ganglion. The diseased cells are not confined to any one part of the ganglion. Once of twice before I have referred to the investigations of Lugaro and others. These observers found that the cells of the spinal ganglion belonging to the sciatic nerve were much altered when this nerve in the dog was cut, but that no distinct changes in the ganglia were present when the posterior roots or the posterior columns of the cord were cut. Lugaro concluded that the cells of the spinal ganglion are altered in lesions of their peripheral processes, but not in lesions of their central processes. The peripheral process of the nerve-cell in the Gasserian or spinal ganglion has been compared with the dendritic process of the nerve-cell of the spinal cord, and the behavior of the nerve-cell of the ganglion after division of its peripheral process as compared with its behavior after division of its central process indicates that these two processes are of different functional importance. With these facts before us the alteration of many of the nerve-cells in Dr. Cushing's second case is no proof of the primary lesion being in the ganglion. The second division of the nerve had been resected six years previously. Whether the cellular alteration was due to this I can not say, but it is not probable that it was. In this second case the sensory root was normal. We should naturally expect to find many of the nerve-fibers of this root diseased where many of the cells of the Gasserian ganglion are diseased, but nerve-cells may be more altered than the axis-cylinders arising from them.

A Gasserian ganglion removed on account of trifacial neuralgia and examined by Head,³ by the Nissl method, was found to be normal, and the nerve-cells so perfect that they could be used as standard specimens of normal staining of the cells of the ganglion. It is a pity that Head does not give the details of this case. With this exception I know of no published report of the examination of the cells of the Gasserian ganglion by Nissl's method in a case of trifacial neuralgia.

In Dr. Cushing's first case the blood-vessels were not distinctly diseased. This would seem to indicate that in this case at least the process was not primarily vascular.

Recently two cases have been reported in which the Gasserian ganglion was removed and pain returned on the same side of the face (Friedrich,⁴ Garré⁵), but fortunately these cases are exceptions.

A PATIENT—a young girl—in a French sanitarium slipped into the water-closet and bolted the door on her special attendant, then hung herself with a strip of cloth. Her father sued the physician in charge of the sanitarium for negligence and, according to the *Gazette Méd. de Paris*, the courts have awarded him the amount of his claim, \$2000. He stated that he had called the physician's attention to the possible dangers of these retiring rooms, as his daughter had tried to commit suicide before.

SURGERY OF THE FIFTH NERVE FOR TIC DOULOUREUX.*

BY ROBERT ABBÉ, M.D.

SURGEON TO ST. LUKE'S HOSPITAL,
NEW YORK CITY.

It is the uniform experience of surgeons that there is no more fearful pain for a patient to endure than the persistent recurrence of what one of my patients always called "crashes of pain" in the side of the face. Its immediate, though transient, relief by simple section of the superficial nerves, is so much like the magic of art that it has been given as wide a trial as it ever should have. Brodie's reference to the "notorious failure of nerve section," in permanently relieving tic douloureux, echoed by Velpeau, Stromeyer and others of that time, is more emphasized to-day by accumulating experience. The accepted explanation of its failure, in that reunion of nerve channels is effected by natural laws of repair, has led to so many attempts to overcome this mischievous act of nature that we may now consider the success and failure of each and learn their relative values.

If the cause of pain is central, we may rightly assume that operation on the superficial nerve will not destroy the pain sense of the patient—hence it is useless. If the cause be peripheral, we must so far destroy the communicating channel as to prevent bridging over the gap by any reasonable reparative action. Hence the value of extensive resection of the nerve seems to be in direct proportion to its extent.

As the resection of the infra-orbital part of the second branch was replaced by Langenbeck's division on the floor of the orbit, and resection anterior to that, so the latter was displaced by Carnochan's more extensive resection from the foramen rotundum to the cheek. This latter has held its own with more recent methods and may now be fairly considered alongside of the Salzer and intracranial methods.

To speak of the Carnochan operation as "having been done" does not rightly justify the addition of many so-called cases in a statistical list, for like other difficult and dangerous operations it is possible to half do it by a bungling method, poor assistants; bad light, inadequate instruments or encountering very hard, unmanageable, posterior antrum walls.

I have had a case said to have had the operation done before, where I found much of the nerve still remaining. In my own experience I have found considerable inequality in extirpation of the nerve and branches. In judging of the value of methods, all who have had a varied experience may give weight to their personal views. In every field of surgery the statistical method is no more a criterion of value than what I would call the "personal impression" method. I do not hesitate to say, therefore, that the Carnochan operation, thoroughly done, holds a high rank with the deeper and more serious operations, and does not share their gravity.

In emphasizing the value of this operation on one branch only of the fifth nerve, I have often noticed that while the patient has designated the supra-orbital and lower maxillary branches as sharing the neuralgic pain, these two are as a rule at once and completely relieved by operation on the middle branch. Thus we can fairly ascribe much of the pain to reflex effect from some part of one branch to its neighbors. There is also a pain-

*Read in a Symposium on the "Fifth Nerve in Its Neurological and Surgical Relations," before the College of Physicians of Philadelphia, April 20, 1900.

sense, or pain memory, as we may call it, shown in some cases of aggravated and inveterate tic which lingers for a few days in occasional cases, no matter which method of operation has been adopted. Although the majority of operations give instant relief, the patient may complain of the old pain for as long as a week afterward, and then it leaves and he remains cured. This exhibition of persistence of pain I have seen oftener in those who had resorted to morphin. As a rule the morphin habit engendered by tic is entirely dissipated by operation.

My personal experience in operations on the fifth nerve's branches, excluding all those on the inferior dental and on the supra-orbital, includes somewhat more than twenty cases; but of that number only I have notes: intracranial (Hartley's method), 5; Salzer, 4; Carnochan, 11.

Seven patients were 60 years or more, 3 between 50 and 60, 3 were 32 years and 7 from 32 to 50 years of age.

There was but one death, that of a woman 63 years old, with severe tic. She had borne the Hartley operation well, with section and evulsion of the second and third branches. When I was about to close the wound the patient made two feeble attempts to vomit, and breathing and heart action ceased simultaneously. Every effort at stimulating and artificial respiration, even with the Fell-O'Dwyer respirator, failed to resuscitate her.

In reviewing the five intracranial cases, I find most gratifying material to report:

The first patient was a woman of 60 years who had been subjected to a Salzer operation two years before, and had recurrence in three months. The intracranial resection was done with much ease. The second and third branches were seized with forceps and evulsed from the ganglion after section at the foramina and forcing out the stumps. The patient was freed from pain and left the hospital on the eleventh day. Two months later she died of pneumonia.

The second case was a most aggravated one of eleven years, in a woman of 65. I operated it in 1895, by Hartley's method, evulsing the second and third nerves from the ganglion. The woman was at once relieved and remains absolutely free from pain and in good health, approaching five years from the operation (letter received yesterday).

The second patient was a frail woman who had suffered for two years from severe trifacial neuralgia extending even to the neck; the operation was done after the usual Hartley method, and this is the case spoken of previously as a death under anesthesia, from fatty heart or shock.

The fourth, a man, aged 46, had become distracted almost to suicide by inveterate trifacial neuralgia of three years' standing. In July, 1896, I resected the intracranial portion of the second and third branches, between the ganglion and foramina; the operation was suspended on the first day, on account of grave hemorrhage on every side, while exposing the ganglion. The packing was removed the second day and dissection continued; again profuse bleeding and packing of the wound. At the third attempt, excellent exposure of the nerves was obtained, and each being grasped by a broad clamp was cut off and then evulsed from the ganglion, only half an inch being torn out, but with profuse bleeding, which again required packing. When the hemorrhage was controlled, an attempt was made to curette away the Gasserian ganglion, but again bleeding forbid it.

NEW METHOD OF OPERATING.

Fearing that the nearness of the nerve stumps in the canals to the torn Gasserian might allow restoration of function and pain, I interposed a piece of sterilized gutta-percha tissue, more than one inch long and half an inch wide, which more than covered both foramina. This I pressed down by an iodoform-gauze strip, which was continued so as to compress all bleeding. In twenty-four hours—fourth day after initial operation—the gauze was removed, the rubber was seen to be pressed flat on the bone and the brain allowed to settle down on it. Primary union occurred, and now, after four years, the patient remains in perfect health, retaining the rubber as left at operation. The anesthesia in his case is shown in the illustration, from a photograph taken some months afterward, when reporting his case (Surgical Society, October, 1896).

Violent tic douloureux—3 years. Hartley operation; second and third branches excised; rubber tissue interposed. Remains well after 4 years. Dotted surface shows anesthesia; vertical lines, partial anesthesia.

The fifth intracranial case is also one of the same class, but in a woman of 61, who had suffered in the gravest way for twenty-four years. All trigeminal branches were affected and there was tenderness on pressure over the external foramina, with constantly repeated shocks of pain. I did the intracranial operation in July, 1897, and resected only the portions of the second and third divisions, between the foramina and the ganglion. I made no attempt to evulse or disturb the ganglion. The hemorrhage was slight and I carefully interposed a sterilized gutta-percha tissue layer between the Gasserian and bone, so as to more than cover both openings. Primary union of the wound and instant and permanent relief followed. At this date—nearly three years after—I have examined her and find perfect health and no trace of pain. Anesthesia remains as after operation.

Thus, in the five intracranial cases, three remain cured, after the lapse of three, four and five years.

I have operated on four cases after the Salzer method.

The first was a woman of 60 years, operated on in June, 1893, with most satisfactory resection of portions of the second and third branches at the foramina rotundum and ovale. Recurrence of pain occurred in three months, and she was subjected to the intracranial method (Case one).

The second patient, a woman of 50, had been suffering for five years and was relieved for 1½ years after

my operation. Recurrence was in a moderate degree only, and I have never cared to subject her to the intracranial operation, on account of her general weakness and digestive disturbance.

The third case was in a lawyer, aged 32, who had suffered for ten years and had three operations on his inferior branch, by Halsted and Hunter Maguire, with relief a few months only after each. I did a resection of the second and third branches at the foramina retundum and ovale, by a modified Salzer operation, two years since, with instant and permanent relief. I interposed a piece of sterile rubber tissue also in this case, between the resected ends of nerve in the sphenomaxillary fossa, and it remains there after two years.

The fourth case was in a man of 52 years, who had been suffering five years on the right side. A modified Salzer operation was done, with clean excision of a portion of the second and third branches at their exit from the skull. There was immediate relief and he has had not a twinge of pain since then, two years after the operation.

By the Salzer method there were no deaths. By the modified Salzer, adopted in two cases, I found it easy to expose the nerves in the sphenomaxillary fossa, by splitting the temporal muscle fibers vertically, without cutting the coronoid process, simply dividing and depressing the zygoma. When stretched by retractors, ample space was afforded and the coronoid could be lowered by opening the mouth at the same time. Thus the partial ankylosis following the usual Salzer method was avoided.

THE CARNOCHAN OPERATION.

This has been rather a favorite with me and represents 11 of the 20 severe cases operated on. Two patients were 32 years and 4 about 60 years of age; the others ranged between. I have been able to follow 8 of the 11 cases; 1 remains cured after twelve years; 1 after ten years; 1 died after six years, cured; 1 remains cured at five years; 2 remain well after one year; 1 was not relieved even by subsequent operation by Dr. Keen (case reported of Gasserian ganglion); 1 remained well at two years, when he was lost sight of; 3 were relieved and lost to view.

The possibility of thorough removal of the nerve behind the Meckel's ganglion is well shown in the specimen passed around, where the two filaments going to that ganglion are shown.

I have been interested in noticing cases of previous operation for removal of a large branch, that the foramen of exit closes when of no further use. Thus the mental foramen soon wastes to the size of a pin-point after the removal of the inferior dental nerve.

The anesthesia following Hartley's, Salzer's and Carnochan's operations is interesting. The removal of the second and third branches inside the skull leaves the half nose, cheek and upper lip only numb, but not completely anesthetic, as is the rest of the face, owing to a nasal branch of the ophthalmic, which covers the same distribution as the orbital branch of the superior maxillary, which comes off between the external and internal foramina. When the Salzer incision is made, this branch escapes and the nose, cheek and upper lip are often fully sensitive.

In conclusion, my experience leads me to advocate a thoroughly done Carnochan operation, with clean resection of the second branch to the foramen retundum, for most bad cases, even when the first and third branches seem to share the neuralgic shocks. The lat-

ter are usually relieved by operation on the middle branch. If one chooses to do the Salzer, which has some advantages in being less severe than the intracranial and more thorough than the Carnochan method, then I advise a section of the zygoma turned down with skin, and a muscle splitting of the temporal rather than coronoid section. If the intracranial method is adopted, as it must be in many grave cases, I advocate the simple section and limited excision of the second and third branches from the Gasserian to the foramina, and interposition of a piece of sterile rubber tissue, impermeable and non-conducting, adequate to cover both openings. I see no reason for believing that the resection of the Gasserian ganglion is necessary to the thorough severance of nerve connection with the brain. This step may be the greatest element of danger and, unless a tumor of the ganglion exists, is uncalled for. If a tumor exists it seems useless. In most cases of inveterate tic a chronic neuritis exists, usually of the middle branch. Hence the quick and permanent cures which we are able to record by excisions anterior to the Gasserian ganglion. 13 West Fiftieth Street.

NATURAL HISTORY OF TIC DOULOUREUX, WITH REMARKS ON TREATMENT.*

BY CHARLES L. DANA, M.D.

NEW YORK CITY.

If we hope to judge wisely as to how much good certain forms of treatment do for tic douloureux, we must know its natural history, which is not yet very fully understood. For though the disease is common, its origin is often unexplainable and there is none in which so much desperate effort is made to break up the course of the attacks and interfere with the natural symptoms. I have thought, therefore, that I could serve the purposes of this discussion best by devoting a good part of my time to this side of the subject.

It is one of the advantages of somewhat mature years that we are able to take a wider view of the course and of the history of the diseases as shown in our patients, and I have been able to make a close study of a number of my own cases from the beginning to the end. What I have to say now is based very largely on the recorded history of over fifty cases of tic douloureux, some of which I have had under observation for from five to ten years, and most of which I know the entire history of from the outset.

Pathogenesis.—Tic douloureux is, as I understand it, a degenerative neuralgia occurring in the great majority of cases, at or after the middle period of life and due to a degenerative change, sometimes amounting to neuritis, in the nerve and its ganglion, and probably in the blood-vessels which supply it. It attacks women¹ about twice as often as men, taking the whole period of the disease, but it rarely attacks men before the age of 40. I have seen only three cases of this kind of tic douloureux in a man under that age, whereas there have been ten women in whom the disease began under that time. Thus, it may be said to be at least three or four times as frequent in women under 40 as it is in men.

There is rarely any distinct hereditary taint, still, I have had one patient, aged 46, whose father suffered from the disease at the same time. In another patient

*Read in a Symposium on the "Fifth Nerve in Its Neurological and Surgical Relations," before the College of Physicians of Philadelphia, April 20, 1900.

¹As to sex, among 57 cases there were: males, 20; females, 37. Under 35 there were: males, 3; females, 10. Over 35: males, 17; females, 27. Ages at onset of disease: 20 to 30, 5; 31 to 40, 7; 41 to 50, 7; 51 to 60, 17; 61 to 70, 15; 71 to 80, 5; 81 to 90, 1. Side affected: right, 22; left, 14.

the grandmother had tic during her old age, and in a third the mother also had it. The most common neurosis found in the family is that of migraine, but this is so common generally that it can hardly be said to count in the personal history.

The most common previous nervous disorder in the patient, however, is also that of migraine, which I find in one-fourth of my patients. A common exciting cause is some overwork or strain. (14 per cent.)

No doubt many have observed that the initial disease begins as an acute trigeminal neuritis associated with herpes. This was the case in six of my patients. This fact of an initial herpetic neuritis is one of much importance as pointing to the origin of the disease in some cases from an infection causing a distinct peripheral neuritis. In a number we find that the cause is a local disease of the gums or tooth. In about 20 per cent. then there is an initial neuritis or local disease. I have also seen it start as the result of la grippe in three cases, and of exhausting hemorrhage in another.

Tic douloureux is, in the vast majority of instances, a disease of the second or third branch of the trigeminal nerve. It is extremely rare for it to begin in the ophthalmic, or remain localized in that branch alone, whereas it often affects the second and third branch alone for a long period of time. Among forty-five chronic cases I find only one instance in which the trouble was confined alone to the first or upper branch of the fifth nerve.

Types.—Cases which begin in women in early life have always been a puzzle to me, and I have always been doubtful as to their true character, although they do eventually seem to assume the type of a true tic. In carefully studying my own histories, it seems to me that these early ones are to be explained in this way: The patients are almost always young women suffering from migraine, and their trouble is preceded by frequent attacks of this trouble. After a number of years this migrainous disorder seems to become chronic and in a measure localized. It then settles in the second or third, or perhaps all three branches of the nerve. Such patients have, however, in addition to the sharp pains along the course of the nerve, diffused pains involving the head and often each side of the face. Cases that develop at the degenerative period of life are rarely associated directly with migraine, although one often gets a history of some migrainous trigeminal neuralgia, or attacks of migraine occurring early in life. The malady, however, often seems to settle down on the nerve as the result of the exciting causes already referred to, although referring to no particular predisposing neurosis.

I am disposed, in view of the facts referred to, to think that there are at least two particular and distinct types of tic douloureux, not including the purely symptomatic pains due to extra-neural disease.

The first I should call the migrainous type of early life, and I consider it an evolution of a definite trigeminal neuralgia on the basis of a migrainous neurosis. It is seen oftener in women. The trouble is originally central and not a disease of the Gasserian ganglion. Later it is possible that the fibers of the trigeminal nerve, through some inherent defect, incur degenerative changes and a true degenerative neuralgia develops. But it is to be borne in mind that in the early stages at least there is very little real disease in the fifth nerve. It is a disorder of the central sensory neuron.

The second type is the more common one, occurring after the age of 40 and affecting men at least half as often as it does women. Here the disease sometimes

starts as a true infective neuritis in the form of a herpetic or ascending neuritis, due to some local disease of the gums or the antrum, or the osseous tissues. Some of these herpetic forms run an acute course, lasting only a few weeks or months, and are easily cured.

Tic douloureux is sometimes purely symptomatic of local disease of the bone, of a tumor, etc.

Natural Course.—The natural course of these different forms of neuralgia is somewhat as follows: The persons who suffer from migrainous tic in early life, finally localizing itself as a true tic, rarely get cured, but have a long and tedious period of suffering. The prognosis is more unfavorable than that of ordinary migraine; however, like the latter, under exceptionally good constitutional conditions, periods of long remission occur, and sometimes the trouble spontaneously disappears. This tendency to disappear is probably somewhat increased after the age of 50, just as is the case with migraine, and I have a patient in whom the whole trouble disappeared at this age, after she had had a tic for twenty-nine years, the cause of the cure being asserted to be "Christian Science."

These cases also of the migrainous type, so far as my experience goes, are made worse by the ordinary operations for tic. I do not know what the result of the removal of the Gasserian ganglion would be in such early cases, but I have never seen any cures from the other minor surgical operations, although I have had a number of patients who have had these made on them at different times. Such operations may give temporary relief, but not always. Patients of this class are ill adapted for operation, because the trouble does not lie exclusively in the trigeminal nerve, but also in the central nervous system.

Of the second class of patients the natural history is more definitely known. Among seventeen cases of which I have definite histories from beginning to end, in seven the disease has stopped or has been cured. In six others it has been improved and kept under control, while in four its progress has not been affected by anything that has so far been done. Thus it appears that in at least 20 per cent. the disease is amenable to treatment or is relatively benign.

In these cases in which the trouble has been relieved entirely for a period sufficiently long to feel that it is practically under control, one attributes this relief to animal magnetism, two to operations, three to the minor operations of removing the tooth and washing out the antrum, one to "Christian Science" and the remainder to various measures, mostly the use of strychnin, tonics and rest or the natural course of the disease. With two exceptions all the cases which were relieved or cured occurred in persons in whom the trouble began after the age of 40, and in whom it had been lasting for not more than eight years, the average being about four.

The average duration of the disease, in which the malady stopped or was brought under control without any very definite or special medical treatment, was about five or six years, and my conclusion is that tic douloureux, beginning in persons at the age of 40 or over, has a natural tendency to run its course, this course ranging from five to twelve years. It usually reaches its height at the fifth or sixth year, and then has a tendency in some cases to spontaneous cure. The duration* of non-curable forms may be the even life of the patient. I have seen cases in which the duration was twenty-nine

* Duration of cases: cured or well-controlled without surgical measures—At 55 to 60, 5 years; 64 to 72, 8; 55 to 59, 4; 66 to 69, 3; 61 to 64, 3; 21 to 50, 29; 60 to 66, 5; 57 to 61, 4; 58 to 61, 3; 58 to 63, 5; 61 to 71, 10; 82 to 88, 6. Side affected: right, 22; left, 14.

and thirty-two years, others where it lasted twelve, seventeen and eleven.

One of the most characteristic features in the natural history of tic douloureux is its tendency to remissions. These occur for periods of one or two months, but they can be artificially produced by various methods of treatment. The surgical treatment will usually produce a remission of one-quarter to one-half a year; the medical treatment will often produce remissions of from six to ten months. These can be renewed by further systemic therapeutics. After the disease is long established, however, i. e., after six or seven years, there is apparently no measure, except a surgical one, which will absolutely and surely stop it. The surgical operations, except those for the removal of the Gasserian ganglion, produce only temporary remissions; all the medical measures have the same effect. As to the relative efficacy of the two measures, I can say, without any bias, that in most cases we can secure a remission by the medical measures almost as certainly as we can by surgery, except by the major kind. No drugs, however, and no surgical operation will arrest the disorder permanently. They will only lengthen the remissions and perhaps shorten the course.

It is perhaps known that for some years I have advocated a systemic treatment for tic douloureux, by means of heroic doses of strychnin. After experimenting with this method of treatment for now over six or seven years, and including about fifteen cases, I have reached this conclusion regarding it: In early cases of this kind, that is to say in the first and second years, the strychnin treatment will almost invariably arrest or control the disease in anemic and exhausted patients. In cases that have lasted over six or seven years, and in those with neuritis and sclerosis, the result is doubtful, and there may be a failure to secure even a remission. In anemic ones, however, even of long standing, it is often more effective, though relapses will occur. Among fifteen cases I have had only four distinct failures. In the very old cases, lasting fifteen or twenty years, medical treatment is practically valueless, no matter what is done.³

I have few favorable statistics to report of the results of surgical operations. I have seen absolutely none in which these succeeded in curing the patient, although one of my cases included that of a patient in whom the Gasserian ganglion was removed. I have seen operations, however, produce remissions lasting for two years. I have, as already stated, had three patients in whom the trouble ceased after the tooth had been removed and the antrum washed out. In no case have I known relief by the removal of teeth, or at least nothing more than temporary relief. Among 42 cases, 11 had had 24 operations, with no permanent cure in any case. One only was that of removal of the Gasserian ganglion.

As to the general matter of treatment it is better to record experiences than opinions. I have seen one case apparently helped by the opium treatment; but it is dangerous and not usually effective. Three of my patients had become opium habitues. Three patients, after long courses of medical treatment, and in one instance after an unsuccessful operation, were cured by removal of a tooth and washing out the antrum. In another this did no good. One patient thinks she was cured by animal magnetism, and one by "Christian Science." Remission followed in one case after prolonged use of the static breeze an hour daily for two months. This I believe was purely a natural remission. One patient had her ovaries removed with the result that the

face was worse and she had a vaginal neuralgia.

I have seen little good result from aconite or from any of the benumbing or narcotic drugs. Medical treatment is most successful which is addressed to the arthritic state, when that exists, and to the arterial sclerosis and gouty taint. In some of this latter, men of full habit and hard arteries tonic measures do harm and after a course of rest and arteriosclerotic or neuritic measures, surgery should be promptly applied. All measures will be more effective if applied at the beginning of the disease, and again at the fourth or fifth year when the trouble is at its height; or again at the period of the climacteric in those whose neuralgia began relatively early in life.

In conclusion, therefore, I should say that the early forms of tic douloureux, such as I have called a "migrainous tic," occurring usually in women, should not be operated on. There are some exceptions to this, however, in which tic douloureux occurs in early life, due to a distinct local disease, such as an inflammation of the nerve, or of the antrum, or of the jaws. In true tic of the degenerative period of life, prompt medical treatment will usually control the disease and operation is rarely indicated at first. In tic which has lasted three or more years, it may be safely said to the patient that medical treatment may produce a remission and that this remission may be repeated and that eventually the disease may be controlled by repeated treatments, but this is not at all sure. It may be said here too that a minor operation may give more relief than medical treatment. The question of prescribing major operations must be decided in each individual case, on its special merits.

TABLE SHOWING DURATION AND TREATMENT OF 42 CASES.

1. Male. Duration, 55 to 60; spontaneous cure.
2. Male. Duration, 64 to 72; strychnia; relieved; eight months relapse; cured for 3 years by removal of tooth and washing antrum.
3. Female. Duration, 55 to 59; 3 operations; no relief; strychnia; remission 6 months; strychnia; remission 8 months; cured—animal magnetism 10 months.
4. Female. Duration, 66 to 69; strychnia; improved—fairly well 2 years.
5. Male. Duration, 61 to 64; strychnia; relieved 1 year; slight remission; relieved 2 years.
6. Female. Duration, 21 to 50; strychnia; no result; cured by washing out antrum and Christian Science.
7. Female. Duration, 60 to 68; strychnia; relieved; remission; cured by washing out antrum; patient took morphia.
8. Female. Duration, 57 to 61; strychnia; relieved; disease controlled 2 years.
9. Male. Duration, 22 to 31; operation; relieved for 2 years; return.
10. Male. Duration, 31 to 33; strychnia; total failure; operation; no return in 1 year.
11. Female. Duration, 58 to 63; strychnia; relieved; disease controlled 2 years.
12. Female. Duration, 68 to 71; strychnia; relieved 6 months; remission; relieved again; disease still under control.
13. Female. Duration, 52 to 58; strychnia; relieved for 1 year; strychnia; no relief; patient lost sight of.
14. Female. Duration, 55 to 57; strychnia; relieved for 8 months; relapse?
15. Female. Duration, 31 to 47; strychnia; slight relief.
16. Male. Duration, 31 to 35; static electricity; remission 2 months; static electricity; remission 6 months; static electricity; remission 2 months; operation; no relief; strychnia; remission 4 months; strychnia; remission 4 months; return.
17. Male. Duration, 61 to 63; strychnia; no relief; disease still continues.
18. Female. Duration, 25 to 65; 3 operations; no relief; strychnia; no relief.
19. Female. Duration, 30 to 44; 2 operations; no relief.
20. Female. Duration, 45 to 52; strychnia imperfectly given; no relief; disease disappeared; patient suffered from melancholia.
21. Male. Duration, 50 to 62; operation; no relief; 3 other operations; no relief.
22. Male. Duration, 31 to 40; no regular treatment; patient somewhat better.
23. Female. Duration, 65 to 72; 2 operations; no relief; strychnia; no relief.
24. Female. Duration, 24 to 42; not heard from.
25. Male. Duration, 46 to 48; strychnia; somewhat improved.
26. Female. Duration, 25 to 28; relieved without any special treatment.
27. Female. Duration, 45 to 52; morphia.
28. Female. Duration, 30 to 40; nasal pain.
29. Male. Duration, 58 to 67.
30. Male. Operation; relapse.

³ The details of the technique of this method are given in full in the Post-Graduate, July, 1896, and in the 4th edition of my Text-book of Nervous Diseases.

31. Female. Duration, 82 to 88; 2 operations; relief 4 months; operation; no relief; medical treatment 6 months; pain ceased; patient died 4 months later of old age.
 32. Male. Duration, 33 to 43; strychnia; relief.
 33. Male. Duration, 51 to 54; strychnia.
 34. Male. Duration, 50 to 60; strychnia; relieved.
 35. Male. Duration, 39 to 47; operation; relieved 1 year; strychnia; improved.
 36. Female. Duration, 66 to 68; strychnia; relief.
 37. Female. Duration, 60 to 65; general medical treatment; relief; lost sight of.
 38. Female. Duration, 53 to 56; medical treatment; relief.
 39. Female. Duration, 55 to 60; medical treatment; lost sight of.
 40. Male. Duration, 55 to 61.
 41. Female. Duration, 71 to 75.
 42. Female. Duration, 23 to 35.

OPERATION FOR EXSTROPHY OF THE BLADDER BY SONNENBERG'S METHOD.

BY J. RILUS EASTMAN, M.D.
 INDIANAPOLIS, IND.

In January, 1899, a classic case of exstrophy of the bladder in a boy 13 years of age was brought to the writer's notice. The condition of the kidneys was such that rectal implantation of the ureters as a means to relief was not to be considered. The urine discharged from the left ureter contained crystals of the salts of urates and phosphates in great abundance, blood casts, epithelium and epithelial and granular casts. Traces

FIG. 1.

of albumin were also present. The urine from the right kidney was much clearer, of very little more than normal specific gravity, and contained a few granular casts and some epithelium. There was continual pain in the left lumbar region.

In view of these facts, the Sonnenberg method was chosen as the one most suitable for application in this particular case. The operation was made in February, 1899. It consisted in the detachment of the ureters from the extroverted bladder mucosa, and implantation of these into a groove made by a median sagittal incision on the dorsum of the dwarfed and clubbed epispadic penis. The raw and exquisitely sensitive bladder mucosa was cut away and the margin of the defect drawn snugly together and sutured about the two ureters as they coursed over the cartilaginous symphysis pubis.

The left ureter refused to heal in its new position. It became so engorged with inorganic deposits as to become almost pipe-stem-like in consistence, and gangrene of the exposed portion of this ureter developed promptly. There seemed to be no alternative but to remove the left kidney, and this was done. The remaining kidney has since—one year has intervened—discharged the extra

FIG. 2.

work imposed on it, without evidences of serious disorganization. Its condition at present is in no wise worse than before operation. The site of the extroverted bladder is now represented by a tough scar. Several futile attempts were made before the urinal shown in Figure 3 was finally constructed. As will be seen, it consists of a semispheroidal cup with a supplementary sacculatation at

FIG. 3.

its lower margin, extending slightly backward over the perineum. The margin of this cup fits accurately against the pubic and supra- and infra-pubic skin, and is made soft by a thin rubber rim. An ordinary rubber urinal is attached to the cup by a double rubber tube. A spiral wire is placed in this tube to prevent kinking. A valve is inserted in order that the urine may not be

thrown back into the cup by compression of the rubber tank. This urinal neither leaks nor causes pain. No urine whatever escapes, while the patient is in the standing or sitting posture. In the dorsal recumbent posture there is no leakage, but when the patient lies on the side there is an escape of a few drops per hour. A small opening near the upper margin of the cup effectually prevents the passage of air through the valve into the rubber tank. The presence of this opening is very essential; for without it air, which finds its way into the cup under the rubber rim, would be forced through the valve into the rubber tank, thus encroaching on the latter's capacity for containing urine. It is not the writer's purpose to discourse on the respective merits of the various operative methods for the relief of exstrophy of the bladder, but he wishes it to be understood that the operation of Sonnenberg is not presented by him as a substitute for the Maydl operation of rectal implantation. It can not but be conceded that Maydl's method has its distinct indications. Given a case of bladder exstrophy with a robust general constitution and sound kidneys the method of rectal im-

FIG. 4.

plantation must present itself for serious consideration as the only procedure by which the patient can be brought to a condition of passing comfort and happiness. Albert, Roux, Simon, Holmes, Lloyd, Boari, Allen, Hertz, Rudygier, Trombetti, Rosenoiti and Frank have all made successful implantations into the flexure coli, and Krynski, Vignoni, Pisani, and Fowler have made rectal implantations, each by his own method. Maydl's record is undisputably good. The dangers of ascending pyelonephritis seem to have been distinctly reduced by his precautionary removal of the bladder wall flange containing the valve-like openings of the ureter into the *caum vesicæ*, and the dreaded proctitis seems to develop only rarely.

In cases of *ectopia vesicæ*, however, presenting un-sound kidneys, Sonnenberg's operation in the light of present knowledge is certainly the one of choice. Its simplicity of execution is notable. It accomplishes all that can be accomplished by tedious flapping methods in much less time. The patient depicted enjoys very good general health. He attends school regularly and is apparently unhampered in play and work, by his deformity.

VISION AND COLOR PERCEPTION FOR RAILWAY SERVICE.*

BY WM. C. BANE, M.D.

OCULIST AND AURIST, C. R. I. & P. B'Y.
DENVER, COLO.

At the last meeting Dr. Pritchard favored the Academy with an article on the "Physical Examination of Railway Men," which included the test for vision and color perception. In the discussion that followed, many valuable points were brought out, and in considering the vision and color perception for railway service I must necessarily repeat some of the facts mentioned at that meeting. For efficient service it is essential that those who give and receive signals have normal vision and perfect color perception.

At the present time no uniform standard exists among the various roads that require applicants to pass an examination previous to entering their service. Their standard varies from a high to a low one. This is not as it should be, for there ought to be a uniformly high standard for physical examination, vision, and also some uniformity as to the colored yarns, flags and lights used. The vision for enginemen should be 20/20, or normal, with each eye, without the aid of glasses, and they should have normal refraction when entering the service. Those who serve as station agents, conductors, brakemen and switchmen should have vision of 20/20 with one and not less than 20/30 with the other eye, without glasses, and be free from hypermetropia of more than one diopter, on entering the service. Enginemen who have been in the employ of a company for five or more years and have proven themselves competent and trustworthy should be retained, everything being equal, if their vision with one eye is 20/20 and the other 20/40, without glasses.

It is a serious question as to what should be done with a trusted engineer, who has been in the service of a company for many years and become thoroughly familiar with his route, when his hyperopia becomes absolute and impairs his vision for distance. It does not seem just that such an employee should be laid off, when, with the aid of glasses, he is better qualified than a new man without them. Certainly the personal equation should be considered. In deciding on what shall be done with such an employee, the chief surgeon or oculist should have the right to grant some leeway and retain such a one, though he fall somewhat short of the standard properly established for new men. There are serious objections to allowing an engineer or fireman to wear glasses for distant vision. The lenses become dusty, and in cold or stormy weather the moisture will accumulate and blur the vision. Should the glasses become misplaced, the employee may for the time be disqualified for service. Some companies grant old employees the privilege of wearing glasses, while others refuse to permit their use. Without the permission to wear them we must say to the faithful employee: "Thou art weighed in the balances and found wanting." Glasses should be permitted for near vision, with which No. 2 Jaeger type can be read at fourteen inches.

Shall re-examination be required? Most certainly! As it has been clearly demonstrated that the eyes do change, they should be re-examined at regular intervals of from two to four years, and always after an attack of serious illness or accident. The difficulty regarding glasses, which would ultimately be required, is suffi-

*Read before the American Academy of Railway Surgeons, Omaha, Neb., Oct. 12-13, 1899.

cient reason for considering the refraction as well as the acuteness of vision of each new applicant for railway service. As a precautionary measure the pupillary reflexes and fields for form should be tested.

Dr. Williams of Boston, in his contribution on "Form and Color-Vision in Railway Service,"¹ has so clearly presented the subject of color perception and the tests to be made use of, that I here quote a part of his article, which I most heartily endorse: "The standard examination for color-vision should include three things: 1, a test with colored signal-flags; 2, a test by comparison of colors by the Holmgren worsteds; 3, a test with colored lights seen through openings of regulated size, which will form small images on the central part of the retina.

"The acuteness of color-vision varies considerably from the normal standard, as does form-vision. We may have a feeble color-perception, an incomplete loss of color sense, generally for red and green, or a complete loss of perception for one or both of these colors, and in rare cases a complete loss of all color-perception, in which the solar spectrum looks like a grey smear of varying shade, but no color. The object of our test is to discover the extent and character of the defects, and whether they are sufficient in amount to disqualify according to the standards adopted. The test with flags shows whether the man can give correct names to the flags, and can tell their use and meaning. It is also desirable to use one of the flags at a time as a test-object, and get the applicant to pick out from the heap of Holmgren's worsteds all the colors that look like the flag. It will often be found that the correct names can be given to the different flags even when the test by worsteds and colored lights shows a considerable defect of color-sense, but when used as a comparison test a green may be selected among the other colors as looking like a red flag, or vice versa. The second test, by comparison of colors without naming them, selecting from a large number those which appear to the applicant like certain test-skeins, light green or pink, according to the method proposed by Professor Holmgren, is the most satisfactory and easily applied of all the good qualitative tests, but it does not give a sufficient test for small central scotomata.

"I have recently had a conductor who passed both the Holmgren and the Thompson tests without making a single mistake, and who selected his colors without hesitation, but when examined by colored lights transmitted through small openings, or even with switch-light lenses, before a lamp at twenty feet distance, he called a red light 'white' in four different cases; he had a central defect in the retina, probably caused by the use of tobacco in excess, yet the area affected was so small that the retinal image of the flag or the skein of worsted was formed partly on the diseased retina and partly on the healthy portion outside the scotoma, where the color could be easily recognized, but when the retinal image was reduced in size, as with the lights, it was formed entirely within the borders of the scotoma, and red lights were called white or sometimes green. It will not do, however, to substitute the tests with such lights for the Holmgren tests, as the lights give little chance for comparison or for the selection of confusion colors, and for ordinary cases of congenital color defect it would take a long and tedious examination to reach the same result that could be arrived at more quickly by the worsted test. On the other hand, the test with lights, with regulated openings, should be used in addition to the worsted test, as was first proposed in Holland."

The test with transmitted lights may be made at twenty feet, or six meters, through an opening 2 mm. in diameter; through such an opening a person with normal vision and color perception will at once recognize the color. Dr. Williams' instruments for testing with colored lights is so constructed that the standard colors can be exposed through openings of sufficient sizes. By such an instrument the examiner is enabled to test the form-color-sense and detect any defect that may exist in the central portion of the retina.

In reference to the test "with Holmgren's worsteds" it is possible to make a distinction between some of the greater variations in color sense, for if a person is hesitating, picks up some confusion colors and compares them with the test skein, perhaps selects them and then discards them, or picks up some of the true colors, and after comparison rejects them, finally selecting none of the confusion colors, it shows that he has a feeble color perception; if he selects with the green some of the confusion colors, but with the pink or rose skein makes no mistake, it shows he has an incomplete defect; but if with the green skein he selects confusion colors in addition to the greens, and with the rose skein selects with the rose colors some blues or violets, it shows he has complete defect for red, or if with the rose skein he selects in addition to rose colors some greens or grays it shows he has complete defect for green."

"The tests for both form and color-vision should be made when the man is not fatigued by a long tour of duty or exposure, for it has been found that the acuteness of both form and color-perception is often diminished after two hours or more of engine work. After long runs and unusual exposure this temporary reduction in acuteness may be considerable, and it furnishes an additional argument for insisting on a high standard for such service. If one-half of normal vision were to be accepted as a minimum for each eye when the person was rested and in good health, the conditions of service might easily reduce this far below the danger point, but if a high standard is required the vision may be temporarily reduced by fatigue without becoming dangerous."

In conclusion, I would emphasize the following points: 1. The adoption by railway companies of a uniformly high standard of vision for men entering their service. 2. Uniformity of tests with colored flags, yarns and lights. 3. The re-examination of employees at regular intervals and after serious illness or accident.

DISCUSSION.

DR. JOHN F. FULTON, St. Paul, Minn.—It has been my privilege to have had quite an extensive experience in the line of work suggested by Dr. Bane's paper, and in order to make a success of the practical rules for examining candidates for train service as to their condition as to acuteness of sight, acuteness of hearing and color sense it is necessary to have the officials of the road in sympathy with and interested in the work of their oculist. When this subject is first brought to the attention of the railroad officials, they are disposed to look on the work as of little importance, and will give it but indifferent attention, but if you can succeed in obtaining their presence at a few examinations of candidates who are seriously defective, they will at once see the importance of the work and will then be disposed to make the examinations more severe than necessity demands.

For a number of years I have been doing this class of work for two of our Pacific Coast lines, emanating from St. Paul and Minneapolis, and have been consulting oculist for a number of other roads; consequently during the last ten years there has been examined, under my direction, a large number of men in train service, probably twenty-five or thirty thousand. Judging from my own experience in this work I am disposed to look on the requirements as suggested by Dr. Bane as some-

¹ Trans. Am. Oph. Soc., vol. viii, part 1.

what severe. If a man has vision of 20/20 in one eye and 20/40 in the other, I would have no hesitation in passing him, certainly if the slight defect in sight is due to a refractive error which can be completely or partially overcome by proper correction.

How often should each employee in train service be examined? This is a question well worth our careful attention. My own rule on the subject is as follows: All new candidates for train service should be examined before being employed, and re-examined whenever promotion takes place, or whenever they are transferred from one division to another, and all employees in train service should be examined every three years.

In regard to the examination for color sense, I do not know anything that requires more careful and conscientious work on the part of the oculist than those patients who at first hesitate as to matching of colors, it being often difficult to decide whether or not they are really color-blind, or "color ignorant" or "color stupid." It will be frequently found that such men, after repeated examinations, will demonstrate that their color sense is perfect and that they are perfectly safe men to be employed in train service.

The laity and many of the general practitioners look on color-blindness as a congenital and incurable defect. This is by no means always the case. Defects in color sense are frequently due to the excessive use of stimulants, such as tobacco and alcohol, and in the early stages thus acquired the trouble is completely curable by removing the cause; hence the importance of making frequent examinations.

What shall we do with old and trustworthy employees in train service, who have lost one eye while in the employ of the company and have perfect sight in the remaining one? We will all admit that it is not perfectly safe to retain such men, yet it seems like a great hardship to dismiss them on account of an accident which has occurred, while they are rendering faithful service to their employers. This is a matter more for the officials of the road to deal with than for the company's oculist. One of the most serious accidents with which I am familiar was unquestionably due to the defects of a one-eyed engineer. As you know, in all one-eyed men the range of the field of vision is not as large as with both eyes, and in the case alluded to there was an obstruction on the track on a sharp curve, which he failed to see, resulting in a most serious accident, costing a number of passengers their lives and causing the destruction of a large amount of property.

Equally as important as the testing of the eye-sight in railroad employees is testing the acuteness of hearing. General surgeons and inexperienced oculists who first begin the work are apt to depend too much on the tick of the watch as a test, but experience will soon teach them that it should only be utilized when making the preliminary examination. If at this examination the candidate can not hear the watch tick beyond six inches, he should be referred to an experienced aurist, and if he finds no progressive disease of the ears, and that the candidate's acuteness of hearing is normal for whispered and spoken speech, he should have no hesitation whatever in passing him for train service. I am familiar with the requirements of one road in this department where the surgeon required that the watch should always be heard at eighteen inches. It happens to be a small road, so fortunately no great harm was done. Should this rule be enforced on a large one, where they employ seven or eight thousand men in train service, it would mean the dismissal of from five to eight hundred of their best ones. In cases where we are in doubt as to the progressive nature of the trouble, a certificate should be given, limited for one year.

The work of the oculist for the railroad company should be divorced as much as possible from the work of the chief surgeon, because it will always happen that, if the chief surgeon attempts to interfere with the oculist in his work, he will so cripple him that he will not be able to get results satisfactory to the candidates, to the road or to himself. I have been particularly fortunate in my own association with the chief surgeons of the different roads for which I work, as they have not shown any disposition to interfere but, on the other hand, have given their best assistance to make the work a perfect success.

DR. J. T. ESKRIDGE, DENVER, COLO.—I would raise a medico-legal question in this connection. I think the chief surgeons

and managers of railroads are the responsible parties in this matter. This question suggests itself: When a man is re-examined and color perception is less than that of other employees newly accepted, what responsibility would the railroad have to bear if a person should be injured because of the defective vision of an old employee. It seems to me that if it were shown that the old employee did not have perception sufficient to prevent an accident from occurring, the railroad would be responsible, and the chief surgeon, who is mainly concerned in their cases, should co-operate with the oculist and inform the managers of the road when the vision of the old employee is becoming defective.

DR. T. B. LACEY, Council Bluffs, Iowa—There was one feature brought out by Dr. Bane, in his paper, which is worthy of further discussion, viz.: that in the examination of applicants for positions, or old applicants, we ought to have their records as to their condition when they are examined. He referred to the fact that a man in doing certain work has deterioration of vision due to the energy he has expended, and there is considerable truth in that. I have examined railroad employees who have been instructed to come to me for that purpose, and when they came they were in no condition to pass the proper examination, because they had been overworked. These men had not received any treatment. They had not received the consideration that they ought to receive, and still there are times when I do not know how that is avoidable, because they do not feel disposed to lay off from a trip or from their work a day or two to get thoroughly rested; but still, in a great many cases the evident weakness of vision or defect in color perception is largely due to overstrain or overwork, and they are not in proper condition to undergo a satisfactory examination. We all meet with cases of defective color perception in employees to be examined or re-examined, but much of it is due not so much to direct weakness as it is to absolute ignorance of what colors are; I have had applicants come to my office, off and on, and have asked them the color of a certain skein, and they will determine the color correctly at once, and then when they are asked to match or take all the skeins that contain that color, they will immediately go to work and try to match it with another shade. It is a difficult matter to so word our instructions to men who are wanting employment, that they will distinctly understand what we want them to do. If you give them the standard for the simplest green skein, and tell them you want the skeins that contain the green color, they will immediately pick out the shades which most nearly match the sample; you want the dark as well as the light. While a great many employees whom we examine develop a weak color perception, a good many others are simply color ignorant."

DR. JOHN E. OWENS, Chicago—I have been engaged in examining applicants for railroad service for a long time, and I still find some problems very difficult to solve satisfactorily. Not long since, I left Chicago at 6:30 in the evening, and returned the next morning at 8:30, having traveled 794 miles and remained 3½ hours in the town I visited. I say this to emphasize the importance of having men on our trains with normal color vision, on account of the great rapidity with which our trains run at the end of the nineteenth century. A mile a minute is common on many of our first-class railroads, not for the whole distance, but for many miles, and there has been such an advancement made in speed of trains, in equipment, in coaches, in trucks, and everything that pertains to the running of a train, that we certainly are beginning to see more and more the necessity of having men with normal physical endowments, normal functions, and particularly normal color sense to act as engineers. We have had a uniform system for some years on the Illinois Central, and the same system is in operation on the Northwestern. We go much further than examinations for visual defects and hearing. Physical aberrations which impair usefulness, which lengthen the time of disability or which lessen the powers of endurance of the physical strain during the running of fast trains are considered. I find a problem something like this to deal with: A new man reports for examination. He makes the characteristic mistakes of the color-blind and is rejected. He comes again for re-examination, and is again rejected, and even a third time. I have been inclined to be liberal with the men in examining them several

times, seven or eight days apart, to show them that I am disposed to do everything for them that is reasonable and right. A man with defective color sense will pick up the wrong skeins or point out the wrong colors. Others, after repeated examination and more or less outside practice, can key themselves up to pulling through, and the question arises: are we justified, under the circumstances, in passing them, or should they be rejected as the result of original characteristic errors? The latter is the course to be adopted.

When I first began to make examinations of employees on the Illinois Central, the Holmgren worsteds were used, and I was instructed by the general superintendent, as this was a new matter, to go over the road again and re-examine them. With assistance I accomplished it and examined the employees with flags and lanterns. I was a little timid about that part of it. I had every confidence in the Holmgren test for the detection of color sense, but I did not know what the men would do with flags and lanterns. I thought the Holmgren test would catch all, but I feared the other tests might let some slip through. We used flags in the day time and lanterns at night, and I was very much surprised to note the numerous mistakes that were made in naming the flags and lantern colors amongst those who had previously been found defective by the worsteds. The late Dr. Robert Tilley devised a little instrument which he used on a patient who was referred to an oculist, where he had examined the man and found him defective. This instrument was intended to bring out the personal equation in connection with such examinations. We did not bring it out to perfection. It was a domestic affair, but it corroborated the results of our previous examinations of certain men who were found defective in color sense.

DR. A. I. BOUFFLEUR, Chicago.—The old statement that "a chain is no stronger than its weakest link" should be applied in examining men when tired. If a man is color-blind or color defective when he is tired, just after he has quit work, is he a safe man in a responsible position ten minutes before he has quit work? If we are to have perfect men on our railroads, it is best to test them when they are tired. I have to examine railroad employees in Chicago who run their trains by signals from the time they go out until they go off duty, and it is very essential that those men should be perfect in color sense at the close of their day's work, as it is at the commencement of it. I therefore take exception to that part of the Doctor's paper.

DR. J. T. ESKRIDGE, Denver, Colo.—I showed, in my paper, that hysteric subjects and neurasthenics commonly have limited fields of vision. I know not why it is, but in Colorado, particularly among railroad employees, neurasthenia is exceedingly common. I have examined eight or ten neurasthenics from the D. & R. G. Railroad this year, in whom the fields of vision were at their narrowed. It is evident that such men would not make good signal-men. I would like to ask the Fellows of the Academy if they have made any distinction in examining the eyes of railway employees, whether the patients were either "run down," neurasthenic, or hysteric? Those with manifestations of hysteria showed a decidedly contracted visual field.

DR. W. C. BANE, closing the discussion.—As to the point brought out by Dr. Fulton, I agree with him that a man with one eye is disqualified for engine service, and unsafe for signal service. An old employee should be given other work.

As to the question raised by Dr. Eskridge in regard to neurasthenia and hysteria, I can only answer that in physical examination, the Rock Island surgeons include diseases of the Spine. The fields of vision are taken in the eye examinations.

The point with reference to men being tired at the time of examination should be carefully considered. A man at the end of his day's work ought to be able to recognize colors and see the signals quickly enough to protect himself and the passengers. The man who does not recognize colors promptly should not be employed for service where it is necessary to give and receive signals. Such men should be rejected.

I rode with an engineer on the Rock Island for a short distance in coming east, there being an electric headlight on the engine. He stated that for white and red the electric light was far superior to the ordinary light used on the engine, but he thought it was no improvement for green. I was impressed with the thought that the green lights as used on the railroads are not large enough.

THE EARLY DIAGNOSIS OF PULMONARY TUBERCULOSIS.*

BY EDWARD F. WELLS, M.D.

CHICAGO.

The history of pulmonary tuberculosis during the last quarter of the century now drawing to a close may be considered by the physician and humanitarian with a fair degree of complacency. The essential cause of the disease has been discovered; the avenues of infection have been located; promising methods of prevention have been formulated. The physician and the health officer are enthusiastic and alert to their duties and responsibilities, and they are guiding a public fairly intelligent and ready to accept the proffered advice; the malady is being discovered earlier, is probably being more effectively managed, and is declining in prevalence.

If one will but re-read the chapters on the diagnosis of pulmonary consumption, by Laennec, Louis, Andral, Copland, Watson, Eberle, Drake, Gerhard, Trousseau, Flint and Waldenburg—master minds of their day and certainly *au fait* with the literature and diagnostics of their generation—and compare them with the like chapters of Eichhorst, Osler, Anders, Kidd, Cornet and others of to-day, he can not fail to be profoundly impressed by the immense strides which have been made in the possibilities of the early diagnosis of this disease. This, however, only corresponds to my own observation and experience, and I know that appeal can safely be made to those of my hearers of my own age, or who are older, to confirm the statement that the early diagnoses of pulmonary tuberculosis which are now made as a routine, and which are demanded by the spirit of the times, were utterly unknown and unattainable a quarter of a century ago.

It may be admitted by many, and I will state as a proposition which I believe can not be successfully contradicted, that it is not only possible, but practicable as a matter of routine, to make very early diagnoses in cases of pulmonary tuberculosis. In making this statement I do not underestimate the difficulties, but I do feel confidence in the means at our command, and in the skill of medical men generally in their employment, for meeting and surmounting these obstacles. I am quite sure that diagnostic failures are not due to any inherent difficulties. On the contrary, they are usually due to remediable shortcomings on the part of the physician, as, for example, to a hazy conception of the clinical picture of early tuberculosis of the lungs; to obtaining an incomplete history of the case; to superficial physical examinations or to lack of facility in manipulation or interpretation in this field; and, finally, to a peculiar mental bias which renders him loath to acknowledge the presence of that which he dislikes to discover.

The practical importance of the earliest possible diagnosis of pulmonary tuberculosis can scarcely be over-estimated—certainly it is patent to every physician. To the patient it means that he is the victim of a malady which will entail upon him, at the best, many months or years of invalidism, with, probably, radical modifications of business and domestic arrangements, together with a certainty of prolonged incapacity, and death in a majority of cases. On the other hand, complete recovery ensues in a very considerable proportion of cases—probably in from 25 to 35 per cent.—and a fairly comfortable existence may be had in another large contingent

*Read before the Chicago Society of Internal Medicine, Dec. 28, 1899.

of cases which ultimately prove fatal. That the cure of the disease and extension of the life of the patient is largely dependent on the early institution of rational treatment, which presupposes early diagnosis, no one will have the temerity to deny.

To treat exhaustively of the early diagnosis of pulmonary tuberculosis would require a volume. It is clear, therefore, that within the limits of a short paper only a few of the more important points can be considered, even cursorily. It will be my aim, however, to select for comment those which are most apposite, most novel, and which are oftenest neglected.

Without argument it will be taken for granted that pulmonary tuberculosis is due to the lodgment and subsequent growth in the lungs of the bacillus tuberculosis; that the avenue of infection is usually through the inspiration of air which has been contaminated with the dried and pulverized sputa of consumptives; that the germs vary in virility and are inherently short-lived, especially in the light; that in countries where the malady is prevalent all persons are constantly exposed to the germs of the disease, and that some persons are infected because the inspired bacilli meet with present accidental conditions conducive to their growth and inherent or acquired slight powers of resistance, while the majority of persons escape because the germ encounters unfavorable local conditions and ample systemic defensive resources.

In the diagnosis of early and obscure cases it may be necessary to carefully weigh every circumstance which might possibly have any bearing on the probability, or improbability, of the presence of the disease in question. In such cases heredity and environment may be factors of the greatest importance. There can be no reasonable doubt that tubercular persons transmit to their descendants a peculiar and more or less profound susceptibility to the disease, as is proven by the persistency with which it clings, generation after generation, to those families in which it has once obtained a firm foothold. Known, and especially prolonged and extraordinary, exposure to the germs of the disease, or the absence of such exposure, must also be estimated at its true value in forming a diagnostic opinion. It will be readily understood that the chances of an obscure affection, presenting some of the features, but lacking in positive evidence of pulmonary tuberculosis, being in fact this disease are greatly increased in those who have family histories bristling with instances of the presence of this malady, or in those who are closely associated with consumptives who are careless in their habits. In this connection I can not too strongly urge upon family physicians the necessity of carefully examining such persons at regular, and not too infrequent, intervals. Pulmonary tuberculosis is more prevalent in some races, localities, and in connection with some occupations, etc., than in others. For these reasons heredity, susceptibility, immunity, environment, exposure, climate, occupation, residence, etc., should all be given due consideration in summing up the evidence in any given case.

Of special importance in the diagnosis of early pulmonary tuberculosis is a comprehensive and detailed medical history of the case, although the obtaining of this is often a most difficult professional feat. Patients have no desire to withhold needed information or to make wilful misstatements, yet some of the most suggestive of the early symptoms they may consider insignificant and unworthy of mention, or they may not

have noticed them. However, careful and methodical questioning, especially in the presence of an observing associate, will, ordinarily, elicit a fairly clear, and it may be a graphic, description of the early symptoms of the disease. Upon this feature I lay particular stress, inasmuch as long observation in a field of practice peculiarly suited for obtaining exact information has convinced me that, ordinarily, the access of pulmonary tuberculosis is marked by great uniformity of symptomatology.

I can not recognize a "pretubercular stage" of the disease. I do not lose sight of the fact that the disease is often preceded by anemia, gastric and intestinal disorders, etc., but the existence of such conditions, although they may invite infection, are purely accidental and are not necessarily premonitory. The beginning of the attack must be coincident with the implantation and parasitic development of the bacillus of tuberculosis.

The symptomatic development of pulmonary tuberculosis in a typical case may be briefly outlined as follows: There is a slight and unobtrusive cough which insidiously increases in force and frequency; after a few weeks there appears a scanty mucous expectoration, later, becoming mucopurulent and more abundant; there may be hoarseness, hemoptysis and thoracic soreness; there is slight or moderate afternoon fever, which is accentuated by exercise; the pulse is increased in frequency and arterial tension is diminished; the appetite is lessened, nutrition fails and there is loss of weight, strength and endurance. About once in from four to six weeks there is an exacerbation in which all these symptoms are accentuated and some new ones are added: The cough is increased in frequency, is dry and is often accompanied by thoracic soreness or pain; the fever rises higher in the evening and is usually also present in the morning; the head aches, and there are general aching pains; the appetite is poor and the bowels are constipated; weight is rapidly lost and there is marked weakness; the patient is restless, irritable and out of sorts generally. After about a week freer expectoration occurs; the skin becomes moist; the appetite returns and the bowels move naturally; the soreness and aching cease and the patient feels better. These exacerbations recur at intervals of from four to six weeks, each succeeding one becoming more pronounced, and their diagnostic value can not be readily overestimated.

Let us now consider some of these symptoms more fully:

Cough is probably the earliest symptom. It has, moreover, peculiar characteristics. It is slight, unobtrusive, hacking and often consists of a single effort. It may be excited by change of posture, deep breathing, etc., but if the movement or forced inspiration be repeated the cough may not be reproduced. Usually it is infrequent and may not be heard a half dozen times a day, and may be unnoticed by the patient and his associates. Later, and especially during the morbid exacerbations, it increases in frequency and severity, is provoked by changes of posture, sudden exertion, deep breathing, etc., and each repetition of the provocative act is followed by cough. Later it may assume a paroxysmal character and may be accompanied by vomiting. Cough, as above described, and gradually assuming more and more prominence as time passes, is highly suggestive of pulmonary tuberculosis. If hoarseness is also present the chances that the affection is of any other nature are very slight indeed.

Expectoration may be scanty and for a time free from the specific germ and the evidences of ulcerative action. However, if search is made for bacilli and elastic fibers immediately after one of the febrile exacerbations referred to it will usually be rewarded by the discovery of these, practically, indubitable evidences of the disease in question. Boiling the sputum, just long enough, with a caustic alkali, and centrifuging it, increases the chance of finding the bacilli and fibers if sparingly present.

Hemoptysis occurs in only a moderate proportion of the cases of early pulmonary tuberculosis, but it is very significant when it does appear and is a symptom of prime importance. It is usually small, or moderate, and solitary or mildly persistent for several hours, or recurrent. Although a period of cough and one or more febrile attacks will almost certainly have preceded the hemoptysis, yet the spitting of blood is often the first symptom to excite the alarm of the patient and his friends.

Thoracic tenderness, soreness and pain are rarely absent in early—not the earliest—pulmonary tuberculosis. Their favorite location is in the upper part of the chest, in front, although they may be seated in the axilla or back, or even at the base. Their location and character are often indefinite, but this indefiniteness is in itself a suspicious circumstance.

The *fever curve* of early pulmonary tuberculosis is highly diagnostic, and frequent, methodical thermometric observations for several days will clear up many a doubtful case. The temperature in the morning may be normal, subnormal or very slightly elevated. In the afternoon it may range between 100 and 103 F., the highest temperature occurring in the late afternoon rather than in the evening. An important fact is that exertion promptly and decidedly increases the temperature. During the febrile exacerbations the range of temperature is greater, and the type of fever is remittent rather than intermittent. Some other affections, e.g., anemia, obscure suppurations, etc., may be accompanied by evening elevation of temperature, but these are usually readily differentiated.

Gastric symptoms are frequently present. The appetite is somewhat impaired and may be erratic, while in infrequent cases there is a veritable dyspepsia. In rare cases there are no gastric disturbances. During the febrile exacerbations the appetite fails, the tongue becomes coated, the bowels are confined and there may be nausea and vomiting. So marked are these symptoms that these exacerbations are often considered "bilious attacks," with failure in recognizing their true nature.

Nutrition is impaired, and weight, strength and endurance are early diminished, especially during the febrile attacks, each exacerbation leaving the patient on a slightly lower plane. The patient may have the appearance of health, but an appeal to the scales will show a loss of weight and it will be found that feats of strength and endurance which could be formerly accomplished with ease can not be duplicated, or are only possible with difficulty and added exertion. The patient tires easily and unaccountably, and this symptom usually early attracts his notice.

The *blood* is early altered in composition. The number of red blood-corpuscles is diminished, as is also the specific gravity and hemoglobin. It is contaminated by the presence of tubercular toxins and, perhaps, anti-toxins, and by an excess of waste products. There are

probably morphologic changes in the erythrocytes and leucocytes.

The *pulse* is early and decidedly modified in its character. It is usually accelerated, and the rate is changed but little by position. This latter feature is very suggestive, and whenever the pulse-rate is found increased and practically the same whether the patient is lying, sitting or standing, the most careful scrutiny is demanded. The acceleration is usually moderate, but in rare instances it may be very great. The arterial tension is early and notably reduced, especially during the febrile exacerbations. To this, in my experience, I have met with no exception. Normal or an increased tension may be present when the disease attacks persons with arteriosclerosis, but I have had no opportunities for studying such cases.

Sphygmographic tracings give most valuable aid in the diagnosis of early pulmonary tuberculosis, and from these alone the scale may be turned in the great majority of doubtful cases. Typically the tracings show a pulse of lowered tension and infantile character—a small and frequent pulse. From this typical curve there are infinite variations in both directions, approaching the normal on the one hand and reaching the most pronounced dirotism on the other. Words can convey no adequate conception of these changes, and I can only append a number of examples, with the assurance that you will be convinced that we have in the early stages of this affection a distinctive and readily recognizable pulse.

To some I may have been somewhat tedious in my preceding remarks. I can only offer, in apology, my conviction that those points are of primary importance and that they must be fully appreciated and recognized when we come to interrogate the chest by the aid of the percussor and the stethoscope. The importance of a most painstaking physical examination of the chest needs no extended mention. However, those who have had the greatest experience will know that, at the stage of the disease to which my remarks refer, physical signs are often in abeyance or are capable of various interpretations. Localized râles may mean much or little, as they may be heard in a patient with or without the symptoms detailed. It must also be borne in mind that in some cases the progress of the pulmonary affection is slow; and that in these cases symptoms may antedate by several months the appearance of demonstrable signs.

Percussion may elicit diminished resonance or dullness

in some early cases which are rapidly progressive, but as a rule this will not be found in the doubtful cases. Stethoscopic percussion may be an aid. I have thought that during the febrile exacerbations areas of dullness could be detected which did not exist before nor persist after, but on this point my conclusions are indefinite. I am sure, however, that areas of pre-existing dullness

are enlarged at these times. It must be borne in mind that, whereas distinct interscapular, supra- or infra-clavicular dullness is highly suggestive of tubercular consolidation of the lung, the converse does not hold good, as tubercular formation may be present without any impairment of the percussion note.

In *auscultation* it is scarcely possible to overestimate the diagnostic importance of localized crepitation, moist râles, and prolonged, high-pitched expiration, heard, especially between the scapula and the spine, at the apex, or below the clavicle. Fine crepitation and coarse râles may be heard more distinctly, or only on deep inspiration, or with, or after, coughing. All the auscultatory signs are more noticeable during or shortly after a febrile exacerbation. Moist râles are rendered more prominent, or they may be heard only after an iodid has been given in moderate doses for a few days. The iodid causes a flow of serum from the bronchial mucous membranes, and this serum is not readily extruded from consolidated areas. Under these circumstances coughing, deep breathing, or even ordinary respiration will produce râles in these areas. It does not aid in the diagnosis of cases which have not progressed to the stage of some consolidation, except that it may favor the expectoration of bacilli bearing sputum. Some observations upon the use of iodid of potassium in the early diagnosis and the locating of the local lesion in pulmonary tuberculosis I brought to notice a year ago. Since my report I have employed it in every suitable case which has presented itself, and I can only reaffirm what I then said, namely, that in iodid of potassium we have a valuable diagnostic agent.

The *tuberculin test* may be employed in those cases, not syphilitic nor chlorotic, in which the diagnosis can not be made by ordinary means and in which a moderate delay can not be had. Although a valuable diagnostic agent its use is attended with a slight risk and, therefore, tuberculin should be administered only in such manner as to furnish profitable information. The temperature should be normal or have a very low febrile range and thermometric observations should be made and recorded every three hours for several days before the tuberculin is injected. The dose should be a moderate one, say from three to five milligrams, and it should be given in the evening in order that the reaction may begin in the morning. A positive reaction may be considered to have taken place if the malaise, headache, backache and pains in the legs have been marked and the temperature decidedly elevated. The reaction usually begins in about twelve hours and continues for from thirty-six to forty-eight hours. If no reaction follows the injection a larger dose, but not exceeding one centigram, should be given after the lapse of several days. In the tuberculin test a negative result is of great importance, because, if the observations have been carefully made, we may affirm that not only is the suspected pulmonary affection not tubercular but that there are no latent pulmonary foci and that tuberculosis does not exist in other parts of the body.

In a doubtful case the X-ray may tip the balance for or against the probability of tuberculosis being present. This is especially true when thoracic soreness or pain is present, the X-ray revealing restricted movement of the diaphragm upon the affected side.

In conclusion, I will say: Satisfactory diagnoses in cases of early pulmonary tuberculosis can be made only on a broad base of practical knowledge. It must be apparent that it is impossible to compress in a short ad-

dress that which many volumes can not contain. It is believed, however, that sufficient has been presented to lead to the conclusion that the early diagnosis of the affection under consideration presents no insurmountable difficulties, and that the application of a reasonable amount of care and skill, and in a few cases allowing the lapse of a little time, will almost invariably lead to correct results. In attaining these ends no portion of our experience concerning pulmonary tuberculosis can be neglected, but particular attention should be given the points mentioned.

4571 Lake Avenue.

THE SIGHT AND HEARING OF SCHOOL CHILDREN.*

BY H. V. WURDEMANN, M.D.

Ophthalmic and Aural Surgeon to the Milwaukee Children's Hospital and to the Milwaukee County Hospital for the Chronic Insane; Managing Editor, *Annals of Ophthalmology*; Associate Editor, *Ophthalmic Record*; Chairman, Section on Ophthalmology, American Medical Association, 1900, etc.

MILWAUKEE, WIS.

WITH THE COLLABORATION OF
FRANK ALLPORT, M.D.

Professor of Ophthalmology, Chicago Polyclinic; Professor of Ophthalmology and Otolaryngology, Northwestern Woman's Medical College; Oculist and Aurist to St. Luke's Hospital, Consulting Oculist and Aurist to St. Joseph's Hospital.
CHICAGO.

I have been requested by the superintendent of the Milwaukee schools to say something concerning methods for the systematic examination of school children's vision and hearing, which have been instituted in a number of the large cities of America, and have been taken up in this city under the authority of the commissioner of public health.

The enlightenment of the young may be likened to the raising of agricultural products. Not only are proper seeds necessary, but favorable soil and conditions are quite as needful. The means of education: the buildings, properly placed, constructed and conducted, including teachers, systems, books, etc., have been fully developed in our day. The child's mind should be active and its body and senses healthy to render it capable of profiting by instruction. Modern schools, with their effective machinery, are a source of gratification and delight to all; but enthusiastic, progressive and systematic educators do not always consider the soil on which the seed of enlightenment falls; in other words they are disposed to consider children as a massed entity, do not separate them into isolated individuals, with distinct inheritances, and mental and physical peculiarities, rendering them more or less adaptable to the requirements of the modern public school. Children are thrown into the great machinery of school life, are divided into grades, are expected to adhere to them and become educated according to this system. A child may have a weak or crooked back, which will become aggravated by close confinement at improperly constructed desks; he may have lungs handicapped with the incipient germs of consumption, encouraged by the protracted inhalation of vitiated school air; he may languish from an impoverished condition of the blood, and pine and droop under too much study and too little fresh air.

These are some of the conditions noticed in school children, militating against the easy acquirement of an education; but more directly detrimental is the existence

of certain abnormal conditions of the organs of special sense, of *seeing* and *hearing*, which are certainly of prime importance in acquiring an education. If a child can not see well and hear well his position is certainly most unfortunate in the modern public school, where he is expected to keep up with his grade work, or else subject himself to chagrin and mortification. Do not understand me as saying that your schools are to be likened to the car of Juggernaut, that ruthlessly throws down and crushes all who unfortunately come in contact with its destroying wheels. Far from it. I fully appreciate the gentle, humane and sympathetic feelings that proceed from the hearts of most teachers toward the children committed to their care. I am not unaware of their watchfulness and solicitude over their little flock, that prompts them to change the seats of the deaf and nearsighted, to make allowances for any noticeable physical or mental short-comings, to frequently visit parents and urge on them the necessity of action concerning the health of a child; but these are isolated though frequent instances, inspired by individual sympathy and character.

What we want is a paternal school system of health investigation, by which the physical defects of children will be made manifest and steps taken to protect pupils against themselves and in many instances against their parents. We also want a system that, after these unfortunate conditions have been discovered, will not only allow, but insist on, the harmonizing of the studies to the child, and not the child to the studies. I am not unaware of how often this is done; that the doctor's certificate of poor health is usually respected; that the course of study is sometimes changed under the advice of parents or teacher. I think I am not wrong in saying that these changes are so frequent, and so little encouraged, that children will often endure much physical discomfort or even suffering, rather than assume the mortification brought on them by the distinction of a grade change. These changes should be inspired from the intelligent illumination of regular physical examinations, and should be so common as to excite no comment, and give rise to no loss of a pupil's self-respect, or disappointment on the part of the parent, who frequently allows a child to languish and acquire permanent invalidism, rather than interfere with his class standing, or the date of a projected graduation.

I would not be misunderstood as advocating the abolition of systems and grades. It is needless to say that schools can not be properly conducted on other principles. Neither do I advocate the indiscriminate changing of children in grades, without just and adequate consideration. Neither do I ignore the fact that pupils are frequently changed to other grades for ostensibly good and sufficient reasons. I advocate more system and more grades. I advocate a system of physical examination in schools, by which we may know the condition of a child's health, and not trust chance or circumstances to detect it, and I advocate more and shifting grades, commensurate with the physical condition of defective children. In other words, I do not believe in the wholesale education of the rising generation, which is our country's hope, its bulwark and defense, and whose physical and mental condition is a sacred trust which we must guard and cherish. I do not believe in thrusting these little, yielding, impressionable, often sickly, lives into the common crucible, to be moulded and turned out with identical exactitude and precision. I believe that children should not be damaged by their educational existence, but should emerge from the portals of the Amer-

*An Address delivered before the Principals of the Milwaukee Public Schools, Jan. 12, 1900.

ican public school in better physical, mental and, may I say, moral condition than when they were entrusted to its fostering care, and that steps should be taken calculated to bring about the fulfilment of this imperative duty.

We must creep before we walk, and a great reform of this kind can not be accomplished without primitive and pioneer work. The eye is the most important physical element in the acquirement of an education, unless it be the brain, and is fortunately an organ capable of ready examination. The testing of school children's eyes has been systematically performed for many years in Europe, and especially in Germany—that factory of bad eyes—and, since 1895, somewhat in this country, but these examinations have been made by oculists appointed by school authorities, who have personally—with their assistants—examined every child in a given community. This system operated very well in monarchical Europe, accustomed to arbitrary domination, but in America, habituated to democratic rule and individual freedom, the method has given rise to much opposition from parents, children, school authorities and other oculists wherever tried. In fact, the method has been forcibly discontinued, as an element of too much discord and professional strife. Teachers have, sometimes, in a spirit of righteous investigation, made abortive attempts at testing their school children's eyes in various more or less scientific fashions, being forced by intelligent observation to a realization of the truth that many children were struggling under an ocular burden, very heavy to carry.

A systematic method for the examination of pupils' eyes by teachers, comprising simple questions and instructions which, if properly carried out, will detect the existence of most important ocular diseases, has been in use in Minneapolis and St. Paul; Worcester, Mass.; Sycamore, Ill.; Philadelphia and Chicago, for several years, and is being introduced in San Francisco and other cities.

Statistics show the average frequency of defective eyes in American school children to range from 25 to 35 per cent. When it is remembered that the vast majority of these have never sought ophthalmic advice, and are therefore endeavoring to acquire an education under exceedingly disadvantageous circumstances, the importance of this subject can be imagined. Time forbids me to enter into any description of the ocular diseases and conditions chiefly incidental to school life, but you doubtless know that nearsightedness or myopia is quite frequently a development caused by excessive study under poor conditions; that hyperopia and astigmatism are malformations of the eyeball, rendering study exceedingly irksome, because of tired eyes and head and headache; that a cataract is an opacity of the crystalline lens, and may exist and partly blind a child, without recognition, except by skilful examination; that optic nerve, choroidal and retinal inflammations may occur without especially noticeable symptoms to an observant child; that many varieties of "sore eyes" may hinder even reasonable school diligence; in short, that many morbid ocular conditions may obtain without attracting especial attention, and render the acquirement of an education exceedingly burdensome to children who thereby acquire the reputation of being dull, stupid and idle, but whose unenviable record may be completely revolutionized by proper ocular treatment and advice. The same may be said of aural diseases or conditions attended by deafness.

These are the children we hope to reach by these school tests, and especially those poor and almost abandoned

children, whose parents are ignorant, careless and indifferent to the physical conditions of their offspring. These eye tests are now quite generally recognized as being the best practical solution of the question as to how to place children in the proper channel to secure relief from ocular complaints, and as the idea is firmly established, we think that the time is ripe for another advance in the physical examination of the children.

Many children suffer from nasal obstructions and particularly from enlargement and engorgement of the

INSTRUCTIONS FOR THE EXAMINATION OF SCHOOL CHILDREN'S EYES AND EARS
FOR USE BY TEACHERS IN SCHOOLS

1. The child should be seated at a distance of 20 feet from the chart. The chart should be held at eye level. The child should be asked to read the letters from top to bottom, and from left to right. If the child cannot read a letter, the teacher should ask the child to point to the letter. If the child cannot point to the letter, the teacher should ask the child to say the letter. If the child cannot say the letter, the teacher should ask the child to show the letter with their hand. If the child cannot show the letter, the teacher should ask the child to say the letter. If the child cannot say the letter, the teacher should ask the child to show the letter with their hand. If the child cannot show the letter, the teacher should ask the child to say the letter. If the child cannot say the letter, the teacher should ask the child to show the letter with their hand.

2. The child should be asked to read the letters from top to bottom, and from left to right. If the child cannot read a letter, the teacher should ask the child to point to the letter. If the child cannot point to the letter, the teacher should ask the child to say the letter. If the child cannot say the letter, the teacher should ask the child to show the letter with their hand. If the child cannot show the letter, the teacher should ask the child to say the letter. If the child cannot say the letter, the teacher should ask the child to show the letter with their hand.

3. The child should be asked to read the letters from top to bottom, and from left to right. If the child cannot read a letter, the teacher should ask the child to point to the letter. If the child cannot point to the letter, the teacher should ask the child to say the letter. If the child cannot say the letter, the teacher should ask the child to show the letter with their hand. If the child cannot show the letter, the teacher should ask the child to say the letter. If the child cannot say the letter, the teacher should ask the child to show the letter with their hand.

4. The child should be asked to read the letters from top to bottom, and from left to right. If the child cannot read a letter, the teacher should ask the child to point to the letter. If the child cannot point to the letter, the teacher should ask the child to say the letter. If the child cannot say the letter, the teacher should ask the child to show the letter with their hand. If the child cannot show the letter, the teacher should ask the child to say the letter. If the child cannot say the letter, the teacher should ask the child to show the letter with their hand.

5. The child should be asked to read the letters from top to bottom, and from left to right. If the child cannot read a letter, the teacher should ask the child to point to the letter. If the child cannot point to the letter, the teacher should ask the child to say the letter. If the child cannot say the letter, the teacher should ask the child to show the letter with their hand. If the child cannot show the letter, the teacher should ask the child to say the letter. If the child cannot say the letter, the teacher should ask the child to show the letter with their hand.

tissues in the upper part of the pharynx and throat. Such obstructions prevent free nasal breathing and cause a utilization of the mouth for this purpose, besides giving rise to deafness, on account of a lack of proper aeration of the middle ear through the Eustachian tubes, leading from the upper portion of the throat to the ear. These enlargements in the pharynx, called "adenoid growths or vegetations," are productive of a large majority of the chronic ear diseases from which children suffer. Fortunately they can be easily removed, and some of the most satisfactory surgical work ever witnessed follows such operations. These children, called "mouth breath-

ers," present a peculiarly dull and stupid appearance which is aggravated by the almost invariably accompanying deafness. Removal of the growths and proper treatment to the ears completely revolutionize the appearance and character of the child, and if you have ever observed such physical and mental transformations, you will never forget them, nor fail to emphasize the importance of such work.

One important matter should be remembered in these tests, viz.: They are not conducted solely for the purpose of detecting ocular conditions requiring the use of glasses. Many seem to have the idea that they simply detect errors of refraction, but such is not the case, as they will, if properly carried out, detect the existence of almost all serious ocular diseases or conditions. The teacher does not know what disease is present, but that something is wrong; that is sufficient. The sole idea in the tests is to separate those children having good eyes and ears from the defectives. These tests should be made at the beginning of the school year, statistical reports prepared and reports of the defectives again made at the end of the school year. Those passing the tests successfully are returned to school and not re-examined for one year, when they should undergo another examination, as morbid conditions may have developed meanwhile. Those having defective eyes or ears are simply given a card of warning, which they hand to the parent. This card merely states that some eye or ear disease is believed to exist, and the consulting of a physician, therefore, is advised. The matter is not compulsory, as the parent may do as he thinks best; he may consult any physician or dispensary he chooses. In this way the duty is thrown on the shoulders of the parent, where it belongs, but if compliance with the advice is not observed, the teacher may from time to time urge the matter with tact and delicacy, but nothing should be said to make the parents regard the matter as an arbitrary demand.

Many teachers outside of large cities are interested in this work, and are constantly inquiring how they may do it in places where a board has taken no official action along these lines. They may purchase one of these combination charts¹ for twenty-five cents, containing both the test-types and instructions, and proceed with the work in their room or school. To this there can certainly be no objection, as the tests are absolutely harmless in every particular.

In Minneapolis and Chicago, where these examinations were most complete, we know positively that thousands of children were much benefited by these proceedings. Cataracts were removed, cross-eyes straightened, intraocular inflammation relieved, glasses were fitted, etc.; in short, the tests have really been exceedingly beneficial in their results, and while some opposition from parents and teachers was at first encountered, nothing but commendation can now be heard from all sources.

For the Milwaukee tests the commissioner of public health and the superintendent of public schools have authorized me to design a plan for this investigation, embodying the best features from the experience of other cities. To this means I have secured the collaboration of other oculists, Drs. Charles Zimmermann, J. S. Barnes and N. M. Black, who, with myself will at appointed times instruct the grade teachers in the anatomic and physiologic relations of the eye and ear so far as may aid in these investigations, and will also instruct them in the methods of examination and keeping what records may be needed by actual demonstrations on teachers or

pupils at these meetings. The tests and records will be made by the teachers for each grade, under the supervision of the principals of the school. The number of children examined should be noted, but only complete records of the defectives are to be made, which are to be done in duplicate by the room teachers and both copies sent to the principals, one copy to be kept by the principals and the other sent to my address. The cards of warning are to be filled in and sent by the principals to the parents of any child found defective. At the end of the school year the principals are to fill out the duplicate reports, stating whether or not the pupil has profited by the card of warning to its parents, and the results, as well as his impression of the usefulness of such an examination in his school. This duplicate is then to be sent to my address for use in the preparation of a report to the school board.

A compound test-card, based on the standard types of Snellen, has been designed by Dr. Frank Allport—"The Visual and Aural Chart for Schools"—and will be used in the Milwaukee examinations. Roman numerals are on one side of each line and Arabic on the other. Under the twenty-foot line are these words: "This line should be seen by a normal eye at 20 (XX) feet," and would seem to make the matter sufficiently plain. Under the ten-foot line, on the card proper, is a half-broken line at which the lower portion of the compound card should be severed from the upper portion. Just under this line are printed the words: "Please detach by breaking on this line."

The card which is thus detached contains the teacher's instructions as to how to proceed with the tests. The upper or long card containing Snellen's types is the testing card, and should be hung on the wall when in use. On the lower card of instructions is printed the following matter, most of which is already familiar to those who have used this method:

TEST CHART.

Instructions for the Examination of School Children's Eyes and Ears. For Use of Principals and Teachers. After the Method proposed by Dr. Frank Allport of Chicago, Ill.:

First grade children need not be examined.

The examination should be made privately and singly, in a room apart from the general school session.

Ascertain if the pupil habitually suffers from inflamed lids or eyes.

Children already wearing glasses should be tested with such glasses properly adjusted on the face.

Place a card of Snellen's test types on the wall in a good light; do not allow the face of the card to be covered by glass.

The line marked XX (20) should be seen at twenty feet, therefore place the pupil twenty feet from the card.

Each eye should be examined separately.

Hold a card over one eye while the other is being examined. Do not press upon the covered eye, as the pressure might induce an incorrect examination.

Have the pupil begin at the top of the test card and read aloud down as far as he can, first with one eye and then with the other.

If the pupil does not habitually suffer from inflamed lids or eyes, and can read a majority of the XX (20) test type with each eye, and does not, upon inquiry, complain of habitually tired and painful eyes and headache after study, his eyes may be considered satisfactory. But if he habitually suffers from inflamed lids or eyes, or can not read a majority of the XX (20) test type with both eyes, or habitually complains of tired and painful eyes or headache after study, a card of information should be sent to the parent or guardian.

FACTS TO BE ASCERTAINED.

EYES.

1. Does the pupil habitually suffer from inflamed lids or eyes?

¹ Vision Charts for Schools; published by Almer Coe, 65 State St., Chicago.

2. Does the pupil fail to read a majority of the letters in the number XX (20) line of the Snellen's test type with either eye?

3. Do the eyes and head habitually become weary and painful after study?

4. Is the pupil probably cross-eyed?

EARS.

5. Does the pupil complain of ear-ache in either ear?

6. Does matter (pus) or a foul odor proceed from either ear?

7. Does the pupil fail to hear an ordinary voice at twenty feet in a quiet room?

8. Does the pupil fail to hear the tick of a good-sized watch at three feet, with either ear, in a quiet room?

9. Does the pupil fail to breathe properly through either nostril?

10. Is the pupil an habitual "mouth breather"?

If an affirmative answer is found to any of these propositions the pupil should be given a card or letter of warning to be handed to the parent, which should read something like this:

Dear Sir: After due consideration, it is believed that your child has some eye-ear disease, for which an eye-ear doctor of recognized standing should be consulted.

It is earnestly requested that this matter be not neglected, as children with eye-ear diseases can not attain the best results in school

Respectfully.....

Principal.....School

Either the word "eye" or "ear" may here be crossed out, as may be appropriate for the case. If the pupil has presumably both an eye and ear disease, both words may be left, and the space between the words "eye" and "ear" should be filled with the words "and".

It will be observed that these cards are non-obligatory in their nature. They do not require anything of the parent, who is at perfect liberty to take notice of the warning card or not as he sees fit. They simply warn the parent that a probable eye or ear disease exists, thus placing the responsibility upon the parent.

These instructions are repeated in the tabulated reports, and in addition instructions for ear examination as follows:

In a room apart from the general school session examine the pupils singly, ascertaining if the pupil complains of ear-ache, if matter (pus) or a foul odor proceeds from either ear, if the pupil fails to breathe freely through either nostril or if he breathes mostly through his mouth. Have the child turn his back, an assistant plugging up the left ear with a cloth over the finger. The examiner steps away about 20 feet, asks the child a direct question in a low but distinct voice requiring a direct answer. The right ear is then to be stopped and the left ear tested. If after several questions the child fails to hear the spoken words and answers incorrectly he is deemed defective. A good-sized watch is held about six feet away and gradually moved toward the ear to be tested and distance at which the subject says he hears the tick is noted. It should be heard at least three feet away from the ear. If the pupil fails to hear spoken words or the tick of the watch as above noted, if he complains of ear-ache, if pus or a foul odor is observed from either ear, if his nose is habitually stopped or if he is a mouth breather, his name and a detailed report should be entered below on this sheet by the teacher, and a card of information sent by the principal to the parent or guardian.

General suggestions and instructions are likewise found on the tabulated reports as follows:

Examine your entire school by these methods at the beginning of the school year; part of the pupils each day, so as not to interfere with the regular course of instruction. Examine each new pupil entering between beginning and end of terms. Only such pupils as are thought necessary to send to an eye or ear physician need tabulation on this blank. This sheet is to be filled in duplicate, both copies sent to your principal,

one copy of which is to be sent as soon as you have completed the examination of the school to the commissioner of Health for Milwaukee. The other is to be held until the end of the school term by the principal, who will then send the duplicate copy to this address, noting thereon in the two last columns, whether the pupil consulted a physician, or if not, why; describing the results of treatment, particularly as regards the pupil's conduct, health and application to study.

One of the chief obstacles to satisfactory results in Minneapolis and Chicago was the fact that many parents took their children to jewelers and opticians instead of oculists. The cities were flooded with fulsome advertisements, and circulars from opticians and spectacle peddlers to teachers, parents and physicians soliciting their trade and influence.

This preliminary examination is not proposed simply for the purpose of ascertaining the need of glasses, but in hopes of disclosing existence of almost all ocular diseases. The eye is not merely a mechanical apparatus which, if out of order, requires for its correction a pair of glasses. A good medical education is absolutely essential for the diagnosis and treatment of astigmatism, hyperopia, myopia and imbalance of the ocular muscles; the former of which are malformations, and the latter diseases, which, in many cases, need something else than the placing of lenses before the eye as well, for cure of inflammation and work of a surgical nature.

Principals and teachers are, therefore, urged to impress upon pupils and parents the necessity for consulting reputable eye and ear doctors and not unprofessional tradespeople.

SPECIAL ARTICLE.

RELATIONS OF PHARMACY TO THE MEDICAL PROFESSION.

III.

It has been shown that confusion existing in the lay mind, and largely shared by the medical profession, concerning the so-called "patent medicines" for domestic use, is due to the popular incorrect use of the term "patent" to indicate that an article is afforded such protection as rests on priority of registration of a name for the article as a trademark, or through copyright including this. It does not mean the article is protected through letters patent issued on the process of manufacture, or on the composition of the article itself. It has also been shown that a patent is very rarely granted on the combination, or mixtures of various ingredients, or on the process of producing any medicinal preparation or mixture, if for no other reason from the fact that in the vast majority of instances it would be impossible to show any originality, improvement, or invention, even to the often limited extent necessary to satisfy the patent office requirements; hence the almost general reliance on the trade-mark laws, for protection in medicinal articles.

As has already been pointed out, it is not the intent of the trade-mark law to afford protection to the name of an article, but simply through its registration record priority in case of contention over a device, symbol, sign, or figure to distinguish a certain "brand" of manufactures from all other brands.

It is the evident intent of the trade-mark law to protect a manufacturer through some design of his own invention, which must be arbitrarily selected, or, as it is termed, "fanciful," and in the case of a name it must therefore not be descriptive, i. e., too closely simulate the name of any natural substance, mineral, plant, or animal, or geographic name, or that of any well-defined physical, chemical, physiologic process or mechanical or therapeutic uses. That this is a subject of difficult interpretation is self-evident, and the registration by

* The third of a series of articles to appear weekly in THE JOURNAL, designed to correct the abuses from advertising and patronizing pharmaceutical specialties.

different parties, often unwittingly, of names identical or nearly so, has caused endless litigation. Sometimes the difference of a single letter in the termination of a word, as for example, "digestin" and "digestine," applied to different products of different manufacturers, has caused annoyance and confusion. The most interesting illustrations of this character are the adjective derivatives—bromo, chloro, phospho, pepto—joined or hyphenated to some substantive or base, such as caffeine, alum, quinin, mangan, etc. Such compound words have been held as valid trade-marks, and yet they are as nearly descriptive of the articles as any titles could possibly be. "Bromo-seltzer" comes in this category, and yet the name as a trade-mark could probably not be bought for a million dollars! The official nomenclature of the Pharmacopoeia may decide what form of termination should be regarded as descriptive, but since the termination "ine," of a generic plant name, for example, stands for the alkaloid of the plant named, the application of this system to the present trade-mark names would cause a surfeit of active principles of a nondescript collection of medicinal agents as ever graced the apothecary shop, so vividly portrayed by the "bard of Avon." "Heroine," for example, would under the definition become the alkaloid of "hero," and the active principles of the "great fathers" of antiseptic surgery would be ever with us in their "spirits."

CONFUSION OF NAMES.

Much could be said concerning the necessity from the medical standpoint, and especially from that of the prescriber, for a radical change in the system—or lack of system—in vogue for naming medicines. Scarcely a day passes but some new article appears under some fanciful name. The possibilities of the English language are great, but they will soon be exhausted, as the medical and pharmaceutical terms already are, and well-nigh also the dead languages.

So nearly similar terms are bestowed, often on widely differing articles, that, aside from the resultant confusion, there is great danger from serious error. A few illustrations will suffice: "Lactated Mercury" was a name given to a trituration of calomel. On a physician's prescription for this, lactate of mercury, a very potent mercury compound was dispensed.

In another instance a prescription was written for "mercurol," m. 10, water, fl̄ss iv, for an injection. For "mercurol," written illegibly and too recent an addition to be known to the pharmacist, "mercauro" was dispensed instead; and yet the pharmacist can scarcely be blamed—"the pace is getting too swift for him" as well as for the physician.

It is for these reasons, among others, that the use of the names of the article as trade-marks is so objectionable and, in fact, so unreliable that manufacturers wholly familiar with the situation have abandoned reliance on such except when joined with a proper name. The possessive name of a person, especially of the manufacturer, joined with the name of the preparation, is fairly indicative of identity of brand, though not invariably so, as demonstrated in the celebrated cases of "Hoyt's Cologne" and "Brown's Essence of Ginger," the original makers in both instances failing to estop these manufactures by persons of these respective family names.

THE TRUE POSITION.

The very best authorities on trade-mark law at the present time, however, are unequivocally of the opinion that the name of an article can not be maintained as a trade-mark; that such use would give to the trade-mark a power not only not contemplated, but expressly interdicted by the law; that a monopoly of the manufacture of an article must rest on proven originality, invention or improvement, neither of which qualities are inherent in simply the naming of an article; in short, that if the article itself is really valuable, then the invention is entitled to a limited monopoly through patent on the article itself, the preparation, compound or mixture, or on the process of manufacture. Not to be satisfied with a limited protection expiring through limitation granted for a valuable discovery, but to seek unlimited protection—eternal monopoly—on an article unworthy of the few years of protection invested by the letters patent, is a travesty of justice and an absurdity. The justice is therefore apparent of the demand on Congress, by

the National Association of Retail Druggists, submitted to the trade-mark and patent laws, revision committee, appointed by President McKinley, at its recent sitting in Chicago, that the laws should be amended so as "to prohibit the registration of names, combination of names coined or otherwise, and that such registration be confined to brands, symbols, signs and devices." This action is in line with that of the American Pharmaceutical Association, last year, in defining the status of medicinal articles for introduction into the U. S. Pharmacopoeia, presented through its delegates to the Convention for Revising the Pharmacopoeia in Washington, D. C., May 2.

EXTERNAL MEDICINAL AGENTS.

This class comprises all medicinal articles intended for external use; absorbents, antiseptics, astringents, deodorants, disinfectants, protectives, etc., and includes the following pharmaceutical forms:

1. Simple solutions—examples: formalin, hydrogen dioxide solution, hydrozone, glycozone.
2. Compound solutions or mixtures—examples: alphasol, eucacoin, glycothymolin, listerin, bromochloralum.
3. Semiliquid mixtures—non-fatty: lubricichondrin.
4. Semisolids—non-fatty: antiphlogistin, anhydrosin. Fatty—ointments: lyptol, unguentum, vasogen; suppositories, protargol bougies.
5. Plasters, surgical dressings, soap, ligatures.
6. Powders, antiseptic powder.
7. Chemicals of definite composition: nosophen, eudoxin, etc.

In all of the above examples, only the two first mentioned have truly descriptive names, all the remainder having more or less fanciful or suggestive ones, protected, as far as known, by trade-mark or copyright registration. Hydrogen dioxide is the perfect type, since the name is the correct chemical one, and "solution" or "water of" being understood it is also the official title of the U. S. Pharmacopoeia. By affixing the name of the brand, the preparation or rather the particular make of hydrogen dioxide is specified and insures all the distinction required to identify this make against all other makes. This is the ideal method and insures protection; besides, it familiarizes the reader with the name of the brand, and if favorably impressed with the preparation, on its use, he will know that any other article of this same brand is the make of a manufacturer who enjoys his confidence and is entitled to his patronage and preference. The same plan could be adopted for the naming of the two other hydrogen dioxide preparations, instead of "glycozone," the term "glycerite hydrogen dioxide" would at once indicate its character and far better identify the brand than the present title, although "ozone" as compounded with the prefixes "hydro" and "glyco" in these instances is not to be particularly criticized and is permissible. "Lubrichondrin," from "lubricating" and "chondrin," the accepted term for the mucilage of Irish moss, "Chondrus crispus," is fairly descriptive of composition and use, and this may be said also in a more limited degree of "Protargol Bougies," but with these exceptions all the examples in the first four groups have nothing to commend them and simply "make confusion worse confounded," since new recruits are received nearly every day, especially in Group 2. A general title, i. e., "Antiseptic Solution" or "Liquor Boroglycerini Compositus," the name specified, would be far more rational and satisfactory to the physician, pharmacist and dealers than the unscientific, confusing, pretentious and grotesque names bestowed on this class of preparations at the present time.

GENERAL FORMULAS.

The composition of these articles is usually known. A few are secret and these should be tabooed since they are on exactly the same level as are the "patent medicines," and like these will, sooner or later, be exploited to the laity as cure-alls, the testimonials received from medical men being used to "boost" them. Some of them are valuable therapeutic agents, as are the non-fatty mixtures of Group 4, and from their character they can not be so well prepared by the retail pharmacist, as on a larger scale. The following yields a product similar to antiphlogistin: glyceroplasma of kaolin (antiseptic). Kaolin, or white clay, is thoroughly elutriated, dried and made into a semisolid paste with glycerin, containing about 5 per

cent. boroglycerin; methyl salicylate or oil of gaultheria, oil of thyme, or menthol may be incorporated. The clay must be thoroughly levigated with glycerin, best accomplished in a paint-mill. Any fine argillaceous earth will answer, provided it is entirely freed from grit, by elutriation, or water-sifting, the process by which chalk is "prepared."

OINTMENT VEHICLES.

While secrecy should not be tolerated, there is no need of the exact formulas for this class of preparations so long as they are only for external use. Except in the case of powerful germicides—phenol, mercuric compounds, etc.—enumeration of the ingredients without the exact proportions is sufficient. Nor is the process necessary, since any skilful pharmacist should be able to prepare a similar article and others need not be considered.

But in semisolid fatty preparations, the vehicle employed should be designated since it is of great importance that the physician be advised as to the general dermic properties of the preparations. Thus, in the case of ointments, the fatty vehicles determine the respective general uses of the preparation, viz., if the agent is desired merely for protection, a non-absorbent fat such as petrolatum or cerate, is wanted; if intended for subdermic use, animal or vegetable fats and oils, lard, etc., while if systemic effects are desired by inunction, hydrated wool-fat is the vehicle to induce rapid absorption of the medicinal agent.

To summarize: the trade-names should be supplanted as early as possible by pharmaceutical ones, at least as synonyms; the general composition must always be given; the vehicles for fatty preparations should be stated; the article must not be exploited to the laity, in order to secure medical patronage.

Chemicals of Group 7 will be treated under "chemicals made by patent processes."

Therapeutics.

Stomatitis Aphthosa.

Paint the affected areas four or five times with:

R.	Borax	4 parts	
	Tincture of myrrh	8 parts	
	Syr. of mulberries	60 parts

Ichthyol in Burns.

Ichthyol is efficacious in burns of the first and second degrees. It allays the pain at once, and slight superficial burns heal rapidly. It is used dry, diluted with zinc oxide or bismuth—the powder being spread evenly over the surface—in the form of paste, or as a combination of both methods. The zinc-oxid powder may be combined as follows:

R.	Zinci oxid.		5v
	Magnesium carbonatis		5iii
	Ichthyol		5iiss
	Below is the composition of the paste:		
R.	Calcii carbonatis		5i
	Zinci oxid.		5iv
	Ol. olivæ		5i
	Liquor. calcis		5i
	Ichthyol		5i

—Monatsh. f. prak. Dermat.

Seasickness.

From the *Practitioner's Manual* we quote the following:

The mere fact of being upon a vessel does not preclude the possibility that the nausea, vomiting, headache, depression, sleeplessness, pallor, perspiration, may have other causes than the one most likely under the circumstances, or that there may be some complications requiring most prompt and urgent attention. Examination of the abdomen may disclose signs of volvulus, appendicitis, obstruction, etc. Begin three days before sailing and continue for first three days out to take:

R.	Ext. taraxaci		
	Ext. colocynth. comp, āā		gr. xx
	Ext. hyoscyami		gr. iiii
	Ext. nucis vomice		gr. v
	Masse hydrargyri		gr. xv

M. Et fiant pil. No. xx. Sig. One or two each night. During this time let the diet be simple. Avoid fluids. Keep the recumbent posture on deck.

PREVENTIVE TREATMENT.

For an hour before embarking give every quarter hour, strychnin sulphate (arseniate or hypophosphate) gr. 1/20, in granules or tablet triturate. A combination of these three salts of strychnin, gr. 1/20 of each, can be given for three days, three times daily, and each night half a grain of podophyllin. —Le Griæ.

Wear a tight bandage or belt from the ensiform cartilage to below the umbilicus. Potassium bromid, 5ss—3i; take, upon embarking, in a large glass of soda water and repeat for long voyages in perhaps smaller dose; or take chloral in corresponding large dose. Remove bile by giving hot water to provoke emesis. —T. Lauder Brunton.

Bromization is demanded, and this must be induced and kept up two or three days before, and continued for several days after sailing, and sometimes even through the entire voyage. The amount necessary to produce mild bromization varies in individual cases. Thirty grains three times a day may be sufficient, but in many cases it is necessary to give much more than this. Because of its greater acceptability to the stomach, the bromid of sodium is much to be preferred to the bromid of potassium. —Rockwell.

TO ARREST VOMITING.

Asthmatic Bronchitis.

Torres Homem recommends, in O Brazil Medico, a tablespoon of the following, five minutes before the two principal meals, in cases of bronchitis with asthma:

- R. Sodii arseniatis.....gr. iss | 10
- Aque destil.....ʒixss | 300

Treatment of Seborrhea.

Dr. J. F. Payne, in "Allbutt's System of Medicine," says:

There are many popular remedies for dandruff. Washing, alkalis, lime-water, borax, etc., have some efficacy in removing the scurfy condition, for a time. And admitting that this condition is almost certainly due to the action of microbes, we treat it upon this supposition. Hence, first we shall disinfect the skin of the head as thoroughly as possible. For this purpose an antiseptic soap may be used; I prefer

one containing biniodid of mercury. After washing with this a few times the scalp is to be brushed over with perchlorid of mercury solution (1 to 1000), either aqueous or alcoholic. But this treatment is not sufficient, and irritation is often produced by the antiseptic; we then have recourse to sulphur combined with carbolic acid or tar, as follows:

- R. Sulph. præcip.....gr. xv
- Acidi carbolicii.....m. xv.
- Olei amygd. amar.....m. iij
- Paraffin moll.....ʒi
- M. ft. Unguent.

Coal-tar solution may be substituted for carbolic acid, and the ointment may be scented with an essential oil. Resorein, either in a lotion—2 to 5 per cent.—or combined with sulphur in an ointment—the same proportions as given for carbolic acid—is also a very efficacious means. The ointment should be rubbed thoroughly into the roots of the hair once a day for a fortnight, and afterward used occasionally. Since patients will not tolerate greasy applications for very long, a lotion or hair wash must then be substituted. The following prescriptions are useful:

- R. Liq. carbon deterg.....m. iv ad x
- Glycerin.....ʒss
- Aque rosæ ad.....ʒi
- M. ft. lotio.

- R. Glycerit. acidi tannici.....ʒi to ʒii

The latter is used only when there is an entire absence of inflammation, as a stimulant to hair growth.

Too frequent washing with insufficient drying greatly favors the production of dandruff, and must be avoided. Seborrhea of the body, if not complicated with eczema, is easily got rid of by thorough washing followed by a sulphur ointment or lotion, or one of the other remedies recommended above for the scalp. In all affections of the head, brushes, combs, and other articles should be kept thoroughly disinfected with borax or carbolic acid.

TREATMENT OF SEBORRHEA OLEOSA.

The first step here is thoroughly to remove the sebaceous crusts, for which purpose imunction with some oily substance—such as pure olive oil, carbolized oil, a mixture of equal parts olive oil and fresh lard, or others—is necessary. These should be left on for twelve hours, and the head then washed with soap or, if the skin is inflamed, with yolk of egg. The subsequent treatment is the same as for the other variety. Sulphur in some form is the most efficient remedy.

INTERNAL TREATMENT OF SEBORRHEA.

Generally speaking, no internal treatment is necessary, and from my own experience I believe that internal conditions have little to do with the production of seborrhea. But two points have to be considered. 1. Gastric dyspepsia, though far from producing seborrhea of the scalp, may aggravate the condition when present, chiefly by producing irritation of the skin and consequent scratching. The same is true of constipation. It may then not be superfluous to correct morbid conditions of the stomach and bowels as far as possible. 2. The general nutrition of the skin may be bad, and consequently the seborrheic process gets firmer hold. Hence it may be advantageous to give a course of arsenic, which has acquired a special reputation in the treatment of certain forms of seborrhea corporis.

Medicolegal.

Five Hundred Dollars for Four Hours' Pain and Suffering.—The Supreme Court of Arkansas holds not excessive, in St. Louis, Iron Mountain & Southern Railway Company vs. McCain, Administrator, an award of \$500 for the pain and suffering caused by an injury which terminated fatally in four hours' time.

Liability for Infection of Assistant.—The declaration in the New Hampshire case of Edwards vs. Lamb, an action for negligence, alleged that the defendant, a physician and sur-

geon, was employed to treat the plaintiff's husband for a wound which became an infectious sore; that the defendant knew the danger to the plaintiff of infection therefrom but negligently informed her that there was no such danger, and on one occasion directed her to assist in dressing the wound; that she, in justifiable ignorance of the truth, and relying on his assurances, did so assist him, whereby she became infected with septic poison. The defendant demurred to the complaint. But the Supreme Court of New Hampshire has overruled the demurrer. It says that the question presented was not one of breach of contract and that it was not necessary to consider how far the defendant's contractual duties extended. Nor was it necessary to decide whether, in the absence of any statement by the defendant, he would be liable. The case was one of positive action, not merely of failure to act. The declaration alleged, as above stated, that the defendant informed the plaintiff that there was no danger of infection, and when he did this he voluntarily assumed certain obligations. The fact that his duty, as to her, was merely to advise, and not to administer treatment, was immaterial. The situation was such that she needed the advice of a physician. This the defendant knew. He knew of her danger, and negligently advised her as to it, and she was injured by following his advice. That when he advised her he assumed the obligation to use due care in so doing was not open to doubt. Moreover, the court goes on to say that, if the contract to attend the plaintiff's husband were eliminated from the case the liability would be the same. The gratuitous character of the services rendered to the plaintiff would not excuse the defendant's failure to exercise such care as the circumstances demanded. On the other hand if the advice to the wife was treated as a part of the performance of the contract with the husband, the defendant still owes her the noncontractual duty to use care in the performance of such of his services as concerned her personally. Then, it was urged that there would have been no danger but for pricks in the plaintiff's fingers of which the defendant was ignorant. The court replies that there was danger unless the plaintiff's hands were free from the slightest wounds. And it adds that it can not be said as a matter of law, that a perfect physical condition is so common that the defendant could reasonably rely on it in giving advice, or that the plaintiff ought, as a reasonable person, to have understood that he was acting on the assumption that such was the fact.

Crooked Ankle Indicative of Malpractice.—Certain physicians in Kentucky were sued for damages for negligently setting a broken ankle, by reason whereof it was alleged that in healing it was crooked, and painful to use in walking. The answer denied any negligence, and alleged that the crooked condition was caused by the negligence of the plaintiff alone. On trial before a jury at the conclusion of the plaintiff's evidence, the court gave a peremptory instruction to find a verdict for the defendants. This, the Court of Appeals of Kentucky holds, was error, on account of which it reverses the judgment entered in favor of the defendants, remanding the cause for a new trial. There was no proof introduced as to the treatment, except by the plaintiff—that for five days bandages and bags of sand were used around the ankle, and then the leg reset and incased in plaster. No surgeon or expert was called to testify, and it was not shown whether this treatment was the usual and proper treatment for that kind of an injury, or whether it was unskillful to so treat it. However, it did appear in proof that the bones knit together and healed at the place of fracture, but the ankle and foot were crooked, and the ankle-joint stiff. Now the court of appeals is of the opinion that under this proof alone the jury might have concluded that the leg was not set straight by the defendants, and that it knit together as it was set, and might therefore have concluded that the defendants were guilty of negligence in replacing the broken bones. If they so concluded, a judgment for the plaintiff, it holds, would have been authorized. It says that it recognizes the well-settled principle that physicians and surgeons are held to possess only the usual and ordinary skill of the members of the profession in that community where they are engaged, and that without special contract there is no guaranty of a cure. But it goes on to

declare that, in that state—Kentucky—where no person is permitted to practice medicine or surgery without a certificate of qualification from the State Board of Health, and where by the same energy and vigilance of that body the profession of medicine has reached so high a standard, it thinks a jury would be warranted in concluding a physician guilty of negligence, who, in resetting a broken limb at the ankle, would leave the ankle and foot crooked. The question presented, it adds, was not one of cure. The broken bones did unite and grow together, even in the crooked position, and would have, the court thinks, necessarily united if placed straight. This case, of Hickerson vs. Neely, is "not to be officially reported," but will be found in 54, *Southwestern Reporter*, 842, 843.

When Epidemic of Smallpox is Threatened.—Mention was made on page 377 of THE JOURNAL, that the Supreme Court of Indiana had sustained the State Board of Health in its order excluding unvaccinated children from the public schools. The decision thus briefly referred to was rendered in the case of *Blue vs. Beach*. But the court's opinion is rather lengthy and contains several points deserving of notice. First of all, it wants it understood that with the wisdom or policy of vaccination, or as to whether it is or is not a preventive of the disease of smallpox, courts, in the decision of cases of this character, have no concern. That question is one which the legislature or boards of health, in the exercise of the powers conferred on them, must in the first instance determine, as the law affords no means for the question to be subjected to a judicial inquiry or determination. Then, it says that there is no express statute in Indiana making vaccination compulsory, or imposing it as a condition on the privilege of children attending the public schools, but holds that, in the absence of such a law, the exclusion in question was justified, as a public emergency, under the rules and orders of the state and local boards of health respectively. And it emphasizes that it does not here go beyond holding that such exclusion may be made during the continuance of an emergency, as where there is a threatened epidemic of smallpox, as that it considers it as far as the rule or order objected to went. Nor does it think that either the holding of the Supreme Court of Illinois or of the Supreme Court of Wisconsin can, under the facts, be said to militate against the conclusion reached in this case. Here there had been an exposure to smallpox on the part of the community. This being true, and an emergency on the account of danger from smallpox having arisen, and the board of health of the city believing, as may be assumed, that the disease would spread through the public schools, and further believing that it would be prevented, or its bad effects lessened, by the means of vaccination, and thereby afford protection to the pupils of such schools and the community in general, the court holds, it would certainly have the right, under the authority with which it was invested by the state, to require, during the continuance of such danger, that no unvaccinated child be allowed to attend the public schools; or the board might, under the circumstances, in its discretion, direct that the schools be temporarily closed during such emergency, regardless of whether or no the pupils thereof refused to be vaccinated. And, under the circumstances, this power the court holds, was lodged in the local board of health, irrespective of the rule of the state board. It also declares that it would be an absurdity, under such circumstances, to require the health officials, before taking action to prevent the spread of the disease, to investigate in order to determine the degree of exposure to which every person in the community had been subjected. Besides all this, it says that it is a well-recognized fact that our public schools in the past have been the means of spreading contagious diseases throughout an entire community. They have been the source from which diphtheria, scarlet fever, and other contagious diseases have carried distress and death into many families. Surely, it then adds, there can be no substantial argument adverse to the reasonableness of a rule or order of health officials which is intended and calculated to protect, in time of danger, all school children, and the families of which they form a part, from smallpox or other infectious diseases.

AMERICAN.

1. **Senile Arterial Plethora.**—Allbutt treats especially of the senile fluctuations of the blood pressure, which is often temporarily increased in the aged. He quotes from Savill, his post-mortem findings showing the general increase of the arterial coats, more especially of the muscular coat, and his views that senile vertigo and senile syncope are clinical manifestations of this arterial hypermyotrophy.

2. **Infection Through Tonsils.**—The routes of infection through the system are first noticed by Packard with special reference to the mouth, where it would seem from the abundance of micro-organisms that there must be constant infection of the mucous membrane. The tonsils are especially exposed, and he briefly reviews the comparative anatomy and concludes that they are not evolutionary vestiges. He is inclined to believe that they have certain protective functions, acting as do lymph nodes, and form a defensive outpost of the digestive tract. We have, therefore, to consider them as dangers to the organs no more than we should look on the inguinal glands as a danger point in venereal disease. Diseases of the tonsils are evidence of the protective conflict in retaining the bacteria and destroying their virulence. He reviews the various disorders which have been found to follow or complicate tonsillar inflammation, as they have been observed by various authorities. Among these are cardiac disease, pleurisy, synovitis, skin lesions and chorea. Of this last he reports two cases. He refers to the infection theory and its origin.

3. **Fracture of Radius.**—After first noticing the usual textbook statements as to diagnosis of fracture of the shaft of the radius, Louman says his experience has been contrary to these. The cases he reports and illustrates he thinks could not be diagnosed without the use of the X-ray. Both were of interest to him on account of the uncertainty of the fracture of the bone, one being misled by the arm being straight, the ulna being in position.

5. **Appendicitis.**—Harper reports a case of operation for appendicitis in country practice, under unfavorable circumstances, with success, excepting the occurrence of stitch abscess along the upper part of the incision. The disorder appeared to be a sequel of typhoid.

6. **Cancer of Stomach in Young.**—Cancer of the stomach in persons under 30 years of age is here considered as occurring in the young. Cases occurring before the age of 20 are clinical and pathologic curiosities. Those in the third decade of life, however, are more numerous, and show fairly uniform symptoms. Osler and McCrae analyze a few cases in the first and second decades, which are in most cases rather rapid, though in accordance with Dock's experience cancer of the stomach in early life runs a slow course. They next report six cases occurring in the third decade, which constitute 4 per cent. of the total of their series. In all the disease was rapid and the onset abrupt in 4 of the 6. Certain symptoms are mentioned in detail: Loss of appetite was present in 2 cases, pain in all but one and fairly serious, and accompanied with vomiting, which was absent in the others. Tumor was present in 5, though found only at autopsy in 1. In none of these 6 was there ascites, and 3 were febrile. Only 1 was prolonged over eighteen months, and in 4 others the duration was known; all were under six, and the fifth was also probably of short duration. The authors quote the two following conclusions: 1. Cancer of the stomach below the age of 30 has generally a rapid progress in some months, and often ends suddenly by incidents more or less abrupt. 2. Early cancer is not latent—it is often overlooked.

7. **Epidermolysis Bullosa.**—Elliot describes and discusses at length cases of this disorder, which he thinks is not easily confounded with other bullous affections.

8. **Hip-Joint Disease.**—The spasmodic muscular symptoms and the functional disturbances of hip-joint disease are noticed by Shaffer. The special practical points are the question when to discontinue immobilizing and rest treatment, and to allow

free movement and use of the limb. He favors the use of prolonged protective treatment until he is satisfied that the reflex muscular spasms have ceased to exist and the damaged joint is in a state of true convalescence. The latter does not begin in hip-joint disease before the important symptoms which enable us to make a diagnosis are present or before the joint disability is relieved so as to make the hindrance to locomotion of lesser effect than that occasioned by simple disuse, and not so long as any deformity is present. Still, the danger of too long immobilization is a real one, and when the joint is free from reflex muscular spasm, it may be at once placed on gradual treatment by use and movement.

9. **Widal Reaction.**—Gnerard concludes, from a review of the published facts and his own experience of three years including the examination of about fifty specimens a week, that the Widal reaction is as reliable a test as any bacteriologic one now in use. The serum reaction is never present in other diseases if correctly tested and in proper dilution. It does not appear as a rule during the first few days of disease, but is usually manifested before the eruption appears and is only occasionally late in its appearance and very rarely absent. While it has its undoubted limitations, it is nevertheless of value to diagnosis in irregular and mild cases of typhoid.

10. **Mysticism Among Negroes.**—Carroll describes the superstitious ailments of negroes and his success in treating them under the advice of an old experienced physician. The treatment was purely mental, the performances largely to affect the imagination, and its success was brilliant.

12. **Clinical Examination of Blood.**—The vital facts to be ascertained in the examination of the blood are: 1. Number and character of red corpuscles. 2. Number and character of white. 3. Proportion of various kinds of white. 4. Presence of parasites. He details the method of counting, but the study of stained films is much more valuable. The usual method of making them is given. The latest formula for Ehrlich's "triacid stain" is the best he has ever worked with. None but Grüber's colors should be used in compounding it. Of the primary diseases of the blood, chlorosis, pernicious anemia, and leucemia can be diagnosed as a rule in from a few minutes to an hour's study with the Ehrlich stain. He has not found any case of filaria sanguinis, but as regards malarial parasites he directs as follows: To prepare fresh blood for examination, take three covers and three slides, cleaned. Draw the blood—a minute fresh drop—touch the cover with it, drop each cover on a slide and see that the blood spreads without pressure. Put by in a warm place if immediate examination is not practicable. By coating the margin of the cover with vaselin the blood will often stay good for an hour or more, though the fresher the specimen the better the chance of showing the characteristic amoeboid movement of the plasmodium, which is invaluable for identification. We should try to get the specimen during or just after or before the paroxysm, and he thinks it bad practice to give quinin before the parasite has been found if the chances of finding the germ are considered. When fresh specimens can not be examined, dry films properly made and properly stained will be nearly as good. He describes a quick method for this.

13. **Ectopic Pregnancy.**—After giving some illustrative cases showing the peculiarities of the symptoms in ectopic pregnancy, Coe concludes that pain alone, when not accompanied by a clear history of menstrual irregularity, symptoms of pregnancy, and the presence of a tumor at the side of the uterus or in Douglas' pouch, is pathognomonic of extra-uterine pregnancy only under certain conditions, viz.: The pain is of a sharp colicky character, distinctly localized on one side, attended with faintness more or less marked, and is usually followed by intervals of hours or days of complete remission. The pulse is accelerated during the attack, but there is no rise of temperature. The latter is an important symptom, distinguishing ectopic from inflammatory conditions. The violent tearing pain attending intraperitoneal rupture is accompanied by the unmistakable evidences of internal hemorrhage. In extraperitoneal rupture the symptoms vary in severity according to the amount of blood lost, but soon subside, being succeeded by the usual evidences of pressure resulting from a mass in the folds

of the broad ligament which displaces the pelvic organs. A persistent pain following the acute attack may indicate localized peritonitis.

14. Tuberculous Disease of Urinary Organs.—Gile finds that tuberculous disease of the urinary organs is a condition of considerable frequency, more so probably than the number of cases diagnosed would indicate. Its course is variable; it may be rapidly fatal or chronic, and for certain diagnosis one must depend on the bacteriologist, though this course does not always definitely localize the trouble. He does not think that the affection originates in the kidneys as a rule, but that many cases start primarily from the bladder. The hereditary character of the disease appears to be more definitely marked than in pulmonary tuberculosis. From his own cases he thinks it occurs more frequently in early adult than, as frequently said, in middle life.

15. Accidental Malarial Inoculation.—Katzenbach reports a case of a physician, thoroughly examined bacteriologically, where malaria was apparently contracted through an operation of hysterectomy on a woman who had recently come from a malarial district in North Carolina. The parasite found was of the estivo-autumnal type, which has not prevailed in New York, and the patient had previously been in good health.

16. Curability of Early Phthisis.—Hazelton reviews the statistics reported by various authorities as to the proportion of cured cases of tuberculosis. He thinks the fact established that from 10 to 50 per cent. of cases, according to individual resistance and promptness of treatment, are curable.

13. Artificial Anus.—The difficulties of properly producing an artificial opening of the intestines are noticed by Weir, who reviews the different methods and sums up as follows. 1. An artificial anus of a temporary character can be best established by Maydl's operation or by Bodine's modification. 2. Overslipping of feces may be prevented by proper spur formation, by narrowing the rectal opening, or by occluding the rectal end of the bowel, which may be fastened in the wound or dropped into the abdominal cavity. 3. Continence of the abnormal outlet is aided by muscle separation (Maydl) or by muscle bridging (von Hacker and Hartmann), or by the use of inflatable or moulded plugs or other apparatus. 4. It is only, however, to be satisfactorily effected—though larger experience in this is desirable—by an extra-abdominal iliac outlet (Witzel's iliac colostomy) to be made by opening the bowel outside and behind the iliac spine. In this procedure the bowel is compressed between the edge of the bony pelvis and the skin.

Many other methods have been proposed. Some, like Witzel, have made the outlet externally, but by gouging a hole through the iliac bone. Other schemes have been tried and have failed. A few are unsurgical. Perhaps some have promise, and may in time, their value not now being recognized, develop into methods of note. He has himself operated in 30 cases with 9 deaths, 2 from cancer, 3 from ulceration and 4 from obstruction. In 18 of these, colostomy was a preliminary to operation or was a curative agent. There were 7 in which the opening was subsequently closed.

19. Constitutional Treatment of Catarrh.—The catarrhal affection of the upper air-passages, or what may be so-called, from diseases of other regions of the body are noticed by Wells. He thinks that the responsibility for much of the greater number of secondary catarrhal affections of the upper respiratory organs belongs to the gastro-intestinal system. Among these he specially mentions a form of throat disorder involving the lingual tonsil as connected with dyspepsia, and he also notes the condition of intestinal flatulence insisted on by Moritz Schmidt as a factor in the production of catarrhal diseases of the upper air-passages. Those of the reproductive organs, etc., are also noted, and especially the so-called uric acid diathesis. This last he considers as often having much to do with the nervous irritability, which he calls neurohyperkinesia, and this, with other conditions like hysteria and neurasthenia, is often responsible for catarrhal disorders. He gives a few brief indications as to treatment for each of these.

21.—See abstract in *THE JOURNAL* of April 14, p. 934.

22. Intermenstrual Dysmenorrhea.—After briefly reporting twenty cases of his own observation, Storer remarks that he

has collected twenty-five more from the scanty literature on the subject. He found that in these the pain appeared regularly every month, within a few days of a definite period, generally along about the 12th to 16th day. In most cases it was paroxysmal, in about one-half it resembled that of menstruation. Its duration was generally two to three days. The pain was sharply limited in 14 cases; in 12 it was more general. In no case was there any discharge. It certainly is not always ovarian and in a large proportion there was a more or less inflammatory condition of the appendages. The various theories of the condition are reviewed and the objections to them stated. The author offers the following theory which, for the want of a better name, he calls "the awakening of menstrual activity" theory: "The intermenstrual pain coming about the fourteenth day from the beginning of menstruation, the nineteenth after the climax of Stephenson's wave, occurs just about the time the pressure line has reached its lowest point. Can not then the intermenstrual wave, if one exists, be one of preparation rather than a subsidence, a nervous explosion, so to say, as if nature were waking up with a more or less violent effort to make ready for the coming activity, whether menstrual or ovarian? We have seen how for nearly three weeks the wave of vital energy has been running down hill and the system has, as it were, got into a rut. Nature suddenly says this decline must be stopped, and in the readjustment of forces that ensues as the human machine begins to work again with greater energy, it is not to be wondered that there should be groaning from some of the machinery, which, however, after a day or two finds its bearings again and then works automatically and in silence. This theory would not be incompatible with the fact that this pain occurs under such a variety of pathologic conditions, ranging from simple endometritis to pyosalpinx and fibrosis. The pain does not of necessity come from any one organ, but from whatever organ is the most irritable or diseased, will come the loudest protest at the sudden arresting of the comfortable vital decline."

26. White Blood Count in Surgery.—Hubbard finds, from an analysis of the surgical records of the Massachusetts General Hospital, that the white blood count may vary very largely without indicating the condition of suppuration, and that from our present knowledge of the cause and variations of leucocytosis, we can not make any deductions simple enough to be of great use to the surgeons at the bedside. In some cases the blood count may indicate an exactly opposite condition to what is shown by the physical signs.

27. Deep Breathing vs. Tuberculosis.—The point of Spiers' article is that by deep breathing we call into exercise the healthy lung tissue we possess, and cause better aeration and better blood-supply. The bacilli of tuberculosis can not act provided the aeration of the blood is perfect. He says that the number of germs in the atmosphere is of little moment provided there is perfect aeration of the blood.

28. Gunshot Wound of Fetus.—Nietert reports a case of gunshot wound involving the uterus and fetus, followed by Cæsarian section and recovery of the mother. The notable points of the case are the rarity of the accident and the absolute lack of any infection, notwithstanding the bullet's passing through several layers of dirty clothes. There was a large powder burn on the skin, and the patient confessed, when confronted by this fact and its necessary inference, that the wound was self-inflicted.

35. Operation in Cancerous Uterus.—Kelly says that his views in regard to extirpation of cervical cancer have changed somewhat during the past year, and that he now believes that glandular metastases are not so important in mammary cancer or are rare until the later stages. He offers a new method of operation which he details at length. He first insists on catheterization of the ureters. Then, after curetting, he cuts through the vagina on all sides, strips it loose from the bladder, opening the peritoneum as widely as possible. If the bladder is diseased, the base of it may be cut off and left sticking to the cervix. The uterus being attached by its broad ligaments alone, a gauze pack is inserted behind it, while the anterior wall is pulled down with the forceps through the anterior incision,

until the fundus appears at the vaginal outlet. The next step is to bisect the uterus from above downward, and half of it is caught by a stout museum forceps. Catching the cervix of the same side, the body is also completely severed from the cervix by dividing from within outward. As soon as the division is done the uterine vessels are clamped in the exposed cellular tissue and the detached body is pulled farther out, the round ligament clamped and lastly the uterine cornu. In this way one quadrant of the uterus is removed. The same method is followed on the opposite side. The ligatures are then applied in place of the clamps. The ovaries and tubes are removed after the body of the uterus, and it then becomes an easy matter to take out the cervix on the side which is least implicated. Under all circumstances give it the widest possible berth, keeping the rigidly catheterized ureter under touch all the time; three-quarters of the uterus having been removed, the remaining quadrant, that half of the cervix on the side where the infiltration of the broad ligament is most marked, is then extirpated. The operator holds in the grasp of his forceps a small nodule, one-half of the cervix, and the idea is to get it out with perfect control of the vessels, giving it the widest possible berth. This may be done in some cases by ligatures, but it will be better done in the other cases by cautery clamps (Skene's), or by igni-extirpation, as done by Mackenrodt. If the ureter lies clearly beyond the diseased area, and is uninfected, it may be dissected out and left intact. In many cases, however, the operator must not hesitate to cut it off above the diseased area and proceed with wide enucleation of the nodule as if it did not exist. After enucleation the ureter may be turned into the denuded bladder and stitched there. The anterior and posterior peritoneal surfaces are then drawn down and attached to the vagina, and are again sutured together in the middle line so as to leave but two small openings up in the pelvis, which are loosely stuffed with gauze.

36. Fibroid Tumors.—Kelly describes two new methods of enucleating complicating fibroid tumors. In the first the large tumor occupies the lower uterine section, elevating the uterus as well as the ovarian vessels and choking the pelvis. He prevents hemorrhage by thrusting two long-jawed pedicle forceps through the capsule of the tumor on each side, at about the level of the round ligament, until the point appears on the posterior surface of the tumor, then clamps powerfully down on the uterine and ovarian vessels. Then pulling the two cornua in opposite directions, he bisects and cuts down into the tumor as far as the vesical peritoneum, which is freed and pushed down; then he enucleates the left and right halves of the tumor by a blunt crenated spatula. The uterine artery is then easily reached and tied at a point below the body of the uterus, then the bed of the tumor closed by buried sutures and the vesical peritoneum drawn over and attached to the posterior peritoneum concealing the wound and the operation finished. "The enucleation of the bisected uterine body may be done after the removal of the tumor in one or two ways—either by tying the ovarian vessels, now easily reached, and the round ligaments and lastly the uterine vessels and then amputating, or by severing first one then the other half of the uterus from the cervix, below, cutting from within outward, from the center of the cervix toward the broad ligament, and so exposing and catching the uterine vessels, after which they are divided and each half is pulled up in turn by its cervical extremity and the round ligaments of the ovarian vessels tied in order. The direction of the enucleation in this case is from below up, the reverse of the direction ordinarily taken; the extirpation in this way is facilitated by the sagittal bisection of the uterus." The second operation, which he has performed but once, is, he thinks, adapted for those cases in which there are dense adhesions of the upper pole of the tumor, which can not be dealt with without great risk by operating from before backward. In this operation he caught up the cervix by short-toothed museum forceps and brought it up within reach. The vesical peritoneum was then detached and pulled down, exposing more of the cervix, which was caught with a second pair of forceps. A knife was then passed through the cervix in the antero-posterior direction between the two pairs of forceps, and the cervix was cautiously divided from side to

side, and pulled apart. The cellular tissue to the left was first exposed, the uterine vessels clamped with short, stout forceps, and the right one treated in the same way. The upper forceps was then used to drag up the tumor and the uterine body, rotating them on a transverse axis, first exposing the round ligaments and then the ovarian vessels of the left and right sides, respectively; these structures were clamped and the whole mass disconnected from its pelvic attachments. The tumor now only remained adherent by the dense adhesions at its upper pole. The next step was the rupture of an enormous abscess lying behind it and extending from the center of the tumor into a sac bordered posteriorly by the lumbar vertebrae and above by the mesocolon, and discharging through a large opening into the transverse colon. The tumor now rolled out, being enucleated from behind forward without added injury to the bowel, other than was rendered necessary by the opening into its lumen. The contaminated abdominal cavity and the abscess cavity, containing at least a liter of thick yellow pus, were cleansed, the opening in the bowel sutured and the long abdominal wound closed, leaving a large iodoform gauze drain about the umbilicus into the remainder of the sac under the colon. The patient made an excellent recovery.

38. Melanosarcoma of the Skin.—Schalek finds, from an observation and analysis of the literature, that while the final decision as to the histogenesis of melanosarcoma is not easy, it appears that the standpoint taken by Unna and his followers is probably correct. Melanosarcomata of the skin do arise from the pigmented epithelial cells of the epidermis; these cells proliferate into the connective tissue and become entirely detached from the epidermis; still further proliferating, after having been cut off, these cells lose their epithelial character and assume that of ordinary connective tissue elements and that of those particular pigmented cells known as chromatophores. This view, that epithelial cells may undergo such a metaplasia under pathologic conditions, is not at all improbable, since L. Loeb has also stated in another paper that chromatophores of a typical character originate from epithelial cells. Concerning the pigment, we have found that it is finely granular and not very dense in the epithelial cells from which the melanotic tumor arises. The pigment becomes more coarsely granular, the more pigmented cells assume the character of connective tissue cells, more particularly that of chromatophores.

39. Malignant Tumors.—The following is the summing up of Buxton's paper: 1. Carcinomas contain connective tissue stroma because there is an attempt at defense on the part of the organism. 2. Their increase is not prevented, because the cells can multiply in the newly-formed lymph spaces of the stroma. 3. Sarcomas, as a rule, contain non-connective tissue stroma, because they consist of the very cells which would be called on to form it, and which are now in revolt. 4. Sarcomas contain numerous blood-vessels, because these always penetrate masses of immature connective tissue cells, whether in the embryo or the adult. 5. Certain sarcomas contain connective tissue stroma because the cells composing them are ordinary connective tissue cells, so that the latter are able to attempt defense. The defense fails for the same reason as it fails in the carcinomas. 6. Tumors containing connective tissue stroma form metastases via lymphatics, because the newly-formed lymph spaces in which their cells are growing open up communications with the regular lymphatic channels. 7. Tumors containing no connective tissue stroma form metastases via the blood-vessels, because the cells can easily break through the immature walls, while lymph spaces are absent.

44. Rhinitis Due to Tooth in Nasal Cavity.—Dupuy reports a case of purulent rhinitis the source of which was finally discovered to be a carious tooth growing in the nasal cavity. The only case in literature which he has found similar to this was that of Tyler, which was a supernumerary tooth, while in this case it was a misplaced one.

48.—This paper appeared elsewhere: See abstract in THE JOURNAL of Oct. 21, 1899, ¶ 68, p. 1033.

51. Medical Science of the Talmud.—Imber claims that the Talmud anticipated the discovery of many valuable methods

and hygienic facts. It ascribes all diseases to certain little dangerous ones which it calls "shedins"—destroyers. In accordance with this bacilli theory the following hygienic laws were enacted: "1. If an animal was killed, the Talmud urges, under certain penalty, to cover its blood with the dust of the ground or with ashes. (As it has been proven that the belly of mother earth is the best of bacilli destroyers.) 2. No Jew was allowed to wear hide in its raw state as a garment. 3. No tannery was allowed to be established, except two miles from the city and not on the east side, for the wave in the Orient was mostly easterly winds. 4. No spitting was allowed in the city of Jerusalem. (Our moderns have realized the danger 2000 years later.) 5. Four cubits of space shall be allotted to each person in a room. (Our modern board of health of course ignores that law and the tenement houses in the big cities have not a yard to spare for a person.) 6. To beware of flies of lepers, as they are transmitters of the disease. (In perfect harmony with views of modern science.) 7. To investigate every slaughtered animal, if it had not a lung or liver trouble. (If our inspectors sent out by the 'board of health' to investigate the slaughter houses would observe that law, the Christian people would enjoy the sanitary benefit which the orthodox Jew enjoys in regard to health.) 8. To throw out the water where a person just died, and destroy all his clothes. (That law was most beneficial to the human race, and I think, if the board of health should take it into consideration, they will not give a permit to the second hand clothes dealers until their goods were disinfected.)"

53. **Incurability of Leprosy.**—Ashmead reviews and discusses the cases of reported cure of leprosy, and finds that with no case was there more than temporary relief of symptoms. He is especially critical of Dyer of New Orleans, and his views as to the possibility of the cure of this disease.

57. **Strangulated Hernia.**—The frequency of this accident renders it a part of the experience of almost every general practitioner. Wahrer therefore insists on the necessity of the physician being able to operate; in many cases the question of prompt operation is one of life or death; the patient has everything to gain by it, as it may save his life, and otherwise he will surely die. He advises the physician who has such a case to call in the assistance of a neighboring practitioner, or two are better, and to follow the following technique: Wash the patient clean, shave off all hair over and near the site of the operation, wash the hands clean, boil the instruments—in a bread pan if there is no regular one in the surgeon's outfit—in a solution of soda, then spread a boiled towel over a small table and lay the instruments on it—if the towel is wrung out of a 5 per cent. creolin solution so much the better. The patient is placed on a kitchen table, and when he is under the anesthetic an incision is made through the skin and fat in a semicircular line, the convex side toward the umbilicus, then through the three layers of muscles. The sac of the hernia is then followed down to the ring and an incision made large enough to enable return of the bowel. The sac is drawn out as far as possible, tied off with a stout catgut, or better a kangaroo tendon, and in a similar manner, any redundant mass of omentum cut off, dropping both stumps back into the abdomen. One must carefully avoid including the cord in the ligations or the coverings, and sew up the peritoneum with catgut, also the three layers of muscles, lastly the skin with catgut, silkworm gut or silk—which is better. Over the wound gauze is applied, a good layer of absorbent cotton over that, and it is secured with adhesive strap or bandages and the patient put to bed. He says expert surgeons must not criticize him for this unrefined technique and gives also in detail the directions for antiseptics. The instruments are simple and inexpensive. As regards antiseptics, he says: "Get a bread pan or two, put your instruments and needles into one of them, some boiled water in the other; it does not matter if you put any drugs in as antiseptics or not, so you have things clean. Wash your hands, if you have nothing better, in boiled water and soap, then more water and soap, then some more water and soap. Keep this up for fifteen or twenty minutes and your hands will be as clean as those of Lawson Tait." Avoid rough and useless

effort at taxis and rough handling of the bowels and avoid rough handling of the cord.

60.—See abstract in *The Journal* of March 17, p. 688.

69. **Ureteral Fistulae.**—Bullock reports a case of ureteral fistula which seems to have been caused by an infected ligature in close proximity to the ureter, producing ulceration. The tumor opened externally through the inguinal opening, and is now nearly closed.

70. **Nitrous Oxid.**—After giving the chemistry of the drug, Grant describes the methods of its use. The known rules in anesthesia should not be overlooked with this anesthetic. An empty stomach need not be insisted on, but it should not be distended. The sitting posture for short operations may be maintained throughout, and the head should be bent forward rather than backward as there is less danger of the tongue falling back. All foreign substances should be removed from the mouth, such as plates, etc. A prop should be placed between the teeth. The first impression on the patient is a sweetish taste of the gas and a certain sense of oppression. In the second stage there is a tingling sensation and consciousness is lost, and the narcosis deepens into the third or anesthetic stage. The circulatory system is but little disturbed, but the respiratory is more affected and the physical indications are those of asphyxia. Then the anesthetic is profound enough for minor surgery, and the inhaler should be withdrawn and the operation performed. The hemorrhage following the use of nitrous oxid is generally venous and may be profuse an hour or more after extraction. Recovery is usually rapid. The dangers are through the respiratory function, and intensified lividity of the face, great and sudden pallor, and cessation of respiration must be regarded as symptoms thereof. The secondary effects of nitrous oxid are trivial; there is no proof of secondary serious complications.

71. **Lobar Pneumonia.**—The treatment of lobar pneumonia, according to Venable, is first, proper feeding, milk diet, meat broth, etc., with stronger and more soluble foods after the crisis is past. Cardiac stimulants should be used when the first signs of heart failure appear. He employs alcoholics in this case, in moderate doses. In an urgent need he uses strychnia, hypodermically. Like strychnia, digitalis may be valuable—10 minims of the tincture every three or four hours. Nitroglycerin is an excellent adjuvant and useful when renal secretion is scanty. Aromatic spirits of ammonia is an excellent cardiac stimulant in the feeble heart in pneumonia. Beginning cyanosis is a signal for the use of respiratory stimulants, oxygen by inhalation, strychnia and atropia. Hydrotherapy is useful and he relies mainly on cold sponging, but pays little attention to temperature unless above 104 F. If he were to give antiseptics, he would use carbolic acid, 1 minim, or thymol 2 to 3 gr., or mercuric chlorid 1-1000 every four hours. Morphine will do for the initial pain, but it is rarely necessary to continue it after the second or third day. Internal antipyretics are not desirable, and arterial sedatives should also be used sparingly and their effects watched. Nervous symptoms are usually met successfully with bath and the ice-cap, and sometimes in the advanced stages stimulant expectorants may be used, though they are generally useless.

73. **Anesthesia.**—Chloroform and ether are the anesthetics generally used. In this article Guest gives the indications as regards chloroform. He first insists on buying only small bottles, two ounces or less, as the drug is then fresher and better. He has a careful urinalysis made a few days before operation, with a warm bath and moderate supper the night before. If the patient is constipated he gives a cathartic two days before, otherwise a saline only, followed by an enema the next morning. A cup of coffee, tea, milk or water may be given three hours before. If the patient is not desperately ill, no drug should be given before operation. He never gives morphine or atropin before giving an anesthetic, as this takes away the pupil reaction, which is one of the first warning signs. He finds the Esmarch drop-bottle the best method. He warns the patient to expect a choking sensation, and, starting with only a few drops, he gradually increases this until surgical anesthesia is accomplished, then very much less will be re-

quired to maintain it. After the incision is made in abdominal surgery, he uses the lightest possible anesthesia. He thinks there is not much choice as to position, but there is much danger in change of position during anesthesia. It is better not to crowd the chloroform during the stage of excitement, and there is no necessity of touching the conjunctiva to produce the conjunctival reflex. If the eye does not rotate by exposing it to the air, it is a safe rule to withdraw the anesthesia for a few seconds. We should be sure never to miss a heart beat or lose a respiration. No anesthesia should be continued if the pupils commence to dilate after the patient is well under its influence. Before commencing, he rubs the lobe of the ear gently between the fingers and watches the capillary circulation. He repeats this every few minutes and, if the circulation falls, the patient is sinking and requires a hypodermic of nitroglycerin, or digitalin, 1-100 gr., repeated in ten minutes if needed. It is difficult to tell by the breathing whether the patient is taking the anesthesia well. When he can distinguish laryngeal stertor, he throws aside the anesthetic and extends the head and neck pushing the inferior maxilla forward. The most alarming symptom is when the breathing is irregular and spasmodic. He then stops at once and resorts to respiratory stimulants hypodermically, and by inhalation. Warning is given that abdominal breathing is not a constant sign that air is entering the lungs. One of the best and most accurate signs is the circulation. When the pulse commences to lose its *vis a tergo*, the finger on the temporal artery is sure to note it. There is a steady lowering of the arterial pressure beginning and ending with chloroform inhalation.

76. **Typhoid Fever.**—Dock is not prepared to say positively that typhoid fever is specific in the sense that it is caused by a germ of unvarying characteristics. The question also as to whether it is always derived from a previous case he also considers still unsettled, though this may not affect the practical point of avoiding contagion or infection. He also speaks with doubt in regard to its pathology. The fact that we find very few germs in the first stages of the disease is an important one in this regard. Whether the treatment directed to destruction of the typhoid bacilli in the intestinal canal is of great value is also doubtful, but he does think that clinical experience shows some advantage in intestinal antiseptics. It is useful to give a cathartic in the beginning of the treatment, and the choice is calomel, though castor-oil appears to be equally effective. During the course of the disease emata will generally serve the purpose, and in convalescence the febrile rises will also be found connected with constipation. The general infection of the system is not parallel in all cases, but that it is extensive is indicated, among other things, by the recent discovery in regard to bacteriuria. Elevation of the body temperature is only a part of the fever and secondary infections may be a possible cause. The belief held by some that elevation of temperature is a salutary process, he thinks can not be maintained. The good effects of the cold bath treatment are not exclusively in its effects on temperature, and its effect in producing diuresis is one of the most important points in the treatment. We must remember, however, that the mortality is now lower than at any former period, and this may be partly due to more comprehensive diagnosis. Dock believes in the modified diet instead of the exclusively liquid one generally recommended, but the excretions must be carefully watched to see that what is taken is fairly digested. As regards medicines, he uses none except for special symptoms, the rare exceptions are stimulants, such as strychnin, and in less marked indications coffee; he has entirely abandoned alcoholics.

77. **Pulmonary Consumption.**—Flintermann reviews the facts in regard to the contagiousness and infectiveness of tuberculosis, and lays down rules for its prevention. Non-expectoration except in special receptacles, thorough cleanliness of rooms where numbers are gathered together, and sanitary inspection of homes. Tuberculous patients should be excluded from public hospitals and sanitarium and treated in special ones. Dispensaries are dangerous; public laboratories should be provided for the examination of sputa, etc. The dangers of bovine and milk tuberculosis are also mentioned,

but he objects to compulsory notification of cases as useless and cruel.

78. **Early Diagnosis and Treatment of Phthisis.**—Duffield says that statistics prove that 60 per cent. of mankind are affected with tuberculosis, and its death-rate is actually from 15 to 18 per cent. He calls attention to certain early symptoms, such as the facial expression, inspection of the chest, scars of old strumous abscesses, physical signs, necessity of attention to the temperature and pulse, small rapid pulse in the young frequently being an early symptom. A large part of his paper is devoted to the treatment by tuberculin, or rather the watery extract of tubercle bacilli of von Ruck, which he thinks is of decided value. He has had twenty patients under treatment in the past fourteen months, and in all there is a marked improvement. He starts the treatment by giving .1 c.c. of Solution No. 1, containing .01 of 1 per cent. of solid extract free from water. He first administers .1 c.c., increasing every day or two until .5 c.c. is taken, then gradually increasing this until 1 c.c. is reached. The injection is made in the loose skin between the shoulder blades. After 1 c.c. is reached, it is continued for about a month, and then he takes Solution No. 10, which is ten times as strong, and, starting with .1 of 1 per cent. increases it by 1-20 until .5 c.c. is reached.

79. **Intestinal Wounds.**—Several cases of injuries of the intestines are reported by Wyman, and in conclusion he summarizes as follows: 1. A wound of the portal vein should be treated by ligation and suture of a part of the omentum to the peritoneum, so that collateral circulation can take place. To do this the free border of the omentum is dragged into the wound made to open the abdomen, and by intercepted sutures fastened to the margins of the peritoneum. 2. Hemorrhage from liver wounds, if not involving large arteries, may be controlled by gauze packing. Arteries may be controlled by cauterization, clamp, forceps or ligation. 3. An effort must be made to preserve the contents of a wounded uterus. A temporary urinary fistula must be provided when the ureter or kidney is wounded.

81. **Cleanliness in Minor Gynecology.**—Skene insists on the importance of the utmost cleanliness in minor gynecology. It is far from easy to keep all the instruments and appliances surgically clean in ordinary office practice. On this account he has adopted the following method: Sterilized cotton kept in a clean vessel is used for sponges and thrown away afterward; wool is resterilized before use; pessaries, hard and soft rubber, are sterilized before using, as are also specula, sounds, forceps, etc., when they are applied in cases suspected of being septic or specifically contaminated. Instruments used in cases free from septic or specific contamination are simply washed in boiling water and dried with a sterilized towel. Vaseline is sterilized by heat and applied with a sterilized paint brush, and sterilized rubber gloves, disinfected each time after use, are employed in digital examinations. In order to insure great cleanliness he uses liquid soap discharged from the lower end of the soap bottle by a movable valve-stopper and running water for ordinary washing. He thinks the steam sterilizer has given him the most satisfaction for the sterilization of gauze, pessaries and towels. Instruments are kept in a sterilized towel, which he thinks is as advantageous as having them put in an antiseptic solution. For surgical cleanliness of the hands he uses a solution of carbolic acid, glycerin and water—5 per cent. of the acid and 25 of the glycerin. In conclusion he cautions about handling money, and he now picks up his fees with a forceps, drops them in a money box, and at the close of a day disinfects them at the same time his instruments are cleaned.

87.—This paper has appeared elsewhere. See THE JOURNAL of March 3, title 176, p. 549.

88.—See abstract in THE JOURNAL of Oct. 28, 1899, p. 1104.

90. **Vaccination.**—Engelhardt reviews the statistics of vaccination. He doubts the existence of natural immunity. The length of immunity against natural infection is longer than that against vaccination. Scars are not reliable indications as to immunity. The only way to insure this is to be re-

vaccinated over and over again. As regards the time of vaccination, he thinks the hot months are most liable to produce complications. The infant is best vaccinated when it is from four to six months old.

91. **Scalp Wounds.**—Fowler notices the common statement in text-books, as to the refractory character of scalp wounds, and gives his experience, which is against this. He thinks the method of using hair to secure the edges of the wound pretty sure to bring on suppuration, and plaster is almost as bad. His own method is to shave away the hair for about one-half inch along each side of the wound, thoroughly cleanse it with warm carbolic water and close the wound with silk sutures, spray and seal with absorbent cotton, and collodion with .1 per cent. iodoform. The sutures should be inserted at least one-fourth inch away from the wound, as too close insertion in the dense tissue of the scalp may cause necrosis.

92. **Electricity and Gynecology.**—Grace considers electricity the most effective remedy in postperperal metritis. It is of value in uterine engorgement, in amenorrhea and scanty menstruation, especially in cases caused by constipation, dysmenorrhea and menorrhagia.

Non-Diabetic Glycosuria. ROBERT SAUNDY.—The occurrence and significance of glycosuria is discussed, and Saundby notices the pseudoglycosuria, where the copper reaction occurs, but which is prevented by repeated filtration through animal charcoal, which removes other reducing substances than sugar. The alimentary and physiologic glycosuria is also noted, and in some cases it may be rather persistent, according to the cases he reports. The other forms mentioned are alcoholic, hepatic, gastric, neurasthenic, and senile glycosuria. In many of these forms, however, there may be an alcoholic factor not given in the history. The author is inclined to think, however, that in many cases there is a disturbance of the liver that is not detected. Senile glycosuria is a symptom of the general tendency to break down, and care must be exercised in ordering strict diabetic diet. The object of his paper, in noticing these different forms of glycosuria, is to call attention to the conditions under which these symptoms may occur, so that the practitioner when meeting it may properly value it and possibly avoid serious errors in diagnosis.

Some Cirrhoses of the Liver. W. B. CHEADLE.—This author briefly mentions the drug treatment, three drugs being more reliable than all others, viz., mercury, potassium iodid and digitalis, the former two in cases with specific complication, the latter in those numerous instances where there is weakness of the heart. He condemns the use of purgatives as a pernicious and fatal practice, and diuretics as of little value. In some cases the limitation of fluids may be of use, but the only reliable way of relieving the condition of ascites is by paracentesis, and the earlier this is performed the safer it is as a rule. He also believes that in the majority of cases cardiac insufficiency, though it may be unrecognizable by the usual physical signs, is a factor in the causation of the more acute cirrhosis of the large alcoholic liver and its accompanying ascites.

The Lancet, April 14.

Typhoid Bacillus and Typhoid Fever. P. HORTON-SMITH.—This lecture by Horton-Smith deals with the Widal reaction. He points out that as the result of investigations by Gruher and Durham, as well as by Widal, credit belongs to three countries, Germany and England as well as France. The dilution to be used, the time limit and culture are discussed, and he thinks the facts show that 1/20 dilution with the time limit of one hour is a reliable standard. If the serum would suggest typhoid fever, producing clumping of the bacillus within one hour with a dilution of 1/20, it can rarely be due to the presence of Gaertner's bacillus or any other than the typhoid. In rare cases the test may be at fault, but the proportion is very small, not over 3 per cent. As to the nature of the agglutinating substance, he thinks the evidence points strongly to the view that the agglutinins are ferments not directly secreted by the bacilli themselves, but produced by the cells of the

body and especially those of the spleen, lymph glands, and bone marrow, under the influence of stimulus produced by invading micro-organisms. The agglutination is a reaction of infection, but Horton-Smith does not fully accept the opinion of Emmerich and Loew that it has a connection with immunity. If this is possible, he says that if we picture to ourselves the delicate changes which occur in the blood of a patient during the course of typhoid fever, we should say that very early in the disease, as a rule during the commencement of the second week, agglutinative properties are in general acquired. But the date at which the agglutinins appear, the amount in which they may be present, and the length of time during which they persist are subject to extraordinary variations. The reaction is undoubtedly one of infection and its connection with immunity, though probable, has not as yet been proved. A little later in the disease bacteriolytic properties make their appearance, and with the gradual increase in their amount the further growth of the bacilli in the body is checked, and finally the latter are gradually digested and destroyed. But even now the disease is not quite at an end, for the toxins set free by the destruction of the bacilli have first to be dealt with. In part they may be neutralized by antitoxins, but of this we have as yet no direct evidence; in part they are probably excreted by the usual channels and thus eliminated from the body. In conclusion he calls attention to the methods of preventive inoculation, the results of which are encouraging.

Plague Viewed From Several Aspects. W. J. SIMPSON.—After noticing the history of the plague, Simpson says there are no productive localities, where it could be said to always exist, neither is it confined to low marshy regions. The present endemic center, Yunnan, China, is 5000 to 7000 feet above the sea. The general mildness of the plague in many places is not to be trusted in, as the ordinary behavior of plague in new localities is slow and insidious. In Calcutta it has existed since 1896, but it is only now that it is beginning to be an epidemic. He thinks the danger of infection from rats a real one, and calls attention to the special danger during the early and late stage of the disease for other countries. The symptoms and treatment are reviewed, and he thinks the only rational treatment is neutralization of the toxins and destruction of the germs. The results so far with the protective curative serum are at least encouraging, and for preventive measures Haffkin's plague prophylactic is of the greatest importance.

Experiments on Intestinal Suture. WALTER EDMUNDS AND EWEN C. STABB.—These authors experimented with the following methods: Halsted's inflated rubber cylinder, Murphy's button and Laplace's forceps, each on seven dogs, and, as far as actual results go, the verdict is in favor of Halsted's cylinders. Their effect is to push back the mucous membrane, which otherwise always everts itself so much as to materially interfere with the suturing of the outer coats and the adaptation of the peritoneal surfaces. The cylinder also prevents the escape of the intestinal contents. They do not think the Murphy button entirely trustworthy without the external suturing, which they did not use in their experiments, and they do not recommend Laplace's forceps. In the seven dogs in which the Halsted cylinder was used, the intestines united circularly in all and the animals recovered. With the Murphy button without sutures, only five were successful, and of the seven with Laplace's forceps, four succeeded; all failures were due to non-union. They do not think the difference in the intestinal muscular coats in man and dogs invalidates their conclusions.

Presse Medicale (Paris), March 31, April 4 and 11.

Alcohol in France and Germany. DE LAVARENNE.—"France produces 311,952 hectoliters of alcohol a year, an increase of 282,760 in thirty years, and, with the colonies, drinks nearly all of this amount, which includes 192,866 hectoliters of absinthe. Germany produces much more alcohol than this, about 800,000 hectoliters more than France in 1897, and has 12,500 distilleries for the production of alcohol from potatoes alone. Part of this alcohol is exported. Part is consumed in heating and lighting, and part has contributed to the great development of chemical industries in Germany. The Germans took coal

and combining it with alcohol, changed it into gold." The world has been flooded since with German anilins, antipyrins, benzins, etc. The exports of chemical products amounted to \$80,000,000 in 1897.

At What Age is Syphilis Contracted? E. FOURNIER.—Investigation of 11,000 private and over 5000 hospital patients, reported in this communication, strikingly confirms the assertion that syphilis is usually contracted very young. In men, by far the largest percentage is during the twenty-third year; earlier in the lower than in the middle classes. Among women the overwhelmingly largest percentage occurs between 19 and 21, on an average, but among girls of the lower classes between 16 and 20, and among prostitutes primary contagion is less frequent after 23 than before 15 years of age. Prostitutes over 23 seldom present the manifestations of primary syphilis, as they are usually past at that age. The figures show that 14 to 20 out of every 100 male syphilitics are infected while still minors, and the proportion is much larger among the females: in private practice, 31 out of every 100; in the hospitals, 48, and among prostitutes, 63, were infected with syphilis while they were still minors. The importance of protecting young girls is emphasized by these facts, and also the exceptionally great danger of contagion from young prostitutes.

Insomnia Due to Disturbances in Ocular Refraction. A. TROUSSEAU.—Ocular disturbances should be thought of when a young person is affected with insomnia at a period of excessive studying or other exertion, with headache on waking and better sleep after days of comparative rest of the eyes, as on Sundays. Trousseau relates a number of instances in which the patients had applied to physicians and neurologists in vain, and were finally cured in a few hours with appropriate eyeglasses.

Prophylaxis of Rheumatismal Endocarditis. E. BARIÉ.—Observations have been reported of the invasion of the heart by the rheumatism several days before the joints were affected, but they are rare. In such cases sodium salicylate is not given until the pains appear, and consequently its action on the heart is less than when given before the endocarditis occurs. Barié attributes the effect of the salicylate to its analgesic and antithermic action. As a prophylactic of endocarditis, he approves of doses of 4 to 5 gm. a day at intervals during the twenty-four hours, as long as the pains last, and 3 gm. for a week afterward. But his first choice is for an iodid medication, to prevent or check endocarditis under these circumstances. Sodium iodid with supralimentation and rest in bed, to prevent overexertion of the heart, has proved extremely successful in Potain's experience in arresting the affection, curing it completely in several cases. Recovery is most frequent in children.

Technique of Pylorotomy. H. HARTMANN.—The extensive experience of the writer has shown that cancer of the pylorus has very little tendency to extend toward the duodenum, probably on account of the lack of continuity between the submucosa of the stomach and of the intestine, which he has established, but is apt to invade the lesser curvature, and especially the ganglia in this direction. He first exposes the posterior surface of the stomach. The lesser omentum can be slit for this purpose without fear of hemorrhage—in the avascular middle portion. The great omentum should be opened close to the stomach, at the point where the incision is to be made, allowing access to the posterior cavity without danger of injury to the transverse mesocolon. The liver is drawn out of the way and the stomach pulled out to expose the coronary, which is ligated and cut. The viscus is then held with forceps as near the cardia as possible, and almost the entire lesser curvature is removed, leaving only the large expansion and a portion of the greater curvature. The gastroduodenal artery is then easily exposed and ligated in the angle between the first portion of the duodenum and pancreas. The operation is completed by freeing the pylorus, cutting the great omentum which holds it, and at quite a distance from the stomach, in order to remove with the tumor the subpyloric and retropyloric ganglia. After ligation of the gastroduodenal artery these ganglia can be detached from the pancreas without hemorrhage, which is almost certain in operating by other methods.

Deutsche Medicinische Wochenschrift (Leipsic), March 20.

Treatment of Hemorrhages from Uterus. H. OSTERMANN.—Hemorrhage occurring with complicated endometritis is very difficult to cure; internal medication is apt to derange the digestive apparatus and local cauterization aggravates the endometritis. Ostermann announces that he has been unflinchingly successful in curing these and all cases of uterine hemorrhages, aside from the puerperal, by the simple method of hot local applications of a mixture of equal parts of antipyrin and salol after the uterus has been wiped out dry. It is applied on cotton wrapped on an aluminum rod; the inner surface of the uterus smeared with the syrup-like fluid. Thirty observations are described, showing the great variety of uterine hemorrhagic affections amenable to treatment by this means. A large number were definitely cured by one application; others required two more at intervals of three to five days.

Medical Experiences in Arctic Regions. B. RAWITZ.—During the first part of Rawitz's stay on Baereninsel, the air was extremely dry; fish, meat, etc., dried in the open air very rapidly, and without a trace of decomposition. The men in the expedition were all robust, and their numerous scratches and other injuries, acquired in fishing and oil-trying, did not show a trace of suppuration, but neither did they heal. All had a red, dry surface, with healthy granulations, but no tendency to cicatrization. A long period of foggy weather followed and all the wounds began to suppurate violently, although the lesions were much less severe than at first, as the men had become more skillful in their work. As soon as the pus was evacuated, however, remarkably rapid healing followed. This absence of healing in aseptic conditions and the rapid healing when the air became septic, as manifested by the invariable suppuration, suggest to Rawitz that there may be some still unknown factor in healing processes, which bacteriology has failed to elucidate. He describes the cod-liver oil industry and states that the oil is mixed with that from the livers of other fish besides the cod, in many instances. It is derived from the livers by the cold process, that is, a keg is filled with the livers and left for three weeks, by which time the oil has been drained out without other heat than the sun, which shines day and night. The livers show no indication of decomposition. Oil drained by steaming the livers is of a poorer quality.

Muenchener Medicinische Wochenschrift, April 10.

Transplantations of Tendons Into Periosteum for Paralysis. F. LANGE.—Vulpus has a record of 80 transplantations, and Lange has performed the operation fifty times, but he modifies the usual method by implanting the tendon of the paralyzed muscle in the periosteum. A new muscle is made by combining paralyzed and sound muscle, and it is connected directly with the bone by implanting the tendon in the periosteum at any convenient point. The tendon is lengthened, if necessary, by cutting it in steps (Bayer), and shortened by running a thread lengthwise through it, doubling on itself like a hairpin; when the ends are drawn up tight, the tendon is made shorter and wider as it crinkles. The principal advantage of this method is the solidity of the result, as it is unnecessary to use an atrophied tendon, and also the latitude it allows the surgeon in locating the transplantation. Observations are described and illustrated showing the fine results attained in cases of a paralyzed hand, foot, knee or hip-joint. In the latter case the biceps and semitendinosus are united to the anterior surface of the femur, but as there is no tendon that can be utilized, an artificial one is supplied, made of strong silk braided in with the fibers of the muscles and brought down to the periosteum of the femur. It has filled in with connective tissue, in his three cases, and is now, after six months, the diameter of a pencil in one. In another the length of the artificial tendon was 15 cm. He considers tendon transplantation for paralysis, especially in children, and the use of the solid, light, inexpensive and durable orthopedic apparatus now made of celluloid, stiffened with steel wire, wonderful progress in the domain of orthopedics.

Asepsis Contra Antiseptis. O. LANZ.—Our instruments and dressings can be considered aseptic after the usual heat

sterilization, but the patient's skin, the surgeon's hands and the ligatures are still dubious links in the chain. Lanz has for years been using a receptacle for ligature silk, which he urgently recommends to insure against thread abscesses, while it saves silk and is extremely convenient in every way. The silk is wound in a loose oval ball, and placed in a glass or porcelain shell like a capsule, with a hole at each end for the thread. There are three holes near the edge of each half, allowing free access to the fluid, while by pressing the halves closer together these openings are closed. The silk nut, as he calls it, is sterilized with steam under pressure for a short time, and then boiled for a minute in sublimate, after being treated with ether and alcohol. It is then placed in a glass vessel with a overhanging telescope cover. This receptacle spreads out above the nut into a second wider chamber, and the lower, holding the nut, is closed with a watch-glass with a hole in the middle for the silk. The receptacle is filled with a solution of sublimate in which the end of the silk rests. He indorses Kocher's advice to scab over with iodine at once, even the slightest erosion. He also recommends disinfecting the hands immediately after any septic contact, as if for an immediate aseptic operation, to prevent the germs gaining access to the nails, etc.

Restriction of Aseptic Field in Operations. G. WALCHER.—It is a great mistake, Walcher thinks, to train young surgeons in the idea that expensive aseptic operating-rooms are necessary, as few are able to meet with similar conditions in their practice. He thinks that sepsis should be absolute, but limited to a small area, and outside of this area everything be considered dangerous. For a laparotomy, for instance, in his clinic or maternity, the table is covered with a clean sheet, and after the abdomen has been shaved and thoroughly disinfected with soap, ether and sublimate, the limbs are covered with towels lying in sublimate solution, as far as the mons veneris, and the trunk from the stomach down to the umbilicus, all fastened with aseptic safety-pins. This area alone is considered aseptic, with the hands and forearms of the operators and three dishes holding the instruments, dressings and sponges in a sublimate solution. Everything else, aprons, tables, napkins, etc., although clean, are yet considered septic, and any contact with them requires new disinfection. If a thread hits against anything in being handed over, it is thrown away and a fresh one substituted. The results of this restricted aseptic area seem to be highly satisfactory as only one death from sepsis has occurred in 8000 deliveries, and only two in the last 100 laparotomies, and in both of the latter there was pre-existent infection.

Surgical Suture and Ligature Material. H. BRAUN.—The chief point in this communication is the author's recommendation of "collodion thread," that is, thread rendered impermeable for secretions and bacteria by being soaked in collodion. It has all the advantages of celluloid thread without its disadvantages.

The Catgut Question. C. LAUENSTEIN.—The seven principal methods of rendering catgut aseptic are described and compared, and Lauenstein considers that each is able to guarantee absolutely germ-free catgut. If infection occurs when catgut thus prepared is used, it must be attributed to secondary infection, either from the air or hands of the operator or from the skin or mucosa of the patient. For this reason each individual case must be studied to determine the most advantageous and appropriate manner of using the catgut in each instance. It seems perfectly rational from the practical as well as the theoretical point of view, to impart antiseptic properties to the catgut. The demonstrated possibility of rendering catgut absolutely aseptic, combined with its absorbability, ensure it the highest place in the equipment of the surgeon. It can only be surpassed by the discovery of an absorbable thread that does not swell in the living tissues nor offer a favorable soil for the development of microbes.

Pocket Sterilizer. BOFINGER.—A zinc box, $1\frac{1}{2}$ by $9\frac{1}{2}$ by 4 cm., holds the instruments usually necessary, in a folding duck case in the lid. The perforated trays hold a bottle for alcohol, and two small square alcohol lamps, with other compartments for syringe, etc. The legs are folded against the side when not in use. The instruments, etc., can be sterilized

in the steam or laid directly in the boiling water in the bottom of the box, which boils in five minutes over the two lamps. With an ample supply of instruments the total weight of the box is about 2 $\frac{1}{5}$ pounds.

St. Petersburger Medicinische Wochenschrift, April 7.

Bacillus of Whooping-Cough. A. UCKE.—Reviewing the various communications that have been made in regard to the causal agent of whooping-cough, Ucke concludes that the majority of the authors, Czaplowski and others, have described one and the same bacillus, a very small rod with swollen ends, which can easily be mistaken for a diplococcus. Found in large amounts in fresh sputum, it may assist in differentiating the affection.

Gazzetta degli Ospedali (Milan), April 8 and 17.

Morphologic Modifications of Koch Bacillus; Their Prognostic Significance. S. MIREOLI.—A number of experiences are related in detail, showing that in cases of latent tuberculosis and cases improved with serotherapy, the tubercle bacillus changed its shape and simulated the streptococcus in appearance, both in the clinic and in experimental research. The author concludes that these "streptococciform modifications" indicate a more favorable prognosis, as they are evidences of attenuated virulence. The chief modification is in the length; the bacillus becomes two, four or eight times its typical length, stretching out thin and long, and also shows granulations.

Circular Suture of Arteries by Direct Coaptation of Endothelium. A. SALOMONI.—The intima of each stump is exposed and the two parts brought together, with temporary hemostasis with fingers or forceps. The stumps are then sutured together with very fine silk, in a "knotted suture" including the entire thickness of the walls of the vessel. In a dog killed eighteen days after the abdominal aorta had been sutured in this way, the artery was found practically normal in every respect. The suture healed over with no contraction of the lumen of the vessel. "Coaptation of endothelial portions of the stumps prevents the formation of fibrous deposits and ensures adhesion with the caliber of the vessel unaffected."

Case of Tabes Consecutive to Trauma. E. GASPARDI.—This is a typical observation of locomotor ataxia developing a few months after a stab wound in the brachial plexus, in a young man with no venereal history nor heredity, always very robust. The symptoms were particularly pronounced on the side of the lesion.

Action of Chloroform on the Blood. V. BACCARINI.—In the summary of this report of extensive experimental research the writer asserts that chloroform has an intense hemoglobinolytic action, also a cytolytic, but less pronounced, and it diminishes the respiratory capacity of the red corpuscles. The latter die sooner and in greater numbers than normally, especially the young corpuscles. This action lasts from a few hours to a few days, and is more pronounced as the narcosis is longer and deeper. Not all the modifications noted are to be ascribed directly to the chloroform, but rather to a circulus vitiosus, which it establishes.

Differences Between Pathogenic Action of Behring's and Tizzoni's Tetanus Toxin. G. TIZZONI.—First establishing that every tetanus toxin rapidly deteriorates with age, which accounts for the contradictory results obtained by different investigators, Tizzoni shows that there are evidently substantial differences in the constitution of his and Behring's toxin. The pathogenic action of his toxin is $\frac{3}{5}$ that of Behring's in animals most sensitive to it—guinea-pigs—and 166 times as toxic for less susceptible ones—rabbits.

The Bicycle and Insanity. C. LOMBROSO.—As the result of extensive research Lombroso announces his conviction that the introduction of the bicycle has materially increased the number and the causes of cases of insanity. He admits that it has added much to the pleasures of life and put an end to the isolation of remote hamlets and farms, but at the same time its criminal influence is so great that the old formula: "look for the woman," should be changed to "look for the bicycle," in the majority of cases.

Societies.

COMING MEETINGS.

- AMERICAN MEDICAL ASSOCIATION, Atlantic City, N. J., June 5-8.
 Illinois State Medical Society, Springfield, May 15-17.
 American Pediatric Association, Washington, D. C., May 7-9.
 Ohio State Pediatric Society, Columbus, May 8.
 Nebraska State Medical Society, Omaha, May 8-10.
 Washington State Medical Society, Spokane, May 8-9.
 Oklahoma Territory Medical Society, Oklahoma City, May 9.
 Ohio State Medical Society, Columbus, May 9-11.
 Kentucky State Medical Society, Georgetown, May 9-11.
 Medical Association of State of Missouri, Mexico, May 15-17.
 Medical Association of Montana, Butte, May 16.
 Iowa State Medical Society, Des Moines, May 16-18.
 Arkansas Medical Society, Jonesboro, May 14-16.
 American Medico-Psychological Association, Richmond, Va., May 22-25.
 Connecticut State Medical Society, New Haven, May 23-24.
 Association of Military Surgeons of the United States, New York City, May 31 to June 2.
 American Laryngological, Rhinological and Otological Society, Philadelphia, May 31, June 1 and 2.
 North Dakota State Medical Society, Grand Forks, May 23-24.
 Indiana State Medical Society, Anderson, May 24-25.
 New Hampshire Medical Society, Concord, May 31 and June 1.

New York County Medical Association.—Dr. Charles E. Denison has been made treasurer, and Dr. J. W. Draper Maury, corresponding secretary of the Association.

Paducah Medical and Surgical Society.—The annual election of officers for this Society occurred at a recent meeting held in Paducah, Ky., resulting as follows: president, J. D. Robertson; secretary, J. E. Caldwell; treasurer, Horace Rivers.

Erie County Medical Society.—Officers were elected as follows, at the April session of this Society, held in Sandusky, Ohio: president, Charles Graefe; first vice-president, E. Stanley; second vice-president, M. J. Love; secretary and treasurer, H. C. Schoepfle.

Tolland County Medical Association.—The annual meeting of this Connecticut organization was held April 17, in Rockville. Following are the newly-elected officers: president, F. L. Smith, Stafford Springs; vice-president, T. F. O'Laughlin, Rockville; clerk, E. T. Davis, Ellington.

Windham County Medical Association.—This Association's 107th annual meeting was held at Norwich, Conn., April 12. The following are the newly-elected officers: president, S. B. Overlock, Pomfret; vice-president, Laura H. Hills, Willimantic; clerk and treasurer, James L. Gardner, Plainfield.

Medical Association of District of Columbia.—At the recent meeting of the standing committee of this Association, Washington, D. C., Dr. G. S. McLean was elected president and Dr. Clifton Mayfield secretary. The committee will continue its efforts, begun last year, to enforce the strict observance of the medical practice act of the District.

Austin Flint Medical Society.—The annual meeting of this Society was held in Waverly, Iowa, recently, and the following officers elected for the ensuing year: president W. A. Rohlf; vice-president, G. W. Appleby; secretary and treasurer, J. C. Powers of Hampton. Clear Lake was chosen as the place for the next meeting, to be held in July.

Conference of Health Officers.—The tenth annual conference of Indiana health officers will be held in Indianapolis, May 8-9, under the auspices of the State Board of Health. The meetings will be held in the Medical College of Indiana, the first session at 10 a.m., May 8. There will be a symposium on

school hygiene, opened by a paper on "The School House," by Louis Gibson, and following this a consideration of the various phases of school hygiene and papers on various sanitary subjects.

Louisiana State Medical Society.—At the close of the annual meeting, just held in New Orleans, the following officers were elected for this Society: president, F. W. Parham; vice-presidents, C. J. Landfried, J. Callan, C. M. Smith, T. G. Ford, O. M. Patterson and R. C. Webb; treasurer, H. S. Coeran; recording secretary, H. B. Gessner; corresponding secretary, A. G. Friedrichs.

Texas Medical Association.—At the annual meeting of this Association held in Waco, Texas, April 24-27, it was decided to recommend that the state health authorities adopt the quarantine regulations agreed on at Atlanta and indorsed at New Orleans. The question of medical legislation was also given consideration, and representatives are to be urged to support the bill for the regulation of practice in the state.

Medical Society of the State of California.

Annual Meeting, San Francisco, April 17-19, 1900.

Dr. George Chismore, the President, presiding.

MEDICAL LEGISLATION.

DR. THOMAS ROSS, Sacramento, read a paper on this subject, in which he reviewed the work done by the profession and presented the status of the people and the states in their attitude toward the profession. He insisted on a higher and a better preliminary education than many medical schools have heretofore possessed, if we desire to raise the standard of professional attainments, for to be a competent physician to-day requires the highest order of attainment, untiring industry and unselfish devotion to the interests of the profession and the wants of suffering humanity. The examination for license to practice should only be open to graduates of colleges having a four-years course. These examinations should not be too technical but should fairly test the professional knowledge of the applicant. There should be one board of examiners only, and the examination should be the same for all, except that on materia medica and therapeutics. He thought that the fairness and liberality of the provisions of such a law would command the respect of the people, and would elevate the profession by excluding the illiterate from the study and practice of medicine.

PATHOLOGY AND TREATMENT OF ANEMIA.

DR. W. N. SHERMAN, Fresno, treated of the changes in composition, and the varying relation of the corpuscles, and their changes in shape, size and color. He spoke of the value of an early and frequent microscopic examination of the blood for diagnostic purposes. He classified anemias with reference to their origin, the primary forms including chlorosis, pernicious anemia, etc., and the secondary, resulting from nutritive disturbances in the blood, and the direct loss of blood by hemorrhage. The rest of his paper consisted in a consideration of chlorosis and idiopathic anemia. He entered rather exhaustively into the technique of both microscopic and chemical examination of blood. In regard to treatment of severe anemias, he placed rest as the most important measure, and cited cases where all therapeutic treatment failed, while, placed in bed for a time, patients respond quickly to medicine. Attention to the secretions, diet, and skin, and mental condition, are all-important. The great therapeutic agent in this disease is the Bland pill, no other preparation of iron comparing with it. The next best is arsenic; the improved Bland pill contains this article and is a very desirable combination. In severe cases oxygen by inhalation is good.

BUBONIC PLAGUE.

DR. HENRY A. RYFKOGEL, Oakland, presented a paper on the "Present Pandemic of Bubonic Plague." He considered the history of the disease, and gave a resumé of former epidemics. He also referred to the origin of the present pandemic and its progress; the plague in China; in Japan; in South America; in the Sandwich Islands; in Australia; in the United States; and gave a description of the specific bacillus, and discussed

the methods of carrying infection, and the possibilities of further invasion, closing with a few words on prophylaxis.

TUBERCLE BACILLI IN URINE.

DR. MAURICE W. BROWN, Alameda, referred to a class of pyuria in which tuberculosis of the kidney or bladder is probable. He spoke of the differentiation of tuberculosis of the bladder from tuberculosis of the kidney. In obtaining urine for examination, the smegma bacillus is the principal source of error, therefore disinfection of the prepuce and glands should be most thorough. He considered the microscopic technique for the demonstration of tubercle bacilli, and reported two cases of tuberculosis of the kidney.

PNEUMONIC COMPLICATIONS IN PHTHISIS.

DR. W. OPHULS, San Francisco, read a paper on this condition, which he thought most often due to aspiration of contents from pulmonary cavities. They differ according to whether they are due to simple tubercle bacilli infection, or to mixed infection of these bacilli with other pathogenic bacteria. These pneumonic complications have a great influence on the general course of the disease. The paper was based on the personal study of about sixty post-mortems.

BRONCHOPNEUMONIA.

DR. WM. FITCH CHENEY read a paper describing the nature of the disease and its dangers to life, the latter being: 1, mechanical, from obstruction, and 2, toxic, from infection. Probably the greatest menace to life is that of diminished air space from occluded tubes and collapsed sacs, which leads to deficient oxidation of the blood, and thence death from asphyxiation. Looking at the disease either from the standpoint of pulmonary obstruction or toxemia, our first duty in treating a case of bronchopneumonia is stimulation. The more stimulant furnished the patient the more opposition offered to the progress of the disease. Nutritious food should be given in sufficient amount, for there is no drug equal to food as a sustainer of life. Milk, peptonized if necessary, is the best diet, and at least two quarts should be taken in twenty-four hours for an adult. There is no objection to animal broths if the patient tires of milk, but milk gives a maximum of nutrition with a minimum of bulk, and always deserves first choice. Alcoholic stimulants are next in importance, and should anticipate symptoms of depression. Chief among stimulant drugs comes strychnin sulphate. 1. It acts as a stimulant to the respiratory center. 2. It increases the reflex activity of the spinal cord, exaggerates the impression conveyed to it by the mucus in the tubes, making the cough in turn more forcible and efficient, and so helps to cause elimination, or at least to prevent accumulation of the viscid exudate. 3. It acts as a direct stimulant to the heart, increasing the force of the contractions of the right ventricle, and so helping it overcome any obstacle in the way of its work.

moderate, 1/30 gr. every eight hours as indicated, to once in six or once in four hours, for an adult. The only other drug advocated for routine administration in this disease is the carbonate of ammonia, for its stimulating rather than its expectorant qualities. The temperature must be taken at least three times a day, and the number of respirations and pulse counted frequently. The cough should not be interfered with unless it becomes troublesome. Dover's powder is the author's favorite remedy for this affection. Pain can usually be overcome by hot applications to the chest. He thinks the fever rarely becomes high enough to constitute a source of danger. He decries all high depressing antipyretic drugs, a high temperature usually meaning a wide area of infection and excessive productions of toxins, calling for additional stimulants rather than depressing drugs. He would rather recommend sponging of the extremities or entire body with equal parts of water and alcohol for high fever. Cyanosis demands stimulation, atropin and digitalin should be here added to the strychnin, and given hypodermically. Caffein is another useful drug. Oxygen should be administered continually until normal color is restored. The author closes his paper with some remarks referable especially to the treatment of this disease in infants.

MANAGEMENT OF LABOR.

DR. WM. J. G. DAWSON, St. Helena, in a paper on "A Few Practical Points in the Management of Labor," called atten-

tion to the ordinary duties of the obstetrician, to the use of unguents in dry labor; douches and chloroform in rigidity of the os, and referred to ordinary measures for protection of the perineum. He believes that modern teaching is somewhat responsible for laceration of this body, and that forceps are too frequently applied when not needed. He deprecates the modern method of external examinations only, and advocates repeated examinations during the first and second stages. In the third stage of labor he depends on uterine contractions for delivery of the placenta, and does not use the Credé method. He applies pressure over the uterus and traction on the cord, and keeps up firm pressure on the uterus by the hand as a preventative of postpartum hemorrhage.

UTERINE SCRAPINGS.

DR. HAROLD BRUNN, San Francisco, in a paper on the "Value of Microscopic Examination of Uterine Scrapings," referred to the frequent curettement, and the prevalent ignorance as to the pathology of the endometrium. He called attention to the similarity of the symptoms and microscopic appearance of the endometrium in benign and malignant diseases. He gave the details of performing a diagnostic curettement, and preservation of scrapings, methods of mounting, and called attention to the relations between the pathologist and surgeon.

SHOCK.

DR. E. H. WOOLSEY, Oakland, read a paper citing cases of shock from a variety of causes, from mental emotion to grave injuries, including shock from cold drinks, renal calculi, catheterization, intestinal perforation, rectal dilatation, etc. His remarks dealt chiefly with the tracing of the process from cause to effect; entertaining the view that the phenomena of shock are reflex effects.

SUBARACHNOID SPACE.

DRS. DUDLEY TAIT AND G. E. CAGLIERI, San Francisco, presented a paper on "Experimental and Clinical Notes on the Subarachnoid Space." This paper was awarded the prize, by the prize essay committee, and will appear in THE JOURNAL.

SURGERY FOR GALL-STONES.

DR. BEVERLY MACMONAGLE, San Francisco, presented a paper on "Some Surgical Methods of Treatment for Gall-Stones," the first method being the removal of the gall-bladder with gall-stones, with drainage. The second is to open the gall-bladder, remove the gall-stones, and attach the gall-bladder to the abdominal parietes, with drainage. The third method is to open the duodenum, dilate the opening from the common duct to the duodenum, and remove the stones, closing the duodenum and abdomen. A fifth is to open the gall-bladder, remove the gall, and close the gall-bladder and abdomen, without drainage. Dr. MacMonagle cited illustrative cases for each of these methods and considered the technique of each. He believes that the second meets the requirements of most operators.

DR. J. HENRY BARBAT said the removal of the gall-bladder is unjustifiable if the cystic duct is patulous, and gall-stones exist much more frequently than recognized. He recently removed 286 stones from the gall-bladder of a patient who had been treated for almost everything else.

DR. CLINTON CUSHING thinks it perfectly safe to remove the gall-bladder, and that it is of no more use than the appendix vermiformis.

DR. F. B. CARPENTER, San Francisco, thinks that if the gall-bladder is diseased, it should be removed. The common duct should be thoroughly examined before the gall-bladder is closed, in all cases in which it is incised.

APPENDICITIS.

DR. J. HENRY BARBAT, San Francisco, presented a paper entitled "A Few Notes on Appendicitis." This paper will appear in THE JOURNAL.

LIGATION OF INTERNAL JUGULAR.

DR. CHAS. G. LEVISON, San Francisco, presented a paper on "Ligation of the Internal Jugular Vein During the Removal of a Malignant Growth of the Neck." It discusses a case operated on by the writer, and followed five days after by death from a thrombosis of the jugular vein, lateral and sigmoid sinuses.

ABORIGINAL TREPHINING.

DR. PHILIP MILLS JONES, San Francisco, presented a paper treating of the methods in vogue in the Pacific Islands, within

historic times, and of the experimental work of the author. He exhibited some trephined skulls.

PROSTATIC CALCULUS.

DR. JOHN C. SPENCER, San Francisco, in this paper reviewed the pathology and etiology, dividing all cases into either essential or adventitious, and treating especially of the essential form. He cited the conclusions of many authorities as to the origin of the trouble, made suggestions as to treatment, and reported a case.

IS GONORRHEA CURABLE?

DR. M. KROTOSZYNER, San Francisco, read a paper expressing his opinion that gonorrhoea is in many instances an incurable disease. Our diagnostic apparatus does not enable us, in some instances, to demonstrate with safety that the disease is permanently extinct. Everybody who has ever suffered from gonorrhoea should permit a most careful examination in order to remove diseased foci amenable to our diagnostic apparatus.

Sacramento was selected as the next place of meeting. The officers elected for the ensuing year are president, Thomas Ross, Sacramento; first vice-president, W. J. G. Dawson, St. Helena; second vice-president, Wallace A. Briggs, Sacramento; secretary, George H. Evans, San Francisco; treasurer, E. E. Kelly, San Francisco.

Medical Association of Georgia.

The Fifty-first Annual Meeting, Atlanta, April 18-20, 1900.

DR. F. W. McRAE, President, presiding.

REPORT ON MEDICAL LEGISLATION.

The Committee on Medical Legislation reported, through its Chairman, Dr. W. S. Elkin: 1. In favor of making renewed efforts to secure the passage by the legislature of the two bills introduced last session, providing for privileged communications to physicians and patients and for expert services in the courts of the state. 2. In favor of so amending the by-laws that the committee on medical legislation shall consist of six members who reside at the capital of the state, instead of nine members from different parts of the state. 3. In favor of an appropriation from the treasury of the Association of \$50 or so much thereof as may be necessary, for the use of the standing committee on legislation.

The report was unanimously adopted.

A PASTEUR INSTITUTE.

A committee was appointed to investigate the matter of establishing a Pasteur institute in Atlanta for the treatment of hydrophobia. This committee subsequently reported that it had investigated the matter and was persuaded that the establishment of such an institution would be a great benefit to suffering humanity, not only in Georgia, but throughout the entire South. It would also benefit the profession by furthering scientific investigations. As to the best method for raising the means to establish the institution, or whether it should be in connection with the Grady Hospital, or College of Physicians and Surgeons, the committee did not decide, and asked for further time, with power to act, such action to entail no financial obligations on the Association. The following resolutions were accordingly introduced and adopted:

Resolved, That the Medical Association of Georgia endorses the establishment of a Pasteur institute and laboratory in Atlanta and pledges its hearty support.

Resolved, That the profession will endeavor to secure through legislation 50 per cent. of the dog tax to support said institution when established.

HEALTH MEASURES, ETC.

A bill was framed, introduced, and adopted, creating a department of health and health officers in the state.

A committee appointed last year to confer with the medical societies of other states, inviting their co-operation in a memorial to Congress asking an increase in the rank, pay, and allowance of the Surgeon-general of the United States Army, reported favorably, and the report was adopted.

President McRae read letters from Senators A. O. Bacon and A. S. Clay in which it was stated that these gentlemen would do their utmost to defeat the Gallinger bill when it

comes up for discussion and final disposition in the Senate of the United States.

CONTINUED USE OF ANTISEPTIC AND ELIMINATIVE TREATMENT OF TYPHOID FEVER WITHOUT ANY DEATHS.

DR. T. VIROIL HUBBARD, Atlanta, read a paper with this title. The author has treated twenty cases of typhoid fever by the antiseptic and eliminative method without any deaths. Other men have treated a larger number without any, and the collective results give a mortality of less than 2 per cent. The physician who has never witnessed the contrast in the clinical picture of a typhoid patient on the eliminative treatment, as compared with the expectant plan, can no more appreciate its efficacy than a person born blind can appreciate the beauties of Nature. If he has never witnessed the prompt disappearance of delirium, the restoration to consciousness to the clouded intellect, prompt return of the appetite and digestive capacity, and gradual but sure reduction of temperature, he has in store for himself one of the triumphs of his profession, and a scene which will give him renewed confidence in the healing art.

TYPHOID FEVER, WITH REPORT OF CASES AND COMMENTS.

DR. W. B. HARDMAN, Harmony Grove, followed with a paper on this subject. He thinks the Brand treatment of the disease by plunge baths is impracticable, because it **can not be used** in the country or in small towns. He vigorously defended the Woodbridge treatment, and cited sixteen cases, with details, which he had personally treated the past year, using the Woodbridge method in each. Of the sixteen, only two patients died. In all of the others the temperature was brought to normal within fourteen days, and they were put on the road to convalescence. He does not follow the directions of Woodbridge to the letter, but uses his own judgment in modifying his instructions. Still, the principle of this treatment is adhered to, and calomel freely used in all cases.

SURGICAL CASES.

DR. WILLIS F. WESTMORELAND, Atlanta, reported a series of interesting surgical cases, and exhibited specimens. One was a case of carcinoma of the cecum; one a case of suprapubic cystotomy for stone in the bladder; one arthrotomy with excision of the head of the humerus for an old dislocation of the shoulder-joint. He showed typical specimens of osteomata.

BRAIN TRAUMATISMS.

DR. HOWARD J. WILLIAMS, Macon, read a paper on this topic. Except in the grosser lesions involving the motor areas particularly, localization of disturbed cerebral functions has generally been of but little practical value in indicating the point of the brain most importantly involved; he said: The reasons for this are: 1. In the large majority of brain traumatism multiple lesions exist; many special functions are implicated and conflicting symptoms appear. 2. The general symptoms of cerebral shock, or of concussion, and compression usually so mask the symptoms pointing to special regions involved that important lesions can not be discovered. 3. The general depression common to various lesions may be so prolonged that when it is relieved, the symptoms pointing to special obtunded functions may be discovered too late to be of working value, secondary changes having destroyed the cells of the particular regions involved. 4. While in some regions of the brain a cerebral function is circumscribed, in other parts it is diffused over large areas. Here compensation of the obstructed functions is early taken up by unaffected cells, the functions are restored, and the significant symptoms have disappeared before the general depression has passed off; partial loss of power of the part affected may later become permanent when secondary changes have destroyed the involved area. Dr. Williams reported nine interesting cases.

SPLENECTOMY FOR CONGESTIVE HYPERTROPHY.

DR. J. WESLEY BOVÉE, Washington, D. C., reported "a successful case of splenectomy for marked congestive hypertrophy, with remarks." The principal reason, usually, for removal of the spleen is its enlargement, and this produces marked distress according to its size, the number and character of adhesions and the interference with the function of other organs. The sense of intolerable dragging when the tumor

is large often demands removal, provided other conditions permit it. This enlargement is usually due to paludal, tubercular or idiopathic causes, malignant disease, wandering of the organ, axial rotation, echinococcus and other cysts, chronic congestion, amyloid disease and injuries, such as rupture. Perhaps the most frequent cause of enlargement—leucocythemia—is the one condition in which the operation of extirpation should almost never be performed. More than one hundred cases of splenectomy for leucocythemia have been reported and in but three of them was it successful. Such results should be sufficient to put this indication for the operation practically beyond dispute. Some writers, however, believe the operation is justifiable when the relative proportion of red to white blood cells is not lower than fifty to one. In some cases perhaps this proportion may not be markedly dangerous, but we must remember the spleen does reach a tremendous size in leucocythemia, often weighing from twenty to fifty pounds and the adhesions may be formidable. In such cases, certainly, the fifty to one rule would be a very dangerous one were it not that in these very marked cases of enlargement, the ratio is usually greater than the one mentioned. It shows, however, the necessity of knowing the blood conditions. Nor should the proportion of red and white blood-cells be all we should attempt to learn in examination of the blood. It is well known that different varieties of both red and white blood-cells have different functions and that the relative numbers of these species of them vary quite markedly in different specimens of blood, whether taken from the same or different patients. This is certainly an element of great importance. Aside from this, it is of the greatest moment to know the hemoglobin percentage of the blood of a patient suffering from a leucocythemic spleen. If this be not far below the normal, as shown by the present inaccurate instruments, the prognosis of the surgeon is less grave.

Splenectomy is not an operation to be lightly entered on with scarcely any knowledge of the conditions demanding it and of those absolutely contra-indicating it. It is fully important to know when not to do the operation as when to intervene surgically. He reported a case in detail.

The following officers were elected for the ensuing year: president, Samuel C. Benedict, Athens; vice-presidents, R. M. Harbin of Rome, and V. D. Lockhart of Mayesville; secretary, Louis H. Jones, Atlanta. The next place of meeting is Augusta, the third Wednesday in April, 1901.

Philadelphia Pediatric Society.

March 13, 1900.

TUBERCULOUS CAVITY IN CHILD.

Dr. D. J. M. MILLER presented a girl, 8 years of age, with a tuberculous cavity in the lung, with skiagraph. The child's father died of phthisis, and was constantly attended by her. One year after his death she first showed symptoms of the disease. As a rule cavities are not so frequent in children as in adults. In this case a residence of twelve weeks in a hospital brought about marked improvement. Within six weeks she gained six pounds. When first admitted she had night sweats and considerable fever.

SECONDARY ANEMIA IN CHILD.

Dr. D. J. M. MILLER also presented a case of profound secondary anemia in a girl 2 years old, who had been under observation for three weeks. The disease probably originated eighteen months ago, with general increase in pallor and loss of appetite, but there was no diarrhea. The spleen and liver were slightly enlarged, but there was no lymphatic enlargement. There was slight tenderness over the tibia. First examination of blood showed: red cells, 3,984,000; leucocytes, 24,000; hemoglobin, 23 per cent. Several weeks later the red cells numbered 3,984,000, leucocytes 12,200, and the hemoglobin was 23 per cent. The condition therefore appeared to be one of chloro-anemia with moderate leucocytosis. There were no nucleated red cells.

Dr. ALFRED STENGEL, in discussing the first case presented by Dr. Miller, said that the diagnosis of small cavities in the lungs in children is extremely difficult, since many of the physical signs present under normal conditions prevent the

signs from becoming manifest. Thus a cracked-pot sound may be obtained in a healthy chest during the time the child is crying.

Dr. F. SAVARY PEARCE thought the symptoms of the second patient pointed to rickets.

Dr. ALFRED HAND thought the condition might be brought about by rickets, or by gastro-intestinal disturbances due to bad hygiene.

VALVULAR ENDOCARDITIS AFTER CHOREA.

Dr. JOHN M. SWAN presented a case of chronic valvular endocarditis following chorea. The child was first seen in June, 1898, and was suffering from short cough, dyspnea and edema of the ankles. The family gave a history of rheumatism. In 1897 the child had been treated for arthritic troubles and later for chorea. The disease first began in the hands, then in the arms and legs. The tongue had manifested choreic movements. A soft murmur had been heard over the base of the heart, the pulse was accelerated and still later a double mitral murmur was transmitted to the axilla. The heart's action became tumultuous. There had been no albumin nor glucose present. The child was sent to the country but became worse, the feet and hands became swollen and ascites developed, followed by the appearance of albumin and casts in the urine. During the treatment the urine suddenly increased to a very large quantity, after which steady improvement set in and the child was able to get out of bed. Mitral regurgitation and also aortic stenosis were now detected. Hot baths were given daily, milk diet, digitalis, strychnin and Rochelle salts when needed. In February, 1900, the child weighed 60 pounds, attended school regularly and was able to do general household work. The pulse is now full and the rhythm regular. The apex is in the sixth interspace. The murmurs are not so distinct as formerly, and the urine is practically normal.

Dr. F. A. PACKARD thought that probably the valvular leakage might in part be due to pericarditis which had been present.

TUMOR OF KIDNEY IN CHILD.

Dr. J. H. MCKEE reported a case of large tumor of the kidney, occurring in a girl 6 years of age. There was no history of tumors on the father's or mother's side. The child had been healthy and strong, her only previous illnesses being measles and chicken-pox. Three months previously she began to lose flesh and later a pain in the leg developed. Still later there was abdominal enlargement, constipation, and cachexia. The abdominal enlargement was irregular on the left side, and dullness extended downward to the anterior superior spine, and in this region bulging was noticed. At one time a peristaltic wave had been detected, but there had never been much tympany. A nodular growth was also found in the region of the ribs. The urine contained no albumin, nor glucose, but some time later albumin was found, together with casts and red blood-cells. On October 4 an operation was performed by Dr. T. S. K. Morton, followed by temporary improvement, but death occurred later, probably from a recurrence elsewhere.

Detroit Medical and Library Association.

Detroit, Mich., April 9, 1900.

Dr. Carl Bonning, President.

SYMPOSIUM ON ENDOCARDITIS.

Dr. W. M. DONALD considered the etiology and pathology, saying, in part: Valvulitis and endocarditis are synonymous terms. Three classes exist—acute simple, acute malignant and chronic. It is claimed that 20 per cent. of all cases of acute simple endocarditis result from rheumatism, but almost any of the infectious diseases may be a predisposing factor. Chorea must not be forgotten. Chronic valvular defects seem to be the predisposing cause of malignant endocarditis. Following this come pneumonia, meningitis, septicemia and erysipelas. The chief causative agent of the third form is a pre-existing acute endocarditis. Alcohol, syphilis, gout, overindulgence in rich food and severe exertion must also be considered as of etiologic value. In the first form the principal pathologic lesions are vegetations—granulation tissue capped with fibrin on the valves at their point of closest contact.

These vegetations are in time absorbed, leaving only a nodular thickening of the valve. In the second form the vegetations go on to necrosis, with frequently more or less ulceration, and even abscesses may form. Bacteria are present in large numbers, among which are the bacillus of pneumonia, and the staphylococcus and streptococcus pyogenes. In the third form, the edge of the valve is thickened and has nodular outgrowths. Advanced stages show curling up and retraction of the valve's edge. Adhesions may co-exist as well as calcification of the valves and surrounding tissues.

DR. W. R. CHITTICK presented the symptomatology, and said: The signs of acute simple endocarditis may be vague. A systolic murmur heard at the apex of the heart, indicating mitral regurgitation, is the sign most frequently met with, though not a settled question. The aortic valve may become involved and cause a double aortic murmur—a diastolic murmur being always organic. Accentuation of the pulmonary second sound, and dullness on percussion when due only to rheumatism are certain signs of endocarditis. The symptoms and signs of the second variety are precordial distress, pain, shortness of breath, dropsy, extreme pallor, great rapidity of the pulse, diastolic aortic murmur. A systolic mitral murmur with accentuated pulmonary second sound and evidence of engorgement of the right heart, with the presence of fever and other grave symptoms are characteristic. The spleen is enlarged and tender, and changes in the urine, paralysis, delirium, convulsions, headache, coma may follow. The symptoms often closely resemble those of typhoid fever. The symptoms of the third variety are usually shortness of breath on exertion, cough, and later dropsy. Palpitation, intermittent action of the heart and derangements of the digestive tract may occur. Blueness of the lips, ears, nose, etc., and enlargement of the veins of the cheeks and nose are often present.

DR. G. W. WAGNER considered the diagnosis and prognosis. If in the course of any acute infectious disease, especially rheumatism, a heart murmur is discovered, the time of its occurrence, its distribution, accentuation of the second sound and the changes in the heart's action which follows will usually indicate endocarditis. Chief among the points brought out were: In aortic lesions the stethoscope should be placed over the carotids in the neck, to diagnose the presence or absence of the second sound; the differentiation of aortic stenosis from certain changes due to anemia; of aortic incompetency from syphilis and degeneration changes; of mitral incompetency from accidental murmurs; the signs of mitral stenosis, and pulmonary stenosis and insufficiency. As to prognosis, we must base our conclusions on a careful study of the nature of the disease and degree of compensation present, as well as on the general condition of the patient, his occupation, habits, etc.

DR. F. L. NEWMAN took up the question of treatment. In acute endocarditis it should be directed toward limiting the course and effects by modifying the cause. The cardinal point is to quiet the restlessness of the heart by absolute rest in bed. In the sthenic cases, aconite is given; if there is pain, *pulv. Doveri*; in asthenic conditions, when the heart weakens, digitalis, strychnin, ammonia or ether—usually digitalis is not required until later on when valvular disease is supervening. As to local measures, authorities differ. Ice to the region of the heart is often very grateful to the patient. Belladonna plaster over the heart, by its very pressure, is soothing. In chronic endocarditis no treatment is necessary until symptoms of dilatation appear. Up to this time the patient should avoid anything that subjects the heart muscle to sudden strain. Drugs are prone to do harm during the stage of compensation. When the latter is only partially established and signs of cardiac failure occur, the patient must be put to bed and carefully nursed. In all forms of cardiac dilatation from valvular lesions, our sheet-anchor is digitalis. Strophanthus is next in importance. Strychnin is one of the best cardiac tonics. Caffein has a very uncertain action on the heart, but a very decided one on the kidneys. Nitroglycerin has no action on the heart, but decreases the resistance against which systole is performed. The doctor spoke of the action of heroin, gr. 1/12 every two hours for three times, as relieving a patient of his distressing cough and vomiting after all other regular means had failed.

New York Academy of Medicine.

April 5, 1900.

Dr. Wm. H. Thomson, President.

PREVENTION, MANAGEMENT AND EARLY DIAGNOSIS OF SCARLET FEVER.

DR. FLOYD M. CRANDALL presented this paper. Scarlet fever is peculiarly a disease in which much can be accomplished by prophylaxis. Sometimes children will be exposed quite thoroughly, even so late as after the initial vomiting, and still escape. In 90 per cent. of his cases, the period of incubation was between two and six days. The symptom-complex of vomiting, fever, rapid pulse and sore throat, when present, made it highly probable that the disease was scarlet fever. In his experience, the vomiting was the most constant symptom of all, and had often been violent and projectile. A pulse of 150 was not unusual at the outset. The so-called "strawberry tongue," i. e., a tongue in which the red papillæ show on a white ground, is not the true "strawberry tongue;" the latter, like the fruit after which it is named, has dark red dots or papillæ on a red and roughened ground. This kind of tongue is very characteristic of scarlatina, but unfortunately it is of so late occurrence that it is not of much diagnostic value. In estimating the progress of the disease, and when it will be proper to raise the quarantine, one should search with special care for desquamation around the fingers and on the hands. It is only in a very general way that the statement that the disease lasts forty days can be accepted. Another fact that should be borne in mind in this connection is that there is danger of contagion so long as there is any purulent discharge present as, for instance, a suppurative adenitis or otitis. The question of the advisability of closing the schools because of an outbreak of such a disease as scarlet fever must be decided by the character of the community. For example, in a large city like New York, the closing of the schools would bring the children more closely together, whereas in rural districts such a measure would probably keep them apart, and so tend to check the spread of the disease. When in attendance on a case of scarlet fever it is the part of prudence for the physician to wear, while in the sickroom, a cotton gown reaching from the head to the feet. This garment should be kept in the sickroom. People, as a rule, did not object to such a precaution, but, on the contrary, think all the more of a physician who is so careful about the welfare of others; moreover, if scarlet fever should break out mysteriously in another of the families attended by the same physician, the latter is not so likely to be censured, or suspected of having carried the contagion. During an attack, the anointing of the body surface with some bland oil not only prevents the dissemination of the disease but soothes the patient and often reduces the temperature. However if irritating antiseptics are employed, they are likely to do harm, and will most probably prolong the period of desquamation. Pruritus is relieved by a 5 per cent. boric acid ointment. Lard is objectionable because of its proneness to get rancid.

TREATMENT OF SCARLATINAL NEPHRITIS.

DR. ROBERT COLEMAN KEMP read a paper on this topic. He expressed the opinion that this form of nephritis is one peculiar to scarlet fever. It usually develops between the second and fourth weeks of the disease, and is a diffuse nephritis associated with general dropsy. The first sign is a sudden fall of the specific gravity of the urine, followed shortly afterward by a rise in specific gravity, a diminution in the quantity of urine, and a deepening of its color. It is during this early stage that active treatment should be instituted. As a rule, albuminuria and anasarca do not occur until later. As oxygen is a good cardiac stimulant, and an aid to the elimination of toxins, it is a very useful remedy in scarlatinal nephritis. Its early use is the keynote of success here. Enteroclysis with saline solution at 110 to 120 F. will be found very beneficial. As a rule, it will cause the secretion of four or five times as much urine as the quantity of saline solution used.

DR. H. D. CHAPIN said that in recent years he had seen a much milder type of scarlet fever than formerly. In this city the most prolific causes of the spread of such diseases as scarlet

fever are the dispensary waiting-rooms and the crowding of school children's clothing in close wardrobes.

DR. C. G. KERLEY said that the most characteristic symptom of scarlet fever is the sore throat; the other symptoms may be exceedingly slight and easily overlooked. He has known the period of incubation, in exceptional instances, to be as long as twelve and fourteen days. He has found colonic washings at 110 F. the most successful treatment for the nephritis.

DR. J. E. WINTERS insisted that it was rare for physicians to meet with a fatal case of scarlatinal nephritis. Albuminuria is no more frequent in the early stage of scarlatina than in measles, and even when it does occur in those cases which subsequently develop nephritis there is invariably an interval in which no renal disease is present. It is worthy of note that scarlatinal nephritis occurs most commonly in mild epidemics, in the mild season of the year, and in dispensary and tenement house practice or among those children who are allowed to get out of bed too soon. It is invariably a glomerular nephritis, and it is always ushered in by a sudden rise of temperature. The indication for treatment is to diminish the quantity of blood going to the Malpighian tufts, and this he has found best accomplished by the administration of aconite up to its physiologic effect. Such treatment will speedily cause an increase in the quantity of urine, and associated with this will be an increased activity of the skin, so that abundant opportunity is afforded for the elimination of toxins. Enterocolitis with saline solution is useful in certain forms of nephritis, he says, but he is totally opposed to its use in scarlatinal nephritis.

Surgical Section, April 9, 1900.

RELATIVE BEARING OF CONJOINED TENDON AND INTERNAL OBLIQUE MUSCLES ON RADICAL CURE OF INGUINAL HERNIA.

DR. JOSEPH A. BLAKE read a paper based on twenty-five dissections he had made, and which went to show that the conjoined tendon never extends on the internal surface of the rectus for more than five-eighths of an inch, and that it is such a weak structure as not to be worthy of consideration in hernia operations. The main reliance must be on the external oblique.

STERILIZING CATGUT.

DR. C. A. ELSBERG presented "A Preliminary Report and Demonstration of a New Method of Sterilizing Catgut." The method is simple and inexpensive, and bacteriologic investigations prove it to be thoroughly efficient and reliable. The fat is first removed from the catgut by immersion for forty-eight hours in a mixture of chloroform, one part, ether, two parts. After this mixture has evaporated from the catgut, the latter is tightly wound in one layer on glass spools, and immersed for twenty or thirty minutes in a hot saturated solution of ammonium sulphate in water. When removed from this it is immersed and agitated for a few minutes in sterile water, or in a weak solution of bichlorid of mercury or of carbolic acid to remove the salt which tends to crystallize upon it. It is then sterile, and can be preserved in alcohol, or in the dry state. Such catgut has been found to be remarkably strong, soft and pliable, and yet is absorbed in the tissues in from four to eight days. If it is desired to chroicize the catgut it is only necessary to substitute a 1 to 1000 solution of chromic acid in water for the plain water used for making the saturated solution of ammonium sulphate. Catgut prepared by this new process has already been used by several surgeons with the greatest satisfaction.

Topeka Academy of Medicine and Surgery.

Topeka, Kan., April 2, 1900.

President—B. D. Eastman.

TYPHOID FEVER.

DR. S. G. STEWART read a paper on this subject, and laid special stress on some of the more common symptoms observed at the bedside. The disease is characterized by being an acute infectious disease transmitted chiefly by water and milk, the latter usually infected by washing the milk cans with infected water. The course is from three to four weeks, and frequently from one to three months. During the second week the rose

spots in various degrees of severity make their appearance. The pathology is the most important part of the disease. Lesions may be extensive over the intestines. Some have been found in the duodenum and even in the stomach. There is no organ in the body that does not suffer from the arrest of nutrition. In making the diagnosis one must always take into consideration the degenerations in all parts of the body. If we had the ideal sanitary regulations we would have no typhoid fever. The typhoid cases in Topeka are in the people who drink well water.

Besides the poison from the typhoid bacilli, the system absorbs an additional amount from the decomposition of intestinal contents. Putting antiseptics into the intestines has been overdone. Iodin is used largely, as some think it increases nutrition, but if given for a long period it produces iodism. It is the same with many other drugs; if given too long depression results. Many are not so harmful, e. g., creosote, carbolic acid and salol. The latter is probably one of the safest and best. However much we put into the intestinal tract, we do not make it aseptic. We have very little to hope for from such medication. Opium should not be given to control the bowels, as it makes them more tympanitic. The doctor relies principally on *fel bovini purificati*. He reported a case of a family of twelve, all taken down with typhoid about the same time.

One of the family did hard work on a farm for several weeks, after being directed to go to bed and stay there. Finally he came down with sharp pain in the right inguinal region. Dr. McClintock performed an operation and found peritonitis from typhoid perforation. Drainage was established and the patient rallied for a little over a week, when an abscess formed in the left lung and large quantities of gangrenous pus were expectorated. Then abscesses formed all over the body, and later the right lung became involved and the patient died after an illness of twenty-one weeks. Peptonized milk was used entirely. He especially emphasized the fact that one must not depend too much on chemical antiseptics, and must meet the indications as they arise.

DR. O. P. DAVIS spoke on the pathology of typhoid, and said that Dr. Osler and others describe general systemic typhoid without intestinal lesions. The characteristic lesions are found in the intestines, particularly in the region of the ileocecal valve. In the first week there is a condition of hyperemia and catarrhal symptoms, in the second a condition of hyperplasia, in the third necrosis begins, and in the fourth cicatrization. The scars in typhoid lesions are pigmented, and a diagnosis may be made some years after the disease. He described the bacteriologic examination of the feces, blood and urine. Leucocytosis is never present in the early stage of typhoid, but is found in some other infectious diseases.

DR. R. E. MCVY spoke of the treatment. The trouble begins in the sympathetic nervous system, and so there are two factors to treat, the nervous system and the glands. The majority of patients are overtreated. He spoke of a patient being overdosed and having forty-six movements a day. He stopped all medicine when he took charge, and then gave bismuth. Recovery followed. He gives milk chiefly because it is absorbed by the veins, and does not see any use in pepsin or pancreatin. Acids are frequently of some use e. g., nitrohydrochloric. He does not object to exercise in the early stages, as it keeps up the tone of the muscular tissue, nor does he think a typhoid runs over thirty days; when the patient is ill longer it is something else.

DR. STEWART, in closing the discussion, said that the bacilli do live outside the body, but do not propagate outside. They will live for months and months in ice. The nervous system is affected by the degenerations.

Water treatment takes the place of any antipyretics. Sponge baths are better than opium, to treat delirium, restlessness, etc.,. He disinfects both the stools and urine, and never uses chemical antipyretics, for we lessen the chances of the patient's life when we lower the temperature with the latter. His advice is to sit down and study the case and meet the indications as they arise.

THE JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION.

61 MARKET STREET, CHICAGO.

SATURDAY, MAY 5, 1900.

TRIGEMINAL NEURALGIA.

Pain may arise from irritative disturbance at any point in the course of a sensory nerve between the cerebral cortex and the periphery, and the exciting cause may be of most varied character—inflammatory, degenerative, toxic, organic, structural. The treatment must necessarily vary accordingly. To functional disturbances we shall make no reference further than to express the opinion that derangement of function always depends on, or at least is associated with, physical alteration of structure, although this may be of such an impalpable nature as to be beyond our present powers of observation. It is probable that under these conditions the alterations that take place may be looked upon as of a nutritional, chemical or toxic origin. These considerations are of importance in connection with the treatment of the group of disorders known as neuralgias, and than which no more painful affection exists.

At the recent joint meeting of the College of Physicians of Philadelphia and the Philadelphia Neurological Society, the subject of "The Fifth Nerve in Its Surgical and Neurological Aspects" was taken up for consideration, by eminent authorities, and a number of important facts brought out. Among other things the first American case of tumor of the Gasserian ganglion and the third in the literature was reported, the new growth being an endothelioma. The patient survived two severe operations, but unfortunately obtained no relief, and in view of the nature and extent of the lesion recurrence is almost certain. In the next place a new operation for the removal of the ganglion was described, which commends itself for its simplicity, its bloodlessness, its ease of execution and its effectiveness. This consists in resection of the zygoma, turning back of the temporal muscle, trephining of the temporal bone, retraction of the middle meningeal artery, and exposure and removal of the ganglion, without the necessity of entering the meningeal cavity. The operation has already been performed successfully in four cases that were reported.

The discussion failed, however, to settle conclusively the ultimate pathology of tic douloureux and no evidence was put forth to show that the disease may not be due to disease of the cortico-medullary neuron. The tendency for the pain to return after removal of the nerve-trunk or even of the ganglion, and to appear in a second nerve after one previously affected has been resected would seem to indicate that, in some cases at least, the source of pain is beyond the ganglion. Of the util-

ity of operation, peripheral or central, sufficient evidence was afforded, but no assurance of success can be predicated in advance of the operation. As in other matters, time alone is here the final arbiter. The suggestion that instead of removing the ganglion division of the root of the sensory portion of the nerve, between the pons and the ganglion, should be practiced, is worthy of serious consideration.

Considering that the discussion was from a surgical standpoint, little was said of medicinal treatment, although it was pleasant to hear that occasionally spontaneous disappearance takes place. Nevertheless, it would seem axiomatic that all ordinary therapeutic resources should first be exhausted before surgical intervention of any sort is undertaken; and then it will be wisest to first attempt the simpler operation of stretching or resection, reserving the more radical procedure of excision of the ganglion as a final resort.

BLEEDING IN THE TREATMENT OF UREMIA.

It is probable that bleeding will never be employed again to the extent it has been in the past, but the question is frequently raised whether it is at present being practiced to the degree that its efficacy makes it worthy of. There can be no doubt that there are certain conditions that nothing will relieve so promptly and so certainly as does free venesection. One of these consists in the state of venous stasis resulting from failure in the activity of the right heart, whether due to degeneration of its muscular wall or secondary to similar failure on the part of the left heart or to pulmonary obstruction or to regurgitation through the tricuspid valves. Probably some conditions of local hyperemia or stasis, as of the brain or the lungs or the kidneys, may be relieved by the same measure. Then there is reason to believe that various toxic states, such as diabetic coma or uremia, or such as sometimes occur in the course of infectious diseases, can be ameliorated by free bleeding, and the results are probably even more satisfactory when subcutaneous infusion is practiced at the same time. By the bleeding it is hoped to remove from the circulation certain noxious substances that have failed of elimination through the natural channels, either because of their production in excess or because of deficiency in the functional activity of the emunctories; and by the infusion to maintain the mechanical integrity of the circulation, and perhaps also to effect dilution and elimination of toxins remaining in the tissues. It is a question, however, whether sufficient of the poisonous matter can be removed by even a free bleeding to bring about a distinct effect on the general condition, although it may be that when the system is partially relieved it becomes capable of ridding itself of the remaining incubus.

After all has been said, however, the fact remains that a satisfactory explanation of the mechanism by which the therapeutic effects of bleeding are brought about has not yet been forthcoming. In view of this fact Richter¹

¹The papers presented at this meeting appear in this and last week's JOURNAL.

¹Berliner Klin. Wochn., Feb. 12, 1900, p. 138.

undertook a series of experiments with the object of deciding the question in so far as it concerns uremic intoxication. He points out that uremia may be accepted as an indication of renal insufficiency. Now, it has been shown that this latter condition is attended with retention in the blood, of the molecular products of disintegration, with increased molecular concentration. Increase of the osmotic pressure, as indicated by a reduction in the freezing-point of the blood, may under certain circumstances be considered the index of deficiency in the activity of the renal function. It has, however, not yet been demonstrated that this increase in osmotic pressure is the cause of the uremia. In fact, on the one hand, increased molecular concentration of the blood in cases of disease of the kidneys may be unattended with uremic manifestations; while, on the other hand, it may be wanting in the presence of profound uremia. It is thought that increase in the osmotic pressure and the poison that gives rise to uremia have a common origin, namely, the proteid molecule. Richter has found, however, that profound uremia is almost invariably attended with increased molecular concentration of the blood. He undertook, therefore, to determine how the latter would be affected as a result of venesection, with or without subsequent subcutaneous infusion, in animals in which renal insufficiency was induced by previous treatment with substances capable of exciting nephritis or which had been subjected to nephrectomy.

It has been shown that the normal molecular concentration of the blood is not influenced by bleeding alone. It was found, further, that the renal insufficiency that was developed slowly and gradually as a result of cautious administration of renal poisons, such as cantharidin and aloin—as indicated by increased molecular concentration of the blood—was not influenced by bleeding. A distinct parallelism was observed between improvement in the nephritic process and the degree of molecular concentration of the blood. With the disappearance of the symptoms of nephritis the reduction in the freezing-point was restored to the normal. Also, when the molecular concentration of the blood was rapidly increased by the administration of renal poisons capable of inducing acute toxic diffuse nephritis, no noteworthy diminution in osmotic pressure was observed after bleeding, with or without subcutaneous infusion.

Although these observations fail to supply an explanation of the mechanism by which bleeding affords relief in cases of uremia the results obtained clinically by this measure are not therefore to be impugned.

DANGERS FROM FORMALDEHYDE.

The local newspapers have, within the past few days, contained accounts of accidents from disinfection by formaldehyde gas, and it was said that a number of the employees of the Chicago Health Department were suffering from its effects. In one case insanity was reported as the result. A careful inquiry reveals that the reports were somewhat exaggerated, and that in no case

was serious permanent injury received so far as known. The method used in Chicago is that of spraying on sheets, and there are certain dangers connected with the use of formaldehyde in this way especially to those who, as public disinfectors, are compelled to repeatedly expose themselves to its vapor, but these are chiefly confined to the disinfection of large spaces that necessitate a comparatively prolonged stay in the gradually vitiated atmosphere; in ordinary-sized rooms, they are minimal if they exist at all. There is also a certain inconvenience from the temporary irritation of the air-passages, and catarrhal affections from these are common from this cause. The skin must also be protected, as exposure produces a troublesome eczema that sometimes leaves a permanent thickening. In two cases a temporary mental derangement, lasting for a few hours, has been observed, and a dazed condition for a brief period in others after excessive exposure. In one case complete unconsciousness for a number of hours followed the accidental douching of the head and face with the formalin solution, but left no permanent ill effects. There are reports also of alopecia having occurred from this cause, though the Chicago health officers have had no such experience. So far as known all the accidents have occurred to those who have had to expose themselves professionally as disinfectors; none are reported to others.

These facts show that formaldehyde is an agent that must be handled with some care, and that while the sheet method of disinfection has its advantages, it also has its perils when applied to very large spaces, such as storehouses, large hospital wards, dormitories, etc. The fact, however, that the Chicago Health Department's officials have made many thousand disinfections with but few such accidents, and without serious permanent injury to anybody, shows that these may be exaggerated, and experience will probably develop some appliance that will reduce them to a minimum. Perhaps also some form of generator may be produced that will be as efficient as the sheet method, although, according to the Chicago experiences, this is still a desideratum. Like every other powerful agent used in medicine for good, formaldehyde needs careful handling, but the fact that with all its powerful toxic action on the nervous system, as well as its action as a local irritant, no permanent injury has been received from it by any one, is strongly in its favor as a comparatively safe disinfectant.

THE MASSACHUSETTS GENERAL HOSPITAL.

The eighty-sixth annual report of the trustees of the Massachusetts General Hospital is an interesting document, as this hospital shows a high grade of organization in all its various departments and has excellent plans for increasing its usefulness in the future. Without going into unnecessary details, mention should be made of certain things that must be of great interest to medical men. Thus we find that the library of the hospital maintains a healthy growth; it now contains something

over 5000 volumes. The trustees have assumed the expense of publishing reports of the clinical meetings of the staff and steps have been taken for the immediate publication of important investigations in clinical pathology. The clinical-pathologic laboratory of the hospital has successfully demonstrated its increasing usefulness in the general work of the institution, and its needs as outlined by its directors have received full recognition. From the report of Dr. Wright, the director of the laboratory, we learn that the existence of the latter is due to a special fund raised by friends of the hospital. He calls especial attention to the need of such laboratories in order to bring the work of hospitals up to the standard, and he emphasizes also the scarcity of properly-equipped special ones of this sort in this country. While we have a multitude of public and other hospitals, there are probably not over half a dozen laboratories in connection with them worthy of the name. And yet it is safe to say that if the medical staffs of hospitals of fair size will make determined efforts toward securing properly-equipped laboratories and competent pathologists the efforts will be successful. It is generally acknowledged that the strength of Germany and other European countries in medicine, in the broad sense, rests largely on the prominence given the laboratory as a necessary department of a large hospital.

While such laboratories are primarily designed as aid to the medical and surgical work of hospitals, they are also means of advancing knowledge of the subjects with which they deal. The number of interesting and important special studies pursued under Dr. Wright's charge, makes a decidedly creditable showing and clearly demonstrates how such laboratories help to make hospitals useful in the widest sense and factors of great consequence in building up medical knowledge. The trustees of the Massachusetts General Hospital are to be congratulated on the foresight and wisdom they show in fostering laboratory work, and in connection with the other work of their hospital, and it is to be hoped that other hospitals will soon follow the good example they have created. Let it be thoroughly understood that a hospital of any size, without a properly-equipped laboratory in the charge of a competent director, is not doing and can not do its full duty to its patients, to its supporters, and to humanity at large, and the present unsatisfactory condition of things will change for the better. Endowments and appropriations for this good purpose can be secured elsewhere as well as in Boston. The way in which such matters are conducted is a good index of the intelligence and the spirit of the man, medical and non-medical, in a community. It goes without saying that in no way can the medical profession better strengthen its own cause than by securing as many complete and well organized hospitals and similar institutions as possible. There is abundant room for advance in the mere organization of the work of the staffs of many of our hospitals, and in the scramble for position this important work has been much neglected in the past.

THE OHIO MEDICAL PRACTICE ACT.

The passage of the Love bill, by the Ohio legislature, is evidence of the influence that the medical profession can exert in a state when it is duly aroused. There was a vigorous and determined opposition to the movement for medical reform, and an active lobby working against the bill. The newspapers, or at least a large part of them, threw their influence against it, and all the forces of quackery—osteopathy, "Christian Science" and other kindred delusions—were worked their utmost for its defeat. The osteopaths were especially energetic in their endeavor to legalize their practice, but their bill failed to pass and the most they could get was admission to practice on passing examination in the requisite branches. We doubt whether the Kirksville, Mo., institution will turn out many qualified practitioners for Ohio, unless it mends its ways. The power of the 8000 physicians in Ohio was made to be felt by the politicians, and the result should encourage those in other states where medical reform is needed. The unfortunate movement of the medical students—also previously noted in *THE JOURNAL*—which appeared to possibly threaten the success of the bill, also came to nothing practically, and the legal status of the medical profession in Ohio, as a contemporary¹ puts it, "is in better form than ever before in the history of the state."

A MALARIA EXPERIMENT.

The British Government, it is said, is about to inaugurate an interesting experiment of a kind that ought to make the antivivisectionists indulge in one of their customary howls. It is directly in the line of human experimentation, and as condemnable in its way as some of those that have recently given these philanthropists so much concern. It is proposed, so the report goes, to build a hut in the most pestilential spot of the malarial Roman Campagna, make it mosquito proof with screens, etc., and have two medical experts live there during the unhealthy season of May to October. The antivivisectionists may not object to this so far, but the subjects of the experiment are to have servants to wait on them and be exposed to the same risks without having the stimulus of scientific zeal or the hope of honor or reputation. If these four persons do not acquire malaria, it will prove that it is avoidable with proper precautions. As a further proof it is proposed to breed the malaria-bearing mosquitoes, feed them on infected individuals and then transport them to England and have them there inoculate individuals who have never been otherwise exposed, who are expected to develop the disease. If this report is correct, no one can really deny the possible value of the experiments, but the humane societies will probably have their say about it, and would prefer to have mankind go on the good old way and get bitten, "as Nature intended."

THE SUPERVISION OF MEDICAL COLLEGES.

The Superintendent of Public Instruction, of the State of Michigan, recently appointed Judge A. J. Mills, of Kalamazoo, and Dr. F. F. Pitcher, of Detroit, as a commission to visit and report on the medical colleges in the state. They have made their report and, while

¹Cincinnati Lancet-Clinic, April 21.

they put the stamp of their disapproval on the policy of chartering private medical colleges, they suggest certain regulations to be followed in case such a policy is continued. Among these are a fixed standard of preliminary qualifications and graduation and examinations by independent boards for both, the assurance of the financial responsibility and adequate teaching resources of the institutions, and a constant and thorough inspection of them by competent official visitors. They further recommend the refusal of charters for medical colleges in small towns where the medical, clinical and hospital facilities are not ordinarily found. These suggestions are sensible and should be also practical, and, if followed out, will certainly tend to improve matters. This country is suffering from a surplus of medical education, the quality of which is often correspondingly deteriorated. While a certain proportion of our medical colleges are approximately what they should be, there are many that could well be spared, and some of the genuine "cheap and nasty" type. Yet they all turn out M. D's. and, so long as they exist, there will be a surplus of doctors, such as they are. The filtering process of state examinations, if sufficiently rigid, will help matters, but it would be a still further advantage if we could purify the fountain-head by strict state supervision, as proposed by this Michigan commission.

ALCOHOLISM IN MEXICO.

According to an exchange,¹ which from contiguity might be expected to be well informed, alcoholism is making startling strides in Old Mexico. The alcohol habit, it says, is reported to be rapidly spreading to all ranks of Mexican society and the mortality statistics which come from the superior or national health board show, for each year, a steady increase in the number of deaths from cerebral congestion due to alcoholism. The national government has, it is said, become alarmed at this showing, and the increase of poverty and crime that goes *pari passu* with this cause. This increase of alcoholism among the Latin races has also been reported elsewhere, and if we include France among them, it has become one of the more serious problems of their civilization. When the local alcoholic drinks heretofore prevalently used among them are supplanted or supplemented by those of the Anglo-Saxon, the danger-point is brought within the vision of those who had before ignored it. It is an unfortunate fact that wherever the northern races go they carry their vices with them, and the American and English bar is one of the most active factors in their conquering advance. Mexico will do well for herself if she puts a check on the development of this special feature of modern civilization.

PROVISION FOR CONSUMPTIVES.

In view of the influx of indigent consumptives into Colorado, some benevolent gentlemen of that state are reported to have projected a novel sort of institution which will combine the characters of a consumptive sanitarium and a self-supporting farm colony. It is needful they claim, in order to obtain the full benefit of the Colorado climate, to exercise the body and fully inflate the lungs with the rarefied air, hence outdoor occupation is

desirable. The design is therefore to furnish light employment which will enable the not-too-far-gone consumptive to maintain himself while obtaining at the same time the full benefit of the aseptic and stimulating atmosphere. The promoters of the proposed establishment therefore are aiming to secure land near Denver, which they propose to lay out in market farms and gardens for the use of weak-lunged patients. The plans as given out are not detailed in full, but it would seem that the colony idea is most prominent, though the hospital or sanatorium feature will probably not be neglected. The intention is said to be to furnish a means whereby a man or woman can secure the best accommodations and medical attendance at moderate cost, and can, if they are able, earn enough or more to pay their expenses. As yet the project is only embryonic, but it is to be hoped that it may develop and mature to meet the fullest expectations of its projectors. If successfully carried out it ought to be a most beneficent aid to a large number of sufferers, and may also help to relieve the congestion of the cities of the state by needy consumptives. The chief mover in the enterprise is, apparently, the state secretary of the Y. M. C. A., W. M. Danmer, who estimates that about \$100,000 will be required to carry out the project. He thinks that as patients are sent from all parts of the country it is only fair that other regions thus contributing should respond to the appeal.

PATHOGENESIS OF EXOPHTHALMIC GOITER.

Two views in particular have prevailed in the past with regard to the pathogenesis of exophthalmic goiter, according to which the symptoms were considered dependent on disease of the cervical sympathetic, or of the medulla oblongata; but no constant lesion has been found, and such as have been discovered have been present also in association with other conditions. It has been shown experimentally that section of the cervical sympathetic is attended with dilatation of the blood-vessels of the head and neck, retraction of the eye-balls, drooping of the eyelids, contraction of the pupils; stimulation of the central extremity, with contraction of the blood-vessels, protrusion of the eyeballs, retraction of the eyelids, dilatation of the pupils; and stimulation of the peripheral extremity, with increased action of the heart. For the development of the symptoms of exophthalmic goiter through the agency of the cervical sympathetic it would therefore be necessary for some fibers to be in a state of paralysis, and others in a state of irritation. Certain other nervous, respiratory and circulatory symptoms would, however, be left unexplained on the assumption of disease of the cervical sympathetic solely, while within a small area on the floor of the fourth ventricle are situated structures—the vasomotor, the cardiac accelerator, the pneumogastric, and the diabetic centers—derangement of whose function would give rise to many of the symptoms of exophthalmic goiter. It has been further demonstrated experimentally, that division of the restiform bodies is attended with acceleration of the heart, exophthalmos, vasomotor paralysis in the ears, neck and thyroid gland, widening of the palpebral fissure, infrequency and incompleteness of winking, and sometimes enlargement of the thyroid gland. More than fifteen years

¹Texas Medical News, April.

ago it was found that improvement in the symptoms of exophthalmic goiter followed partial or total removal of the thyroid gland, and the operation has since been repeated successfully in a considerable number of instances. It was not, however, until some years later that the conclusion was reached that the manifestations of exophthalmic goiter are probably dependent on deranged functional activity of the thyroid gland, as a result of which either toxic substances are sent into the blood or toxic substances present are not neutralized by an internal secretion of the thyroid gland. Subsequently, however, hypertrophy of the gland was found, and it was definitely concluded that the symptoms of the disease were dependent on intoxication resulting from excessive secretory activity of the thyroid gland. Further, it was learned that similar manifestations could be induced artificially by the excessive therapeutic administration of thyroid gland. More recently resection of the cervical sympathetic nerve has been practiced in some cases of exophthalmic goiter, with reported success. Additional confirmation of the view that the cervical sympathetic is involved is afforded by some observations recently made by Haskovec,¹ who found, experimentally, that acceleration of the action of the heart takes place after injection of thyroid extract when the vagus is divided and when also the peripheral extremity of the nerve is paralyzed by atropin. The cardiac acceleration failed to take place, however, when thyroid extract was injected after division of the spinal cord at the junction of the cervical and dorsal portions, and also after excision of the cervical sympathetic. The only reasonable conclusion to arrive at from the available evidence is that exophthalmic goiter is a constitutional thyroid intoxication expending its force especially on the sympathetic nervous system and the medulla oblongata.

BACTERIOLOGY OF LOBAR PNEUMONIA IN TYPHOID FEVER.

While the bacillus of typhoid fever has been repeatedly isolated from the consolidated lung in typhoid fever, it has not been successfully demonstrated in the sputum during life, though sought for by competent men. It is therefore of interest to note that v. Stühlern² was able to secure this organism as well as the micrococcus lanceolatus in pure culture from the sputum of a typhoid patient in whom consolidation of the lower left lobe developed on the tenth day of the disease. Bacteriologic examination of the blood gave negative results. In a second fatal case of pneumonia developing in the fourth week of the fever, cultures of typhoid bacilli, micrococcus lanceolatus, and staphylococcus were obtained from the sputum and from the fluid aspirated from the affected lung. In this case also the blood remained sterile, but the urine contained typhoid bacilli. Thrombosis of the femoral vein developed, and after death typhoid bacilli and staphylococci developed in cultures from the thrombus. Bacilli like the typhoid were found also in the sections from the pneumonic lobe. In a third case of this kind, examined bacteriologically post-mortem only, typhoid bacilli and diplococci were demonstrated in the

lung. An important fact in connection with the two first cases is this, that the sputum was decidedly hemorrhagic, and in the third case the affected lobe was hemorrhagic; v. Stühlern states that Curschmann has observed that the sputum is hemorrhagic in pneumonia complicating typhoid oftener than in pure pneumonias. Hence it would seem that perhaps this peculiar feature of pneumonia in typhoid is in some way dependent on the typhoid bacilli being present in the consolidated districts. It is to be remembered, however, that the hypostatic congestions of the lungs in typhoid may be the reason for the hemorrhagic sputum. At all events the fact remains that the sputum in typhoid may contain typhoid bacilli—an additional spur to the most careful disinfection of all the external secretions of typhoid patients. Indeed, it is just as essential to disinfect urine and sputum as it is to disinfect the feces on which formerly was laid so much stress. Perhaps more attention should be paid to perspiration also than has been given it.

Medical News.

WE RECENTLY mentioned that the Paris Académie de Médecine had voted in favor of adding measles to the list of diseases required to be reported. "Infectious pneumonia and bronchopneumonia" are now on the list.

NEW MEDICAL JOURNALS.—Three new publications have just appeared: the international journal, *Lepra*, with articles in English, French and German, founded by James Nevins Hyde, Dehio, Ehlers, Hansen, J. Hutchinson and Neisser (J. A. Barth, Leipsic); a journal, published by Fraenkel, Gerhard and von Leyden, devoted to questions concerning tuberculosis and sanatoria (Veit & Co., Leipsic); a third, a quarterly devoted to the scientific, unprejudiced discussion of the alcohol question, published by Baer, Boehmert, Strauss and Waldschmidt (Boehmert, Dresden).

THE HOSPITAL SHIP "MISSOURI."—This ship, which for two years has done excellent service, first between Cuba and Porto Rico and the home ports and afterward between the Philippine Islands and the United States, has terminated her connection with the medical department of the Army. She has been transferred to the quartermaster's department, on the recommendation of the surgeon-general, as the Army Transport Service is now so well conducted that sick men can be brought across the Pacific in comfort on the vessels of this service.

RETIREMENT OF COLONEL ALDEN.—Colonel Charles H. Alden, assistant-surgeon-general United States Army, who has been chief assistant to the Surgeon-General for the past seven years, was retired April 28, on account of having attained the age of 64 years, the age limit for active service. Dr. Alden was appointed an assistant-surgeon with the rank of first lieutenant June 23, 1860. Five years later he was promoted to a captaincy and, July 28, 1866, he was made a major and surgeon. He received his promotion to a lieutenant-colonelcy in November, 1888, and to a colonelcy in 1892. On the evening of April 25, last, a dinner in honor of this officer was given by the medical officers of the Army stationed in Washington, D. C., and at neighboring posts. On the evening of the day of retirement a reception was given by the Surgeon-General of the Army and Mrs. Sternberg, at which the medical profession of Washington had an opportunity to congratulate Colonel

¹ Wiener Med. Woch., January 6, p. 65.

² Centralbl. f. Bact., Abth. 1, 1900, xxvii, 354.

Alden on the close of his long career of active service. This retirement promotes Lieut.-Col. Albert Hartsuff to the rank of colonel, Major Charles L. Heizmann to be lieutenant-colonel, and Captain and Assistant-Surgeon Edward Everts to be major and surgeon, U. S. A.

PROGRESS OF THE PLAGUE.—According to the *British Medical Journal* of April 21, the mortality from plague subsided considerably in Bombay during the last week of March and gave evidence that with the approach of hot weather the health statistics are slowly approaching normal. In Calcutta, the death-rate has run up with appalling rapidity, being, from March 22 to 28, respectively, 112, 156, 116, 148, 138, 119, and 129. The well-to-do natives are still leaving the city in large numbers, so that trade is greatly disturbed and "the markets are dead." The plague, however, is confined for the most part to two wards and fresh cases in disinfected houses seem to be extremely rare. But notwithstanding the fact that considerable success has attended the attempts to popularize inoculation for plague in some districts, the disease is still carrying off about 5000 every week in India, and causing unrest and disturbances in important centers because of the preventive measures which have to be adopted. Editorially, *The Lancet* of April 21 tells of a serious riot where the militia had to be called out because the people had set fire to the segregation camp and thrown the bodies of five of the policemen who had opposed them into the flames. During the week ending April 12, there was only one new case on the Island of Mauritius, but Formosa reported eighty-three. In Buenos Ayres there are still a few cases, while Asuncion has reported none during the last twenty-five days.

NEW YORK.

THE TWENTY-FIFTH annual meeting of the Alumni Association of the Medical Department of the University of Buffalo was held the 27th ult., and the commencement exercises of this institution the same evening.

DR. EVAN BARKER JONES, Brooklyn, has been authorized by the courts to change his name to Barker, in order that he may become heir to \$200,000 left him by a great uncle on condition that he would assume his surname and coat of arms.

HOSPITAL MANAGEMENT.

The signing of the Burnett bill, by Governor Roosevelt, means the beginning of important changes in the management of the Manhattan and Long Island state hospitals for the insane. It is generally understood that back of this bill, which has now become a law, has been the influence of the State Commission in Lunacy, and the measure has been urged in the interest of economy, it being alleged that the new plans contemplated by this bill would effect a large saving in the matter of unnecessary salaries. Four medical superintendents are summarily legislated out of office, viz.; Dr. A. E. Macdonald, general superintendent of the Manhattan State Hospital, on Ward's Island; Dr. Oliver M. Dewing, general superintendent of the Long Island State Hospital, at King's Park; Dr. Robert M. Elliott, medical superintendent of the old hospital at Flatbush, and Dr. Herman C. Everts, medical superintendent of the hospital at King's Park. Under the new law the Manhattan State Hospital will be divided into a female division, a male division and the Central Islip colony. The Long Island State Hospital will be divided into two separate institutions, one at Flatbush, and the other at King's Park.

New York City.

DR. ABRAHAM JACOBI, having reached the age of 70 years, the students of the College of Physicians and Surgeons recently presented him with a silver cup. He intends going to Paris shortly to read a paper on "Infant Feeding," at the International Medical Congress.

DR. H. W. WILEY, chief of the Division of Chemistry, U. S. Department of Agriculture, Washington, D. C., delivered an address on "Food Adulteration and its Relation to Public

Health," at the first anniversary of the Hundred Year Club, held the 24th ult.

MEDICINE IN MISSIONS.

The questions of the advisability of training natives in medical lines and where they should be trained received considerable discussion at a recent meeting of the Ecumenical Missionary Conference. Dr. Edward S. Fry, of Edinburgh, expressed the opinion that the native agency for medical missions is as important as any other, and that the best method of training the natives will depend on existing conditions, but in most cases they should receive their instruction in their own country. Dr. A. P. Peck, dean of the medical department of North China College, spoke of the training in mission hospitals. Dr. John C. Berry, Worcester, Mass., from his experience while stationed in Japan, pointed out that trained nurses are almost as important as trained physicians in medical missions, and disapproved of taking natives to Europe or America to study medicine. Dr. Moses C. White, New Haven, Conn., favored training them in America, and pointed out that the impracticability of dissection, etc., in certain countries makes such training all the more necessary.

PHYSICIAN SUES INSURANCE COMPANY.

Dr. Sidney H. Carney, who for many years was in the employ of the New York Life Insurance Company, brought suit against that company some months ago for \$168,000, claiming that he had been wrongfully discharged, and that he had an oral contract whereby he was to be a salaried expert for life. This contract was entered into in 1869, the agreement being that after the third year his salary should remain at \$6000 until changed by the parties of the contract. He was discharged in 1895, at which time he was drawing a salary of \$12,000 a year. By mortuary tables it was estimated that he should live for fourteen years more, and accordingly suit was brought for \$168,000. Judge Haight, of the supreme court, dismissed his complaint of breach of contract, and an appeal was taken. The appellate division has just handed down an opinion, sustaining the previous decision. The defendant denied that there was a life contract, and asserted that it was void by the statute of frauds.

STRANGE AFFECTON OF MEMORY.

A young student of law recently forgot who he was, and wandered about the city endeavoring to discover his identity and where he lived. He visited the Astor Library and several hotels in quest of information, and finally walked into a police station, and, in a bright, clear voice, astounded the sergeant at the desk by the query: "Can you tell me who I am?" "Where I am, and to whom do I belong?" The sergeant told him he was in New York City, and tried, but in vain, to get the young man to recognize some of the well-known office buildings. Finally, in a sad and somewhat discouraged manner, the young man said: "Could you tell me if there is a young man missing that looks like me?" He was directed to police headquarters, where he repeated this question. A search of the records of those missing showed a description answering that of the inquirer, and accordingly a detective was sent with him to the address given, where his mother and sisters were almost overcome with joy at seeing him again. He did not, however, understand their emotion, and asserted that he did not know them nor the place. When questioned by his physicians, he wrote answers promptly to inquiries regarding persons with whom he had had business dealings, but any reference seemed to be a signal for his memory to fail him again. At latest account he was slowly recovering from his amnesia.

REPORTING CONTAGIOUS DISEASE.

The Health Department is stirred up over the published assertion of Virgil Prettyman, principal of the Horace Mann High School, that the health authorities have been negligent in reporting cases of contagious disease. He charged that out of 20 cases of measles in his school, only 3 had been reported to him by the Board of Health, and only 2 out of 7 cases of scarlet fever. Dr. F. H. Dillingham, assistant sanitary superintendent for the Borough of Manhattan, promptly set on foot an investigation, but was hampered in his work by the fact that some of the cases dated back to January. However,

according to Mr. Prettyman, at least 8 cases of measles had occurred in the present month, and 6 in March. He said that he would not have made such charges in a circular letter addressed to the city newspapers, had it not been that for the past two years he had been protesting to the Board of Health, without result. By a system of co-operation between the Board of Health and the Board of Education, the public schools daily receive a list of those in each district who are sick with contagious disease, or who have been exposed to contagion, and who, therefore, are to be excluded from school until readmitted by certificate from the former Board. While the private schools, being out of the jurisdiction of the Board of Education, do not receive notices from that source, the inspectors of the Health Department are supposed to notify these schools directly concerning every case of contagious disease coming under their notice.

PENNSYLVANIA.

DR. T. LEIDY RHODES, of Boystown, has been appointed a surgeon in the army and has gone to Manila.

TWO MEN living in Norristown, who were conducting a grocery store, were recently arrested and fined \$100 each for selling oleomargarin.

AT CHESTER, on the 23d ult., the J. Lewis Crozer Home for Incurables was formally opened. The home was erected at a cost of \$47,000, is three stories high and has 112 rooms, and accommodation for 160 patients. Dr. T. P. Maddox has been appointed chief surgeon.

Philadelphia.

DRS. JACOB AND FREDERICK DACOSTA will spend the summer months at Villanova.

BY THE will of Lambert Ware \$60,000 will eventually revert to the Germantown Hospital and Dispensary.

A BOARD composed of women has been organized by friends of the St. Joseph's Hospital, to aid in the work of that institution.

ESTABLISHMENT of a systematic instruction of physical culture in the public schools is being considered.

BY THE will of Rebecca Emslie, \$1000 has been given the Pennsylvania Hospital, and \$5000 to the Episcopal Hospital.

DR. W. T. COUNCILMAN, of Boston, delivered an address at the last meeting of the John Ashhurst, Jr., Society, on the "Pathology of Diphtheria."

AT THE last meeting of the Medicolegal Society, Dr. J. Madison Taylor gave an address on "Hypnotism and Some of its Medicolegal Aspects."

THE LATE Dr. Amy S. Barton left her medical and surgical instruments to the physicians who attended her during her last illness.

AT THE recent annual convocation of the College of Physicians, an interesting exhibit was made of microscopic specimens, and a demonstration given on photographing in colors.

A CIRCULAR has been issued by the Journeymen Plumbers' Association, to be sent to physicians, life insurance companies, etc., for the purpose of securing improved sanitary arrangements in the residences of Philadelphia. It is believed that insanitary ones have caused the spread of contagion, especially diphtheria.

A RESOLUTION was passed at the last meeting of the Philadelphia County Medical Society, in favor of giving graduates of literary colleges, who enter medical colleges, credit for the elementary work already done, and that they be admitted to advanced standing.

MORTALITY STATISTICS.

The number of deaths occurring in the city during the week just closed was 618, a decrease of 121 from that of last week and an increase of 117 over the corresponding period last year. The principal causes of death were: apoplexy, 12; cancer, 10; tuberculosis, 54; influenza, 19; measles, 31; pneumonia, 129.

ACT OF A DEMENTED PATIENT.

A physician recently had a most unfortunate experience with a demented patient who had called at his office. Some time ago he had treated a woman for an ear affection, and after a considerable period she again called at the office and, on being greeted with the words: "What can I do for you, madam?"

she said, "I'll show you what I'll do for you," whipped out a pistol and began firing at the doctor. After five shots she walked into the street, and was arrested. It is believed that she is demented. On being questioned, she said she had been prompted by Divine Providence.

MARYLAND.

DRS. CHARLES MATTFELDT and J. C. Schofield have been appointed sanitary officers of Baltimore County.

Baltimore.

AT THE commencement exercises of the University of Maryland, May 1, sixty-five received the degree of M.D.

DR. CLAUDE VAN BIBBEN has been appointed vaccin physician.

DR. F. J. KIRBY, superintendent of St. Joseph's Hospital, sailed on the 28th ult. for Europe, where he will remain till autumn.

DR. JOHN S. BILLINGS, New York City, delivered three lectures on "The History of Medicine," at the Johns Hopkins Hospital, recently.

TWO CASES of smallpox, from a hospital in the northeast section of the city, were moved to the quarantine hospital on the 27th ult. This makes 12 cases, and another suspicious one is under surveillance.

DR. OTTO GUSTAF RAMSAY, instructor in gynecology, Johns Hopkins, has been elected associate professor of gynecology in Yale, and it is said that he will accept.

FOR THE week ending April 28, the death-rate was: whites, 19.31, colored, 33.33 per 1000. Pneumonia caused 25, consumption 28, la grippe 4, and typhoid fever 3 deaths.

THE TWENTY-EIGHTH annual commencement of the College of Physicians and Surgeons was held on April 24. The Alumni Association had its annual meeting, with music and "a smoker," the evening of the 23d. Dr. W. F. Smith was elected president.

THE LIBRARY of the Maryland Medical and Chirurgical Faculty now contains 13,000 volumes. 803 being added during the year; 138 journals are taken. There were 3908 readers during the year, and the expenses were \$984.60.

ILLINOIS.

Chicago.

THE STAFF of the Maurice Porter Children's Hospital has been increased by a large number of recent appointments.

THE COMPETITIVE examinations for internships at the Presbyterian Hospital will be held May 10.

HOSPITAL APPOINTMENTS.

AS A result of the recent examination for internships in the Cook County Hospital, the following have received appointments: Drs. Loeb, Sears, Jakobowski, Kerr, Friedman, Failon, Wendstrand, Hultgen, Tyndale, Cubbins, McNeil, and Riebel. The appointees for the first, fifth and ninth places were from Rush Medical College, those for the second, third and fifth places were members of the College of Physicians and Surgeons, and the other six were from the Northwestern University Medical School. The period of internship is eighteen months.

NEW JERSEY.

AT THE hospital fair held at Paterson, April 22, \$7000 was raised.

DR. A. ARLING HEAD, of Mulford, has been appointed physician of Holland and Alexandria townships.

PROF. JOHN J. MULVANEY, president of the Jersey City Board of Education, in his recent report recommends that a corps of physicians be appointed to look after the health of school children.

DISTRICT OF COLUMBIA.

THE HOUSE committee on interstate and foreign commerce has authorized a favorable report on House bill 9677, known as the Brocius pure food bill.

THE REPORT of the health officer for the past week shows the total number of deaths to have been 137, 81 of white and 56 of colored persons. At the close of the week there were 64 cases of diphtheria, 68 of scarlet fever, and 7 of smallpox under treatment.

OHIO.

THE GRADUATING class of the Toledo Medical College numbered 18, the commencement exercises being held the 26th ult.

THE ANNUAL meeting of the Alumni Association of the Ohio Medical University, Columbus, was held April 24. Dr. C. S. Means was elected president for the ensuing year. The commencement exercises of this school were the same date.

DR. ERNEST SCOTT has been appointed to succeed Dr. H. S. Cozad, at the state hospital, Columbus. Dr. Cozad has gone to Europe for a year of special study.

MICHIGAN.

THE GRADUATING exercises of the Michigan College of Medicine and Surgery, Detroit, were held the 24th ult. There were 25 degrees conferred.

THE APPLICATION of "Dr." Richard Metcalfe of Benton Harbor, for a mandamus to compel the new State Medical Board to register him under the law of 1899, has been denied by the supreme court. This rules out all graduates of medical schools which issued diplomas without requiring attendance.

TENNESSEE.

THE ALUMNI association of the Chattanooga Medical College held a meeting April 24. The graduating class, at the commencement exercises of this institution, numbered fifty-nine. Dr. G. M. Ellis delivered the faculty address.

COLORADO.

AT THE commencement exercises of Gross Medical College, Denver, held April 26, the degree of M.D. was conferred on 22 persons.

IOWA.

THE COMMENCEMENT exercises of the Keokuk Medical College and College of Physicians and Surgeons were held recently. Diplomas were awarded to 42 students.

KANSAS.

A NEW HOSPITAL, costing \$60,000, is to be erected at Fort Leavenworth.

Topeka.

THERE WERE six cases of smallpox in the Topeka pest-house on April 23, with five due to arrive the next day.

DR. L. H. MCKINNEY has filed a claim of \$150 with the city council for damages alleged as a result of the improper fumigation of a residence by the city health officers. He moved into the house after it had been fumigated, and his whole family contracted smallpox soon after.

GOVERNOR STANLEY, in outlining his future policy, has said that the State Board of Health is an unnecessary adjunct of the state, and that the work now done by the Board, consisting of fifteen members, could be done just as well by the secretary alone, who should have all the authority and power now conferred on the Board.

CALIFORNIA.**Alameda.**

The Board of Education has adopted a rule forbidding the employment, as teachers in the public schools, of any persons afflicted with tuberculosis.

San Francisco.

THE CITY'S Board of Health has acted favorably on the recommendation of the Los Angeles Board and will do all in its power to secure the necessary legislation for deportation of all lepers who may be found in this country.

A NEW PLAGUE CASE.

(Special Telegraph to THE JOURNAL, May 1.)

ANOTHER case of plague has been found in San Francisco, in a Chinaman whose body was found April 25 in the Chinese quarter, with a large bubo in the left side, near Poupart's ligament, and with the other inguinal glands swollen. The news was successfully kept from the press by the Board of Health, and smear preparations made. These disclosed the bacillus pestis. Two guinea-pigs were inoculated from gland tissue and one died fifty-eight and the other sixty-one hours after. Both pigs presented the characteristic lesions of the

plague. Extraneous organisms seen in the glands were also present, but in small numbers, while the plague bacillus was present in enormous numbers. The identity of the latter has also been demonstrated by culture methods, by Drs. Ophuls, Montgomery and Kinyoun, all agreeing in the diagnosis made. The Chinaman has lived in San Francisco thirty years and was 56 years of age. No clinical history could be obtained.

AUSTRALIA.

IN VICTORIA the crusade against rats has extended even to the remote country districts, and a sanatorium for plague patients, to be erected by the government, is proposed.

THE GOVERNMENT has decided to establish depots at all the centers of Auckland for the free distribution of phosphorus and other poisons used in exterminating the rats.

SYDNEY'S PLAGUE.

THE plague cases up to the date of this letter (March 19) number twenty-three, with eight deaths. The first case was reported in January. Up to March 17, more than one thousand persons had been inoculated with Haffkine's prophylactic serum, most of these being engaged in waterside occupations. A few hours following the inoculation slight headache and feverishness have been noted, but no illness of any note followed injection. Dr. Ashburton Thompson says that as the plague has gained a foothold in the colony it will not be entirely eradicated for many years. He does not mean that the epidemic will be continually maintained at a high average of cases, but that it will recur at certain seasons. The average duration of each visitation will probably be about eight months. He says that the absolute annihilation of all rats would be followed by entire removal of all infection, but as it is not possible to rid the land of the rodents the disease must remain. The department of health is planning the production of the remedial serum in the colony, but it will be some months before the first results can be obtained. The proposition to erect a special plague hospital for the metropolitan districts has been given up for the present. The dirt and refuse of the city is collected by the city and carried daily, by punt, as far out to sea as the weather will permit, and the government has agreed to bear a large share of the cost of cleaning the city. The opinion of Dr. Thompson is that the only reparation that can be made for long neglect is the obliteration of all existing wharf structures and the erection of solid wharf frontages which will be not only impervious to water but proof against invasion by rats. The campaign against rats was begun late in February. All of the men engaged in the work of extermination being first required to subject themselves to inoculation with prophylactic serum. Posters were also placed in the portions of the city most likely to be invaded by the disease, and a house-to-house distribution of hand-bills carried out.

HAWAIIAN ISLANDS.

THE HILO Board of Health has been considering quarantine against Honolulu goods, in spite of the fact that Honolulu's plague is practically a thing of the past.

ACTION has been taken by the minister of foreign affairs which places Sydney, N. S. W., from now on in much the same quarantine relations relative to the Hawaiian Islands as exists between Honolulu and the mainland ports.

PROPOSED HOSPITAL FOR JAPANESE.

A plea has been made to the public for donations for the purpose of building a hospital for Japanese subjects on the Islands. The proposed cost of the institution is \$6500. Early last year the Japanese Benevolent Society considered building a permanent charity hospital, but the matter was given up and a private one erected by a Japanese physician, this being closed at the time of the plague epidemic.

LOSSES FROM THE PLAGUE.

THE Council of State recently passed a resolution to the effect that the Hawaiian Government should pay all just claims for losses caused by the action taken by the Board of Health in connection with the suppression of the plague, i. e., those caused by the burning of houses, furniture and goods by direct order of the Board, as well as losses caused by the acci-

dental spread of the fire, and those caused by the fencing up of land on which houses have been burned. The Council also advised the appointment of a new Court of Claims (see last week's JOURNAL, p. 1081) to consist of five members, three of whom shall be business men.

HONOLULU'S PLAGUE.

Up to the date of this communication, April 19, there have been no cases of bubonic plague since March 31, and with no cases to May 1, on that date the quarantine by the local board of health will be raised. The plague, which first appeared about four months ago, may therefore be said to have been practically stamped out, there having been only one death per week therefrom during the past six weeks and none during the past twelve days, while the deaths from consumption and pneumonia have averaged fifteen or twenty a month. The cases to date number 71, with 62 deaths. Of these, 17 were cared for in the pest-house, with 9 recoveries. The shipping business of the port has been seriously interfered with by the epidemic, and no communication is yet permitted with the sections of the city in which the deaths occurred. The buildings occupied by Asiatics and others as dwellings and shops, burned on account of the plague raging there, numbered about fifty. Fortunately the sugar plantations are from ten to seventy miles from the city, and no communication has been allowed with them except by telephone. They have therefore remained strictly free from contact with the disease, and the sugar has been shipped direct from the mills to the vessels, the latter not being allowed to go within certain limits. Examinations from the soil, etc., reveal bacteria present, but none of bubonic plague. Other examinations of foodstuffs preserved in acidulated liquids show them to be free from bacilli. Too much credit can not be given Dr. Wood, of the Board of Health, for the work done in stamping out the disease.

CANADA.

SMALLPOX IN WINNIPEG.

Smallpox of a very virulent character has broken out in the General Hospital, Winnipeg. Five cases have so far developed, but it is impossible as yet to foretell the extent of the exposure. The man who brought the disease to Winnipeg was taken to the hospital in a hack and, after his death, the body was handled by the undertakers, who did not know the nature of the death. Subsequently his effects were handled by several people in and about the hospital, and the first thing the medical health officer of the city, Dr. Inglis, knew, he had five cases of smallpox to deal with of a very malignant type. These have been removed to the quarantine station, and this as well as the hospital is now being guarded by special constables. Vigilance will be the motto of the authorities for the next few weeks.

AMALGAMATION OF TORONTO AND TRINITY.

The controversy between these two rival institutions has assumed a new phase. In the April issue of the *Canada Lancet*, a journal markedly in touch with Trinity Medical College, the editor and one of the associate editors come out squarely for the amalgamation of the two schools. Their cue has no doubt been taken from an interview appearing in the daily press, accorded by Dr. Adam H. Wright, professor of obstetrics at Toronto University, who has placed himself on record as being in favor of closer relations between Toronto and Trinity. Then there is the fact also that Trinity University is about to seek federation with Toronto University—the provincial university, and when such federation is accomplished, and Trinity University relinquishes her degree-conferring power, Trinity Medical College will have to look elsewhere for her M.D. degrees. The editorial in the *Lancet* does not deny that Trinity's cause is a righteous one; but expresses the opinion or rather belief that the amalgamation of the two institutions would be "the best solution of the existing difficulty," that it would do away with jealousies stated to exist between practitioners who are connected with these institutions, which also is at times evidenced in the societies as well as in general practice, and further, that medical education would be placed on a more permanent and lasting basis than it is at present in Ontario. Another reason

advanced for the proposal of amalgamation is that this city could then proceed to do post-graduate work; that the men who now go abroad would be accorded advantages at their doors which would induce them to stay at home. There is no doubt that the present time is an important one in the history of medical education in this province; and as the legislature has prorogued without taking up the McKay bill again, the intermission will probably see the discussion of the whole question in all its bearings, and the outcome will be awaited with considerable interest, not unmingled with some anxiety for the proper adjustment of the whole question.

PECULIAR HOSPITAL METHODS.

A private hospital, said to be located in the State of Michigan, whose commercial instincts have no limitation so far as distance in "miles" is concerned, has been endeavoring within the past week or two to entrap some Toronto physicians, ostensibly to secure their appointment on their "staff," but really for the purpose of fattening their own revenues. The plan of campaign was for the surgeon or physician here to act as agent for the concern in Michigan, to whom patients were to be suggested; these would then be written to and, if secured, the surgeon here was to participate in the profits to the extent of one-half. The following is a copy of a letter sent to a "patient" here:

"Dear Sir or Madam: We beg respectfully to call your personal attention to the fact that we have just recently elected and appointed Dr. — of your place to be a visiting and consulting physician and surgeon on the medical staff of our hospital, on account of his excellent medical qualifications and professional standing. We have no hesitation in recommending him to you, and should you, any member of your family, friends or acquaintances become sick and desire medical treatment, we wish to highly endorse the Doctor and recommend you to patronize him. Should you at any time desire the services of our hospital for yourself, friends or acquaintances, the Doctor will make arrangements with you so that you can come here for treatment. We have a first-class up-to-date surgical hospital, with every home comfort and a medical staff of eminent physicians and surgeons, and our charges are less than anywhere else you may go. Trusting you will bear these facts in mind, believe us to remain."

A further additional inducement to the Doctor to seek appointment on this "wonderful" institution was the presentation of a lithographed certificate of membership to the physician himself, 17x22 inches, rated in price according to the quality of paper and the beauty and design of the scroll, at \$5, \$7.50, or \$10. The income from this source was to go into funds which "are devoted to the maintenance of the hospital for the benefit of us all." We do not think that this "up-to-date" institution has been able to land any "suckers" in Toronto.

Montreal.

DR. JAMES BARCLAY, lecturer and demonstrator in obstetrics at McGill University, has entered on his duties there.

TWO CASES of smallpox have appeared within the past week. The first arrived from Rossland, B. C.

DR. A. LAFTHORN SMITH has retired from the Montreal Dispensary, after a service of twenty years. He will continue as surgeon-in-chief of the Samaritan Hospital, surgeon of the Western Hospital, consulting gynecologist of the Women's Hospital, and professor of clinical gynecology at Bishop's College.

A LITTLE NONSENSE NOW AND THEN, ETC.

Generations of graduates of medical McGill, scattered over Canada and the United States, have not forgotten the boys' factotum, Mr. James Cook, or "Cookie," as he is affectionately called by those whose letters, caps and telephone messages he looks after. It is now an annual affair amongst the medicos of McGill, just prior to taking their departure for the summer holidays, to make a presentation to Mr. Cook, in the way of coin and an elaborate illuminated address, in which superabundant flattery and adulation predominate. This year "Cookie" was presented with \$30 in five-cent pieces, all snugly stowed away in a big box of ashes, supplemented with an address, which was headed as follows: To Sir James Rip Van

Winkle Cook, Knight Commander of the Vats, First Lord of the Treasury, President of the Ancient and Illustrious Order of Prevaricators, Lord Warden of the Vault, and Premier of the Dominion of Aesculapius. Mr. Cook, who was dressed in a grand military outfit for the occasion, responded at considerable length in a poem. Afterward a procession was formed and the devoted attendant was shouldered up and down and around the College grounds.

Correspondence.

Medicine in the Far East.

March 30, 1900.

A CEYLON HOSPITAL.

To the Editor: During my stay at Colombo, on the Island of Ceylon, I frequently visited the civil hospital of that place and saw considerable of the medical work done there. This institution has accommodations for 350 patients. The buildings are situated in a beautifully shaded grove of cocoanut palms, and are disconnected pavilions, flanked on each side by open verandas, and to which large windows, for their perfect ventilation, open. There is a medical school connected with this hospital, where seventy-five young men are being educated. The faculty is composed of English, Dutch half-breed and pure Ceylonese natives, and represent all shades of complexion, from the fair-skinned Anglo-Saxon to the Singalese as black as the Congo negro. The color line seems not to disturb the harmony of this mixed body of teachers in the least, but the Dutchman's hatred of the Englishman, since the outbreak of the South African war, I saw manifested on more than one occasion. The students, however, were all dark-skinned natives of the island, and on the whole impressed me as a set of men superior to those I met studying medicine in India.

Before beginning their studies, these men have to pass a preliminary examination that is equivalent to that required to enter the freshman class at Oxford. They have a five years' graded course, and after completing this many of them go to London or Edinburgh to pursue advanced studies.

NO BERI-BERI IN CEYLON.

It is a strange fact that, while the climate here in Colombo is so like that of southern China, I never saw a single case of beri-beri on the island of Ceylon.

ANCHYLOSTOMIASIS.

I saw in the above mentioned hospital my first case of ancylostomiasis, a parasitic disease affecting the intestinal tract, especially the duodenum. The patients all had an aspect as if far gone with Bright's disease, added to which there was a decided jaundice appearance to the skin. The drinking of dirty water from marshes and stagnant pools is the source from which the disease originates. The treatment consists of the internal administration of thymol and iron. The mortality is from 40 to 60 per cent.

TETANUS IN CEYLON.

During my frequent visits to this hospital, I never failed to find a case of tetanus in its wards. A large percentage of these unfortunate patients were hostlers. Dr. Thomas, one of the surgeons, told me that they had found the soil about the horse barns, in Colombo, full of tetanus germs, and that when a man who attends horses gets an abrasion of the skin on any part of his body infection often follows. They treat from 25 to 50 cases of this disease annually, in this institution, which I believe is a larger number than is treated in any hospital of its size in the world. Patients of the acute class all die, while a few of those in whom the disease assumes a mild form at the outset and runs a chronic course, recover. They treat it here with the bromid of potassium, cannabis Indica and opium. It is, however, on the latter remedy that they place main reliance, and they give it to an extent that keeps the patient in a condition of deep narcosis.

NO DIPHTHERIA NOR SCARLET FEVER IN CEYLON.

Professor Sinnetawby tells me that he does not believe that there has ever been a case of either diphtheria or scarlatina on the Island of Ceylon. Here in the Far East I find that where one of these diseases is absent the other never prevails, which

would seem to be an argument in favor of their common origin.

DIABETES MELLITUS.

I saw here a large number of cases of diabetes mellitus. The physicians tell me that in some sections of the island among certain classes of the population, one-half of the inhabitants suffer from glycosuria. Even the small land-holders in Ceylon lead a life of perfect idleness. If the proprietor owns a cocoanut grove of only four or five acres, and a rice field of the same size, he can live the kind of a life that he does without ever doing a single stroke of manual labor. His dwelling is an unfurnished, mud hut, to which he resorts only when it rains. He spends his days basking in the shade of a tropical grove, and hires, for a pittance, a coolie who runs at his bidding and attends to his every want. This man's diet is composed largely of rice, and to this class belong those who suffer so often from diabetes mellitus. On the contrary, the coolie, who serves this land-holder, and the jiriksha man, who plays the rôle of a horse, under the hot rays of a tropical sun, though they may both live on the same diet as the man who pursues a sedentary course in life, scarcely ever have this disease. The physicians in the hospital tell me that if early in the course of the complaint you can induce the sufferer to take an abundance of active exercise, you can in this way often arrest the disease. They treat the patient by eliminating rice and bread from his diet, but allowing the free use of meat, beans and vegetables that contain little or no starchy elements. As for medication, they rely entirely on nitric acid and opium.

INTESTINAL DISEASES.

Bowel complaints, consisting of diarrheas, dysenteries and the like, I found here as everywhere in the Far East, extremely prevalent. Dysenteric troubles often assume a chronic form and, despite all manner of treatment, run on unchecked for months or years. Here they treat the acute form of this trouble by first giving a free dose of castor-oil, and follow this by the administration of opium and ipecacuanha. The latter drug they give in large doses, often administering as much as 30 grains twice in the twenty-four hours. They claim that patients thus treated are less liable to hepatic abscesses and other sequelæ than those treated without this remedy. The chronic form of the disease they treat by keeping the patient on a milk diet, freely irrigating the lower bowel with a boric acid solution, and following this by a rectal injection of a rather strong solution of nitrate of silver.

The craze for opening the peritoneal cavity does not yet seem to have invaded the Island of Ceylon. I saw a myomectomy done for the removal of a subserous uterine fibroid as large as my fist. From the sensation produced among the hospital staff by this operation I concluded that operations of this kind were very rare here. In fact, the doctor who did the operation told me that there had never been a complete hysterectomy done on the island. Cases that require expert surgery, in this line, are sent to Madras to be operated on.

MEDICAL TEACHING IN CALCUTTA.

Calcutta is the medical center for all the vast empire of India. There are, however, medical schools at Madras, Bombay and Lahore; but by far the largest and most important of them all is the one located at the capital of British India. The medical class here numbers about 600 students. Before beginning the study of medicine, they have to pass a preliminary examination and the requirements are the same as at Colombo. I attended several clinics here, where I came in contact with these students, and while a few of them seemed bright and intelligent, the majority were a sorry-looking set out of which to attempt to make doctors. Their course of study is a graded one of five years, and as only about fifty are graduated annually their examination must be a quite rigid one. The teaching is all done in English, which I found many of the students with whom I conversed, did not understand perfectly. A professor told me that they were trying hard to cut the class down as they now had more students than they could properly teach. I asked him what fees these men would be able to command when they had finished their studies and began practice in a purely native community. He said that after furnishing their own drugs they would not get more than ten cents a visit on an average. The whole subject of medical education

in the British possessions in India is under one general law, and is therefore uniform. The professors in the medical colleges, as well as the surgeons to the various hospitals, all over the country, are officers in the English service, and receive no pay from the students they teach, or the hospital patients they attend. These men have, however, the right to carry on private practice when that does not interfere with their official duties, and in this way many of them earn large salaries. In India, though medical teaching and the granting of a diploma are under strict legal surveillance, there is no law preventing any one who chooses from practicing medicine. In fact, there are not qualified men enough in all this great empire to attend to the wants of the sick. Besides, associated with the healing of the sick, among the great mass of Indians there is a certain amount of religious ceremony with which, since the last mutiny, the British government seems little inclined to interfere.

CALCUTTA'S MEDICAL COLLEGE HOSPITAL.

To this institution, which contains 300 beds, only natives are admitted, and the sick are freely utilized as material for teaching. Diseases of the skin and gastrointestinal disorders were the prevailing complaints that I saw in the wards. Patients suffering from dysentery and hepatic troubles as sequele filled at least one-half of all the beds in this institution. Operations for hepatic abscesses are probably as frequent here in India as those for appendicitis in America. The frequency of this disease very often leads men, I suspect, to a too hasty diagnosis, as well as carelessness in the examination of their patients. I saw a case operated on here for what was diagnosed as a hepatic abscess, but which turned out to be an encapsulated empyema of the right side of the chest. The doctor saw his mistake, which was a pardonable one, but I did not pardon him for trying to make me believe that his first diagnosis had been a correct one.

IMMUNITY OF NATIVES TO TYPHOID.

Croupous pneumonia and acute rheumatism are extremely rare diseases in Calcutta, if they ever prevail at all. I saw illustrated the fact that the native Indian is practically immune from the infection of typhoid fever, for in this native hospital, I am told, there has never been a single case of the disease, while at the civil hospital, where foreigners only are treated, I saw at least a dozen patients suffering from this complaint.

SURGERY AND ENVIRONMENTS.

How a surgeon—as one in this hospital—in these last days of the nineteenth century, can see no impropriety in making his visits to his wards, dressing filthy wounds, opening abscesses and then going directly to his operating-room and performing operations that require the most scrupulous cleanliness is something that I can not comprehend. The doctor apologized to me for some of his loose habits in his asepsis by saying that the men he taught, when they went out to practice on their own account, would not be able to practice perfectly clean surgery, and therefore he thought it best to teach them only such modes as they would be able to copy in after life.

This puts me in mind of an occurrence, that, though it may have nothing to do with medicine in the Far East, I feel inclined to relate: Some time back in the eighties, a professor from Chicago, myself, and a recent graduate from Harvard, were seated at a table in a café in Vienna. The former was a man of great natural ability, and was endowed with an energy that enabled him to surmount every difficulty he met in life. He had a commanding appearance, a huge frame, and a heart to match. He had been appointed professor of obstetrics in a new medical college, and had come on to Vienna to post up on the branch he was to teach. Our young companion took him to task for being a party to the organization of a medical school that was not needed and the requirements of which, for the graduation of its students at that time, were not very high. The professor defended himself by an argument something like this: He said that in the agricultural sections of the Far West the life of the doctor was so rough, and his labors so hard, that men who were highly educated, like our companion, would not occupy these fields. Therefore a class of men must be taken with less education and taught the more practical branches of the profession, and sent out to occupy these

territories that would otherwise be occupied by men who had had no medical instruction whatever.

HYDROCELE IN INDIA.

Everywhere in India this is extremely prevalent, and I have seen an operation for its relief in nearly every hospital I have visited in the Far East. Dr. Murphy, of Calcutta, operates by opening up the sac freely, cutting away about one-half of its serous surface, then stitching this to the skin, swabbing the remaining portion of the sac with a concentrated solution of carbolic acid, approximating the edges of the wound by a few disconnected sutures, and then packing the whole wound with iodoform gauze. He claims to never fail of a perfect cure after this mode of operating. I saw him remove an elephantiasis of the scrotum that weighed twenty-five pounds. When I expressed my astonishment at the size of the growth, he assured me that this was a small affair, and that he had lately, successfully, removed one that weighed 100 pounds. The civil hospital in Calcutta is devoted to the care of the sick of all nationalities except the native Indian. I saw more patients suffering from gonorrhœa in this institution than I ever saw before in a hospital of its size in my life. The treatment used for the relief of these patients is extremely antiquated, consisting of urethral injections without any relation as to what part of the urethra is involved, and the administration of balsam of copaiba. Of this last remedy Nothnagel says: "While it disgusts the palate, nauseates the stomach, and irritates the kidneys, it has no influence upon the course of the gonorrhœa for which it is given."

I saw here a number of cases of typhoid fever, and amid the different shades of complexion of the patients was impressed by the fact that the disease has a most decided preference for the man with a white skin. They treat the cases in this institution by the administration of chlorin water and the regulation of the bowels by the use of copious injections of warm water.

W. S. CALDWELL, M.D.

Medicine as an Art.

PHILADELPHIA, April 9, 1900.

To the Editor: If we take from the medicine of to-day that which is art, we will leave, surely, not more than one-half to the scientists pure and simple—a class that would perhaps be more aptly designated as materialists. When the old-time writers styled their works on physics, "The Art and Science of Medicine," they gave unmistakable evidence of their appreciation of this quality in medicine. With them healing was more than a science to be learned from books. Indeed, it comprehended so much more that was not to be found anywhere in books that great minds in medicine were earnestly sought after as preceptors. The relations between master and pupil were very like those that bound together master and pupil in all the other realms of art. With the passing of the preceptor there has gone out from among us a something that our present-day system seems not yet to have made good. Have we gained or lost? Who shall say?

Every art contains within itself known or unknown elements of one or more sciences. Drawing rests on the laws of perspective; painting on the laws of color harmony and contrast; sculpture on the science of anatomy; music on the laws of sound harmony and contrast; photography on the laws of optics and chemistry; and so on. Even good literature—as Herbert Spencer has shown—must conform in greater or lesser degree to the philosophy (i. e., laws) of style. There seems an indissoluble relation. Medicine has by some been placed among the useful rather than the fine arts; and yet healing has to do with nothing less than living and the life principle itself. Professor Griggs has said that of all the fine arts the art of living is the finest. Viewed from this standpoint healing rises above the level of the purely useful arts. Too, medicine is no mean art in its embrace of the major and minor sciences, most of which pay daily tribute to the thinking men of our guild. Other things being equal, the fullest measure of professional success is most likely to attend him who brings the various 'ologies to wait upon Nature in her allwise healing. At some point in almost every severe illness Nature craves a mo-

mentary lift from some one of the sciences, ready then to work out alone her hidden processes; and so unconscious has become our impressment of these aids into the healing art that we take little thought of it. Thus it appears that all art is, at bottom, science—that is to say, has its nucleus of classified facts or knowledge. But he who would attain to the art must first grasp well the science, and then resublime it with his own personality. Then, and then only, does it become art. It would be difficult to say just what the materialist lacks as he essays a canvas, a bust, a bas-relief, a sonata, a sonnet. It would be unfair to say that he is wanting in color sense or perspective in the fundamentals of modeling, of the laws of harmony or of the construction of verse. Without these he is nothing. They are the cardinals of his work. What he does seem to lack is the Divine spark that, fusing all these needed things, rises above them and imprisons Nature's secrets, even the most elusive. With some—indeed, with many—this height will be attained only by the fiercest, the most intensive industry. But the man is none the less an artist, neither a genius because of that fact.

Equally difficult is it to criticise the medical man who brings nothing but pure science to his patient's bedside. He certainly does not lack book or laboratory knowledge of physics, chemistry, bacteriology, biology, physiology or pathology; neither is the work of his brethren in foreign fields unknown to him. These are the very tenets of his faith. Of things material he is easily master. But that is only half the proposition. This materialism reveals itself in the tendency to look on patients as so much flesh and blood; to treat the outer casement rather than the individual within; to forget that "we are such stuff as dreams are made of"; to take little thought of hereditary impress, prenatal influence, temperament, domestic and commercial status and a host of other nonmaterial factors. Any or all of these may produce all manner of perversions of nerve function. The insufficiency of such methods has been shown by none more clearly than by Weir Mitchell. Mind and matter sustain a practically complete relation to each other in the healthy human body, and the correlative of this quality in the body is the dual nature of medicine.

So, if the ultrascientist would realize the full measure of his possibilities, he must possess more or less intuition. He must have a genius for affinity—what Goethe called *Weltverwandtschaft* and Griggs "humanism". It is really a species of telepathy. Discreetly used, it is the best and safest short-cut into the patient's confidence, without which we are powerless in most cases. This faculty of insight—of seeing the unseen—is what distinguishes the *artist* physician from the materialist. It removes him infinitely from the monger of patients who plies his profession for revenue only. It is difficult to believe there are many of these inside the guild. Moreover, if such there be, they are "punished, not for their sins, but by them." Innate, instinctive appreciation of the myriad outworkings of human nature makes of the clinical worker at the bedside, the artist physician. Of the well-rounded man of science it makes a mental giant, a savant—the very flower of our cult.

It should be the aim of the body medical of to-day to cultivate this spirit of affinity in every way, and to multiply its present great usefulness by evolving its members into the artist physician with wide-angled mental vision. This is the man who, while ministering to the physical sufferings of his patient, will never lose sight of the psychic element—which is no small matter in this day of exceeding heteropathy (mental healers, "osteos" quacks and fortune-tellers included!).

We to-day hear much of the *science* of medicine. It is not amiss to reiterate that, classify our knowledge as we will, there remains an outlying, an unaccountable factor in successful healing, the presence or absence of which marks the true physician from the medicine giver pure and simple. This is the *art* factor. The true physician is no less a genius in striving for perfection in healing than is the painter, the sculptor, the orator, the musician, the literateur, in trying to attain their highest ideals. The passion for perfection is the hall-mark of the true artist in medicine as in all things pertaining to the higher life. All art is one, and not least among its votaries are the priests of Hygeia.

WENDELL REBER, M.D.

The Journal's Advertising Policy.

TOLEDO, OHIO, April 17, 1900.

To the Editor: When THE JOURNAL'S recently announced policy concerning advertising is in full force, the enjoyment I have heretofore gotten out of its perusal will be heightened, because there will be lopped off from it the only disquieting feature which has ever manifested itself. I have always had an antipathy for unethical medical advertisements, possibly from pharisaical inclinations, but then, the antipathy exists nevertheless.

My thoughts on the subject of medical advertising have been the same for so long that grooves have been worn so deeply in my gray matter that now I can not change my views. I am in fact a crank on that subject. In consequence of this life-long habit, whenever I come across a quack advertisement in a religious newspaper, or in any paper which claims to be respectable, I make a note of it, and when I have spare time I write to the one who is responsible for its appearance. I have written to judges, reverends, D.D.S.'s, mayors, in fact, to all sorts of people, who have given testimonials, and to editors and publishers of all kinds of periodicals. I have had more enjoyment and entertainment than would pay me for the trouble of writing the letters, out of nearly all of my correspondence. The exceptions have been when some publisher told me that he was advertising the same secret preparations to his subscribers that the best medical journals were advertising to physicians, and that their readers know as much regarding the composition of the medicines as do the physicians. Not all of them would see that point, but whenever I have received a letter like that, I have written my next rainy day letter to some one else; because, while I like argument, and have never been known to stop arguing as long as the other man would talk, still, when I can get out of so doing, I never go up against a stone wall. The carrying out of THE JOURNAL'S policy will remove what has been to me a thorn in the flesh.

I tell the publishers of religious newspapers that if they would get out and hustle for business the same as other men do, they could get advertisements and not be obliged to sell their columns to quacks. I know that many physicians differ with me, but I can see no harm in publishing in THE JOURNAL advertisements of every good thing which people buy.

It is our business to oppose everything of a medical character which is not in accord with the best teaching of scientific medicine. That we may do so successfully and consistently, THE JOURNAL must not only be as clean as the best, but absolutely above reproach. It ought not to be a question with us whether THE JOURNAL is a financial success, so much as whether it represents only the principles of scientific medicine. We surely should never think of blaming the Trustees or the Editor if THE JOURNAL met with a financial loss on account of the rejection of bad and questionable advertisements. Scores of times publishers of religious and other papers have sought to justify the appearance of quack advertisements in their columns, by telling the money value of those they had rejected. THE JOURNAL should be, and is, governed by a higher standard. Success to it!

JAMES L. TRACY, M.D.

Deaths and Obituaries.

GEO. E. FROTHINGHAM, M.D., Detroit, Mich., died April 24, aged 64 years. He was born in Boston, in 1836. He attended St. Phillip's Academy, in Andover, Mass., then went to Ann Arbor, Mich., where he was graduated from the medical department of the University of Michigan, in 1864, and in 1867 was made demonstrator of anatomy there. In 1870 the chair of ophthalmology was created, and he was appointed to fill it. In 1889 he resigned and went to Detroit.

WILLIAM F. ROBINSON, M.D., editor of the *Hatborough Free Spirit*, died in Philadelphia, April 15, aged 63 years. He was born in Boston, and was a graduate of the medical department of the University of Pennsylvania, and practiced for ten years in Hatborough, where, in 1873, he established the journal which he edited until his death. He was for six years a

state quarantine physician, and for eight years connected with the health bureau. During the Civil War he served four years as surgeon of the 104th Regiment of Pennsylvania Volunteer Infantry.

J. N. O'BRIEN, M.D., Milwaukee, Wis., died April 22, aged 62 years. He was a native of Pennsylvania, and received his early education there, in the state university; he also studied at the University of Notre Dame, after which he was graduated from Rush Medical College, Chicago. He was a member of the AMERICAN MEDICAL ASSOCIATION and of the Wisconsin State Medical Association.

WILLIAM G. COOPER, M.D., died at the Toledo State Hospital, Toledo, Ohio, April 19, aged 34 years. He was graduated from Findlay College in 1891, and from the Baltimore (Md.) Medical College in 1895. He had been assistant physician in the hospital for five years, and resigned April 1, with the intention of beginning the practice of medicine in Findlay.

HARVEY C. JOHNS, M.D., Jefferson Medical College, Philadelphia, died at his home in Decatur, Ill., April 22, aged 81 years. He was surgeon of the 129th Illinois Volunteer Infantry.

ERASMUS DARWIN HILLIS, M.D., died at his home in Montour Falls, N. Y., April 19, aged 61 years. He was a captain of the 189th Regiment, New York volunteers.

J. C. MORGAN, M.D., died at Sioux Falls, S. D., April 19, of pneumonia. He was a veteran of the Civil War and had been prominent in state medical circles.

EDWIN O. BAKER, M.D., Spokane, Wash., died April 18, aged 70 years. He formerly practiced medicine at Lake City, Minn., and Menomonee, Wis.

RIPLEY CLARK, M.D., Windsor, Vt., died April 23, aged 83 years. He had been medical director at the state prison for twenty years.

CONRAD SPENS, M.D., born in Stockholm, Sweden, in 1844, died in Joliet, Ill., April 27.

S. G. TUTT, M.D., died April 25, in Kirkwood, Mo., of bronchial pneumonia, aged 81 years.

S. S. PITTMAN, M.D., Chipley, Ga., died April 21. He was 41 years old.

A. M. BEACH, M.D., Niles, Ohio, died April 20, of pneumonia, aged 52 years.

P. C. WOOTEN, M.D., died at Lafayette, Ky., April 23, of la grippe. He was 75 years old.

W. P. SMITH, M.D., Salina, Kan., died April 23, after a lingering illness.

A. M. DENT, M.D., Coshocton, Ohio, died April 5. He was graduated from the Columbus Medical College in 1882.

W. G. COOPER M.D., formerly assistant superintendent, Toledo State Hospital, died at his home in Van Buren, Ohio, April 20.

FRANK F. MYERS, M.D., University of Pennsylvania, 1890, died in Allegheny, Pa., March 29, aged 33.

DEATHS ABROAD.

O. LEICHTENSTERN, M.D., Cologne, Germany, an indefatigable scientific investigator and writer on internal medicine died recently.

JOSEPH GRUBER, M.D., died recently at his home in Vienna. He was a recognized authority on laryngology and otology.

Association News.

Annual Announcement.

The fifty-first annual session (53d year) of the AMERICAN MEDICAL ASSOCIATION will be held in Atlantic City, N. J., on Tuesday, Wednesday, Thursday and Friday, June 5, 6, 7 and 8, commencing on Tuesday at 11 a. m.

REGARDING REPRESENTATION.

The delegates shall receive their appointment from permanently organized state medical societies, and such county and district medical societies as are recognized by their respective state societies, and from the medical departments of the Army and Navy and the Marine-Hospital Service of the United States.

Each state, county and district medical society entitled to

representation shall have the privilege of sending to the ASSOCIATION one delegate for every ten of its regular resident members, and one for every additional fraction of more than half that number; *Provided*, however, that the number of delegates from any particular state, territory, county, city or town shall not exceed the ratio of one in ten of the resident physicians who are entitled to membership.

PERMANENT MEMBERS.

The permanent members shall consist of all those who have served in the capacity of delegates, and of such other members as may receive the appointment by unanimous vote, and shall continue such so long as they remain in good standing in the body from which they were sent as delegates, and comply with the requirements of the By-Laws of the ASSOCIATION, so long as they shall continue to conform to its regulations, but without the right of voting; and, when not in attendance, they shall be authorized to grant letters of introduction to reputable practitioners of medicine residing in their vicinity, who may wish to participate in the business of the meeting, as provided for members by invitation.

MEMBERS BY APPLICATION.

Members by application shall consist of such members of the state, county and district medical societies entitled to representation in this ASSOCIATION as shall make application in writing to the Treasurer, and accompanying said application with a certificate of good standing, signed by the president and secretary of the society of which they are members, and the amount of the annual subscription fee, \$5. They shall have their names upon the roll, and have all the rights and privileges accorded to permanent members, and shall retain their membership upon the same terms.

A distinctive badge will be provided for delegates.

Secretaries of societies are requested to forward names of delegates as soon as possible, as a list of these will be prepared before the meeting.

GEORGE H. SIMMONS, M.D., Secretary.

61 Market Street, Chicago.

Railroad Rates for Atlantic City Meeting.—As announced in these columns last week, the Trunk Lines Association has granted one and one-third fare rate on the certificate plan for the Atlantic City meeting. Tickets will be on sale in the territory of this Association from May 30 to June 7, and good to return to June 23. Action has also been taken by the Central Passenger Association, and the same rate announced from all points in the territory of the latter Association, tickets also to be sold on the certificate plan, the dates of sale and the return limit being the same as above. The certificates will be signed at Atlantic City by Dr. W. Blair Stewart, N. E. Cor. Pacific and North Carolina Avenues, and a special agent will be present on June 6, 7 and 8. Up to date no advices have been received from other passenger associations. The territory covered by the two first named includes practically everything north of the Ohio River and east of the Mississippi from Cairo to St. Louis, thence east of a line drawn from St. Louis to Chicago, through Jacksonville, Decatur, Gibson, etc.

Section Headquarters at Atlantic City.—Following is a correct list of the hotels selected as headquarters for the different Sections. These hotels, with two exceptions, are all located on the board walk, directly fronting the ocean, and are considered the best hotels. Every effort will be made by the proprietors and their managers to furnish proper and pleasant accommodations to all who elect to stop with them. Each Section has been located separately, with a view of avoiding the crowding and general annoyance that has characterized a number of the previous meetings. The hotels are all well located and are comparatively near the place of registration and the general meetings in the assembly hall, as well as the meeting places of the different Sections, hence no member need hesitate to arrange his accommodations at the one selected as the headquarters for his Section. The names and addresses of the presidents and secretaries of the different Sections have been placed in the hands of the managers of the respective hotels,

and the latter have been requested to correspond with the former, asking for a list of the Sections' membership, that they may address each member and ascertain early about how many will be in attendance, and acquaint themselves as near as possible with the desired accommodation expected by each individual. Every member of the AMERICAN MEDICAL ASSOCIATION and all other physicians who expect to be in attendance should arrange for their quarters as soon as possible, as this will assure to them satisfactory accommodation and avoid disappointment at the last moment.

AMERICAN MEDICAL ASSOCIATION, Hotel Dennis.

American Academy of Medicine, Hotel Shelburne.

SECTION HEADQUARTERS.

Section on Practice of Medicine, Hotel Traymore.

Section on Surgery and Anatomy, Hotel Windsor.

Section on Obstetrics and Diseases of Women, Hotel Garden.

Section on Materia Medica and Therapeutics, Hotel Luray.

Section on Neurology and Medical Jurisprudence, Hotel Brighton.

Section on Ophthalmology, Hotel Haddon Hall.

Section on Laryngology and Otology, Hotel Seaside.

Section on Physiology and Dietsics, Hotel Islesworth.

Section on Diseases of Children, Hotel St. Charles.

Section on Cutaneous Diseases, Hotel Rudolph.

Section on Stomatology, Hotel Senate.

Section on State Medicine, Hotel Pennhurst.

The Official Program.—In order to avoid misunderstandings and to protect the interests of advertisers, attention is called to the fact that there is but one official program. This program is copyrighted by the Board of Trustees and contains no advertising matter.

Miscellany.

Vomiting Coffee-Ground Masses After Gynecologic and Obstetric Operations.—Bentner has described (*Corr. f. Schweizer Aerzte*, 1899, 18) seven patients in whom a coffee-ground substance was vomited during or soon after the operation, with subsequent severe anemia. There was no stomach nor heart disease in any case, and the technique could not be incriminated. One came to the autopsy and numerous hemorrhagic erosions were found in the stomach. He suggests that the coffee-ground substance may have been produced by the venous congestion caused by the narcosis, and the action of an exceptional amount of hydrochloric acid in the stomach.

Deprivation of Salt in Treatment of Epilepsy.—THE JOURNAL has called attention to Richet's recent announcement that the bromids can be rendered doubly effective by depriving the patients of salt in their food. Roux confirms this statement and asserts that the simplest manner of depriving the food of salt is to place subjects on a milk diet. He found very small amounts of bromids effective in arresting and preventing seizures when combined with a milk diet, while if salt were added to the milk the seizures appeared in one of his four patients.

Sectional Limits of Cutaneous Anesthesia on the Head.—F. V. Soelder found cutaneous anesthesia limited to certain regions on the head, identical and constant in six cases of syringomyelia. They were not found in any of the cases of hysteria he examined, and consequently can assist in the differentiation, as he announces in *Jahrb. f. Psych.*, xviii, 3. The sectional limits on the trunk and extremities are the same with lesions of either spinal cord or roots, but this coincidence does not occur in the localizations on the head.

Vital Statistics of Havana, Cuba, March, 1900.—The report of the chief sanitary officer, Major W. C. Gorgas, surgeon, U. S. A., shows 605 deaths in an estimated population of 220,000. In the list of deaths are 96 from tuberculosis; 48 from pneumonia, 45 from bronchitis, and 23 from la grippe; 40 from enteritis and 4 from typhoid fever; 23 from meningitis; 24 from malaria, 9 from pernicious malarial fever and 12 from cirrhosis of the liver; 45 from arterial sclerosis; 16 from tetanus; 2 from leprosy; 2 from beri-beri and 4 from

yellow fever. Eleven new cases of the last mentioned disease occurred during the month. The births number 553, of which 225 were illegitimate; marriages 142. The average number of gallons of electrozone applied daily for the disinfection of catch basins, sewers, streets, urinals and houses was 9715. Nothing is said as to the efficiency of the electrozone.

Boards of Health in Porto Rico and Cuba.—The past week has brought to the U. S. War Department information of an order for the establishment of a board of health in every municipality of the island of Porto Rico and of a board for the city of Santiago, Cuba. General Orders No. 66, Headquarters, Department of Porto Rico, March 29, 1900, publishes the requirements called for by the Porto Rico Department Commander, General George W. Davis, U. S. Volunteers, on the recommendation of the Superior Board of Health of the island, of which Major J. Van R. Hoff, chief surgeon of the department is president. The order provides for a board of health in each municipality, to be constituted as follows: The alcalde, a municipal physician, the president of the school board and the president of the board of charities, all of whom must be residents of the municipality in which they are to serve. Where there is more than one municipal physician, the other members will elect one of these to membership on the health board. The alcalde will be president, the municipal physician health officer and the board will elect a secretary from its other members. One regular meeting will be held each month and special ones on the call of the president or any two members. At special meetings only the business designated in the call will be transacted. Three members will constitute a quorum. An estimate will be placed on the municipal budget each year to cover the expenses of the board. The municipal judge, on or before the fifth day of each month, will furnish the board of health with a report of the vital statistics of the municipality for the month immediately preceding. On the same day General Orders No. 67 gave further information on matters relating to public health. These require each municipality in Porto Rico to provide in its annual budget for the payment of municipal physicians and practicians, for medical attendance on the poor and for medicines for the same class, and money appropriated for medical attendance and for medicines is to be used for no other purpose. Each municipality shall have at least one municipal physician. If the population exceeds 10,000, there shall be not less than two municipal physicians, and for every 6000 or major fraction thereof above this number there shall be an additional municipal physician. When there is more than one municipal physician the territory will be divided among them as equally as possible, taking into consideration both population and accessibility. Remote and inaccessible barrios must be provided with resident physicians or practicians. Whenever a barrio is not so provided it will petition the municipal council, and if without result, then the Superior Board of Health, stating in the petition the population of the barrio, the time required for the nearest physician to reach the central and remote portions of the barrio and the number of poor who can not pay for medical aid. The board will, if it deems it necessary, appoint a physician or practicante who will be paid from the municipal treasury. These physicians or practicians must attend all calls made by the sick poor in their respective districts. All physicians, practicians, dentists, pharmacists or nurses holding public positions must be licentiates of the Superior Board of Health.

The commanding officer of the Department of Santiago and Porto Principe, Cuba, on March 30, provided for a board of health for the city and district of Santiago, to consist of the chief surgeon, president ex-officio; the director of the civil hospital, vice-president ex-officio; the sanitary inspector; the surgeon of the Marine-Hospital Service and five resident physicians. The Board will elect one of its members as secretary, who will receive \$75 a month, the other members serving without pay. The duties of the Board are to advise in all sanitary matters in the city and district, to recommend all measures deemed necessary for the public health and to collect and publish complete vital statistics. All cases of contagious or infectious diseases or diseases suspected to be such are to be reported to the president of the Board, who will immediately notify at least three of the members to examine and decide the

nature of each case so reported. The opinion of the examining members will be expressed in writing over their signatures and handed to the president of the Board. All measures of isolation and disinfection deemed necessary by the Board will be carried out through the Sanitary Department.

Peculiar Sites for Epitheliomas.—A curious bit of medical geography is reported in the *Indian Medical Gazette* for March. Dr. Neve, of the Kashmir Mission Hospital, finds that in Kashmir, epithelioma, instead of affecting the neighborhood of mucous surfaces, has its usual seat on the skin of the abdomen and thighs. It is so common that the name Kangri-burn has been given to the lesion, which is a squamous-celled epithelioma of the skin. The cause of it is evident: instead of dressing for warmth every Kashmir man, woman and child carries, during the severe winter and indeed for a great part of the year, a sort of portable stove or charcoal brazier under the single garment next the skin. Slight burns from this source frequently occur and there must be a more or less constant irritation, actually producing a peculiar mottled appearance in many. The frequency of the disease may be estimated when he reports operating on 20 patients in two months, not counting several inoperable ones. This condition is of interest as a medical curiosity, especially when its peculiar cause is taken into account.

Diagnosis and Treatment of Hepatic Abscess.—It must be admitted that at the present day the diagnosis of hepatic abscess remains in a quite unsettled condition. According to Loomis, with a correct history of the case the diagnosis is easy, while DuCosta, on the other hand, regards the symptoms as being obscure, and in many cases the diagnosis a difficult matter. The diseases with which hepatic abscess has most frequently been confused are: malarial fever, typhoid fever, cancer, impacted gall-stone, hydatid cyst and actinomycosis. The etiologic factors which have heretofore been regarded as most conducive in the production of abscess of the liver are: history of amebic dysentery, traumatism, embolism from pyemic foci, malarial fever, gall-stone, rectal abscess, bone disease, and excessive use of alcohol in warm countries. One of the most frequent causes seems to have been overlooked, namely appendicitis. The disease is rare in children. The symptoms vary, according to different writers on the subject. Osler states that in the tropics the disease may remain latent for long periods of time. The most common symptoms and physical signs set aside as being characteristic of this condition are: intermittent fever, night sweats, irregular chills, slight icteroid—muddy—condition of the skin, diarrhea, vomiting, throbbing in the right lobe of the liver referred to the shoulder, pain, and a dragging sensation over the right hypochondriac region. Vierordt states that when the abscess is parietal and involves the peritoneum, there is great tenderness, but when deeply seated there is none. As to the physical signs there appears to be a diversity of opinion. The following have been recognized: enlargement of the liver, mostly in an upward direction, especially noted in the dorsal region of the chest, pain on palpation over the hypochondrium, bulging of the right hypochondrium, with fluctuation or edema, pulsation of the liver, a peritoneal friction, and lastly presence of pus as told by the aspirating needle. All writers agree that the enlargement of liver extends upward and posteriorly. Jackson, after a study of 17 cases of hepatic abscess, regarded the following as the most frequent signs and symptoms: presence of a tumor, fever, chills, leucocytosis, and slow pulse. The latter sign he regards as being quite characteristic. The less important symptoms he considers as pain, tenderness, vomiting, jaundice, and enlarged spleen. Johnston and Pontain enumerate the principal signs and symptoms as follows: pain, indigestion, nausea, intestinal disturbances, irregular fever, jaundice and enlargement of the liver. Malbot, whose experience has been great (*Archives Gén. de Méd.*, August, September and October, 1899), regards pain as the most important symptom. Cyr endeavors to bring order out of chaos by describing the symptoms and signs with reference to the position of the abscess, and this seems the most logical. He believes that when the abscess is on the convex surface of the liver, there is pain radiating toward the shoulder, but no jaundice. When it is large and deeply situated, jaundice is present. If the abscess occupies the under surface of the liver,

thoracic symptoms will be absent, but gastric ones, especially uncontrollable vomiting, will occur and the pain will radiate toward the right groin. Loomis had previously recognized this phase of the question and stated that when the abscess occupied the posterior portion of the right lobe of the liver the organ would be pushed downward and could be felt below the free margin of the ribs. Jaundice is said to occur when there are multiple abscesses present. Osler describes the liver dullness as being normal in the sternal and parasternal line, but in the mid-axillary region it may reach as high as the fifth rib, and posteriorly as high as the angle of the scapula. Malbot (*The Lancet*, February 24) has seen 222 cases of hepatic suppuration, and regards pain as the most important symptom. This pain was said to be sharp in character, as if something was being torn, and was always brought on by muscular effort, or by succussion, and radiated toward the right shoulder, pit of the stomach, lower part of the abdomen or right iliac fossa, according to the location of the abscess. He has never met with the peritoneal friction, nor has he seen a case complicated with jaundice. The pus in abscess of the liver is usually chocolate in color. The following micro-organisms have been found: ameba coli—most common—colon bacillus, staphylococcus and streptococcus. The diplococcus of Fränkel was found in a case reported by Hermes. Flexner found ameba coli in the sputum as well as crystals supposed to be bilirubin. Loison found a mixture of the colon bacillus and a diplococcus in one case. Reviewing the recent cases of hepatic abscess reported, together with the etiologic factors, the following are noted: Slaughter (1896) collected the history of 27 cases of hepatic abscess occurring in children, and Gassicourt, in 1899, reported an additional one. Rouis (1896) of Algiers collected 250 cases, only 1 in a child. In these cases 9 were supposed to have resulted from injury. Hermes (1896) reported 4 cases of hepatic abscess, one of which resulted from appendicitis, a condition said to be prone to produce suppuration in the right lobe of the liver; one resulted from gall-stone and another from perityphlitis. Of two reported by Flexner (1897), no lesion of the bowel could be found in one instance, while in the other the lesion of the bowel probably followed the disease of the liver. Rendu (1898) reported 2 cases following dysentery, and in the same year Wilson reported 3 due to the same cause. In 1899 Dielafay reported the case of a man, 34 years of age, who suffered from slight jaundice, and in whom hepatic abscess was found. Deaver (1899) reported a case which occurred in a woman 24 years of age, which had produced a large tumor but without marked symptoms; there was no history of dysentery nor malaria. In 1899 Jackson analyzed 17 cases of hepatic abscess: in 10 instances the disease probably originated from appendicitis, 2 were from amebic dysentery, 2 accidental, and 3 of unknown origin. Marshall, in 1899, reported a case due to amebic dysentery. He points out the danger of recurrence of those cases should the person reside in a tropical country. In 5 cases reported by Grant (1899), 1 probably arose from disease of the small intestines or colon, 1 from typhoid fever, in 1 the infection could not be traced, and 2 were from appendicitis. In the same year Eisendrath reported a case probably having its seat in the large intestine. In this instance the disease was multiple, affected the left lobe and produced no clinical symptoms.

In the treatment, the following named believe in incision and drainage: Rendu, Roger, Loison, Dielafay, Jackson, Marshall, Grant, Deaver and Cadet de Gassicourt. Hadra advises costotomy. Grant advises aspiration followed by incision, flushing and drainage. He believes that more than 60 per cent. of abscesses of this region are accessible through the diaphragm, by excising a part of the eighth and ninth ribs, and if possible stitching the liver wound to the diaphragmatic wound to prevent reinfection. He believes that the prognosis will be favorable in 75 per cent. of such cases. Hadra advises that the abscess cavity be not flushed, owing to the danger of reinfection. Fonan states that in cases of migrating abscess of the liver the pus shows a tendency to follow the anterior abdominal wall, and that the incision should be made so that it will hug the lower limit of the thorax, to promote drainage. In one case reported by Jackson, three attempts were made to aspirate, but proved ineffectual.

Queries and Minor Notes.

PRACTICE IN NEW MEXICO.

To the Editor.—Please advise me as to the laws governing medical practice in New Mexico. J. O. P.

ANSWER:—If the terms and regulations for practice in New Mexico are still those cited in the Illinois State Board of Health Report for 1898, they are simply the presentation of a satisfactory diploma, or examination by a non-graduate. The diploma must be from a school that requires a sufficient preliminary examination and has a four years' course. One from another school would not be sufficient and examination would be required.

PRACTICE IN TEXAS.

To the Editor.—Will you inform me regarding the medical laws of Texas? I am a graduate of Vanderbilt University, and wish to know whether it will be necessary for me to take a state examination. R. L. G.

ANSWER:—The medical laws of Texas, we understand, are rather lax. We are informed by the *Texas Medical Journal* (November, 1899) that a diploma from an accredited medical college chartered in the state where located will make the holder a legally qualified physician, provided the diploma is registered in the court records of the district in which the holder is practicing.

CONCERNING SODIUM CHLORID.

To the Editor.—It has lately come to my notice, through a patient, that sodium chlorid is an "antifat" agent, if taken in teaspoonful doses before meals. I would like to know whether sodium chlorid is recognized as possessing this power of reducing tissue. How does it do it? Is it harmful to the human economy? R. S. B.

ANSWER:—We are not informed as to the specific effect of sodium chlorid as an antifat agent, though its use has been recommended to increase metabolism, and carry off waste products. Certain saline waters, like Kissingen and Hamburg, are recommended as good treatment for obesity. The action of the sodium chlorid should be favoring tissue change and elimination.

ADDRESSES OF SECRETARIES, ETC.

To the Editor.—Will you kindly give me the names and addresses of the secretaries of the state boards of medical examination in the following: Kentucky, Rhode Island, Ohio, Louisiana, Maryland, Massachusetts, District of Columbia, Idaho, Minnesota, South Dakota, Wyoming, etc. W. H. D.

ANSWER:—The names and addresses desired are, or were: Kentucky, J. N. McCormac, Bowling Green, secretary of the State Board of Health; Rhode Island, J. T. Swartz, Providence, secretary of the State Board of Health; Louisiana, T. S. Kennedy, New Orleans, president of the State Board of Medical Examiners; Maryland, J. McP. Scott, Hagerstown; Massachusetts, Edward Harvey, Boston, secretary of the State Board of Registration; District of Columbia, Geo. C. Ober, Washington; Idaho, C. L. Sweet, Boise, Idaho; Minnesota, J. B. Prinnhall, St. Paul; South Dakota, F. H. Files, Sioux Falls; Wyoming (data not at hand). These addresses are taken from the Report of the Illinois State Board of Health and there may have been some changes. Ohio has just passed a new law and we are not informed as to the appointments under it.

PRACTICE IN RHODE ISLAND.

To the Editor.—Will you inform me regarding the medical laws of Rhode Island? F. A. B.

ANSWER:—Rhode Island requires a diploma from a reputable medical college requiring a four years' course, endorsed by the State Board of Health, or an examination.

BOOKS AND PAMPHLETS RECEIVED.

Acknowledgment of all books received will be made in this column, and this will be deemed by us a full equivalent to those sending them. A selection from these volumes will be made for review as dictated by their merits, or in the interests of our readers.

BOOKS.

INJURIES TO THE EYE IN THEIR MEDICO-LEGAL ASPECT. By S. Baudy, M. D. Professor in the Faculty of Medicine, University of Lille, France, etc. Translated from the Original by Alfred James Ostheimer, M. D., Philadelphia. Revised and Edited by Charles A. Oliver, A.M. M.D. Attending Surgeon to the Wills Eye Hospital; Ophthalmic Surgeon to the Philadelphia Hospital; Member of the American and French Ophthalmological Societies, etc. With an Adaptation of the Medico-Legal Chapter to the Courts of the United States of America, by Charles Stuker, Esq., Member of the Philadelphia Bar. 5 1/2 by 7 1/2 inches. Pp. 161. Extra Cloth, \$1 net. Philadelphia: The F. A. Davis Co.

OPERATIVE SURGERY OF MALIGNANT DISEASE. By Henry T. Britton, F.R.C.S., D.C.L. Surgeon to St. Bartholomew's Hospital. With the Co-operation of James Berry (The Typhoid), W. Bruce Clark (The Kidney), Alban Doran (The Ovary and Uterus), Percy Furnival (The Stomach, Intestine and Rectum), Walter Jessop (The Eye), H. J. Waring (The Liver and Gall-Bladder). Second Edition. Cloth. Pp. 422. Price, \$4.50. Philadelphia: P. Blakiston's Son & Co. 1900.

ULCER OF THE STOMACH AND DUODENUM AND ITS CONSEQUENCES. By Samuel Fenwick, M.D., F.R.C.P., Consulting Physician to the London Hospital and W. Soltau Fenwick, M.D., M.R.C.P., Senior Physician to the London Temperance Hospital. Cloth. Pp. 392. Price, \$2.50. Philadelphia: P. Blakiston's Son & Co. 1900.

STUDENT'S HANDBOOK OF SURGERY OF ALIMENTARY CANAL. An Abridged and Amended Edition of the Author's Treatise on the

Same Subject. By A. Ernest Mayland, M.B., B.S., Surgeon to the Victoria Infirmary, Glasgow. Cloth. Pp. 510. Price \$3. Philadelphia: P. Blakiston's Son & Co. 1900.

ANATOMY OF THE BRAIN. A Text-Book for Medical Students. By Richard H. Whitehead, M.D. Professor of Anatomy in the University of North Carolina. Illustrated with Forty-one Engravings. 6 1/2 by 9 1/2 inches. Pp. 90. Extra Vellum Cloth, \$1 net. Philadelphia: The F. A. Davis Co.

PARALYTIC DEFORMITIES OF LOWER EXTREMITIES. The principles of their Surgical Treatment. By E. Noble Smith, F.R.C.S., L.R.C.P., etc., Senior Surgeon to the City Orthopedic Hospital, and Illustrations. Cloth. Pp. 99. Price, \$5. London: Smith, Elder & Co. 1900.

PUBLIC HEALTH PAPERS AND REPORTS. Volume 23 Presented at the Twenty-Seventh Annual Meeting of the American Public Health Association, Minneapolis, Minn., October 31 and November 1, 2 and 3, 1899. Columbus, Ohio. Berling Printing Co. 1900.

TRANSACTIONS OF MICHIGAN STATE MEDICAL SOCIETY. For the Year 1899, Vol. 23. Cloth. Pp. 481. Grand Rapids, Mich.: Published by the Society, 1899.

TRANSACTIONS OF MEDICAL ASSOCIATION OF STATE OF MISSOURI. Forty-second Annual Session, May 16, 17, 18, 1899. Cloth. Pp. 387. Kansas City, Mo.: Burd and Fletcher Printing Co. 1899.

TRANSACTIONS OF STATE MEDICAL SOCIETY. Vol. 17. Forty-eighth Annual Session, 1899. Cloth. Pp. 420. Waterloo, Iowa: H. G. Middlechild. 1899.

TRANSACTIONS OF NEW HAMPSHIRE MEDICAL SOCIETY. One Hundred and Ninety Anniversary, May 25 and 26, 1899. Cloth. Pp. 308. Concord, N. H.: Evans, C. 1899.

TRANSACTIONS OF COLORADO STATE MEDICAL SOCIETY. Twenty-eighth and Twenty-ninth Annual Conventions. By-laws and List of Members. Cloth. Pp. 513. Denver: Published for the Society, 1899.

TRANSACTIONS OF SIXTY-SIXTH ANNUAL SESSION OF THE MEDICAL SOCIETY OF STATE OF TENNESSEE. 1899. Cloth. Pp. 325. Nashville: John Ruddle & Sons, 1899.

TRANSACTIONS OF MEDICAL ASSOCIATION OF GEORGIA. Fiftieth Annual Session, 1899. Cloth. Pp. 575. Atlanta, Ga.: Published by the Association, 1899.

PROCEEDINGS OF KANSAS MEDICAL SOCIETY. Thirty-third Annual Meeting. Topeka, Kans., May 3, 4, and 5, 1899. Cloth. Pp. 192. Topeka: A. D. Bauer Printing Co. 1899.

ANNUAL REPORT OF FRANK J. IVEY, Surgeon U. S. Volunteers, Chief Surgeon, Department of Matanzas and Santa Clara. Paper. Pp. 30, 1899.

CONTRIBUTION TO HISTOGENESIS OF MELANOSARCOMA OF THE SKIN. By Alfred Schalek, Chicago. Reprinted from *Jour. of Cut. and Genito-Urinary Dis.*

GYNECOLOGICAL COMPLICATIONS OF NEURASTHENIA FROM A NEUROLOGIC STANDPOINT. By John Funton, Kansas City, Mo. Reprinted from *Western Medical Review.*

A MEDICO-RELIGIOUS CHARITY—THE GUILD OF MERCY. By W. Thornton Parker, Westboro, Mass. Reprinted from *Atlanta Jour. Record of Medicine.*

REPORT OF COMMISSION ON CHICAGO RIVER. Submitted December 11, 1899.

SOME POINTS IN DIAGNOSIS OF TRAUMATIC INJURIES OF CENTRAL NERVOUS SYSTEM. By J. T. Eskridge, M.D., Denver, Colo. Reprinted from *THE JOURNAL.*

STRUCTURE OF ESOPHAGUS AND ELECTROLYSIS BY NEW ESOPHAGEAL ELECTRODE. By Charles D. Aaron, Detroit, Mich. Reprinted from *Phys. and Surg.*

TENTH ANNUAL REPORT OF ST. MARY'S HOSPITAL, Rochester, Minn. Conducted by Sisters of St. Francis. Rochester, Minn.: Daily Bulletin Press.

TRANSACTIONS OF PHILADELPHIA COUNTY MEDICAL SOCIETY for January, February, March, April, May, September, October, November, and December, 1899. Philadelphia.

TWENTY-SECOND ANNUAL REPORT OF THE PRESBYTERIAN EYE, EAR AND THROAT AND NERVOUS HOSPITAL OF BALTIMORE. Baltimore: J. S. Bridges & Co. 1900.

The Public Service.

ARMY CHANGES.

Movements of Army Medical Officers under orders from the Adjutant General's Office, Washington, D. C., April 21 to 27, 1900, inclusive.

Calvin DeWitt, lieutenant colonel, deputy surgeon-general, U. S. Army, leave of absence on account of sickness.

William W. Quinton, captain and asst. surgeon, U. S. Army, relieved from further duty in the Division of Cuba to proceed to New York City, N. Y., and report by telegraph to the adjutant-general of the Army for further orders.

Najeeb M. Saleeby, acting asst. surgeon, leave of absence granted.

Charles F. Sanborn, acting asst. surgeon, previous orders, directing him to proceed from Willard, N. Y., to the Department of California, revoked.

Alfred A. Woodhull, lieutenant-colonel and deputy surgeon-general, U. S. Army, to report to the surgeon-general of the Army for duty in his office.

NAVY CHANGES.

Changes in the Medical Corps of the U. S. Navy for the week ending April 21, 1900.

Medicinal Inspector G. E. H. Harmon, detached from the *Baltimore* and ordered to the *Oregon*.

Surgeon F. B. Stephenson, detached from the *Oregon* and ordered to the *Baltimore*.

Passed Assistant Surgeon L. Morris to the *Baltimore*.

Passed Assistant Surgeon S. G. Evans, orders of April 13 modified; ordered to proceed home, when detached from the *Marblehead*, and to be ready for sea duty.

MARINE-HOSPITAL CHANGES.

Official list of changes of station and duties of commissioned and non-commissioned officers of the U. S. Marine-Hospital Service for the seven days ending April 19, 1900.

Surgeon A. H. Glennan, to rejoin station at New Orleans, La., April 18, 1900.

Surgeon W. P. McIntosh, detailed to represent the Service at the meeting of the Medical Association of the State of Alabama, to be held at Montgomery, Ala., April 17-21. To proceed to Tarpon Springs, Fla., for special temporary duty.

P. A. Surgeon G. M. Gutieras, bureau order of March 5, 1900, relieving P. A. Surgeon Gutieras from duty at Matanzas, Cuba, revoked.

Asst.-Surgeon V. G. Heiser, detailed as delegate to the Congress "for the struggle against Tuberculosis" to be held at Naples, Italy, April 23-25, 1900.

Asst.-Surgeon D. E. Trotter, Bureau order of March 5, 1900, detailing Asst.-Surgeon Trotter for duty as quarantine officer at Matanzas, Cuba, revoked and directed to proceed to Cienfuegos, Cuba, as quarantine officer.

Acting Asst.-Surgeon J. C. Ballard, granted leave of absence for 31 days from May 1, 1900.

Acting Asst.-Surgeon W. Havelburg, granted leave of absence for thirty days from May 10, 1900.

Hospital Steward G. C. Allen, granted leave of absence for 27 days from April 19, 1900.

Hospital Steward G. W. Iltis, to proceed to Cleveland, Ohio, and report to medical officer in command for duty and assignment to quarters.

BOARD CONVENEED.

Board convened to meet at Washington, D. C., April 19, 1900, for the physical examination of candidates for appointment as Second Assistant Engineer in the U. S. Revenue Cutter Service.

Detailed for the Board.—Surgeon, P. M. Carrington, Chairman; Asst.-Surgeon L. D. Fricks and Asst.-Surgeon W. C. Billings, Recorder.

APPOINTMENT.

George W. Iltis, of Minnesota, appointed Junior Hospital Steward.

HEALTH REPORTS.

The following cases of smallpox, yellow fever, cholera and plague, have been reported to the Surgeon General, U. S. Marine-Hospital Service, during the week ended April 28, 1900.

SMALLPOX—UNITED STATES.

Alabama: Mobile, April 14-21, 12 cases.

District of Columbia: Washington, April 14-21, 2 cases.

Florida: Jacksonville, April 14-21, 1 case.

Illinois: Ancona, April 1-7, 1 case; Chicago, April 14-21, 4 cases.

Indiana: Evansville, April 14-21, 5 cases; Indianapolis, April 1-21, 8 cases.

Kansas: Wichita, April 14-21, 11 cases; Thirty-three towns and counties, March 1-31, 456 cases, 5 deaths.

Kentucky: Covington, April 14-21, 7 cases; Lexington, April 14-21, 2 cases.

Louisiana: New Orleans, April 14-21, 75 cases, 19 deaths.

Maine: Portland, April 14-21, 1 death.

Michigan: Detroit, April 14-21, 1 case.

Nebraska: Omaha, April 14-21, 2 cases.

Ohio: Cleveland, April 14-21, 15 cases.

Pennsylvania: Philadelphia, April 21, 1 case; Pittsburg, April 14-21, 2 cases.

South Carolina: Greenville, April 13-20, 3 cases.

Utah: Salt Lake City, April 14-21, 3 cases.

Washington: Spokane, April 14-21, 3 cases.

Wisconsin: April 14, 1 case.

SMALLPOX—FOREIGN.

Austria: Prague, March 24-31, 5 cases.

Belgium: Ghent, April 1-7, 2 deaths.

Egypt: Cairo, March 18 to April 3, 16 deaths.

England: Liverpool, April 1-7, 8 cases, 2 deaths; London, April 1-7, 2 cases; Southampton, April 1-7, 1 case.

France: Paris, April 1-7, 2 deaths; Gibraltar, April 1-8, 4 cases, 1 death.

Greece: Athens, April 1-7, 4 cases, 2 deaths.

India: Bombay, March 13-20, 163 deaths; Bombay, March 20-27, 133 deaths; Calcutta, Feb. 4 to March 3, 21 deaths; Kurrachee, March 11-25, 24 cases, 12 deaths.

Mexico: Chihuahua, April 1-14, 2 deaths; Vera Cruz, April 7-14, 6 deaths.

Russia: Odessa, March 24 to April 7, 9 cases, 3 deaths; St. Petersburg, March 18-24, 30 cases, 3 deaths; Warsaw, March 18-31, 2 deaths.

Spain: Madrid, March 24-31, 8 deaths.

Strait Settlements: Singapore, March 3-10, 3 deaths.

YELLOW FEVER.

Costa Rica: Limon, April 20, 1 case.

Mexico: Vera Cruz, April 7-14, 2 deaths.

CHOLERA.

India: Bombay, March 13-27, 11 deaths; Calcutta, Feb. 24 to March 3, 70 deaths.

PLAQUE—INSULAR POSSESSIONS, U. S.

Hawaii: Honolulu, March 26 to April 2, 3 cases, 3 deaths; April 9, 1 case.

PLAQUE—FOREIGN.

Brazil: Rio de Janeiro, April 20, 6 cases, 6 deaths.

India: Bombay, March 13-27, 1428 deaths; Calcutta, Feb. 24 to March 3, 411 deaths; Kurrachee, March 11-31, 292 cases, 223 deaths.

Anderson, R. L., from Charleston to Fort Mill, S. C.

Appleton, H. L., from Cedar Bluff to Custer, Ala.

Arnutt, J. H., from Kansas City, Mo., to El Paso, Texas.

Arnold, J. P., from Philadelphia, Pa., to Clinton and Monmouth Streets, Trenton, N. J.

Bennett, P. R., from Daytona, Fla., to Urbana, Ohio.

Brown, Leroy, from St Paul Park, to Endicott Arcade, St Paul, Minn.

Bell, J. R., from Charleston to Due West, S. C.

Benepe, J. L., from Imperial Hotel to Willoughby Building, Indianapolis, Ind.

Boyd, S. J., to 413 Washington Boul., Chicago, Ill.

Bowser, O. B. H., from Washington, D. C., to 513 N. Adams Street, Richmond, Va.

Colson, A. C., from Manassas to Quince, Ga.

Corry, F. M., from Milwaukee to Fenimore, Wis.

Crockett, E. N., from Lone Creek to 348 Main St., Portland, Oregon.

Cooper, A. R., from 3121 Dearborn Street to 2970 State Street, Chicago, Ill.

Cannon, J. J., from Des Moines, Iowa, to 407 Security Building, Chicago, Ill.

Cozard, Henry Irving, from Columbus, to 633 W. Market Street, to Akron, Ohio.

Corasan, J. C., from Iowa City to Doryville, Iowa.

Cady, C. C., from Des Moines to Truro, Iowa.

Coulter, W. J., from Toledo, Ohio, to Milverton, Ontario, Canada.

Clement C. A., from Danville to Rover, Ark.

Chambers, G. P., from Atlanta, Ga., to Fort Mitchell, Ala.

Dickinson, F., from 70 State to 169 S Clark Street, Chicago, Ill.

Dowdall, W. T., from 3316 Rhodes Avenue, to Rand McNally Building, Chicago, Ill.

Davis R. B., from Henderson to Henderson, Tenn.

Deters, W. A., from Iowa City, Iowa, to Woodatock, Minn.

Elrod, J. O., from Atlanta to Adairville, Ga.

Evans, H. C., from Cleveland to Superintendent of State Hospital, Massillon, Ohio.

Estopinal, J. A., from St. Bernard to Estopinal, La.

Edwards, J. M., from Chicago, Ill., to West End Hotel, St. Louis, Mo.

Elarbee, G. W., from Atlanta, Ga., to Macon, Fla.

Frank, I., from 1929 Deming Place to Michael Reese Hospital, Chicago, Ill.

Fuller, J. L., from Oblon to Gadsden, Tenn.

Pife, J. D., from Proctor, Ind., to Glad, W. Va.

Findley, P. A., from Des Moines, Iowa, to Ozark, Mo.

Fleisher, Rubeca, from 621 No. 16, to 1505 Locust Street, Philadelphia, Pa.

Francis, J. H., from Milwaukee to Medford, Wis.

Grinnell, W. B., from Chicago, Ill., to Wykoff, Minn.

Goggel, R. J., from Suring to Oconto Falls, Wis.

Henrich, H. C., from 2228 Euclid Avenue to 2531 Euclid Avenue, Cleveland, Ohio.

Homer, H. C., from Horton, Iowa, to 2301 Indiana Avenue, Chicago, Ill.

Hummel, E. P., from Chicago, Ill., to La Porte City, Iowa.

Hines, C., from 543 3d Street to 692 Front Street, Portland, Ore.

Hartley, H. H., from Prairie City, Ore., to Centerville, Wash.

Hinde, J. R., from Chicago to Lewiston, Ill.

Hirschman, L. J., Harper Hospital Detroit, to 420 Underwood ave., Detroit, Mich.

Jones, D. W., from New Orleans, La., to Port Gibson, Miss.

Johnson, J. C., from Walsfield, to Mary Fletcher Hospital, Burlington, Vt.

Kirk, A. B., from Chicago, Ill., to Hibbing, Minn.

Kincald, G. E., from 2920 Pine to 4533 Labadie, St. Louis, Mo.

Kinsinger, J. B., from St. Joseph, to Mound City, Mo.

Kuehler, V., from Kansas City, Kan., to Yukon, O. T.

Krebs, L., from Springfield, to Ha-Ha-Touka, Mo.

Little, W. H., from Kansas City, Mo., to Buhler, Kan.

Lymao, T. P., from 2124 to 2070 Wilcox ave., Chicago, Ill.

Lewis, Le Roy, from Auburn, N. Y., to 90 Warren ave., Chicago, Ill.

Law, S. P., from Bryn Maur, Pa., to H. L. Law, 100 Washington Street, Hartford, Conn.

Lukens, A., from Pelham to 1068 Lexington Avenue, New York City, N. Y.

Lindsey, R. C., from Atlanta, to Irvington, Ga.

Lyon, E. A., from 4658 State street to 534 E. 47th Street, Chicago, Ill.

Morris, J. L., from Chicago, Ill., to Columbus, Ind.

Mels, E. W., from Dyersville to Zwingle, Ia.

McCormick, Olin, from Chicago to Sanneim, Ill.

McClure, C. F., from 1256 to 1106 Lawndale Avenue, Chicago, Ill.

McClure, C. P., from City Hospital to 1822 Market Street, St. Louis, Mo.

McGahan, C. F., from Aiken, S. C., to Bethlehem, N. H.

McKelway, G. I., from 255 S 17th to 114 S. 18th Street, Philadelphia, Pa.

Neid, D. W., from Box 294 to 3222 Spencer Terrace, Philadelphia, Pa.

Perry, J. C., from Port Townsend, Wash., to Mailla, P. I.

Pinkerton, R. G., from St. Louis, Mo., to Care British Post Office, Reynout, Syria.

Painter, F. W., from Bloomfield to Pilot Point, Tex.

Runyon, C., from Chicago, Ill., to 901 W. South A. Elwood, Ind.

Sweet, A., from 4839 to 4785 N. Clark Street, Chicago, Ill.

Savre, L., from Indianapolis, Ind., to Lake Mills, Ia.

Sholars, A. R., from New Orleans, La., to Orange, Tex.

Sale, H. M., from Washington to Levert, Ga.

Sassaman, F. W., from Boone Grove, to Valparaiso, Ind.

Spring, C. K., from 46 Fowler to 1451 Dakin Street, Chicago, Ill.

Stevenson, A. F. Jr., from Presbyterian Hospital to 378 La Salle Avenue, Chicago, Ill.

Scholtes, T. W., from Chicago, Ill., to Reads Landing, Minn.

St. John, H. II., from St. Louis to La Belle, Mo.

Sheppard, J. E., from 135 Clinton to 108 Pierpont Street, Brooklyn, N. Y.

Strow, R. M., from 422 Sherman to 1519 Cherry Street, Toledo, Ohio.

Sicker, A. W., from Chicago, Ill., to Franklin, Wis.

Thornton, J. W., from Lansing to Agreshire, Ia.

Twitty, W. S., from Charleston to Kershaw, S. C.

Warrell, J. B., from Strimboyn, to Coc, Ga.

Weston, F. R., from Okawala to La Crosse, Wis.

Wood, G., from 903 W. Monroe to 348 E. 55th Street, Chicago, Ill.

Winnington, F. L., from Ritchey, Mo., to Miami, J. T.

Wilkins, A. E., from Kansas City, Mo., to Cerea, O. T.

THE TENEMENTS AND TUBERCULOSIS.

BY S. A. KNOPP, M.D.

NEW YORK CITY.

If I should be asked what conditions are most conducive to the propagation of tuberculosis, and especially pulmonary consumption, I would have to reply: the conditions that prevail in the old-fashioned tenement houses as they still exist by the thousand in this and other large cities. In these tenements there are not only a far greater number of consumptives than in the same area elsewhere, but the proportion is actually greater per number of inhabitants. Thus they not only contain countless centers of infection for old and young, and multiple foci of reinfection for those already afflicted, but these dwellings, with their bad air, darkness and filth, make a cure of the disease impossible, and a lingering death for all those infected by the germ of tuberculosis a certainty. If any one thinks me an alarmist, let him glance at the charts exhibited in this building. There he will see that there are houses in which can be counted as many as twenty consecutive cases of tuberculosis during the last four years. This number represents, however, only the cases reported to the Board of Health. Now, you must not think for a moment that these represent the actual number of cases of tuberculosis existing in that particular tenement. They are only the ones where the disease had so far advanced that medical aid became imperative, a physician had to be called in, and the case was reported. But how many of the moderately advanced cases are made known to either physician or board of health? I venture to say those not reported are more numerous than the reported ones. They constitute that class of pulmonary invalids who are still able to work, and who imagine themselves to be suffering only from chronic bronchitis, and the equally large number of children suffering from tuberculous manifestations other than pulmonary. To the uninitiated it may sound like a paradox when I say that the tuberculous invalid who is still up and about, perhaps supporting his family, is often the greatest danger to the community, to his friends, his neighbors, and to those who may succeed him in the tenement in which he lives. It is this class of consumptives who, either from ignorance or carelessness, spread their disease broadcast by depositing their infectious sputum everywhere without any regard to the danger.

In the many discussions which were raised during the past few months previous to the framing of the bill to establish a state sanatorium for the treatment of incipient cases of pulmonary tuberculosis, it was repeatedly argued that we should rather isolate first the advanced

and hopeless cases. I appreciate the necessity of public care for this class of patients very much indeed, but the advanced and hopeless poor consumptive is usually confined to one or two rooms, and while ten to one he will infect these thoroughly, he can not do as much harm as he used to when he was still up and about and could spit in dark hall-ways of the tenement, on the floor of his workshop, in the street-car, or wherever his calling may have led him. Thus the advantage of curing an incipient case of pulmonary tuberculosis is inestimable. Leaving aside the direct benefit to the commonwealth by making a breadwinner and useful citizen of this pulmonary invalid, who himself and also perhaps those depending on him, might have become otherwise a burden to the community, it is beyond calculation to say how many lives may have been saved by curing that one man before he had a chance to disseminate his disease among his fellowmen in the manner described. To what extent he may do this you can perhaps perceive if I recall to you the fact that the average number of bacilli which the up-and-about consumptive expectorates daily is estimated to be seven billions.

But let us return to our main subject and try to find some explanation for the fearful condition which makes pulmonary tuberculosis an endemic disease of the tenement house. I pointed out to you that there were houses where an unusual number of consumptives have lived and died during the past few years. Now, let us pay a visit to one of them. We pass the throng in the narrow street, make our way through the crowds of children playing on the sidewalk, and enter the dark hallway. The first thing that greets us is the odor peculiar to badly housed humanity. You can not define it, but I know many of you who labor among poor know it only too well. Have you ever thought what this odor really means? It represents the exhalation of a multitude of people, the toxic products expelled during the process of expiration, which settle on the walls, ceiling, and stairs of these hallways. Chemistry has not yet been able to fix its composition: we know it exists and we know its deleterious influence on the individual who is obliged to live constantly in such a house. Some very prosaic people call this smell the smell of humanity, or the smell of poverty. I do not quite like these names for I do not think them either appropriate or just. There can be humanity without smell, and amidst poverty there can be the sweet atmosphere of cleanliness and purity. If the bad odor we perceive in our wanderings through those dark halls must have a name, let us call it the smell of ignorance and greed. It is the result of ignorance on the part of the poor housed there, who do not know the value of fresh air, sunlight, and the cleansing property of water—the trinity which is the best antitoxin against those poisonous products. It is the result of greed on the part of the owner, for only a heartless man could tolerate such a condition of filth, foul air, and darkness as is characteristic of these tenement halls.

*Delivered before a conference held under the auspices of the Tenement House Committee, of the Charly Organization Society, New York City, Feb. 20, 1900.

We ascend one more flight of stairs, in the rear or front, it makes little difference, since there is probably a consumptive on each floor. Owing to the expense of artificial lighting the halls are very dim, and though we can not see the dirt on the balustrades we feel that it is there and only reluctantly take hold of them in order not to fall. We arrive at the rooms we are seeking. A knock at the door, a feeble invitation to come in, and we are in the midst of tuberculosis. There are two or three small rooms, but only one receives direct air and light. In a small, dark bedroom lies the patient; there is a different odor in this room, a distinct smell of disease mingled with the odor of cooking. We ask to have the window open, but the patient fears the draft. He is a husband and the father of six children of whom two have died within the last year. The youngest of the remaining children is a few months old; the eldest, a girl of 10, attends to the household duties while the mother goes out to work. We greet our consumptive friend lying there, bid him cheer, and tell him we came to investigate his case. He faintly smiles, and we ask him to tell his story. In a feeble voice, interrupted by fits of coughing, he tells us that up to two years ago he was a strong and vigorous man, he had a good position as a mechanic, lived in a better tenement than now, and drank only occasionally, when life at home became too dull. Once he caught a severe cold. He went to a doctor. A few weeks of rest followed, some medicine, and he got well. After some months he had another cold, the same treatment, the same result. And then again a cold, and so on, until the periods between the times when he could labor and earn became longer and longer. The savings from better times gradually disappeared; a cheaper tenement was sought; the visits to the doctor were given up, and the patient finally ceased to work. To go to the dispensary was too much of an exertion. The faithful wife nursed him tenderly, but soon all the savings were gone. The burial of the two little ones—one having died of bowel complaint and the other of brain trouble—had cost so much that the mother decided to go out to work in order to support the family. While listening to the pitiful story we look around the scantily furnished rooms. The babies are playing on the dirty floor, touching everything with their little hands, putting their fingers in their mouths, and inhaling the dust laden with disease germs. When we consider that this case has only been reported a few weeks ago, and that until then the patient had hardly taken any care with his expectorations, can we wonder that two of the children died within a few months, one from bowel-complaint—which probably was nothing else than intestinal tuberculosis—and the other from brain trouble, which is only another name for tuberculous meningitis. The remaining little ones look pale and underfed. The little mother preparing the evening meal has seemingly a better appearance. She has to do much running out in the street to buy the provisions for the family that she gets more air, and if the father does not feel too badly she wheels out the baby sometimes. Yet to the experienced eye there are already traces of overwork in this delicate child organism. The precautions the patient takes now with his expectoration consist in having placed before him on the floor a cuspidor partially filled with some antiseptic fluid. Owing to his weakness he does not always succeed in depositing his sputum exactly in the center, and sometimes he even fails to hit the vessel at all. We call his attention to this lack of precaution and advise him to use a light mug which he can bring near to him, or moist rags which he should have burned in the evening on his wife's return.

We bid adieu to this interesting family to visit another case which had been reported two flights higher up. But on the next floor we pass a door wide open and hear the rattling of sewing machines, suddenly interrupted by a terrible cough. We halt and listen for a moment—another cough of different pitch, coming evidently from another person. We enter—again a different picture. The air is filled with dust and steam, the odor indescribable. The room is filled with people: an elderly man with dark features, a velvet cap on his head, a wife, a son, a daughter-in-law, two young girls and a number of children, all in one room, the growing persons working over their machines or pressing garments with heavy flat-irons, the little ones playing on piles of cloth or unfinished clothing. These latter with the children playing about them are the mysterious agents which, as newly-made garments, are not only capable of spreading tuberculosis, but are frequently the very medium whereby acutely contagious diseases, such as smallpox, diphtheria, scarlatina, and measles, are carried into the homes of the well-to-do. The description of the home we are visiting has already told you that we have before us a small sweat-shop. Without questioning we recognize in the young mother and in her unmarried sister the two coughers. We venture to ask them as to their condition, but they tell us that they are well. One says she coughs only because she is going to become a mother again; the other assures us she coughs only when she bends too intently over the machine or when the little ones raise too much dust. Both women are plainly in a state of evolution of pulmonary tuberculosis. Both expectorate freely and, alas, indiscriminately, spreading their disease among their own kin and others. They have not yet consulted a physician; they did not feel the need of one, and besides this, it takes time and money. They occasionally get some patent cough-mixture in the nearby drug store. As a matter of course, these cases belong to the class of unreported ones. Should these people ever move before their cases become known to the Board of Health they would leave the germs of tuberculosis in every portion of the rooms, and the new occupants would have all possible chances to contract the disease, for you must know that tuberculosis sputum often retains its virulence in the dried state for a long period of time, but especially so in places where fresh air and sunlight have little access.

Ducor, quoted by Dr. Park of the New York Health Department, in his recent book,¹ relates an instance of a healthy family having been infected with tuberculosis from living in a room which had been occupied by a consumptive two years before, and on examining the sputum-stained wall-paper not only were tubercle bacilli found in it, but on guinea-pigs being inoculated with scrapings from the walls they died of tuberculosis.

We advise the two young women to call in a physician or to go to a dispensary, and urge them not to expectorate except into a vessel partially filled with water, and if this is impossible, owing to the crowded condition of their workshop, to use a small pocket flask for that purpose.

We have one more family on our list, which we desire to visit. Again a cough re-echoing in the hallway would guide us even did we not know where to go. This cough, which is heard on nearly every floor, recalls to one's mind a hospital ward of consumptives. Our third visit leaves a less painful impression, for the rooms we enter are clean. The sufferer is a widowed mother. Thanks to

¹ Wm. H. Park: *Bacteriology in Medicine and Surgery*. Philadelphia: Lea Bros. & Co.

the conscientious advice of the physician the disease seems here to be under control and confined to one member of the family. There is little hope for her recovery, and her total helplessness makes it necessary for her only maiden daughter, otherwise a regular breadwinner, to remain at home and consecrate her entire time to the nursing of her mother. In the home and the faces of both of these women one can still see the traces of refinement and culture. What calamity has brought them into these surroundings must remain their secret, but we know that only with reluctance do they accept the much needed help which comes to them regularly through the medium of the charity organization.

Such and sadder pictures you can see daily in visiting the tenement homes of our city. To many of you the thought may have come: why are these people not in a hospital? I must answer you by saying that there is no room for them.

But what can we do to stop this plague if there is no room for the advanced cases in the hospital and no sanatorium for the care of the incipient cases? I believe I may modestly claim that I am an ardent advocate of the establishment of sanatoria and special hospitals maintained by the authorities and private philanthropy, and other public measures to stop the spread of tuberculosis, such as better sanitary laws, more public baths, parks, and playgrounds, especially in the crowded tenement districts, proper physical and hygienic education in our schools, etc.

While the realization of these institutions and proposed improvements will do a great deal toward the decrease of tuberculosis, the greatest factor in solving the tuberculosis problem will, however, be the proper housing of the poor. As long as the law will permit tenements to exist, or to be constructed anew, which, owing to the lack of air and light and want of cleanliness constitute veritable hot-beds of tuberculosis, so long will sanatoria and special hospitals serve only as recipients of the supply of tuberculous patients daily created anew.

Tuberculosis is a preventable and curable disease. Let us emphasize these important points in our crusade against it. In spite of all the opposition which we have encountered I do not fear but that ere long we will have a state sanatorium for the treatment of incipient cases and a special hospital in the vicinity of the city, which will be followed by the establishment of numerous institutions by private philanthropy. My faith in the wisdom of our statesmen and city fathers, and in the generous hearts of the American philanthropists, is too great for me to falter in my hopes. Such institutions—sanatoria and special hospitals—will serve to cure those already afflicted with the disease; but the model tenement house and the model tenement house management will be the greatest factors in preventing the development of the disease. Though, when we consider that we have in this city alone more than ten thousand poor consumptives, those new and model tenements will probably have to at times harbor a few tuberculosis patients; but how much brighter prospect they have of being cured in these new houses with plenty of light and air, perfect ventilation in all rooms, complete sanitary arrangements, and the absence of filth, dirt, and sickening odors.

Since consumption can be successfully treated in nearly all climes, and the essentials of the modern treatment of tuberculosis are plenty of fresh air and light, good food, and judicious medical supervision, the probability of treating an intelligent consumptive patient successfully, even at his home, must certainly be an assurance to us all, since we know that there will not be room

enough for all these patients in the institutions. The danger of infection from such a patient in a model tenement house can be reduced to a minimum, and the same might be said in regard to other contagious diseases.

In Germany it has been proposed that in order to control and combat tuberculosis successfully, every person should submit himself to a periodical examination for the possibility of a tuberculous disease, and that this examination should be compulsory, like vaccination.

As to the advisability of inaugurating such a movement in our own country I prefer to suspend judgment; but if I should be the fortunate owner of a model tenement house, I certainly would make the medical examination obligatory for all those who desired to become my tenants. Should there be one, two, or even more among them, with incipient tuberculosis, I would not refuse to these the blessings of a sanitary home, which, as long as we have so few special institutions, will certainly be an addition to their chances of getting cured. But I would have every one of these prospective pulmonary invalids instructed individually as to the precaution he has to take concerning his infectious sputum, and urge him to place himself under medical treatment. I would warn him that though the hospitality of this model tenement house had been extended to him, if he ever wilfully violated the given instructions and regulations concerning the disposal of his expectorations he could no longer remain in the house. Let me remark here, incidentally, that the application of this injunction constitutes the essential part of the discipline in sanatoria and special hospitals in our own country and abroad. Any wilful violation means immediate dismissal. It is this precaution whereby the healthy individual is more protected from contracting the disease in these very homes for consumptives, than probably anywhere else outside of them. I could verify this statement by statistics which I have published before² in connection with this subject, but I will refer here only to one of our home institutions, the Adirondack Cottage Sanatorium, under the direction of my esteemed friend, Dr. E. L. Trudeau. During the fifteen years of its existence not one of the medical attendants and nurses, who have lived and labored there in close contact with hundreds of consumptive patients, has ever contracted pulmonary tuberculosis. Thus, I believe, the model tenement house could also be made a place safer from the danger of contracting pulmonary tuberculosis than any other. But I would go even a little further in my precautions to avoid a repetition of such sights as we observed in our wanderings through the tenements of the city. I would see to it that all the tenants should get a sufficient knowledge of what to do in case there is a patient suffering from a communicable or contagious disease in their midst. Leaflets such as the Pennsylvania Society for the Prevention of Tuberculosis issues for distribution should be placed at regular intervals in the hands of the tenants. The titles of some of these leaflets are as follows: "How to Avoid Contracting Tuberculosis," "How Persons Suffering from Tuberculosis Can Avoid Giving the Disease to Others," "Predisposing Causes of Tuberculosis and How to Avoid and Overcome Them." In short, I would found a local society for the prevention of tuberculosis, composed of my tenants and those of other model tenement houses. I would institute reunions and invite physicians and sanitarians to address them, not only on the prevention of tuberculosis, but also on the prevention of other diseases. If I could besides this succeed in procuring one of those

² S. A. Knopf: *Prophylaxis and Treatment of Pulmonary Tuberculosis* P. Blakiston's Son & Co., Philadelphia.

noble women who could teach to the women tenants the art of good and economical cooking and careful house-keeping, and procure for all men, women, and children alike, such educational and social features as would make their home life happier and brighter, I would think that the ideal of housing the poor was attained.

After the description of all that you have heard and seen since this splendid exhibition has been opened, there is no need for me to tell you of the urgent necessity of better laws concerning the building of tenement houses, and you will realize that it becomes our duty as men and citizens to no longer tolerate existing conditions. But in the meantime we should combine our individual efforts to further all such enterprises as, independent of legislative help, will attain the same end. Though we may not reap what we sow, as our worthy chairman, Mr. Frederick W. Holls, at the opening of this exhibition so beautifully suggested, let us sow our grains nevertheless, and let us sow them well and diligently. In the proper housing of the laboring classes lies the welfare of the community and the sanitary, social and intellectual prosperity of every citizen.

Think of the difference between the old tenement, which we desire to abolish, and the new one we desire to erect, and you will need no further incentive. The one is a beehive of humanity living in filth and dirt, well-nigh without light and air, but with a multitude of sickening odors; with no attractions to foster home life, virtue and temperance; disease breeding in every room; a hot-bed of tuberculosis and other contagious diseases from which are spread the foci of infection throughout the city among old and young, poor and rich alike. The other is a well-regulated city within a city, its citizens living in airy, sunny rooms, in modest but attractive homes, which make the longing for the rum shop less, and create a love for temperance and purity; a home where infectious diseases can be controlled and from which the most bitter foe of mankind, "the great white plague"—consumption—can be ultimately and lastingly banished.

16 West Ninety-fifth Street.

NOTIFICATION AND STATE SUPERVISION OF THE TUBERCULOUS.*

BY JOSEPH MATTESON, M.D.
CHICAGO.

The general acceptance of the bacillus discovered by Koch as the exciting cause of tuberculosis in man and the food animals is based on the most careful experimental observations. Without the bacillus there can be no tuberculosis. Therefore, if we should destroy all these bacilli there would be an end to tuberculosis. This appears to some logical, simple and, to a degree, possible of attainment. It is a sequence of cause, effect and prevention which has produced a revolution in medical thought and action.

Whereas formerly an occasional instance of apparent communication of the disease from one individual to another excited some speculation as to its possible contagiousness, or was explained by heredity or coincidence, now all is changed—infection or communication from another is almost universally recognized as the essential factor.

Tuberculosis then being an infectious disease affecting a larger number of individuals than any other, it naturally falls into the jurisdiction of state medicine.

Since 1882 there has been an increasing and extending

agitation for the suppression of tuberculosis by special state supervision and control of the tuberculous.

We encounter here enthusiasts and extremists on the one hand and doubters on the other, just as in any other imperfectly understood problem in social economics. To quote one of the former, here is a widely circulated statement by Dr. Biggs, of the New York City Board of Health, whose earnest work for the suppression of tuberculosis in that city has commanded general approval. He says (*Forum*): "With our present knowledge we have in our power to completely wipe out pulmonary consumption in a single generation." Again, Dr. Geo. M. Gould, says: "Phthisis, the most fatal of diseases, causing one death in eight, is now proved to be contagious. Its inception depends upon the passage of the living bacilli from one organism to another. When this is prevented the dread affection will no longer mow down its victims. Its prevention seems easy and by two feasible, simple means—the devaluation of the sputum of consumptives, the inspection of dairies and the slaughtering of animals." Dr. Schonock asserts that "Tuberculosis is a preventable disease and one of the unnecessary afflictions of humanity."

Admitting fully that the essential factor in the spread of tuberculosis is the bacillus, that its definite life history, its food, growth, and decay and manner of transmission have become known, let us consider whether the extermination of phthisis is in sight: whether it has become a simple problem—a bacillary premise and a legislative conclusion—the observation and experience of years as to the numerous contributing factors in the production of tuberculosis nullified, or only temporarily lost to sight.

While the dried sputum of consumptives and the milk of tuberculous cows are known to be the common distributors of infection there are other minor ones which may be noted. Spano demonstrated that seminal fluid may infect even when the genital tract is not involved in the disease. Of eight cases he demonstrated the presence of tubercle bacilli in the seminal fluid of three.

They have been found unharmed in the interior of large underdone joints exposed to the ordinary roasting point. Schugard demonstrated their presence in chancres and soft sores and gonorrhoeal pus. Successful inoculations are reported with the tissues of tuberculous infants, and the amniotic fluid of a tuberculous woman. Hirschfeld recently found the bacilli in the placenta and in the capillary vessels of the fetal liver. It is estimated that from 6 to 20 per cent. of cattle and 5 per cent. of milk cows are infected, and the bacilli may rest in the discharge from the mouth, nose and bowels, drying upon hay and grass. Hogs and domestic pets are not infrequently infected. Jensen reported 44 cases in dogs and 33 in cats. In Berlin an examination of a large number of parrots showed that 25 per cent. were tuberculous. Lortet demonstrated that earthworms are capable of ingesting and ejecting tubercle bacilli without the microorganisms losing their virulence, and that the bacillus has retained its virulence after being buried for one year. Experiments in the laboratory of Professor Flügge proved that it is possible to carry particles of infected sputum in the act of speaking, to a distance of four feet.

Besides the direct inhalation of bacilli from desiccated sputum we must note their deposit on bakers' goods and all articles of food consumed in the raw state. Schnirer rinsed the dust from grapes bought at a street stand and developed tuberculosis in two guinea-pigs out of three. Hoffman found that flies may carry the germs in their intestines and deposit them in their droppings.

*Read before the Chicago Medico-Legal Society, Dec. 2, 1899.

It has been estimated that a consumptive may expectorate several billion tubercle bacilli in twenty-four hours, and that there are at least 500,000 living individuals in this country with pulmonary tuberculosis.

What innumerable foci for the spread of the disease are thus provided in houses, railroad cars and public halls. We should expect an epidemic of a clearly communicable disease under such opportunities. At least tuberculosis should be increasing in frequency, but the opposite seems to be true: it has been decreasing for many years.

Heretofore no measures to isolate or disinfect consumptives have been in force, yet the disease is less prevalent than formerly.

The death-rate from consumption in England, from 1838 to 1852, decreased 26 per cent.; from 1852 to 1892, 50 per cent., all ascribable to general sanitary improvements, such as the extension of main sewers and house drainage. Sandberg made a critical inspection of vital statistics in England from 1850 to 1886, and proved that phthisis has steadily decreased in the agricultural districts; the decrease was 50 per cent. in females. Billings shows a decrease of 10 per cent. in the phthisis mortality of the United States between 1880 and 1890. Dr. E. F. Wells, of this city, has personally collected the death returns of the seventeen principal cities of the United States for such periods as they were matter of record, showing a marked decrease of the phthisis mortality in nearly every instance. And yet the centers of infection, though decreasing in numbers, must have been increasing in volume of expired bacilli if it be true, as Theodore Williams, supported by Pollock, claims, that the average duration of phthisis is now four times as long as in the time of Laennec and Louis.

In the extension of tuberculosis we should expect physicians and nurses who are in most frequent and close contact with consumptives and inferentially their bacilli to be unusually liable to infection. Making all due allowance for the errors, inconsistencies, and contradictions assignable to such collections we have considerable evidence on the negative side.

Haupt investigated the history of 275 female nurses who had been in habitual attendance on consumptives; only two became tuberculous. The collective investigation committee of the British Medical Association, in 1883 instituted an inquiry into the communicability of phthisis. Out of 1078 who returned answers less than one-quarter had seen cases which they believed had originated by communication from one person to another.

Da Costa says that in the Vienna General Hospital—before disinfectants were used—there were in three years nearly 3000 deaths from phthisis and not one medical officer or nurse became affected. In the Pennsylvania Hospital there never had been a time when there were not many consumptives in the medical wards. Of 147 resident physicians whose history he had followed but one died of tuberculosis. Of 93 male and female nurses employed in the last twenty-five years, only one showed signs of tuberculous disease.

Williams and Humphrey state that at the Brompton Hospital, during thirty-six years; not one clearly authenticated case of pulmonary consumption originated among all its staff and employees.

The statistics of Friedrichshain Hospital in Berlin, as given by Fürbinger, show that during sixteen years, out of 887 physicians and nurses there were only 9 who became consumptive and 3 of these were tuberculous before entering. Out of 108 Victoria nurses in the hospital 2 to 5½ years each, only 1 become tuberculous.

It will not do to attempt to attribute this immunity to disinfection of sputum, as much of the period covered was before the recognition of this source of danger.

There should be plenty of evidence also of the frequent communication of tuberculosis by married persons to their partners in the closest association of life. Dr. Cooper reported, on the other hand, that he had personally known and followed the history of 55 cases of phthisis in married persons; 40 of them had died of it, the surviving partners all living and free from the disease after six to thirty years. Flint, in 670 cases of death from tuberculosis of married persons, found but five cases in which the partners became similarly diseased. Dr. Schnyder observed 844 cases in married people. In only 32 were both husband and wife affected, or one in thirty.

Longstaff has made the calculation from averages that for every 148,000 men who die during the age of married life there would be 4358 of their wives who would have consumption without reference to contagion from their husbands, that is, 1 in about 33.

There is also experimental evidence on the negative side of easy infection from supposedly infected places. Praussnitz unsuccessfully tried to inoculate animals with dust from the floors of railway compartments carrying consumptives for many hours. Kusterman also failed to develop tuberculosis from the dust from the walls and floors of the Munich prison. Herne and Chaplin report, in the London *Lancet*, that they made inoculations of 100 guinea-pigs with dust from various, probably infected, parts of the City of London Hospital—and note that there must have been dry tuberculous sputum in the pathologic workroom. They met with evidence of tuberculosis in only two of the guinea-pigs.

Gardiner has recently inoculated with dust obtained from different rooms in the largest hotel in Colorado Springs, Colo., occupied by consumptives, with negative results in eight cases.

It is frequently asserted, in an offhand way, that certain resorts have become dangerously infected by the concourse of consumptives. Among others, Mentone is cited as a place where tuberculosis has become common among the resident population. But when we read the report of Dr. Bennett, the resident physician, which appears to be the foundation for this opinion, we find that what he actually notes is an increase among the women of the town who formerly worked in the fields with their male relatives, but who subsequent to the incursion of numerous consumptives became laundresses and domestic servants, and he asks if the increase of consumption which he notes only among these workers be not due to change from outdoor life to work in damp, close and ill-ventilated rooms.

Recent statistics of Falkenstein show that the village mortality from phthisis has been reduced 40 per cent. since the establishment there of the sanatorium for consumptives—an odd revelation of the death table, however, is the fact that the mortality from phthisis has increased from 5 per cent. to 15 per cent. in 1892-94, under the antiseptic régime, though still remaining lower than before the establishment of the sanatorium. So also at Göerbersdorf, the site of the largest sanatorium of the kind in the world, many thousand consumptives have deposited their expectation in the streets of the village, so that the inhabitants continuously respired air potentially more or less laden with tubercle bacilli, with the result that the absolute number of deaths among them from phthisis is about half as many as before the estab-

lishment of the sanatorium, and the population has doubled.

It is rumored that Colorado resorts have become infected by the numerous consumptives who have sought the benefit of its climate, that there has been a great increase in the cases of tuberculosis originating there, and that the State Board of Health had under consideration the advisability of quarantine against more consumptives. Dr. S. G. Bonney, of Denver, has made a careful investigation and proves these statements to be untrue. The death-rate from indigenous cases was less in 1896 than in 1895—one-third of the patients were under 15 years of age—some the children of tubercular parents. Dr. Solly, of Colorado Springs, says that living for sixteen years among a people of whom many came to the country with tuberculosis, and not a few of whom live in crowded lodgings where free expectoration is commonly practiced, he knows of only four cases which could fairly be assumed to have originated in Colorado.

Dr. Gardiner reports that as a result of a circular letter of inquiry to many physicians of Colorado he could learn from them of only ten cases in fifteen years.

It certainly is a fairly reasonable conclusion from these facts that the spread of tuberculosis is not in accord with the degree of exposure to the bacillus.

The wide diffusion of the bacillus tuberculosis makes inevitable contact with it on the part of every individual in thickly-settled communities—the marvel then is not that one-sixth become fatally infected, but that more than half entirely escape. The evidence presented as to the escape of those in contact with the tuberculous is not offered in abatement of the claim of the bacillus as the essential factor. It is evidence, however, of the fact that one in fair health, living a regular and hygienic life, has little to fear from contact with the bacillus. We must assume, moreover, for those who do become infected, a weakness of resistance to the lodgment and multiplication of the bacilli, inherited or acquired. Hereditary predisposition, however explained, remains practically a factor to be dealt with in the genesis of tuberculosis. There is no time to even suggest all those circumstances of external environment, bodily formation, habits and degenerations which favor acquired predisposition.

A quotation from Jaccoud, recently cited and endorsed by one of our oldest and most eminent teachers, summarizes the interdependence of the bacillus and the predisposition most aptly in these words: "With this class of organisms pathogenesis by changes in the organism is the rule, and its traditional etiology based on heredity, congeniality, predisposition, temperament, somatic or cosmic influences retains all its force." That the natural history of infection, depicted as an active bacillus on the one hand and a comparatively passive resistance of the organism on the other, has been overdrawn, is confirmed also by recent bacteriologic development. H. P. Loomis made inoculations with the bronchial glands of persons dead from accident or acute disease apparently free from tuberculosis. One-fourth of the rabbits developed tuberculosis. Pizzini made observations on the lymph glands of thirty individuals who had died without any clinical evidence of tuberculosis—in twelve instances he developed tuberculosis by inoculation of guinea-pigs.

The recent bacteriologic work of Dr. Adami¹ of Montreal, so graphically presented to our local medical society recently has added new and convincing evidence of the not occasional, but constant, presence of noxious bacteria in the organism, and the equally constant bactericidal activity of the leucocytes and the disintegration and

elimination of the bacilli in the glands, the liver and kidneys. His observations point also to the etiology of cirrhosis of the liver by overwhelming invasion of the bacillus coli through coincident breach of the natural line of defense produced by catarrhal disease of the intestinal tract. These additions to our knowledge emphasize the belief that we are to rely for immunity from infection, not solely on an artificial absence of bacteria, but at least in equal degree on the maintenance of the inherent germicidal activity and vigor of the organism.

Until recently public preventive measures against tuberculosis have been directed only to the abatement of the predisposing conditions. The reduction in phthisis mortality as a result of these sanitary measures has been general and in many cases remarkable.

Acquainted now with the exciting as well as the predisposing cause of tuberculosis we are no longer restricted to defensive measures of increased vital resistance, but may undertake offensive action to destroy or limit the bacillus. The ubiquity of the bacillus suggests the magnitude of the task and assigns its accomplishment to that happy period when all men are honest, all women virtuous and the poor no longer with us.

We have it in our power, however, to greatly lessen the dissemination of the bacilli by practicable methods and thus decrease the chances of new infection. While there are many who do not share in optimistic enthusiasm as to the results to be anticipated, few will question the desirability of the attempt by unobjectionable methods.

The measures to be taken for the prevention of tuberculosis naturally divide into those directed against its dissemination by infected food animals on the one hand and those directed against infected man on the other. In regard to the former it may be briefly said that the conditions of success are comparatively simple. Rigid inspection of herds and dairies and the destruction of the infected animal solve the problem, requiring only the necessary law and its efficient execution.

Knopf, in 1897, reported that twenty-three states of the Union provided for official distribution of circulars of instruction as to the dangers of communication of human tuberculosis and the precautions to be observed as safeguards against infection. In Michigan and Pennsylvania resolutions had been adopted to include consumption in the official list of diseases dangerous to public health. In New York notification of all cases is compulsory. It is evident then that action against human tuberculosis has been confined, with few exceptions, to a commendable effort of education of the people, but that there is a growing tendency to more radical action. The statement was recently made in a medical journal that not long ago, in Detroit, Dr. E. A. Shurly was prosecuted by the local board of health because he refused to report his cases of phthisis; that in the defense Dr. Gibbes took the ground that there was no proof that consumption is contagious. Judgment was rendered against the physician and appeal taken to the supreme court. The report of the Department of Health of New York City, 1897, laments the difficulties of effective preventive measures because of the lack of special sanatoria, that is to say segregation, and incidentally intimates that "the work of restriction of tuberculosis has just begun."

On Sept. 15, 1899, the following preliminary resolution was passed by the State Board of Health of California: "Resolved, That the State Board of Health consider the propriety of quarantining against human beings and domestic animals with tuberculosis entering the state."

¹ THE JOURNAL, Dec. 16 and 25, 1899

In its present form the New York City compulsory registry law stands as a compromise measure: the result of attrition between the enthusiastic contagionists of the Department of Health and the opposition of the local practitioners. It may serve as a model of the most advanced action which will at present meet general approval. With the copy of the act requiring registration of all cases public or private coming under the observation of the physician within one week, is mailed a circular of information for physicians, which says that there will be no sanitary inspection or interference by the Health Department in private cases unless requested by the reporting physician, nor in those in lodging-houses or tenements where the reporter specially asks for non-interference. The law further provides for inspection of the premises occupied by the tuberculous, and the instruction of the family in preventive measures, and the disinfection of premises vacated by the affected, which must not be reoccupied until orders of the Health Department are complied with.

Preventive measures against infectious diseases self-limited, of brief duration, meet common approval, and are enforced with little inconvenience or difficulty. Tuberculosis, on the contrary, affects the individual for a number of years. During this period, instead of being confined to bed by the severity of his illness, the consumptive is little incapacitated for movement: he engages in the ordinary occupations and diversions of life, and frequents stores, factories, public halls and conveyances. During all this time he is hypothetically an ambulant source of infection. If these patients be put on the infectious list by compulsory registration, the first step is to instruct them in the danger of infection from their expectoration, and direct the means by which they shall dispose of this source of infection. If there be no further procedure it would seem as if registration were but a means of obtaining statistics as to the location, age and occupation of the tuberculous not worth the consequential interference in private affairs: for it is evident that the carrying out of the preventive measures must be left to the care and conscience of the individual: any practical degree of surveillance of the careless and indifferent while at large, by the authorities, being of course impossible.

To be more than of instructive benefit there must be, for the careless or incapable, penalties, or means of enforcement of the preventive measures. Segregation offers itself as the only reliable protection. The state must then provide places where these people may be separated from the community with favorable conditions for recovery. Needless to say these places do not yet exist.

The next step in preventive measures against tuberculosis easily suggests itself as a sequence to segregation. If it were well to isolate the tuberculous already in the community, it were better still to prohibit the entrance of more from the outside. So we have quarantine as the legitimate outcome of compulsory registration. The California Board of Health, with characteristic western disregard for precedent, jumped the intervening steps and landed at the top.

While I share in the general recognition of the value of instruction of the people in the danger of the dissemination of tuberculosis by the sputum of the consumptive, and in the method of disposal or disinfection by which this danger may be minimized, I believe that in spite of the agitation for state preventive measures there exists in the mass of the medical profession a strong, if quiet, opposition to any radical steps in state interfer-

ence with the tuberculous, and that it is based on: 1. An underlying belief that there is a variance between the infectiousness of tuberculosis, predicated on scientific experiment and deduction and the actual everyday facts of common observation. 2. On the instinctive recoil of reason and humanity at the difficulties and hardships of the progressive measures which are the logical sequences of the first step. 3. On the evidence we have that tuberculosis in man is to be decreased by increasing vital resistance, discouraging tuberculous marriages, and improving general and individual sanitary environment and living.

70 State Street.

DISCUSSION.

DR. E. FLETCHER INGALS, Chicago.—The control of tuberculosis is one of the most important problems that confront the science of medicine at this time, and this very fact has led to a vast amount of visionary talk by some members of the profession, and to some vicious legislation, in an attempt to accomplish something toward the diminution of tuberculosis. This problem, in its effects on the human mind, excites action similar to that called forth by the financial problem, which is always paramount with the majority of mankind.

A considerable percentage of men will at once accept the most visionary schemes if they promise speedy riches, and a much larger percentage will place implicit confidence in other schemes, right in part, but lacking in one or more of the essential elements of success; so some physicians and laymen adopt, with more or less enthusiasm, absurd, or more or less visionary propositions for stamping out tuberculosis, while they ignore some of the essential facts that must be considered if anything of value is to be accomplished.

Pulmonary tuberculosis is in many respects analogous to croupous pneumonia: both are very frequent and both are frightfully fatal; both are recognized as of microbial origin, and consequently both are considered by some to be contagious; however, it is only in very rare instances that we can find any evidence of contagion in pneumonia, and it is in a very small percentage of cases only that we are able to find anything like proof of tuberculosis having been contracted by one person from association with another suffering from the disease. The diplococcus pneumoniae is thought to be present in all or nearly all cases of croupous pneumonia and the Koch bacillus may be found in practically all cases of pulmonary tuberculosis; but the diplococcus pneumoniae is also present in the secretions of the mouth in a large percentage of healthy people, and the tubercle bacillus is also present in some of the tissues of the body in a very large percentage of perfectly healthy subjects, facts which prove beyond doubt that there are other elements entering into the etiology of these diseases. These two diseases present so many points of similarity that we can no more hope to stamp out one of them than the other. A well-known pathologist said to me recently, that before we were able to stamp out pulmonary tuberculosis the human family would, in the natural course of events, have become immune to the influence of the Koch bacillus.

We must do all in our power to control both of these fatal maladies, but we can not accomplish much by attacking any one of their several etiologic factors. We should work for that which is possible, and not waste our time crying out and striving for what is far beyond our reach. Before making up our minds what should be done toward requiring physicians and friends to report all tuberculous cases to the Board of Health, we should carefully consider some facts that are often ignored.

Although it is recognized that the tubercle of Koch bacillus is the essential cause of tuberculosis, yet no one has thus far been able to determine why certain individuals are attacked by the disease and why others escape. The knowledge that these bacteria cause tuberculosis under certain conditions, has led many to believe that nearly all persons affected by the disease are infected through some other individual. All told, a considerable number of cases have been reported that can be fairly charged to contagion, but as against this there are hundreds of thousands in which there is not the slightest evidence to justi-

fy such a conclusion. Out of about 1600 of my carefully kept records of private patients suffering from pulmonary tuberculosis, I have taken at random 100 records which may be supposed to give a fairly good idea of how the rest would run. Of these 100, only 1 or 2 per cent. show any evidence of contagion. There were just two cases of this sort, in one of which there was no evidence of heredity, but a history of having been associated with a friend who had phthisis. In the other, a widow free from hereditary taint developed tuberculosis 2½ years after the death of her husband from consumption. These may both have been contagious, but either or both may have resulted from some of the other causes of the disease and the association may have been merely a coincidence. In 27 per cent. of these cases, however, it is found that some other member of the family had had tuberculosis. Some of these may have resulted from contagion, however, in many instances of this kind, as, for example, when the person had grown and left home the patient may never have been at all intimately associated with the other member of the family who had tuberculosis, and there is certainly no proof when we consider the influence of heredity. A summary of these cases shows that in 1 instance the father only had died of pulmonary tuberculosis; in 12 the mother only; in 2, both father and mother; in 5, a brother only; in 5, a sister only; in 1, a son only, and in 1, a daughter only had died of pulmonary tuberculosis. All of these may have been the result of inheritance, and certainly they could not be taken as even circumstantial evidence of contagion. That only one should have inherited or acquired pulmonary tuberculosis from the father, but that twelve did from the mother affords an opportunity for interesting speculation. Was it because the young child was so much more with the mother than with the father? The answer would have to allow for the fact that after a father had become seriously sick with consumption he would be quite as likely to be with the children as the mother. Was it because the mother's milk contained the bacilli or because her depraved condition prevented the furnishing of adequate nutrition to the nursing infant? As these were all patients from 20 to 36 years of age, neither of these suggestions would seem to account for the condition. In studying this subject we must take into consideration the very great prevalence of tuberculosis, a fact which of itself would explain the occurrence of the disease in a considerable percentage of the patients in whom it has been attributed to contagion. I believe that by the most liberal estimate less than 2 per cent. of all cases of the disease result from contagion by association with another person having consumption.

Surgeons claim that 80 per cent. of the human family have tuberculosis in some form. Vital statistics show that 12 per cent. of the human family die of pulmonary tuberculosis, and the records from the dead-house show that 25 per cent. of those dying from other than pulmonary diseases have previously had and recovered from pulmonary tuberculosis, which has left distinct scars, therefore, there must be at least 37 per cent. of the human family who at one time or another suffer from pulmonary tuberculosis, and it is probable that the percentage is much larger. Tubercle bacilli have been demonstrated in the bronchial glands in about 40 per cent. of a series of cases of persons dying from acute injury who had never presented any evidence whatever of pulmonary tuberculosis. If this 40 per cent. be added to the 37 per cent. already found we find that 77 per cent. of the human family, at one time or another, harbor the tubercle bacillus either in the lungs or the bronchial glands. If careful examinations were made of all the mesenteric glands and other tissues of the body, it is probable that these bacilli would be found in nearly all; even from the evidence we now have it appears that practically every member of the human family, at least in civilized countries, harbors the tubercle bacillus in some part of his body at some time. Personally I doubt very much whether there is a person in this room who is not at this moment carrying about a greater or less number of tubercle bacilli.

For the sake of the argument let us admit that not more than 75 or 80 per cent. of the human family ever suffer from tuberculosis. An important thing to be considered in our efforts to prevent tuberculosis is that it also affects many of

the lower animals, as cows, chickens, birds, monkeys, fish, etc., and also plants. The facts just presented indicate some of the difficulties which will be met in the outset of this undertaking. Notwithstanding the very great prevalence of the disease, as I have already shown, only a very small number can reasonably be supposed to have contracted it from other persons. It is commonly believed, though we must admit upon very insufficient evidence, that tuberculosis is nearly always caused by the inhalation of bacilli which have been taken up in the air from dry sputum; yet it is a well-known fact that these germs are usually destroyed by a short exposure to the air and sunshine. I am inclined to the popular belief, but we must admit that no one knows the origin of the bacillus. Pathologists have recently shown that these bacilli are often branching like the ray fungus of actinomycosis, and that their passage through cold-blooded animals produces bacteria morphologically very different from the Koch bacillus. Miller has succeeded in obtaining bacilli from grasses that are morphologically identical with the bacillus of tuberculosis. Much valuable information concerning the branching forms of the tubercle bacillus will be found in an article by Friedrich and Nöske (*Beiträge zur Pathologischen Anatomie und zur allgemeinen Pathologie*, Jena, 1899), and in the articles by Schulze and Mubarsch; the two latter will be found in *Zeitschrift für Hygiene und Infektionskrankheiten*. Among others who have worked with these actinomycelial forms of the bacilli are Coppen Jones, E. Klein, Babes, Dixon and H. Bruns. Lydia Rubenovitch has succeeded in obtaining the bacilli from butter, and the experiments of Strauss with cooked meat show that the bacilli may retain their virulence for a long time under most adverse circumstances and be introduced with the food.

When the state labels a person as a consumptive it places on him a brand like that of Cain, which can never be effaced. I have seen many patients who believed they had consumption, who insisted on not being told of it even though they came to me for a diagnosis. In the majority of cases that I see the friends request me not to let the patient know that he has consumption, believing as they do that it would work great injury to the sufferer. From my experience it is my impression that at least 75 per cent. of those having this disease do not wish to be told of it even by their physician, and it is my uniform practice not to tell a patient that he has it unless he requests the information, while it is comparatively rarely that one of these unfortunates asks me what is really the matter.

I am confident that a law requiring physicians to report to the state all cases of tuberculosis that come under their observation would cause patients and friends, from fear of being reported, in a large percentage of cases to avoid the physician as long as possible, thereby losing the most important, and in many cases the only, chance for successful treatment. Bringing the matter directly home, I would ask how many of you physicians would report to the state a case of consumption in your own household. I have no doubt that some would do so from conscientious motives, but I am quite as confident that the majority of physicians would feel that their duty to the patient required them to protect him from this stigma. Two results of such a law would be that many patients would not consult the physician until it was too late and that the majority of physicians would consider themselves in duty bound to protect their patients rather than to turn them over to the tender care of the state.

The branding of consumptives could not fail to be detrimental in many cases. To many a person the mere knowledge that he had consumption would be like a warrant dooming him to slow death, and of the 60 or 70 per cent. of those having pulmonary tuberculosis who now recover, many would die from the depression caused by the mortification, disgrace or despair of being thus pointed out. So true is this that I firmly believe that in many cases it would be much more humane for the state to give such persons an overdose of morphin or chloroform.

Our duty as physicians is not only to heal the sick but to comfort them and their friends, and I can hardly conceive of a more cruel thing, in some instances, than it would be to inform on them to the public officers, especially as there is

little reason to think that these officers could do any good to the patient or in protecting others. As not only friends but physicians would probably conceal the majority of tubercular patients as long as possible, if we had such a law, it could not be thoroughly enforced and it would be worse than useless. It will be urged that the good of the many must be considered, as in the case of diphtheria, scarlet fever and other markedly contagious diseases, but when we recollect that 80 per cent. of the human family have tuberculosis, the impracticability of such a law seems self-evident, and it appears clear that it would be much better to banish the 20 per cent. who can not be proved to have the disease, in order that they may be removed from its dangers. They certainly would be better able than consumptives to fight the battles of life alone. Even if the application of the law were confined to the 12 or 20 per cent. of the consumptives who can not be recognized even by the laity, we would have to reckon with very many hostile to the law because each of these consumptives has friends who would not tolerate his banishment. There are not a few who would object even to killing off cows and other domestic animals that might possibly be harboring the bacilli. With the tuberculin test tuberculosis in the lower animals can be readily detected, in most cases at an early stage, but it is not infallible; therefore, in order to be sure that we are getting rid of all of those infected it would be necessary to destroy a great number that were simply suspected, although a positive reaction may be accepted as practically a sure sign that the disease is present somewhere in the animal. If we could destroy all suspected animals and the 80 per cent. of the human family who have tuberculosis, it is a question whether the 20 per cent. that were left would be free from infection. As I have already stated, no one can tell whence the tubercle bacillus comes, and no one can be certain that he is not already tuberculous or that he is not at least harboring this omnipresent microbe. It does not appear to me practicable to quarantine or sequester those suffering from consumption.

From what I have said many may think me pessimistic and hopeless about the management of these unfortunate cases. This is not the case, but I have no sympathy with the extravagant views entertained by those who believe that the prevention of tuberculosis is to be carried out on the same lines as that of yellow fever, and who believe that if this be done the disease would be stamped out within a few years. Although libeling and quarantining tuberculous patients can not be satisfactorily carried out, and although it would be of doubtful utility if it could, I think there is much that may be done to check the spread of the disease, or to cure it in individual cases, in its early stages. Although we do not know where the tubercle bacilli come from, it is believed by most physicians that most patients acquire tuberculosis through the atmosphere from the dried sputum of tuberculous human beings, the only animals so far as I know that have the disgusting habit of spitting; therefore, everything practicable should be done to prevent expectoration on the streets or in other places where the sputum may become dried. This should apply not only to those who are recognized as tuberculous but by every one else, for it is probable that the majority of persons suffering from consumption recover before the disease is detected.

Friends and physicians should do all in their power to dissuade consumptives from marrying.

Children predisposed to consumption should be carefully watched to prevent deterioration in the general health and they should as far as possible be placed in good environment.

The most important thing in the prevention of consumption is attention to the general health, especially of children and young people, so that in case the bacilli find entrance into the system the local power of resistance may be sufficient to prevent harm. The person affected with consumption should, if possible, be immediately removed from a damp or otherwise deleterious atmosphere; the pale, feeble child should be kept in the open air as much as practicable and his diet should be carefully watched to secure proper nutrition. Such persons should be carefully clothed, sleep in well-ventilated rooms, and should not be overworked. The young man or young woman predisposed to consumption, if in school, should be carefully

guarded to prevent excessive application to books and undue confinement. They should be induced to take an abundance of vigorous exercise, and they must be supplied with good food; if away from home they should be especially cautioned to shun poor boarding-houses.

Those having the responsibility for the young should attend at once to the first evidences of impaired nutrition or strength, and should not wait for the development of cough or other suspicious symptoms before they adopt proper methods for the prevention of disease. With the first evidences of the approach of tuberculosis, such as pallor, weakness, malaise, acceleration of the pulse and daily rise in temperature, symptoms often attributed to malaria, the best methods for detecting the disease should be at once adopted, and the measures most calculated to abort or cure the individual case should be instituted at once. Physicians and enlightened laymen should join forces in disseminating among the people a knowledge of the predisposing causes of this disease and of the methods best calculated to prevent or abort it.

In conclusion I would ask, should we have laws requiring all physicians to notify the state authorities whenever they find a patient suffering from consumption? To this I would answer emphatically, No! not only because of the injustice and inhumanity of such a law, but because it could not be enforced.

Shall consumptives be proscribed, sequestered or quarantined? To this I would also answer, No! because at best only a limited number of those so affected could be thus treated, because of the deleterious effects on the patients themselves, because these patients are sick and need sympathy and care rather than banishment, and because it would be cheaper and more humane to banish those who have never been infected by the tubercle bacillus.

DR. H. N. MOYER.—In discussing the subject of the control of tuberculosis, there has been not a little narrow reasoning based on the idea that it was only necessary to catch and kill the germ of tuberculosis in order to stamp out the disease. This conception of the public health duties is reflected in the laws which it is urged should be adopted in the prevention of this malady. They include quarantine, notification, and other equally drastic measures. The essayist, and Dr. Ingals, in the discussion, both point out that such laws are foredoomed to failure. It is not practicable to try to stamp out the disease in this way. All that such laws can possibly do is to educate the people to the view that tuberculosis is to a moderate extent contagious, and that care should be exercised in the disposal of the sputum of these individuals, and that such a patient may be dangerous to those about him. The failure of attempting to stamp out tuberculosis by quarantine and segregation is shown by the efforts which have been made in Hawaii for the past twenty-five years, to banish leprosy. During all this period the Sandwich Islands have tried to enforce a law compelling lepers to live upon an island separate from their friends. Every effort is made to detect cases of leprosy, and, as soon as found, they are sent to the island. Most of those who have studied leprosy on the islands agree that all of these efforts have failed—that leprosy is now quite as common as it ever has been. This is due to the fact that people have no fear of the leprosy; that cases are concealed as long as possible, and that in this class of infections quarantine is of but little value. In diseases in which duration is short and the period of danger of infecting others is comparatively brief, then segregation may be useful. Such is not the case with tuberculosis. The histories of leprosy and tuberculosis are quite parallel.

Control of tuberculosis is to be effected by general hygienic methods which look to improvement of dwellings and food of consumptive patients. Much is to be hoped from the establishment of sanatoria, to which cases may be sent in their incipient stage. It is just as important that hospitals should be located for the care of this trouble as that we have hospitals for the care of those attacked by the acute infections. An individual should not be compelled to work in confined and ill-ventilated quarters until his lungs are so diseased that he can no longer follow his employment. He should be given a chance early in the history of the disease. This, however, should not

be compulsory. Medical men should not be compelled to inform on their patients, but the state should co-operate with them in securing early treatment for tuberculosis.

Legislation must always be behind and not in advance of public opinion. Public health laws which seriously interfere with personal liberty can only be enforced when an active public sentiment is behind them.

DR. A. R. KLEBS—I quite agree with Dr. Moyer that we must have public sanatoria, but how many? In Chicago alone we would require 20,000 beds. It is not possible to seclude all these patients—to take them away from their families, or the workshops or from the schools, but we must look to reducing this danger as much as possible. We must have physicians appointed to inspect schools; if a school inspector finds a child that expectorates an enormous quantity of tubercle bacilli each day, that child must be excluded from the school. The dissemination of tuberculosis in the workshop is another source; there should be an inspection of these people. If they can not be excluded, there must be means furnished by which the expectoration may be sterilized or destroyed. In tuberculosis, the state has very great duties to perform, and it is a matter for careful consideration; radical measures, however, should not be resorted to.

DR. A. R. REYNOLDS—I have never been able to make myself believe that good could be accomplished by insisting on exclusion of tuberculosis. I am of opinion that we already have law enough in the state to insist on tuberculosis being a notifiable disease, but I believe, with the essayist, that it would be a difficult matter to segregate patients. If a patient knows how to take care of himself, he need not be excluded. It is along this line that the laws must be shaped; the state can only help in disseminating this information. I think the public is well informed on these matters at the present time, considering that it is only a few years since the discovery was made; and understand that this is an infectious disease and are eager for information regarding protection against it.

I do not quite agree with Dr. Ingals in his assumption that patients do not wish to be told of their ailment, especially when I consider that 70 per cent. of his patients are consumptives. Although I have no reason to doubt his word, I can scarcely conceive that so large a percentage would shrink from a knowledge of their trouble. It is for this reason that they consult physicians, and if it were not for the skill that physicians have in diagnosing disease, the calling would not be so much sought as it is. In the treatment of consumption they are not altogether successful. This subject can not be discussed too often nor published too widely.

DR. JOS. MATTHEW—I did not suppose that this was the popular side of this subject at the present time, judging from the extended discussion it is receiving and the number who seem to be in favor of excluding tuberculous patients. I have been gratified by the substantial concurrence of opinion expressed by the gentlemen who have discussed the paper this evening.

TRAUMATIC PERFORATIONS OF THE MEMBRANA TYMPANI.*

BY FRANCIS R. PACKARD, M.D.

Aurist to the Out-Patient Department of the Pennsylvania Hospital; Instructor in Laryngology in the University of Pennsylvania; Dean of the Philadelphia Polyclinic, Etc.
PHILADELPHIA.

In 1500 consecutive cases taken from the out-patient record books of the Pennsylvania Hospital there were eleven in which the membrana tympani was ruptured by traumatism. The cases were as follows:

CASE 1.—An Irishman, aged 46 years, a longshoreman, was struck on the head by a hammer weighing 3 pounds, which had fallen forty feet. He sustained a severe lacerated wound of the scalp and was rendered unconscious for some minutes. On recovering consciousness, he was deaf in the left ear and suffered from much roaring noise in it. The left auditory canal con-

tained considerable blood. There was a large laceration in the anterior lower segment of the left membrana tympani. At the end of three weeks' treatment his hearing was normal and he had no tinnitus.

CASE 2.—A longshoreman, five days previous to presenting himself at the dispensary, had fallen thirty feet, sustaining severe contusions of the head and shoulders. Ever since the accident there had been considerable bloody discharge from his left auditory meatus, and he had had much tinnitus in that ear and been totally deaf in it. Examination showed that while sound conduction through the external auditory canal was lost, bone conduction remained normal. There was a large perforation in the central portion of the left membrana tympani. This case pursued a very tedious course. Three months after the patient's first visit the discharge had ceased, but hearing was impaired and there was considerable tinnitus.

CASE 3.—A telegraph operator, aged 39 years, who one week before coming to the dispensary was poking in his left ear with a penholder, suddenly felt something give way and suffered a sharp pain and heard a roaring noise in his left ear, which at once became deaf. Next morning there was much bloody discharge. Examination showed his left external auditory canal full of bloody pus, and after careful cleaning a large ragged perforation was found in the lower posterior portion of the left membrana tympani. The handle of the malleus was fractured, the two fragments being bent on one another at an angle of 45 degrees. This man recovered perfectly in six weeks, the discharge ceasing, tinnitus disappearing and his hearing becoming as sharp as ever. His right membrana tympani was perfectly normal.

CASE 4.—An Italian musician, three weeks before presenting himself at the dispensary, had been struck by a very high sea-wave, while bathing in the surf. It knocked him down and when he arose and got out of the water, he found he was deaf in his left ear, and had much roaring and pain in it. The next day a bloody discharge made its appearance at the left external auditory meatus. Examination revealed a small amount of purulent discharge in the external auditory canal, and a linear, vertical perforation in the lower posterior segment of the membrana tympani. He remained under treatment for some weeks, and when last seen his discharge had stopped, but his hearing remained somewhat impaired, and he still had a slight amount of tinnitus.

CASE 5.—An Italian artist, who had received a blow on the left ear two days before coming to the dispensary, presented himself, complaining of deafness and roaring in the left ear. Examination revealed a considerable bloody muco-purulent discharge in the left external auditory meatus. On removing it, a large tear was visible across the center of the left membrana tympani. This man's discharge ceased in a few weeks, and his hearing was restored and the tinnitus checked.

CASE 6.—A married woman, aged 36 years, presented herself at the dispensary with a history of having received a blow on the left ear one week before. Since then she had been deaf in the left ear, and had had much tinnitus in it, and considerable bloody discharge. The left membrana tympani showed a large perforation, the definite location of which was not obtained at the first examination, and subsequently, through neglect, no note was made of it. This woman pursued a good course to complete restoration of function and cessation of symptoms.

CASE 7.—A laborer presented himself complaining of

*Read before the Philadelphia County Medical Society, Dec. 13, 1899.

pain, deafness and tinnitus in the left ear, from which there was considerable bloody discharge. He said that three days before, while working in a caisson these symptoms had suddenly presented themselves. Being a very unintelligent man, no more definite history could be obtained. There was a large perforation in the center of the membrana tympani. He recovered perfectly in a few weeks, except that when last seen he complained that he still had a sensation of fulness in his left ear.

CASE 8.—A Russian carpenter had been struck on the head eight days before coming to the hospital. No history was obtained as to how or with what he had been struck. He complained of pain and deafness. The right external auditory meatus was full of bloody pus, and there was a large ragged perforation in the right membrana tympani, the exact location of which, however, was not noted. The man did well and was discharged as cured in a few weeks.

CASE 9.—An Italian laborer was struck on the left side of his head with the handle of a pitchfork, one week before coming to the hospital. From that time he complained of pain, deafness and roaring in his left ear. There was a small amount of bloody discharge and a round perforation just posterior to the central portion of the left membrana tympani. Within ten days the discharge had ceased and function was restored.

CASE 10.—An errand boy, sent to the out-patient department from the wards of the hospital, had one week before fallen down an elevator shaft and sustained many lacerated and contused wounds of the scalp. From this time he had pain in the left ear and some deafness and tinnitus. Some bloody purulent discharge was removed from his left external auditory meatus; after this a perforation in the anterior lower segment of the left membrana tympani became visible. Within ten days the discharge and other symptoms had ceased.

CASE 11.—A laborer came to the out-patient department with a history that a heavy bag of corn had dropped on his head four days previously. Since that time his right ear had been the seat of continuous roaring noises, much pain, and considerable discharge. He suffered much from vertigo. After cleansing a considerable quantity of dried blood from the right external auditory canal, a large ragged perforation was revealed in the anterior lower segment of the right membrana tympani. His left membrana tympani was very opaque and considerably retracted. After treatment for about six weeks he was discharged cured, with complete restoration of function.

As to the relative frequency of such lesions compared with other pathologic conditions of the ear, it will be readily seen, by reference to the figures I furnish, and to those given in many statistical articles on the subject, that their number is not very great; this in spite of the fact that the injury is such as to produce symptoms which stand in such immediate relation as to cause and effect, and possess such an alarming significance in the patient's mind as to prompt his early recourse to a physician for relief.

Randall,¹ in a tabulation of 5412 cases of ear disease, found but five traumatic perforations of the ear drum.

Treitel² in 831 cases occurring in thirteen months in Professor Gottslein's clinic, found 18 of traumatic perforation.

Politzer³ says that traumatic lesions of the drum may be produced: 1. by direct penetration of a foreign body into the membrana tympani; 2. by the extension of a fracture of the cranial bones to the membrane; 3. by a sudden condensation of air in the external meatus or in

the tympanic cavity, more rarely by a rapid rarefaction of the external air. He gives the statistics compiled by Brigade Surgeon Chimani, from 5041 cases of ear trouble. Of these 54 were cases of traumatic perforation of the drum. They were caused in 38 cases by falls on the head, in 3 cases by a kick from a horse on the head, in 2 cases by strokes upon the head with wooden clubs, in 2 cases by the playing of brass instruments (signal trumpet and helicon), in 2 cases by the report of a loaded gun in the immediate neighborhood of the ear, and in 1 case by a fall into the water from a considerable height."

G. P. Field⁴ analyzed 400 perforations of the membrana tympani and found that eighty of them could be attributed to traumatism. In a number of instances the perforations were double, so that the number of cases does not correspond to the number of perforations.

As to the causes producing these traumatic perforations, he found them to be: Falls on the head, 11 perforations; other injuries to head, 30; boxing ears, 8; from other blows on head, 16; penholder in ear, 1; hair-pin in ear, 1; foreign bodies in ear, 4; kick of a horse, 1; blows from cricket balls, 2; injury from football, 1; fall of flower pot on head, 1; violent sneezing, 2; pouring turpentine in ears, 2; pouring urine in ear, 1; syringing by a doctor, 1; scald of ear, 1; silver nitrate used by patient in ear, 1.

The causes of the traumatic perforations in the cases I report were as follows: Struck by weight falling from a height, 2; fall upon head, 2; the result of introducing a foreign body, 1; struck by wave while bathing, 1; blow on ear—fist—2; working in caisson, 1; struck with weapon, 1; blow on head, but from what not ascertainable, 1.

But one of the cases which I report was the result of direct penetration of the membrana tympani by the introduction of a foreign body. This was Case 2 who penetrated his drum with a penholder with which he was scratching his ear.

Sajous⁵ reports two cases from Turnbull's clinic, in which the perforation resulted from this cause. In one there was a fracture of the malleus similar to the one seen in mine, and appended to the article are references to cases of the same nature accompanied by a like fracture reported by Meniere,⁶ Politzer,⁷ R. F. Weir,⁸ and Hinton,⁹ with mention of a short notice of such a case with specimen in Toyne's collection, now in the Hunterian Museum of the College of Surgeons of London.

Gorham Bacon¹⁰ reports a case of perforation of the membrana tympani by the twig of a tree, which occurred in a man who was walking through some woods. He also¹¹ reports two other cases, one due to puncture with a piece of stick, the other occurred whilst scratching the ear with a pin.

A. H. Nott¹² reports the case of a man whose left membrana tympani was ruptured by the penetration through it of an umbrella rib. The injury resulted in the entire loss of the sense of taste on the left side of his tongue.

A most interesting case from a medicolegal point of view is reported by A. S. Barling.¹³ A man, while in a brawl, was stabbed in the right ear with a knife. The knife blade was so very thin that it caused no external wound, but produced an incised one of the membrana tympani, one-fifth of an inch long, just posterior to the handle of the malleus; this wound was only found after careful examination. There was considerable hemorrhage. At first a defense was made that no stabbing

had been done, although the victim insisted that his assailant had a knife in his hand. Finally, after some interval of time, the knife was found near the scene of the assault, where it had been thrown away by the aggressor as soon as he had done the stabbing.

Urbautschitsch¹⁴ reports a case in which a man attempted suicide by shooting himself in the right temple. The bullet could be detected through the external auditory meatus in the tympanic cavity. It was extracted by chiseling away the surrounding bony structures.

A. M. Shield¹⁵ saw an interesting case in which molten lead had been splashed over the side of the patient's head and some had run into his right external auditory meatus, almost entirely filling his tympanic cavity, some even entering the Eustachian tube. The lead was removed by filling the ear with liquid mercury and allowing it to remain in the ear for sixteen hours, when the softened mass was easily syringed out.

Among other interesting cases of penetration of the membrana tympani by foreign bodies introduced through the external auditory canal may be mentioned those reported by Mandelstamm,¹⁶ Treitel,¹⁷ F. L. Jack,¹⁸ Barr,¹⁹ Tangeman,²⁰ Braislen,²¹ L. S. Somers²² and A. H. R. Stewart.²³

Oftentimes the drum is perforated during clumsy efforts at extraction, as in one of Bacon's cases, and not by the unaided impact of the foreign body.

Cases of rupture of the membrana tympani due to syringing the ear are not rare. Such cases are reported by S. Latimer Phillips²⁴ and Sexton.²⁵

In all the above-mentioned the foreign body causing the perforation was introduced through the external auditory canal. Cases have been reported, however, in which the membrana tympani was perforated by a foreign body entering the tympanum through the Eustachian tube. P. Hoover²⁶ reports such a case in a child 2 years old, who swallowed a pin, which subsequently emerged point first, through the membrana tympani. The child had been given an emetic, and it was probably forced into the Eustachian tube by the effort of vomiting. L. W. Reynolds²⁷ reports a curious case occurring in a woman who was suffering from the vomiting of pregnancy, and in her expulsive efforts ejected a number of round worms from her mouth, nostrils and both ears. The drums were torn and free bleeding from both external auditory meati occurred.

None of the cases in the series I report were due to extension of a fracture of the cranial bones. Cases of this nature are reported by J. M. Ray,²⁸ Gorham Bacon,²⁹ Cornelius Williams,³⁰ J. D. Rushmore,³¹ Scheibe,³² A. Alt³³ and R. Barclay.³⁴

In the 11 cases which I report there were 4 patients with perforation of the membrana tympani due to the sudden condensation or rarefaction of air in the external auditory meatus, beyond a doubt. Three more could be with probability assigned to this cause. One of the latter had been struck on the side of the head by a bag of corn falling some distance, another had been struck in a quarrel, most likely by his opponent's fist, the third had received a blow directly over the ear from the blunt handle of a pitchfork. Of the 4 undoubted cases, 1 was the result of the impact of water, 1 resulted from working in a caisson, and 2 were the results of blows with the fist.

Probably the latter is the commonest cause of perforation due to sudden condensation of air in the external auditory meatus. In the cases which result from it the lesion is usually unilateral and found in the left membrana tympani, because the person who strikes does so

with his right hand as a rule. In former days, when boxing the ears was a popular manner of administering reproof in school, the number of cases of perforation resulting from this form of punishment is said to have been very large. One recalls the method of punishing school boys by boxing both sides of the head simultaneously with two books, referred to by Thackeray in his *Roundabout Paper* entitled "De Juvenile." In Chimani's 38 cases of rupture of the ear drum due to blows with the fist, 36 were in the left ear, only two in the right.

Dalby³⁵ says that the injuries resulting from boxing ears are of three kinds: 1. The hearing may be immediately damaged without injury to the membrana tympani, the loss of hearing being due to injury of nervous structures. 2. The membrana tympani may be ruptured, the perforations usually assuming the form of a vertical slit which, if left alone, heals in a few days, though occasionally suppuration is seen. 3. Without rupturing the membrana tympani an acute otitis media may occur, with possible ultimate perforation of the membrana tympani and loss of hearing.

Cases resulting from blows with the fist upon the ear are reported by C. R. Agnew,³⁶ Dills,³⁷ Core,³⁸ Gorham Bacon,³⁹ Treitel,⁴⁰ H. Richards,⁴¹ W. H. R. Stewart,⁴² A. A. Hubbell,⁴³ Fetterhoff,⁴⁴ Braislin⁴⁵ and R. Barclay.⁴⁶ C. R. Agnew and D. Webster⁴⁷ and A. H. Cheate⁴⁸ report cases of double perforation of the membrana tympani resulting from blows with the fist.

Cases of rupture of the tympanic membrane from the condensation of air produced by discharge of artillery or the explosion of powder are reported by Sexton,⁴⁹ Bates,⁵⁰ and C. C. Colles.⁵¹ C. H. Alden⁵² reports a case of repeated ruptures of the membrana tympani occurring in an artilleryman, finally resulting in total deafness, requiring his discharge from the service. Moos⁵³ reports one of a chemist who was working with some chlorophthalic ether which exploded. Both of his membranae tympani were ruptured as a consequence, and he developed a suppurative otitis media.

Cases of traumatic perforations of the membrana tympani as the result of working in caissons or diving bells have been reported by Moos,⁵⁴ Sexton,⁵⁵ G. E. Bellows.⁵⁶

Two interesting cases of loss of hearing due to condensation of air in the external auditory canal, by the impact of water in diving, are reported by H. Augustus Wilson.⁵⁷

Of air pressure on the inner surface of the membrana tympani causing rupture, I have gathered three cases: A. G. Welsford⁵⁸ reports a man who suffered from chronic bronchitis, and during a violent coughing spell ruptured both ear drums. S. L. Phillips⁵⁹ patient with perforation due to syringing the ear, subsequently sustained another rupture of the same drum while blowing his nose. C. R. Agnew⁶⁰ reports the case of a man who ruptured his left membrana tympani while blowing his nose. Agnew thinks there was undoubtedly pre-existing disease of the membrana tympani, but the man positively denied ever having noticed any previous trouble with his ear. E. D. Clark⁶¹ reports one in which a man was struck by lightning, sustaining burns of the left side of the head, the neck and breast. Some days after the accident the ear began discharging pus, and an examination revealed a perforation in the left membrana tympani. The auricle had not been injured in any way. The difficulty in this case lies in deciding whether concussion caused the perforation, or whether it was due to a burn produced by the lightning. The perforation

healed, but the man remained deaf and suffered much from tinnitus. Ludewig⁶² reports a case in which the drum membrane was undoubtedly ruptured by the shock of the lightning bolt.

The location of the perforation in the drum membrane varies with the cause producing it. In those cases due to penetration by a foreign body, Politzer states that it is more frequently in the posterior than in the anterior portion of the drum; when due to extension of a fracture of the cranial bones, the perforation extends fissure-like from the superior or anterior wall of the meatus, and, if resulting from sudden condensation of air in the external auditory meatus, it presents itself as a gaping orifice, more frequently in the posterior portion of the membrane. Treitel⁶³ carefully studied eighteen cases of traumatic perforation, in 11 of which the perforation was in the inferior half; of these, 8 were in the anterior inferior portion, and 3 in the posterior inferior portion, from which he concludes that the inferior and anterior portions constitutes the elected region. This statement agrees with Schwartze, but differs from Hasenstein, who considers a traumatic perforation in front of the malleus as very rare. Treitel makes the statement, which is now acceded to by most authorities, that rupture of the drum from sudden condensation of air can occur in the perfectly healthy drum and with a free Eustachian tube, but that it is more apt to occur in persons whose Eustachian tube is not perfectly patulous or who have ear drums which have been the site of previous pathologic changes. In Chimani's 38 cases of rupture due to boxes on the ear, 27 were in the posterior inferior quadrant, 9 in front of and below the malleus, 2 in the posterior superior portion of the membrane.

As to the ultimate termination of such injuries, if the perforation is uncomplicated with injury to the ossicles or labyrinth, the prognosis is good, the perforation usually healing. In Nott's case, which was followed by loss of taste on the injured side, there was evidently accompanying injury to the chorda tympani. All authorities agree that the best possible treatment is to leave the handling of the case to Nature as far as possible. In those I report a little clean, dry cotton was kept constantly in the external auditory meatus, and no attempt made to do anything beyond the gentlest possible cleansing in cases where there was much discharge. In Chimani's 38 cases of perforation due to boxing the ears, perfect recovery without functional disturbance occurred in 34; in 4 only complete cure was effected.

Cases of traumatic perforation of the drum present several points of medicolegal importance: 1, to determine that the rupture is due to traumatism; 2, to determine the amount of permanent functional or organic damage wrought by the injury, if it exists.

In the 1500 cases from the books of the out-patient department of the Pennsylvania Hospital, there were 3 in which it was claimed that the patient's ear condition resulted from an injury. One was a man who claimed to have fallen from a trolley car. He had chronic suppurative inflammation of the ear, which, he said, had only begun to suppurate since the accident. That this was chronic was proved by the fact that the ossicles were necrosed, and, moreover, there was evidence of old mastoid trouble, notwithstanding the fact that the injury was said to have been sustained only a few days before his visit to the hospital. The other two cases in which injury was claimed were both school children, whose ears were said to have been boxed, but in whom careful examination and questioning elicited history of previous suppuration. Politzer says that the most de-

finite evidence of the traumatic origin of a perforation is its rapid cicatrization. The only way in which the amount of functional disturbance can be determined is by repeated careful tests of the hearing power by the usual methods employed for that purpose. Much care must be taken in these tests to detect simulated deafness, as in many of these cases the examination is required to determine the claims for damages of the patient. It must always be remembered that the amount of disturbance of hearing bears but little proportion to the amount of destruction of drum tissue. Patients are frequently seen in aural clinics who have suffered complete destruction of the drum and yet retain their hearing to a remarkable extent. In cases of traumatic perforation which are accompanied by labyrinthine involvement the amount of labyrinth mischief will be the chief guide as to the functional disturbance which the patient's organ of hearing has sustained.

I desire to express my thanks to Dr. George C. Harlan for his kindness in permitting me to avail myself of the records of the Pennsylvania Hospital.

MANY HAVE a history of specific disease in early life, with no symptoms after the first two or three years following the initial lesion, and then are returned in late life.—*A. Nevins Hyde.*

THE USE OF ADRENAL SUBSTANCE IN THE TREATMENT OF ASTHMA.

BY SOLOMON SOLIS-COHEN, M.D.

Professor of Medicine and Therapeutics in the Philadelphia Polyclinic;
Clinical-Lecturer on Medicine, Jefferson Medical College; Physician
to the Philadelphia and Rush Hospitals; Consulting Physician
to the Jewish Hospital, etc.
PHILADELPHIA.

The experience I have to submit in the use of adrenal substance in this particular connection, is of but little importance, except as a link in a chain of studies.

The synthesis of disease—i. e., the manner in which syndrome groups are built up, and the reason of their association—is beginning to attract the attention of students who recognize that pathology is something more than morbid anatomy or bacteriology.

That wonderful system of compensations found throughout all Nature, the balanced action of contending forces producing mobile or stable equilibrium, and the motion that takes place in the direction of an inferior force, are not merely problems of physics, but also of biology, and of that special branch of biology which deals with the disturbances we call disease. The disruption of a planet, the aberration of a comet from its calculated orbit, may differ in magnitude from the destruction of an animal cell or the aberrant action of the heart and vessels, but essentially the same forces are at work. Provocatives in such disturbances are often forces of the environment, but sometimes the disturbing elements arise within the animal organism itself. Often the nature, and nearly always the order—for in Nature there is always order in disorder—of succession of these disturbances depends on the inherent properties of the organism attacked rather than on the attacking agent—be this microbial, chemical, or less tangible than either.

Within the human economy, a constant struggle of opposing activities—or perhaps it would be more accurate to say tendencies to action—results in orderly growth, development and function. The agents of these activities or tendencies are cells and their products. Deficiency or excess may lead directly to disorder or render order so unstable that it is easily overthrown by slight addition to the forces acting in some special direction.

We have not yet learned to realize the large part that the activities of the blood-vessels may take in determining symptomatology and lesions. A and B may both be exposed to the same storm, and the same incidence of pneumococci, yet A may escape and B suffer with lobar pneumonia. Why? Possibly, even probably, because B's vascular tone is more readily overthrown than A's, because the branches of his bronchial arteries are through permanent or temporary relations of vasomotor control, more readily paralyzed, permitting congestion to occur, and favorable culture conditions for the cocci to be established. But the same instability of vascular tone which, under certain conditions, leads to the development of pneumonia may, in other degrees and under other conditions of internal metabolism and of incidence of external forces, lead to other morbid phenomena, perhaps to Graves' disease; or will modify the symptomatology of visceral diseases or infectious fevers; or will be manifest in certain so-called idiosyncrasies to drugs or articles of diet. Thus a varied and apparently unrelated semeiology may be correlated with some structural, functional, or metabolic condition peculiar to the individual or, more frequently, to classes of men; and these peculiarities may be acquired or congenital.

On the other hand, a certain symptom-complex, or symptoms-complex closely similar, may arise in differ-

ent individuals, not only from different causes but even by apparently opposed mechanisms. Thus we can distinguish between two varieties of hemicrania, the one due to vascular spasm—anemic migraine—the other to vascular paresis—congestive migraine; the syndrome accordingly being relieved by nitrites and aggravated by adrenalsubstance, if spasmodic; or aggravated by nitrites and relieved by adrenal substance, if parietic.

Similarly I look on asthma, not as a definite nosologic entity, but as a morbid condition symptomatic in its nature and associated with various and varying pathologic processes and physical states. Every form of dyspnea, however, can not properly be called asthmatic, even those forms that by common consent have come to be designated as cardiac asthma and renal asthma; and while the former is sometimes susceptible of relief through the action of adrenal substance on the heart and vessels, I shall not in this paper refer to such cases.

Without restricting the term asthma, as is the tendency of most modern authors, to the typical paroxysm of dyspnea, arising suddenly and terminating with equal suddenness, it is, nevertheless, distinctly a paroxysmal disorder, arising independently of gross lesions of the circulatory, respiratory or excretory systems; although it may be associated with any or all of these, and be the more readily provoked through such association.

The disputes over its pathology are probably due to one-sided studies of one or another variety. Basing my opinion purely on clinical studies, as the question could scarcely be decided post-mortem, I have no doubt that in certain cases of asthma the immediate mechanism of the paroxysm is bronchial spasm, not only muscular but also frequently vascular; though perhaps in many cases of vascular spasm the pulmonary rather than the bronchial vessels are affected. I have equally no doubt that in other cases the immediate mechanism of the paroxysm is dependent on irregular turgescence of the bronchial mucosa; and equally no doubt that in some cases turgescence of the bronchial mucosa is preceded, accompanied or succeeded by inflammatory or subinflammatory conditions, associated with exudation into the bronchioles. Again we find, as an underlying diathesis in some patients, gout or, if that term be preferred, lithemia; in others rheumatism. In some patients, but by no means all, nasal abnormalities exist. They may be causative or merely coincident; the most intractable case I have had was in a man from whom I removed a large nasal polyp and in whom, although the relief to nasal breathing was marked, the asthma persisted. In other cases abnormalities of the upper pharynx, of the lower pharynx, of the tongue, of the thyroid gland are found. In one case, referred to me by Dr. Weir Mitchell, there was tonic spasm of one vocal band apparently due to pressure by a hardened right apex upon the recurrent laryngeal nerve. In this case several nasal polypi had been removed by the late Dr. Harrison Allen without relief to the tendency to asthmatic paroxysms. Many patients subject to asthma are highly neurotic and some have hay-fever; the asthma occurring both in association with this latter syndrome and during times of freedom from nasal and ocular symptoms. In other cases there is associated with the tendency to paroxysmal dyspnea, a paroxysmal albuminuria; the latter occurring both during the period of respiratory distress and during the intervals of freedom, although in some instances they may seem to alternate.

In this outline I have not attempted to exhaust the list of associations, but merely to indicate the great variety of the conditions under which asthma may be manifested

as one of a group of symptoms, or even as the single prominent symptom of a general disorder.

Adrenal substance is not applicable to the treatment of all asthmatic patients or to all varieties of asthma. It is applicable in the treatment of some of those in whom this affection is associated with other manifestations of what I have elsewhere termed vasomotor ataxia,¹ of the relaxing variety. Under this head I include, among others, patients who are subject to urticaria or in whom factitious urticaria may be readily produced; those who are, vascularily, extremely sensitive to slight changes in weather and climate, or who exhibit peculiar idiosyncrasies in this respect, as in their reaction to drugs; those whose cardiovascular balance is easily disturbed by emotion or by digestive disorder or other slight intoxication; some hay-fever subjects; persons subject to congestive hemicrania; and those who show signs of renal leakage, either by intermittent albuminuria, or by the occasional presence of red blood-cells in the urine, without decided hematuria and without the persistent presence of tube casts; in whom, therefore, we are dealing with what may be termed functional rather than organic renal lesion. By the apparent paradox of "functional lesion," I do not mean to imply the absence of structural change—on the contrary, to indicate that there is a distinct structural—or perhaps it would be better to say "compositional"—abnormality, not sufficiently gross to be detected by our present methods of research. But this abnormality in the great class of patients herewith included is congenital and is thus, as it were, normal to the individual.

Whether it be metabolic or of other nature in ultimate analysis is a subject too recondite for present discussion. Biochemistry and biophysics are neither sufficiently advanced to answer. Clinically, however, the fault is found in the vascular taxis.

Believing that in such cases the immediate mechanism of the obstruction to respiration, manifested by the asthmatic paroxysm, is an irregular swelling of the bronchial mucosa, allied to the condition of circumscribed edema—angioneurotic edema—or urticaria, and that by increasing the vascular tone through the administration of that substance which Nature seems to have designed for its maintenance, we might prevent such attacks, I have, during the last few years, used adrenal substance in the treatment of such patients. It has in but one dubious instance served to cut short a paroxysm, though it has occasionally mitigated distress in greater or less degree. It has, however, been useful in averting the recurrence of paroxysms and in finally bringing about a state of freedom from fear of their recurrence. I, therefore, speak of the use of adrenal substance not as "a treatment for asthma" but as a measure "applicable in the treatment of certain cases" of that affection. Physicians accustomed to exactitude in language will readily discern the difference between these methods of statement.

As illustrative both of the usefulness and of the limits of usefulness of this agent in the management of certain cases of asthma, the following case may be given in outline:

Miss X. Y. Z., aged 22 years, was first seen in consultation at Atlantic City, in June, 1897. She was then confined to bed with constant dyspnea, aggravated in paroxysms, the paroxysms occurring at night and relieved after an hour or two of orthopnea by critical expectoration of large quantities of a thin watery fluid. During the day this expectoration would continue in less degree, but would cease during sleep. Sleep would be broken in on by the asthmatic paroxysm and return with

the re-establishment of the discharge. Attacks of excessive rapidity of the heart and paroxysms of distressing sweating were also complained of. It was stated that this condition had followed an attack of influenza which occurred during the preceding February, since which time the patient had not been out of bed. She was feeble, nervous and apparently anemic, but not hysterical. The temperature ranged between 99 and 100.5 F., irregularly. Physical examination gave hyperresonance of the upper portion of the right lung; normal resonance elsewhere, and diffuse mucous, sonorous and sibilant râles in all portions of the chest. The heart was feeble and rapid, rate 96. No murmur was heard. Precordial dulness was perhaps slightly enlarged. This was during a period of comparative quiescence, the respirations being shallow and slightly accelerated to 24 to the minute, and considerable subjective distress being complained of, but no asthmatic paroxysm being manifested. Dermographism was readily produced; the nails showed typical red crescents and were of a peculiar lemon tint not due to artificial coloring. The father of the patient was said to have died of asthma and tuberculosis, following pneumonia. At that time, eight years previously, the patient had suffered similarly to the present attack but not for so long a period. Examination of the patient's sputum for tubercle bacilli had not been made during either attack. The urine was free from albumin.

Apart from diet, the treatment tentatively advised was the injection of very small doses of hyoscin hydrobromate with morphin and strychnin at night, for at most three consecutive nights, and during the day the use of a mixture containing ammonium bromid. Iron preparations and syrup of hydriodic acid had been used without much good effect. Slight relief followed. The patient was brought to Philadelphia in July, where she was placed under the care of my friend Dr. Eshner, with whom I again saw her in consultation. Examination of the urine now showed the absence of albumin; examination of the sputum showed the absence of tubercle bacilli, and examination of the blood showed reduction of red corpuscles to about 70 per cent. and hemoglobin to about 60 per cent. of normal.

The treatment proved to be most difficult. Apart from hygienic and general tonic treatment, many approved remedies were used without benefit. Some of the drugs that gave greater or less relief may be mentioned. Atropin checked sweating and expectoration temporarily, but the symptoms recurred in greater degree on its withdrawal. Picrotoxin was employed on the theory that the paroxysms were due to vasomotor paresis with turgescence of the bronchial mucosa. This gave some relief, but recovery seemed still distant. Thymus gland substance gave better results, but asthmatic paroxysms still recurred. Albumin appeared in the urine. It was then determined to use adrenal substance. Burroughs & Wellcome's tablets, 5 grains each, were prescribed once daily, then twice, then three times daily, and finally the patient for a short time took 90 grains daily. A striking improvement shortly became manifest. The constant dyspnea first disappeared, then the paroxysmal nocturnal attacks became less frequent and less severe. Recovery was not rapid but was continuous.

In October the patient was able to go out of doors, and inhalations of compressed air with exhalations into rarefied air were then added to the treatment for its effect as a method of neuromuscular gymnastics, as also for direct effect on the blood-vessels at fault. The albuminuria noted was intermittent and disappeared after ten months. Since this time the patient has had no recur-

¹ Am. Jour. Med. Sci., February, 1894.

rence of symptoms similar to those of the original attack; though being allowed to go without medicine on account of the improved condition, there is at times recurrence of albuminuria, which quickly disappears under treatment with adrenal extract; and once there was a brief attack of dyspnea with asthmatic exacerbation, which likewise yielded quickly to treatment. While it is obvious that dependence in this case was not placed alone on the adrenal substance, yet its marked effect in heightening the tone of the blood-vessels, in diminishing and finally checking the peculiar expectation, and its similar effect on the night sweats, favor the belief that it was an active agent in the control of the asthmatic symptoms. The tachycardial paroxysms had ceased before it was administered—under the influence of rest, medication, and allaying of fear.

In other patients the result has been about the same as that already narrated. Hyosein, morphin and strychnin have been given for immediate control of paroxysms, sometimes aspidospermin or other appropriate remedy for the quick relief of dyspnea, and adrenal extract for control of the underlying condition.

It would be wearisome, as well as useless, to detail histories. Apart from so-called hay-asthma—which is another story and belongs to another speaker—success has been reached only in those cases, about twelve in the course of a little more than two years, in which from the crescentic markings on the nails, from the tendency of the hands to excessive color changes, or to sweating on slight temperature variations, from the facility with which dermatographism or factitious urticaria could be produced, from the enlargement of the thyroid gland, from the tendency to cardiac palpitation, or even tachycardia, or from the occurrence of other vasomotor crises, such as migraine or angioneurotic edema or nervous vomiting, or if necessary from the *experimentum crucis* of increased distress on inhalation of amyl nitrite—one could recognize the tendency of the subject to loss of control of vascular tone on slight provocation. In one case the paroxysm of asthma—or perhaps of obstructive dyspnea—was preceded by angioneurotic swelling of the tongue, and when this was reduced by the prompt local application of suprarenal extract, the paroxysm was averted or modified in severity. It was interesting to note that in this case the swelling of the tongue was not always followed by dyspnea, but sometimes by a gastric crisis, of pain, or less frequently, vomiting of a thin, tasteless fluid. I never saw these attacks, and, therefore, rely entirely on the description of the patient and her physician. The circumscribed swelling of the tongue I saw in my office, but it was promptly reduced by suprarenal substance locally, and no other manifestation followed.

I believe that we have in this substance a decided addition to therapeutic resources; quite active when used locally, and hence to be remembered in the prompt treatment of urticaria or edema of the upper air-passages—and less active, but still definitely useful by internal administration in controlling urticaria or circumscribed edema or similar condition affecting the bronchial mucosa.

It is not a specific for asthma. It is without good influence, perhaps capable of bad influence, on cases that are really spasmodic; that is, due to contraction of the bronchial muscles. But it is of definite use in that perhaps smaller number of cases of asthma in which, as I have indicated, the paroxysm is but one other manifestation of a congenital fault of structure or of metabolism, affecting the vasomotor system and thus permitting the

cardiovascular balance, and especially the tonicity of the blood-vessels, to be readily overturned by exciting causes that would have but slight, if any, effect on other individuals. In such cases a more or less continuous administration of adrenal substance, in sufficient quantity to maintain the vascular tone, will act as a preventive, enabling the reactive forces of the individual to combat more successfully the toxins of internal and external origin, the emotional, meteorologic, thermal, and climatic influences, and other sources of disturbance that ordinarily provoke the paroxysm.

As to its dosage, the rule is that of Professor Ellerslie Wallace for bleeding in puerperal eclampsia—"Enough." There is great difference in cases and in individuals. Beginning with small doses frequently repeated, e. g., 1 grain every hour or every two hours, or with a moderate dose, say 5 grains, once or twice daily, we learn the tolerance of the individual, the tractability or intractability of the symptoms, and regulate accordingly. I have given as few as 3 and as many as 90 grains of the desiccated gland substance in the twenty-four hours. Five or 10 grains every second or third hour during waking hours is a fair dose. In some cases, however, the unnecessary animal substances retained in the preparation give rise to diarrhea with offensive discharges. If we could have the active agent alone our therapy would be much more definite.

What the active agent is and how much or how little of that active agent is absorbed, I must leave to laboratory students to determine. Clinically I have watched closely and critically enough to satisfy myself that neither the susceptibility of patients to suggestion, nor the activity of the observer's imagination are sufficient in themselves to account for the whole of the results.

ETIOLOGIC STUDIES ON NEUROSES OF PERIPHERAL ORIGIN.*

BY H. GRADLE, M.D.
CHICAGO.

Medical opinion concerning the frequency and importance of the so-called reflex neuroses has fluctuated considerably within past years. The claims made by American ophthalmologists regarding the effects of eye strain, the startling results announced by Hack and his followers concerning the cure of reflexes of intranasal origin and to some extent, too, the views of gynecologists as regards the etiologic rôle of pelvic anomalies in the production of nervous symptoms have made "reflex neuroses" a topic of the day. But criticism is beginning to show how and wherein some of the enthusiasts have erred, and perhaps an undue skepticism is beginning to prevail. One of our members has not inaptly characterized the trend of medical opinion as "the passing of the reflex." Yet by properly defining the term "neuroses of peripheral origin" it can be made to include a great deal of human suffering, which may be relieved by the knowledge of its etiology.

I do not consider the name "reflex neurosis" an appropriate one, since the definition of "reflex" in physiology implies the motor or centrifugal response of a nerve-center to an impulse coming through a sensory nerve.

Hence, most of the neuroses of peripheral origin do not come under this definition. Even when a motor phenomenon does occur, it depends on the influence which the peripheral stimulus exerts on the excitability of the nerve-center, and is generally not a mere exaggeration of a physiologic reflex.

*Read before the Chicago Neurological Society, Jan. 18, 1900.

The peripheral origin of a neurosis in a given case may be suggested by the coexistence of a peripheral lesion or anomaly likely to cause it, especially when a clear history of aggravation can be obtained under circumstances which can intensify the peripheral stimulus, for instance, when a headache is brought on by use of the eyes or when an attack of asthma follows nasal irritation. But the absolute proof can only be furnished by the prompt cessation of the neurosis after elimination of the peripheral influence. If a relapse occurs, as it sometimes does in asthma of nasal origin, and it can be shown that the peripheral condition had returned because of its incomplete removal, the etiologic relationship is only more firmly established.

As a basis for further discussion I shall hence refer only to such instances in which this convincing proof exists, either in cases of my own observation or in well-recorded reports in literature. The following are well substantiated examples of neuroses of peripheral origin.

Errors of refraction and accommodation may lead to headache, a feeling of pressure in the head, less frequently to vertigo, and even nausea. Astigmatism may bring on periodic attacks of migraine. Suppuration of the nasal passages or accessory sinuses and also intranasal tumors—polypi—may cause headaches, either constant or periodic neuralgic pains, oppression in the head, asthmatic attacks and circulatory and cardiac disturbances.

In some instances these neuroses are started from the nasal lining even in the absence of any other lesion except enlargement and liability to turgescence of the submucous cavernous tissue. Pharyngeal disease may cause cough and laryngeal spasms. Dental disease may induce headache and neuralgia. Outside of my own sphere of observation, but scarcely subject to doubt, is the backache of pelvic disorders.

While the actuality of all these instances can not but be admitted even by skeptics on the subject of "reflex neuroses," the term "neuroses" may be objected to as improper. But we understand by that term any nervous disturbance not dependent on demonstrable lesions in the nervous system and not the normal consequence or symptom of disease of a peripheral organ, and hence the term "neurosis" is proper in the present place.

Much has been described under the head of reflex neuroses that can be severely criticised. Epileptoid convulsions have been reported as of "reflex" origin by many authors. Some of their observations are undoubtedly correct, but not all and not even many of them. After all, the number of cases of spasms permanently stopped by the excision of peripheral cicatrices is very small, although such instances have occurred. Similarly there are a few reports in which years have elapsed without the recurrence of epileptoid fits after the fitting of proper glasses or the removal of nasal polypi, but they can be counted on the fingers. Personally I have seen *petit mal* with laryngeal spasm in an infant cease promptly after a duration of many weeks, on curing a pharyngitis by nitrate of silver application. As this occurred twenty years ago, and the patient—now a young man—has never had another attack, I consider this a well-established instance of epilepsy of peripheral origin—but it is the only case I have ever observed.

Similarly we must admit the symptom-group of exophthalmic goiter as a possible but excessively rare neurosis of peripheral origin. There are five well-observed instances on record of total disappearance of all symptoms of Graves' disease after intranasal treatment, while

in one other the symptoms of this disease came on immediately after a nasal cauterization.

Chorea, too, has often been described as a neurosis of ocular origin. But I can not say that I have seen any reports which to me seem convincing proof of this assertion. I have never seen chorea influenced by the optic correction of an ocular defect, although I have given glasses for good reasons to many such patients at an early period of the affection. I suspect, however, that clonic blepharospasm, really a chorea or habit spasm of the eyelids and adjoining muscles, may be started by disease of the conjunctiva. I have seen it relatively often in connection with chronic follicular conjunctivitis, and have often found it disappearing gradually after treating the lids. But I have always advised other measures as well, and besides, neither the cure of the conjunctival lesion nor the cessation of the twitching could be obtained with sufficient promptness to permit any absolutely positive conclusion. Jacobi's statement regarding the relation of facial chorea to nasal and pharyngeal disease I am also inclined to admit as plausible, but can not consider it definitely proved either by his nor by my own confirmatory observations.

Finally, I wish to dispose of the often reiterated claim that neurasthenia in a given case was cured by spectacles or some operation, be it on the eye muscles or the perineum or uterus, and that it was hence of "reflex" origin. There can be no doubt that a neurasthenic patient may be made comfortable by removing any peripheral source of annoyance, but that is not a cure of his neurasthenia. The intrinsic weakness of the nervous system, which we consider the basis of neurasthenia, is not removed in such a case. One of its manifestations is merely suppressed, perhaps the only one at the time, and the patient is satisfied. But the nervous system is still in the same condition as it was before, ready again to break down, so to speak, under a condition which the normal subject tolerates, although the chance for an ultimate recovery, if that be possible at all, is, of course, improved by eliminating all curable pains. It will be my effort throughout the further part of this paper to show that peripheral lesions are not the cause of neurasthenia, but lead to "reflex" neuroses only in those who are in a certain sense neurasthenic for other reasons.

For the study of the various factors which contribute to the occurrence of neuroses of peripheral origin, patients with optic anomalies furnish the best material since the degree of the peripheral "cause" can be stated numerically and since spectacles furnish such a convenient method of promptly or, if desired, temporarily eliminating the peripheral starting point.

The case-book of every oculist can supply the records of the most variable amount and extent of neuroses of the most variable duration due to eye strain and promptly stopped by proper glasses. But, on the other hand, school and military statistics show how very prevalent are the same refractive errors, without causing nervous symptoms. Indeed, every individual, except a myope, will undergo eye strain when he attempts to use his eyes at short range after age has curtailed his power of accommodation. Sooner or later astigmatism, hyperopia and presbyopia cause eye strain in every individual afflicted, manifesting itself by blurring, inability to read or work and a feeling of painful fatigue in the eyes on persisting in their use. There is thus a minimum or "normal" amount of asthenopia inseparably connected with every degree of optic error. But on the other hand, among the patients who call on us many present an exaggerated amount of asthenopic discom-

fort out of proportion to the causative strain of the ciliary muscle. Observation also shows that a certain degree of hyperopia or astigmatism—.75 or even up to 1.5 D. variable with age—may exist without causing any annoyance whatsoever to vigorous subjects, while many of our patients complain bitterly in consequence of optic errors of even less degree. But of the cases of "normal" eye strain oculists see but a very small proportion; these people mostly go to the spectacle dealer and buy glasses which give them satisfaction. Hence, it seems as if some ophthalmic writers, especially those of the Philadelphia school, were familiar with only those manifestations which may be termed exaggerated asthenopia.

To an unbiased observer, it must be apparent that if one set of subjects tolerate minor optic defects without distress, or complain only of discomfort in the eye from higher degree of ametropia, while another set of patients get distressing nervous symptoms from the same peripheral disturbances, there must be other factors besides the eye strain involved in the latter case. On comparing these two classes of people as regards their general health and physical condition, it is apparent that the former represent on the whole the healthy type, while the latter are sufferers in more ways than one. The neurologist would recognize among them a large proportion of neurasthenics, or at least subjects predisposed to neurotic troubles. By closer analysis it can be learned that but very few of those who suffer to an unproportionate extent from an existing optic anomaly have not been subject to influences which reduce the stability of the nervous system.

Prominent among the pernicious influences is heredity. Whenever I had opportunity to enter into the family history I have found the neuropathic taint existing in a fair proportion of instances. This I have also found true very often in neuroses of nasal origin. It is not, however, the history of the more serious nervous diseases which we obtain, but rather the evidence of "nervousness" in its less grave manifestations. Paternal alcoholism has not appeared to any noticeable extent in my private records.

With or without the hereditary influences additional factors can be elicited in most cases. One—which has not received the attention it deserves—is the malnutrition of bottle-fed babes. Repeatedly, when a single child from an otherwise healthy family was brought to me on account of exaggerated eye strain, I learned that it had not been properly nourished during its first year. It seems that malnutrition during babyhood may sometimes leave a permanent influence on the nervous system.

During school time, as well as later in business work, want of out-door exercise plays an important rôle in predisposing to neuroses. It is striking how few are the instances, at least after school age, in which neuroses of ocular origin occur in persons of active out-door habits or those engaged in manual labor, and equally striking how often the subjects of neuroses admit close confinement, although exceptions do occur. On the strength of very extensive observation, I must insist that the breaking down of the nervous system is much less due to the amount of eye work done, than to the want of out-door employment of the muscles. It has for years been my habit to insist on proper hygiene in this respect, and many a time have I been rewarded by the recovery of the patient, i. e., his ability—after a time—to continue his eye work without glasses and without suffering.

The liability to neuroses of peripheral origin is augmented by all influences depressing the nervous system.

In many histories the coincidence of pregnancy, disturbed sleep, mental anxiety and grief, with the occurrence of nervous disturbances of peripheral origin is quite apparent. Likewise convalescence, for instance from typhoid fever, influenza or in children from measles, is not a rare factor.

An important and frequent condition in neuroses of peripheral origin is anemia. It is probably partly through the production of anemia that some of the pernicious influences just detailed act as etiologic factors. The rôle played by anemia, which its frequent co-existence suggests, can often be demonstrated tangibly by the cure of the neuroses under the use of iron or the employment of hygienic measures which remove the anemia. In suitable cases the most satisfactory proof can thus be furnished that the peripheral stimulus leads to nervous disturbances only when the nervous system has not its normal nutrition.

Toxic influences, which we can not as yet define, are probably, too, of considerable importance. The most distressing instances of exaggerated asthenopia are sometimes observed in subjects with deranged digestion. In some of them correcting glasses do really remove all manifestations of eye strain and headaches dependent thereon. But often optic correction gives but partial relief, and full comfort can only be obtained after the successful management of the stomach and intestinal disturbances. Much can be learned when cases of this type can be observed from the start. I have observed in such instances, of which I have accumulated at least twenty-five records, if not more, that asthenopic complaints, either localized in the eyes alone, or exaggerated in the form of headache, may begin suddenly during a period of intestinal derangement manifested by furred tongue—disturbed appetite and more or less constipation. Most of these patients had neither felt any eye strain nor suffered from headache previously. The dependence of the—apparently—ocular neurosis on the intestinal disturbance was definitely proved in a number of cases by total recovery after dietetic and medicinal treatment directed against the digestive trouble. As the discomfort in the eyes and head was evidently aggravated by eye-use, rest of the eyes was also ordered. The important lesson learned was that while the subjective experience of these patients suggested an ocular origin of the neurosis no optic error worth correcting could be found in many of these instances of asthenopia of acute onset. What becomes of these neuroses if they are not properly stopped by the recognition and treatment of their intestinal origin? From many observations on other patients seen during later periods I conclude that this asthenopia will generally continue as long as the stomach derangement lasts, and that occasionally it will remain even after the digestive disturbance has gradually disappeared spontaneously. Undoubtedly this persistence is due partly to psychic causes and, indeed, yields at times only to psychic or suggestive influences, if at all. I have no doubt that many of the alleged successes attributed to weak glasses—0.5 D. and less—occur in cases of this kind. Observation continued during a number of years has only confirmed my often expressed doubts regarding the direct utility of glasses of such low degree that their selection is a matter of uncertainty on account of their scarcely appreciable optic action.

A psychic factor in the production of ocular neuroses is sometimes observed, too, in another variety of cases. Some patients with medium or low degrees of optic error, formerly tolerated without discomfort, date their as-

thenopia to the time of a conjunctivitis which may or may not be still present at the time of examination. After this is cured the asthenopia still persists and does not entirely yield to appropriate glasses, if such are needed at all. Here, too, an unfortunate rôle is played by the expectant attention which has occupied itself with and intensified the discomfort experienced while the eyes were really sensitive. These cases are also rebellious and yield only to psychic influences. We must recognize that neuroses due to a temporary physical cause may persist after the cessation of the latter on account of psychic reasons. We are treading here on the borderline between the domain of "reflex" neuroses and pure hysteria—usually monosymptomatic hysteria. But, on the other hand, the pure neuroses of peripheral origin, those which are promptly stopped by the elimination of the peripheral influence, have nothing to do with hysteria, even if they should occur in a patient who happens to be hysterical.

It is well to admit that in some instances of neuroses of peripheral origin apparently no deviation from perfect health, except the peripheral anomaly, can be found. It is more logical, however, to concede that we are unable to completely analyze such an apparent exception than to conclude that a peripheral influence which does not affect the nervous system in normal subjects should do so in a given case if it were not for the concurrence of other factors which escape our analysis. Besides, it is an open question whether hypermetropia and astigmatism of more than a minimal degree are not by themselves stigmata of at least imperfect development, if not of degeneration, inasmuch as these optic anomalies have not been observed in the examination of uncivilized races.

What has been said regarding the etiology of neuroses of ocular origin applies more or less to all "reflex" neuroses. In the case of nasal neuroses I wish to emphasize, perhaps even more, the importance of intestinal disturbances. Quite commonly these patients have constipation with flatulency. It can often be learned from self-observing patients that their nasal neurosis, for instance, asthma, is intensified whenever their intestinal disturbance becomes more manifest, and that on the contrary attention to diet and to the state of the bowels relieves their nasal symptoms or any nervous disturbances produced thereby.

In the case of some of the neuroses of nasal origin we must also take into account another factor, which, by itself, may undermine health, viz.: the existence of suppuration. Some of these patients evidently suffer from systemic injury due to the pyogenic infection apart from the "reflex" influence on the nervous system. Indeed, the history sometimes suggests that the nasal irritation caused nervous symptoms only after long-continued nasal suppuration helped to create a predisposition.

The degree of intensity of the peripheral disturbance provoking the neurosis varies considerably in different patients. I need but repeat that many healthy young people can tolerate a hyperopia of perhaps 2 D. or an astigmatism of 1.5 D., without any discomfort, while most distressing nervous symptoms are sometimes relieved by glasses of the strength of .75 D. The readiness with which the nervous system reacts by morbid symptoms to such a peripheral anomaly is an index of its instability. There are all possible degrees of "nervousness" without a sharp line dividing this condition from perfect health.

It is self-evident that in a given case the occurrence of a neurosis may depend on any intensification of the peripheral cause as well as any change in the condition

of the nervous system. An optic anomaly which had hitherto produced only "normal" and local asthenopia may cause diffuse nervous symptoms when the patient taxes his eyes by continued close work. Similarly a nasal condition, which up to a given time had not led to any neurosis, may result in nervous disturbances when aggravated by an acute inflammatory condition or intensified by unfavorable climatic influences.

Due attention to the general health and general medical history of patients with neuroses of peripheral origin as well as the study of variations in the peripheral condition gives us the clue to the fluctuations of their symptoms. It is only by treating them from the standpoint of the physician and not merely through the instrumentarium of the specialist that we can fulfill our full duty toward these sufferers.

100 State Street.

HAIR AND ITS ANOMALIES.*

BY HENRY ALFRED ROBBINS, M.D.
WASHINGTON, D.C.

The poets and sculptors of Ancient Greece have left in verse and marble their admiration of long hair. The Hebrews also looked upon hair as a great ornament, and their women gloried in their luxuriant tresses, bedecked with gold and precious stones (Isaiah iii). The men usually kept their hair short, but there were notable exceptions, as with Absalom and Sampson. With the latter it was accompanied with superhuman strength, and when Delilah, during his sleep, cut off his flowing locks, his strength was gone: "Howbeit the hair of his head begun to grow again, after he was shaven." "But the Philistines took him and put out his eyes and brought him down to Gaza, and bound him with fetters of brass, and he did grind in the prison house" (Judges xvi). When his hair had grown again his enemies sent for him that "he may make us sport." "And Samson took hold of the two middle pillars upon which the house stood, and on which it was borne up, of the one with his right hand, and of the other with his left." "And Samson said, 'Let me die with the Philistines.' And he bowed himself with all his might, and the house fell upon the lords, and upon all the people that were therein. So the dead which he slew at his death were more than they which he slew in his life." Thus Samson added greatly to the death-rate of the Philistines, but he was crushed to death himself.

The Hebrews of the Old Testament particularly deprecated the loss of long hair, but on one occasion, their mocking of a prophet resulted in their being eaten up by she-bears, when they cried out to Elisha, "Go up thou bald head." Fortunately, as civilization has advanced, bears have been almost exterminated.

The priests of ancient times wore long hair, until Pope Anicetus (A. D. 155) compelled them to wear it short. Long and flowing hair was so universally esteemed that the tonsure was regarded as an act of mortification. They declaimed against the long hair of the laity most bitterly. Anselm, Archbishop of Canterbury, pronounced a sentence of excommunication against all who wore long hair. Serlo, a Norman bishop, acquired great honor by a sermon which he preached before Henry I (A. D. 1104) against wearing long and curled hair, by which the king and all his courtiers were so deeply affected that they consented to resign

*Read before the Society of Microscopists of the District of Columbia, Jan. 9, 1900.

their flowing ringlets, of which they had been so vain. The prudent prelate gave them no time to change their minds, but immediately pulled a pair of shears out of his sleeve, and performed the ablation with his own hands. (Encyclopedia Britannica.)

Chemically, according to Mulder and Donders, hair is composed of: carbon, 50.65; hydrogen, 6.36; nitrogen, 17.14; oxygen, 20.85; sulphur, 5. The same products are found in the nails and epidermis, and in the hoof of a horse, the horn of a cow, and in whalebone and tortoise shell. They differ slightly in the quantity of organic matter they contain, but the difference does not vary much beyond 1 per cent. Hair yields from 54 to 1.85 per cent. of ash, containing among other ingredients peroxid of iron and a little silica. Professor Frey of Zurich speaks of hair as being the highest variety of epidermoidal tissue: "An extreme complication of structure welcomes us here all at once."

With the exception of the palms of the hands and the soles of the feet, hair is found on every part of the surface of the body. Being appendages of the skin, a description of hair necessitates a study of all the tissues therein contained.

The hair follicle, according to Tilbury Fox, may be regarded as a depression of the skin, the papilla at its blind end representing one of the ordinary papillæ of the skin; as Frey expresses it, an involution of the corium, and frequently of the subcutaneous cellular tissue. This involution shows externally, longitudinally, then transversely arranged connective tissue, and internally, a hyaline boundary layer. At the bottom it puts forward as a vascular papilla. It is the formative and nutritive organ of the whole. Hair, being modifications of the epidermis, receives the same vascular and nervous supply, and owes its glossy appearance to the sebaceous glands which open near its free extremity.

Dr. L. Duncan Bulkley⁴ says: "At the deepest portion of the hair follicle, or cavity in which the hair rests, there is a certain anatomical structure which is of the greatest importance in reference to the growth and vitality of the hair, namely, the *hair papilla*. This is, of course, quite distinct from the papilla which we have seen to cover the surface of the corium of true skin; it is situated deep in the tissues, at the bottom of each hair follicle, and projects into a small cavity at the lower end of the hair. This little hair papilla, which is only 1-15 of a line, or one hundred and eightieth of an inch long, is of vital importance to the growth of the hair, there being a minute blood-vessel in its interior, and it is believed that the reproduction of the hair, after it is lost from any reason, takes place from this papilla. Conversely, is it also true that as long as this papilla is intact, and in a healthy state, the hair will be reproduced, even though extracted artificially. Thus, 'plucking the hair out by the root' does not destroy the life of the follicle; only the hair is removed, the papilla from which it regrows remains."

As a rule, only the hair of the scalp, and certain other parts of the body, is coarse and long. The soft downy hairs called *lanugo*, on the cheeks of an attractive girl of 16 years have been likened to the down of a peach.

It appears to be the main object in life for men to hold on to the hair they have, but occasionally we come across men and women who possess more wealth of hair than is desirable. This condition is known as *hirsuties* or *hypertrichosis*. My first knowledge of this condition dates back to my childhood days, when at a New England boarding-school I committed to memory, by compulsion, the book of Genesis, where you will find in

chapter xxv the report of the twin delivery of Esau and Jacob: "And the first came out red, all over like a hairy garment; and they called his name Esau." Then came a time when the hairy man became a great hunter, and like those of modern days suffered from starvation, and he sold his birthright to his twin brother for a mess of red pottage. Finally, the sightless old Isaac exclaimed: "The voice is Jacob's voice, but the hands are the hands of Esau."

I will never forget the bearded woman who was on exhibition many years ago. She was of sufficient height to have belonged to the famous giant regiment of Frederick the Great. Her beard was magnificent, and showed to great advantage on her snow-white, depilated bosom. Like the ballroom belle, she thought that "beauty unadorned, was adored the most." Years after I had gazed on this freak of Nature, I met in Brunswick, Germany, Mr. Greenwood, who was the American Consul there. In former years he was business manager of P. T. Barnum. Consul Greenwood told me that the bearded woman caused great excitement, and grave doubts as to the sex of this individual existed. Finally, Dr. Valentine Mott and other eminent surgeons made a physical examination, and they declared that she really belonged to the gentler sex. This was fully and satisfactorily proven, as, shortly after, she gave birth to a son, who, like Esau, was "all over like a hairy garment."

Dr. M. Bourneville² states that he was recently consulted by a young girl for an ordinary affection, and that on seeing her he was struck with the following singular anomaly; the eyebrow and the eyelashes of the right eye were thick and black, while the inner half of the left eyebrow, and that of the eyelashes, were entirely blond. The outer half of the left eyebrow was black, although up to the age of 6 years the entire eyebrow had been blond. The left eye and the palpebral opening were somewhat smaller than the corresponding organs of the right side. The hair was black over the entire front part of the head, but on the right side of the occipital region it was black, sprinkled with a few blond locks, and on the left side it was half black and half blond. The patient assured the author that the hair on the rest of her body was black.

Malcolm Morris, F.R.C.S., in speaking of hair turning suddenly grey through extreme terror, says the evidence on which these cases are reported is not always satisfactory, and refers to Dr. Austin Flint, a distinguished American physiologist and physician, and quotes the following statement of Dr. Flint: "In examining the literature of this subject, it is difficult to find in the older works well-authenticated cases of these sudden changes, and most of those that are quoted are taken upon the loose authority of persons evidently not in the habit of making scientific observations. It is not necessary, therefore, to quote the instances of sudden blanching of the hair recounted by the ancient writers, nor those well-known cases of later date so often detailed in scientific works, such as that of Marie Antoinette or Sir Thomas More; and it seems proper to exclude also cases in which blanching of the hair has been observed only by friends or relatives, for in most of them the statements with regard to time are conflicting and unsatisfactory."

An important case was reported in a medical journal, by Dr. Landois in 1866. In this case the blanching occurred in a single night, while the patient was under the daily observation of the physician. When examined microscopically, the white hairs were found to contain

air globules, but there was no loss of pigment. It was in consequence of the presence of the air globules that the hairs appeared white.

Dr. Parry³ gives the following instance of hair turning white from fright. On Feb. 19, 1859, the command of General Franks, operating in the southern part of the kingdom of Oude, had an engagement with a body of rebels. Several of the enemy were taken prisoners. One of them, a Sepoy, was led before the authorities to be questioned. "I then had occasion," said Parry, "to observe in this man the events that I propose to relate. The prisoner, deprived of his uniform and entirely nude, saw himself surrounded by soldiers. He then began to tremble violently, terror and despair were depicted on his face, and, though he responded to the questions addressed to him, he seemed actually stupefied by fear. Then under our very eyes and in the space of scarcely half an hour, his hair, which we had seen was a brilliant black, turned grey uniformly over the whole head."

Dr. P. H. Pye-Smith, of Guy's Hospital, writes of canities as follows: "General blanching of the hair is a well known senile change. But, like baldness, it often occurs in early adult life, especially when the hair is very dark. Besides losing its natural pigment, and so acquiring a dull, yellowish, "milk-white" appearance, the hair is apt to become dry and admit air-bubbles, which increase its refractive power and produce the glistening steel-gray or "silvery" aspect. . . . Bichat and Alibert record cases which they actually saw, and Brown-Séguard has seen rapid blanching in his own beard (*Archiv de Phys.*, 1869, page 442). A gray patch sometimes follows neuralgia."

Dr. Laycock evidently witnessed the instance of the Sepoy just referred to, who was seen to turn gray in half an hour, and reported it in the *Med. Times and Gaz.*, in 1862. A young man once consulted Dr. Pye-Smith for some slight ailment, who had perfectly white hair. "In answer to inquiry he stated that a few years before he had fallen asleep after a debauch, and on waking in a cold room in the morning found that his hair had turned white. The objection that his beard was brown was answered by the explanation that when the change of color occurred it had not yet grown. This sudden change is probably due to development of air-bubbles in the shaft of the hair."

Dr. Schmitt⁴ of Frankfort, reports a case of sudden turning of the hair to gray. The patient was a laborer, 36 years of age, who at the time was suffering from some affection of the neck. His hair showed two white patches, one in the middle line of the head, the other over the right ear. Eight years previously he had had a severe mental shock while on a railroad journey, and it was noted by his friends and relatives that these patches appeared almost immediately after. The possibility of its having been a congenital or gradually acquired defect covered by hair dye, as has frequently been shown, seemed remote.

Before the Academy of Medicine, in Ireland, on March 24, 1883, Dr. Banks⁵ referred to a case which had come under his notice, that of a young woman. Half of the lashes of one of her eyes became snow white, which she attributed to the annoyance suffered from the persistent gaze of a "wall-eyed" admirer who had white lashes on the defective eye.

Several years ago I reported, in a German newspaper of this city, a case of a man where the hair of his scalp and beard turned white during a single night. I obtained the data from a report of a case by Dr. Landois

von Griefswald. As to the shock which caused it, I could get no information.

The following undoubted case occurred in the clinical service of Professor Mosler of Berlin: A man, aged 34 years, was brought in, profoundly drunk. The next morning the doctors and patients noticed that the hair of his head and beard had turned gray. When he looked at himself in the looking-glass he exclaimed, *Ach Gott, wir sind die Haare grau geworden*. A microscopic examination was made in this case. The white hairs were filled with air-bubbles. There was no loss of pigment.

The hair has turned from white to black after exposure to severe cold. "On the 5th of January, 1895, we had a tremendous fire in Louisville," writes Dr. George W. Griffiths;⁷ "the night was very cold and the streets were covered with ice and snow. The gentleman I shall present as the subject of these remarks is an engineer in the Louisville Fire Department, aged 65 years, who was on duty from 11 o'clock on the night of the 5th of January until 2 o'clock of the following day, except when he was taken away overcome by sheer exhaustion, and sent by my friend, Dr. Marshall, in a carriage to his home, where he remained two or three hours, and again returned to duty. Two or three sections of hose were leaking near his engine, and the spray was blown by a strong north wind until he was covered from head to foot with ice, which became so thick that it had to be cut or broken off from his clothing. This man was constantly at his engine, exposed to the north wind, which was carrying the spray of water from the broken hose. The top of his head was the warmest part of the body; his eyebrows and whiskers became wet and were frozen stiff. He had a red skull-cap over his head, and his helmet on top of that; his head was not exposed at all, nor any of his hair, except the eyebrows and whiskers.

"I saw him the next day, when he had a very feeble pulse, and was much exhausted and worn out. He had not been in robust health for some time. The next afternoon after the exposure to the severe cold, as I have indicated, his hair turned black; and the wonder becomes greater when we consider that his hair was perfectly white; before that he was blonde. Now his hair is black. I have known this gentleman for over forty years. The hair is oily and does not seem to be dead at all. His head has been very carefully scrubbed several times, as I was inclined at first to think that the change in color was caused by cinders or other foreign matter; but such did not prove to be the case."

The French supplement to *Le Greece Medicale* contains a curious account by Dr. Roveas of Amorgos, of a relative of his who died recently, aged 90 years. He had never been ill in his life, but the hair of his head and face had become prematurely white. Six months before his death, however, his beard and moustache suddenly became dark, the color continually deepening. "to the curiosity and stupefaction of all." Dr. Foristanos, the editor, adds a story of an old priest, whose white hair fell off, as the result of erysipelas, and was replaced by a thick growth of raven locks. Perhaps some cases of this kind may have given rise to the ancient Greek myths of rejuvenescence, as when

Medea's spell dispersed
The weight of years
And Orson stood a youth
Mid youthful peers.

—*Medical Magazine*.

Alopecia is derived from the Greek word ἀλωπηξ, a fox—not because the loss of hair gives a man a foxy appearance, but the ancient Greeks thought that the

bushy-tailed little animal was liable to baldness. A French medical paper prints what is believed to be the oldest medical recipe. It is a tonic for the hair, and its date is 4000 B. C. It was prepared for an Egyptian queen, and required dogs' paws and asses' hoofs to be boiled with dates in oil.

Theory after theory continues to be advanced for the cause of baldness. It was stated in an editorial article in the *British Medical Journal*, several years ago, that the "new man" finds it almost as difficult to keep his hair as the "new woman" does to find a husband. The theory of the bald-headed man generally is that his exceptionally active brain has used up the blood-supply which should have nourished his scalp; but those whose crop of hair still stands untouched by the scythe of Time unkindly hint that this explanation is of a piece with Falstaff's excuse that he had lost his voice by "singing of anthems." An American author has assigned indigestion as a cause. "Nature, we are assured, is very careful to guard and protect and supply the vital organs with the proper amount of nutriment, and when Dame Nature can not do it, she naturally cuts off the supply of parts least vital, like the hair and nails. I have observed that as a rule it is the best nourished man who is the baldest. I think that it was the virgin Queen Elizabeth who said that she did not look upon a man as being old until he was 'fat and bald.' Men of the build of John Sherman, who lives still, honored and beloved by his countrymen, and Abraham Lincoln and Gladstone, although thin and spare, had luxuriant hair. Bismarck, on the other hand, was large every way, very well nourished, and he is pictured as having had only three hairs on the crown of his head, and they stood up like quills upon the fretful porcupine."

IN THE JOURNAL⁸ there is an article on alopecia, in which the author claims that residual air is the cause of baldness, and explains why women are almost exempt from it.

Music appears to have an effect on the growth of the hair. Brass instruments have a fatal influence, notably the cornet, the French horn and the trombone. They will apparently depilate a player's scalp in less than five years. The baldness which prevails among members of regimental bands has been given the name of "trumpet baldness." It has been suggested that it is barely possible that the baldness which is said to prevail among the habitues of the front rows at the theater may be due to the proximity of the brass instruments, or may be caught by some contagion from the players themselves. Piano playing, on the contrary, seems to prevent or arrest the loss of hair, as is the case with Paderewski and Emil Sauer, and every noted pianist I ever heard of.

The late Prince Albert, consort to Queen Victoria, became bald at an early age, and he held that loss of hair was a sign of high breeding, of noble blood. This brings up the question of heredity.

At the meeting of the American Dermatological Association, held at Montreal, in September, 1895, a paper was read on "A Further Study of Alopecia Præmatura or Præsenilis, and Its Most Frequent Cause—Eczema Seborrhoicum," by George T. Elliott, M.D. "Also a preliminary bacteriological report on Eczema Seborrhoicum. For the first time successful production of the disease by inoculation of pure cultures of certain diplococci," by Wm. H. Merrill, M.D. Dr. Elliott gave the etiological causes found active in the production of alopecia in 344 patients, mostly occurring in private practice. "Only four, or 1.16 per cent. could be attributed directly to heredity." Dr. Merrill found several vari-

eties of bacilli, and made inoculation experiments on fifty patients. Pure cultures were made use of, and he succeeded, in advance of any bacteriologist, in producing lesions characteristic of eczema seborrhoicum.

Dr. L. Brocq⁹ says that when bacteriology of the hair is taken up various microbes are found in it. Six are, however, discovered quite constantly. These are: 1, a white fungus; 2, a yellow fungus; 3, a bacillus subtiliformis; 4, a bacillus in the form of a boat, staining with difficulty; 5, a special micrococcus which Sabouraud designates provisionally under the name of micrococcus cutis communis; 6, the spore of Malassez, the flask of Unna, which he calls the bacillus asciformis. These two microbes, which appear to be the most important, are found in seborrhoics who are not attacked with alopecia areata.

Dr. R. Sabouraud, of the St. Louis Hospital, Paris, by his experiments has given convincing proof that the microbacillus is the constant microbial expression of seborrhoic infection, causing baldness. Sabouraud says: "The three organs of defense possessed by the skin are the epidermis, the derma and the migrating white corpuscles. Each of these organs of defense defends itself by the same function for which its differentiated form has prepared it. The epithelial cell defends itself by making horny cells, the fiber cells by making fiber, and white corpuscles by their constant rôle of a unicellular amoeboid seizing the enemy, closing in around it and feeding on it. Every microbial lesion must be regarded simply as a battle-field. This conception is the foundation for all pathologic histology, and unless this is thoroughly understood, the whole phenomenon is a mystery, while once grasped everything becomes plain; the exfoliation is merely the epidermis defending itself; suppuration merely the leucocytes defending themselves; and the induration merely the mechanics of the fibrous defense. Each tissue, each element, is independently defending itself, and we know that any direct irritation of a living cell induces its multiplication, whether the irritation is mechanical or toxic. The process is a blind, unintelligent process, often defeating its own aim, as when a white corpuscle seizes a microbe and carries it away with it, but is conquered by the microbe. The microbial lesion, as we see it, is not a passive scene of destruction by the microbe. It is essentially a cellular reaction on the part of the organism against invasion, a defensive apparatus erected by the organism itself, and this conception of it places dermatology in an entirely different light, and renders a new classification necessary. Our present classification is like a pharmacy in which all the drugs are arranged according to the size of the bottles without regard to their contents."

CARCINOMA METASTASIS IN THE SKELETON.—Virchow recently exhibited preparations showing numerous cystic cavities in the bones, particularly numerous in the spine. The bodies of some of the vertebrae had entirely vanished and deposits of lime infiltration were found in the lungs, but never noted to such an extent as in this case. The aspect of the bones resembled that of pernicious anemia.

INSTRUMENT FOR USE IN PHOTOTHERAPY.

BY J. W. KIME, M.D.

FORT DODGE, IOWA.

I have devised and am now using, in the treatment of cases by means of concentrated light, a reflector which is so constructed that the direct rays of the sun falling on it are focussed at a distance of eight feet, on an area six inches in diameter, the reflector being thirty inches in diameter. Thus a light is produced equal in intensity to twenty times that of direct sunlight, and covering an area of twenty-eight square inches. As the actinic rays of the sun are desired rather than the heat rays, blue glass is placed in front of the reflector, which permits of the passage of the light in nearly its full strength, but excludes a large percentage of the heat rays. The reflector is mounted on a metal stand which permits of motion in all directions. The light from

cures of lupus and of tuberculosis of the lymph glands of the neck.

In the treatment of tuberculosis of the lungs in its earlier stages, the light penetrates the chest wall and, I believe, has some germicidal influence on the bacilli in the lung. But the action of the light is not confined to its local effects alone on the parts diseased. The blood, every drop of which passes a number of times through the area bathed in the powerful light during each treatment, is without doubt beneficially influenced by the chemical action of the light upon it. It is still too early to report final results upon cases of tuberculosis of the lungs being treated in this manner, but I have much reason to believe that sunshine thus used will result in permanent good in the treatment of these cases.

In the treatment of chronic joint affections the reflector is used in the same manner, and has, over the ap-

THE KIME PHOTOTHERAPY REFLECTOR.

this reflector is as powerful as it is possible to make use of on account of the accompanying heat.

The method of using the instrument is as follows: The part on which the intense light is to be used is made bare and the patient is placed in front of the reflector, and at a distance of eight feet from it; the rays of the sun fall directly on it, it being so placed that the reflected rays will be focussed on the part to be treated. If the heat be too great at the focal point, the patient may be seated either within or beyond the focal point of the reflector.

Concentrated light is useful in the treatment of a number of diseases and especially in those of parasitic origin. It has long been known that strong light, and particularly the direct rays of the sun, was very destructive to bacteria. For this reason light is practically excluded from our bacteriologic laboratories. Finsen, of Denmark, has established a light institute and reports excellent results in the treatment of lupus and other parasitic skin affections. Abrams, of California, reports a number of cures of tuberculosis of the lymph glands as well as of lupus and other skin diseases of parasitic origin. The writer has reported a number of

AS USED IN TUBERCULOSIS OF THE LUNGS.

paratus in which high temperatures alone play a part, the additional advantage of the beneficial action of the powerful light.

THE INFLUENCE OF HIGH ALTITUDE ON ALBUMINURIA.*

BY EDWARD C. HILL, M.D.

DENVER, COLO.

The following brief remarks are based on the examination of something over 6000 urines in Denver, at an altitude of one mile above sea-level. No statistics having been kept, the few observations I have to make should be regarded as clinical impressions rather than as strictly scientific data.

In my experience, true renal albuminuria is comparatively rare in Colorado. This desirable state of affairs is probably due for the most part to atmospheric dryness and rarity, both of which favor the eliminative action of the lungs and skin and thus relieve the kidneys in a corresponding degree. It is true that frequent

*Presented to the Section on Practice of Medicine, at the Fifth Annual Meeting of the American Medical Association, held at Columbus, Ohio, June 6-9, 1899.

winds and sudden weather-changes are a feature of Colorado's climate, so that patients must be warned to dress themselves accordingly, since acute exacerbations are otherwise likely to supervene.

Acute nephritis, though not common here, is exceptionally severe. Amyloid disease is certainly less frequent under predisposing circumstances than most of our text-books would lead us to infer. Chronic parenchymatous nephritis appears to terminate fatally in about the same time as at lower altitudes. The chronic interstitial type of the disease, on the other hand, is influenced favorably by this climate—a fact which I think may be ascribed largely to its tonic, invigorating qualities.

The reports of the bureau of health of this city show 77 deaths from nephritis in a total of 1838 for the year 1897, and 85 deaths from the same cause out of 1928 in 1898. These statistics are very favorable, but they should be considered in the light of the fact that the population of this city averages younger than that of eastern cities.

I invariably examine the urine of infectious cases, and have found albuminuria at some time or other in the majority of instances, but actual nephritis is quite rare, even in diphtheria and following scarlatina. Renal tuberculosis, as might be supposed from the great number of phthisical persons in this state, is comparatively common. It seems to be little influenced by the climate.

As regards other forms of albuminuria, though pregnancy is not infrequently attended by considerable albumin in the urine, serious eclampsia is, I think, less common than at lower levels. Slight, transient, circulatory albuminuria, due chiefly to high blood-pressure, is frequent here, particularly in the ubiquitous bicycle rider. Hemic forms of albuminuria are benefited by the hematosic action of Colorado air and sunlight. Of heterotoxic forms of albuminuria, that due to metallic poisons is seen rather frequently in our smelters and miners. The albuminuria of pyelitis appears to be of more common occurrence here than at sea-level, which may be ascribed, perhaps, to the greater density of urine, favoring precipitation of uratic and phosphatic sediment and the formation of calculi. The false albuminuria of cystitis and urethritis is doubtless just as frequent in Colorado as elsewhere.

VESICORECTAL ANASTOMOSIS.

WITH SPECIAL REFERENCE TO THE TREATMENT OF EXSTROPHY OF THE BLADDER.

BY JACOB FRANK, M.D.

Surgeon to the German Hospital; Consulting Surgeon to the St. Elizabeth Hospital; Jewish Orphan Home and Home for Aged Jews, Chicago; Corresponding Member of the Sociedad Médica "Pro Escobedo"; Member of the Pan-American Congress. International Medical Congress, AMERICAN MEDICAL ASSOCIATION, etc. CHICAGO.

The methods of treatment of ectopia vesicæ have not been very variable and are confined as a whole to two procedures, viz.: the plastic and the various methods of diverting the course of the urine.

Plastic Methods.—The plastic operations which have been performed, and which have for their object the covering of the exposed mucous surface with skin, aim at remedying only the cosmetic effect, which is but a minor evil. In this category belong those of Holmes, Wood, Le Fort, Thiersch, Hirschberg, Kocher, Hagenbeck, Auger, Greig Smith and many others who added much to this method by their own personal technic. All these methods, although they have done much toward the plastic repair, have many objections. They do not pro-

vide a sphincter, and although by covering the exposed mucous membrane they preserve it from external irritation, they do not prevent the escape of urine. The inverted skin flap with its growth of hair favored incrustations of calcareous salts and so irritated the mucous surface worse than before.

Sonnenburg advocated the entire extirpation of the exstrophied bladder, and the implantation of the ureters at the base of the penis, possessing the advantage that the escaping urine could be more effectually caught in a urinal intended for that purpose. Trendelenburg sutured the edges of the bladder after forcibly narrowing the pelvic girdle, thus resuming the operation conceived by Dubois and Dupuytren in France, a plan which has found little favor, as it is open to the same objections as the other methods above described.

The experiments of Tizzoni and Poggi, while they are ingenious, are of little practical purpose. They first isolated a loop of intestine, after the method of Thiry, and at a subsequent operation they ablated the entire bladder, then sutured the ureters into the artificial intestinal loop, and finally sutured this loop to the neck of the bladder. Recently Rutkowski imitated this procedure in a case of exstrophy of the bladder, but his operation is only a novelty in the history of surgery. In his technic he made an abdominal section above the level of the exstrophied bladder, drew out a loop of intestine and resected six centimeters of it. This he left attached to the mesenteric pedicle to receive its vascular supply. The severed ends were closed by circular enterorrhaphy, the excluded segment was split opposite to its mesenteric attachment and the mucous membrane stretched out and sutured to the margins of the bladder after being freshened. The abdominal walls were next approximated so as to cover the bladder. The patient recovered and eight weeks after the operation was able to retain over an ounce of urine for three-quarters of an hour.

Methods of Diverting the Course of the Urine.—The idea of implanting the ureters into the intestines is not new. Simon, in 1851, attempted it on a human subject, and the failure of such an early effort is not surprising when we consider the imperfection of the technic and the absence of antiseptics. The fruitless attempts of Simon, Lloyd and Roux found few imitators, and the question was held in abeyance for many years until aseptic methods gave a new impetus to operative surgery. The union of the ureters with the intestine is not an unusual condition. It is well known that in birds urine and fecal matter is emptied into the cloaca during the entire life. Embryology teaches us that the secretions from the kidneys in the human fetus empty into the cloaca during the first months of gestation. This continues until the time when, in the developmental progress, the bladder is entirely separated from the rectum.

Simon's effort consisted in passing a loop of thread through the walls of both the ureter and the rectum, and tying them tightly together. Necrosis occurred at the point of ligation, and a communication resulted. The patient died of pyelonephritis. Thomas Smith derived no better results from his case. Since then the idea has been renewed and the answer especially sought from the experimental as well as the clinical standpoint, until to-day the suggestions and methods have multiplied to an almost embarrassing extent.

The first in the experimental field were Glück and Zoller, who tried, on dogs, the effect of total extirpation of the bladder with subsequent deflection of the ureters, sometimes to the skin, sometimes into the rectum. The

latter was in all cases unsuccessful. About the same time Bardenheuer tried unilateral implantation into the intestine. His animals recovered from the operation, but subsequently died from hydronephrosis due to stricture of the ureter.

Novaro reported, to the Italian Surgical Society of Genoa, in 1887, that he had successfully anastomosed both ureters with the intestine, and demonstrated that the intestinal mucous membrane is well able to accommodate itself to the presence of urine—a point already established by Richardson, who cites the case of a patient living seventeen years with a congenital implantation of both ureters within the intestine. Paoli and Busachi reported a number of similar experiments, and in nearly every case a constriction of the ureter developed.

Giordano, VanHook, Tuffier, R. Harvey Reed, Morestin, Chaput, and, recently, Kalabin tried similar experiments on dogs, but their results are no better than those of their predecessors. For the relief of exstrophy, Sonnenburg and Harrison, discouraged by the difficulty of ureteral implantation, tried to divert the urine through a cutaneous fistula, an operation performed before by Glick and Zoller. Among others who have experimented in the same direction may be mentioned Le Dentu, Pozzi, Dastre and Treckacki.

In this hasty review the efforts of Pawlick and Boari to divert the urine through the vagina should be recorded. Küster, in 1891, for cancer of the prostate, implanted both ureters in the rectum, but the patient died on the fourth day, of peritonitis and evidences of renal infection. Chaput, in 1892, performed unilateral implantation for the relief of a uretero-vaginal fistula, with success; in another patient, for tuberculosis of the bladder, he implanted both ureters, but at different times, the patient dying from anuria, after the second operation.

The results of these experiments and isolated clinical attempts are almost uniformly unsuccessful. The technical difficulties have been fairly well overcome, but the dangers of septic peritonitis, secondary pyelonephritis from ascending intestinal infection through the ureters, hydronephrosis from stricturing of the ureter, were still unfavorable and unavoidable complications. In order to overcome these Tuffier and Maydl, each claiming priority, proposed and carried out the implantation of the vesicle trigone, thus avoiding the possibility of stricturing and ascending infection. In fact, it is the preserving of the ureteral sphincter that protects the ureter itself and the kidney against infection. As long as the ureter is permeable and its sphincter functioning, so long is the kidney protected.

Boari and Chalot, subsequent to Tuffier's and Maydl's work, each devised a special button for anastomosing the ureters to the intestine, with only moderate success. Others who have contributed by their efforts, since the advantages obtained by transplanting the vesical trigone, are Fowler, Pisani, Martin, Vignoni and Roux. My own work in this direction was commenced in the spring of 1898, when a series of experiments was conducted on both unilateral and bilateral implantation of the ureters in the intestine after a method of my own, with no better success than those preceding me. I then turned my attention to anastomosing the bladder to the rectum, an idea which I thought was original at the time, but in the discussion of the paper before the Chicago Medical Society my attention was called to an operation performed by Timothy Holmes, mentioned in his "Surgical Diseases of Infancy and Childhood." He attempted to establish a vesicorectal fistula by means of a screw-

blade and forceps, and describes his operation as follows:

In the case of a boy in whom I had planted a bridge of skin in front of the exposed mucous membrane, who found much difficulty in procuring a proper urinal, I endeavored to divert the urine into the rectum by the following plan, which, or a modification of which, I proposed to follow in the next case that came under my care. I placed the blades of a kind of screw forceps (much resembling Dupuytren's entérotome) in the rectum and bladder, and by bringing them gradually into the closest possible contact I destroyed the tissues between them, thus establishing a free communication through the subperitoneal tissue between the bladder and rectum. The attempt failed; for though the urine passed in considerable quantities into the bowel, a good part of it still continued to escape above the pubes. I endeavored to obviate this by closing the suprapubic opening altogether by plastic operation. The opening was thus, in fact, reduced to a sinus, but this caused such intolerable pain when the bladder was distended, and such accumulation of sabulous matter in it, that I was fain to abandon the attempt, break open the suprapubic hiatus again, and allow the rectal communication to close. The original fault of the preceding lay, I think, in my having covered over the opening of the ureters before I applied the screw forceps. Had I been able to comprise these openings in the tissue which I destroyed, so that the ureters would have opened directly into the cloaca between the bladder and rectum, I believe the attempt might have succeeded. In my case, though it was a failure in other respects, the communication between the bladder and rectum was established without producing any unpleasant symptoms, and the communication was well above the sphincter, so that the urine was retained in the bowel, and passed naturally along with the motions.

The operation and technic, which is original, now remains for consideration, and consists of anastomosing the bladder to the rectum with my decalcified bone coupler, which has already been described.¹ The technic is as follows: in a male dog, the incision is made in the groin, and in a bitch, in the median line. Generally the bladder is found distended, and is emptied by squeezing it gently with the hand, when the urine escapes through the natural channel. The rectum is next picked up and freed of its contents, as in any intestinal operation. The bladder and the rectum are then brought forward and placed in position for anastomosis. (Fig. 1.) Two or three interrupted Lembert sutures are now taken about half an inch below the lower ends of the incisions determined on in the bladder and rectum, care being exercised in selecting them that the coupler, when it is inserted, will not encroach on the ureteral openings in the bladder. A longitudinal incision is then made in the bladder, large enough for the coupler selected, and a puckering string, applied over and over the cut margin. (Fig. 2.) The rectum is next opened in its long axis and a puckering string similarly applied. The suture should be taken so that the free ends lie uppermost, thus facilitating easy tying. The operator now slips the coupler (Fig. 3) into the bladder opening, at the same time gently spreading the collars apart, while an assistant makes one knot and draws down on the puckering string until the rubber tubing is felt; another knot is made and the ligature cut off short. The other half of the coupler (Fig. 4) is then slipped into the rectal opening and likewise tied and cut off. Several interrupted Lembert sutures are taken around the borders, to make the work more secure. The operation is very simple and can be accomplished in ten or fifteen minutes.

In the first six experiments, a five-eighths-inch coupler was used, but later, in large dogs, a seven-eighths-inch,

¹ Medical Record, N. Y., Oct. 3, 1896; THE JOURNAL, June 19, 1899; Medicine, January, 1897.

and in smaller dogs a three-quarter-inch coupler was inserted. The small piece of rubber tubing never failed to pass away. Silk was used in all experiments.

The opportunity of trying this new method on the human being has not been afforded me, although it was tried on the cadaver and the technic carried out nicely. Of the fifteen dogs operated on, nine recovered and six died. In the first two experiments the technic was not yet perfected and much unnecessary work was done, which undoubtedly contributed largely to the failures. As a rule, the dogs were quite sick for the first few days, and showed signs of pain, with rise of temperature. For a week after the operation urine and feces were voided oftener than after this period. The dogs would hoist their legs as though in the act of urinating, without accomplishing anything, and finally squat down and

throughout. The ureters were not enlarged, but the capsules of the kidneys were greatly congested. The kidneys appeared normal on cut section. The coupler was still in place and the bone somewhat softened. The rectal mucosa, a few inches above and below the site of the anastomosis, was very much injected. No microscopic nor bacteriologic examinations were made.

EXPERIMENT 2.—A male dog, weight 20 pounds, was operated on April 25, 1899, and died April 27. A post-mortem showed a condition of general peritonitis, with the intestines adherent throughout. A pus-like fluid exuded from the wound incision, and the peritoneal cavity was found full of a serous effusion. The bladder was thickened, contracted and greatly engorged. No urine was present in the bladder. The ureters and kidneys showed a marked congestion, but no enlargement. On cutting open the bladder the coupler was found still in

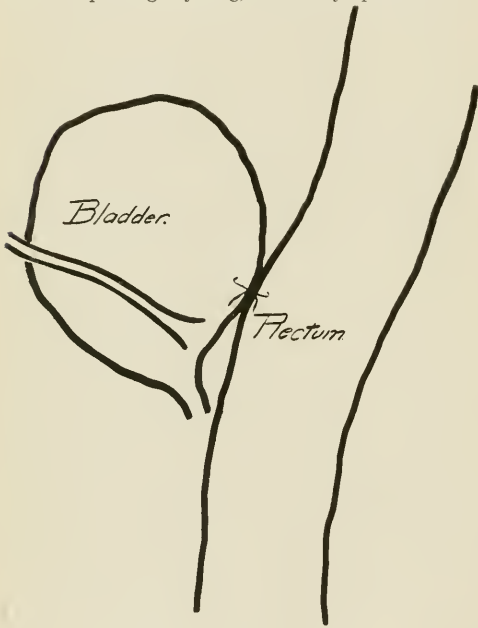

FIG. 1.

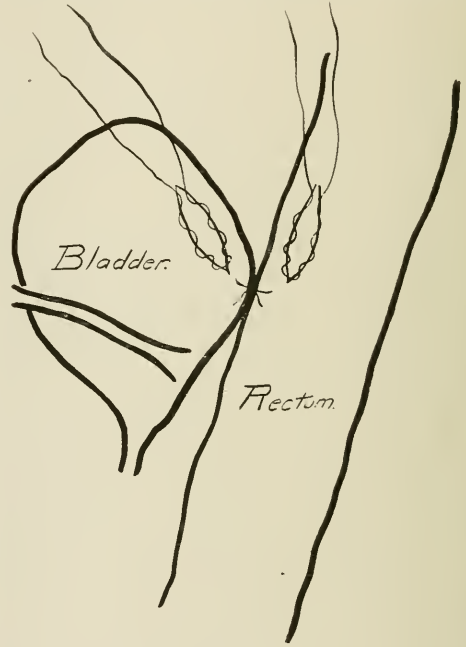

FIG. 2.

urinate from the rectum. The animals that were kept, accustomed themselves to their condition and urinated periodically. The feces were always passed in a liquid form, being softened by the urine. This latter appears to confirm the observation of Novaro, that the rectal mucous membrane readily adapts itself to the conditions of a urinary receptacle. In the following experiments the bacteriologic and pathologic examinations and microphotographs were made for me by Dr. Maximilian Herzog, professor of pathology in the Chicago Poly-clinic.

EXPERIMENTS.

EXPERIMENT 1.—A male dog, weight 25 pounds, was operated on April 18, 1899, and found dead April 22. Rats had disturbed the parts, through the operative wound, so that one could not judge whether peritonitis was present. The autopsy revealed a contracted, thickened, and very much congested bladder. Over the anterior opening the omentum was adherent

place and softened. There was a distinct line of demarcation at the sphincter vesicæ, showing where the inflammation had stopped. The kidneys, on cut section, showed marked engorgement. Here also no bacteriologic nor microscopic examinations were made.

I am satisfied that the rough usage of the parts and the imperfect technic were the prime factors in producing the fatal results in the first two experiments.

EXPERIMENT 3.—(Fig. 10).—A male bull cur, weight 30 pounds, was operated on May 3, 1899, and killed December 15. This dog, before the cold weather set in, was very lively and active, but with the onset of winter and the lack of proper exercise, began to show signs of decline. For several days prior to the killing, he refused food and drink and was moribund when chloroform was administered. At autopsy, externally there was found, to the left of the operative incision, an old, slightly suppurative stitch-hole abscess. The long median post-mortem incision was carried to the right in order to avoid the original laparotomy incision, and the omentum was found

adherent to the anterior abdominal wall and to the left of the laparotomy scar. The adhesions were comparatively firm. The large omentum had been dragged down in such a manner as to pull down the lesser omentum. The latter, in its descent, had displaced the spleen, so that this organ extended from above downward, parallel to the long axis of the body. In a like manner the stomach and duodenum had been pulled down to a marked degree. The adhesions of the large omentum to the anterior abdominal wall had formed, so that they compressed the left ureter near its place of entrance into the bladder. At this point it was slightly bent and constricted, and enlarged to about twice its normal size above the point of constriction, which enlargement extended up to the pelvis of the kidney. The left kidney itself, as a whole, did not appear enlarged. When laid open, its substance looked fairly normal, though dull, as if in a state of cloudy swelling. The pelvis was slightly enlarged and contained a small amount of a yellowish, somewhat cloudy fluid. The right ureter and kidney appeared normal, and the anastomosis between the bladder and rectum was perfect. The bladder was firmly contracted

usual aseptic precautions. The ureters were then dissected free and the kidneys, ureters, bladder and part of the rectum removed *en masse*. Pieces of tissue were taken from both kidneys, the spleen and the liver for microscopic examination. These were fixed in Müller's formalin solution, and subsequently embedded in paraffin, then sectioned, and stained according to various methods. The culture-tubes inoculated from the kidneys developed colon bacilli and a white yeast.

Histologic Examination.—The epithelium of the pelvis was found intact in the left kidney. The subepithelial tissue showed

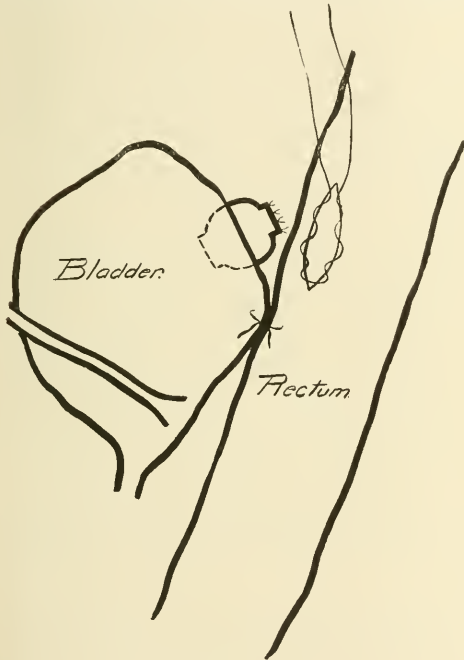

FIG. 3.

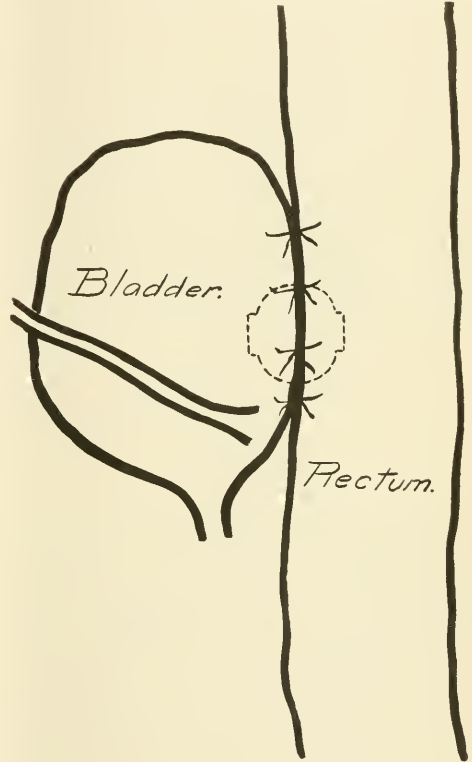

FIG. 4.

and the mucous membrane looked pale on cut section, but showed no evidence of inflammation. The peritoneum in the neighborhood of the anastomosis was smooth and glistening and everywhere appeared normal, except as to the omental adhesions described above. The spleen was dark red in color and its substance firm. The liver was of the same color, but rather soft, and in some places the capsule appeared dull, with circumscribed areas presenting the picture of perihepatic processes. The lungs and heart were normal, although the heart muscle was rather soft and flabby.

At the post-mortem the following technic was conducted and carried out, and in the same manner for all the experiments. The kidneys were freed from the surrounding connective tissue, and a heated platinum loop introduced into the pelvis, and cultures made under the

a very dense round-cell infiltration. The epithelial lining of the uriniferous tubules was in a state of cloudy swelling, and fatty degeneration. Some of the uriniferous tubules contained hyaline casts. Extensive foci of interstitial inflammation were also found and showed a dense round-cell infiltration. They appeared to be of comparatively recent origin, since tracts of fibrous connective tissue so frequently seen in old chronic interstitial nephritis were not found. The whole kidney, from the subepithelial layer of the pelvis to the cortex, was thoroughly infected with colon bacilli, which were found in enormous numbers in some areas.

The right kidney showed changes similar to those found in the left, but they were, however, much less severe. The inflammatory infiltration of the subepithelial layer of the pelvis was well marked, as were also the parenchymatous changes

(cloudy swelling, etc.). Interstitial changes were practically absent. The infection with colon bacilli was moderate when compared with that of the extensive infection of the left side.

The *liver* showed only slight histologic changes. There were present cloudy swelling of the liver-cells and a very moderate amount of small round-cell infiltration around the interlobular veins. The interlobular connective tissue proper was not increased in amount, but a large number of colon bacilli were found scattered throughout the whole liver tissue. The *spleen* likewise showed no very marked histologic changes, but a moderate infection with colon bacilli. Though the cultures from the pelves of the kidneys had developed a yeast micro-organism, none were found in the tissues.

From the above it must be conceded that the dog suffered from a general colon infection at the time when he was killed, but it may be granted, from the histologic examination, that the infection of the kidneys took place only recently, which presumption is borne out by the fact that the dog had been lively and well for six or more months after the operation and had been sick only a short time before it was killed. Probably the omental adhesions with their train of sequelæ, displacement of the spleen, stomach, duodenum and compression of the left ureter, became the agency which led to the infection of the kidneys. The infection of the liver had very likely taken place only recently, by way of the gall-ducts, from the intestinal tract. The generalization of the infection may either have taken place from the kidneys or, what is perhaps more probable, from the liver.

(To be continued.)

SPECIAL ARTICLE.

RELATIONS OF PHARMACY TO THE MEDICAL PROFESSION.*

IV.

INTERNAL MEDICINES.

While considerable latitude may be extended, as mentioned last week, in the ethical requirements, to articles designed for purely external use, such exemption can not be applied to medicinal agents or preparations for internal administration. While it may be broadly asserted concerning every method of medication, oral, subcutaneous or orificial, that the therapeutic effect derived from a remedy depends as largely on the quantity of the particular agent that may "reach the spot" as it does on the amount of the medicine administered, yet for the general therapeutic purposes indicated by preparations for external use, the actual amount of the active agent applied is as a rule of but little consequence compared with the quantity given as a dose of any internal medicine. The only safe rule, therefore, governing the administration of medicine for internal use, is that the composition must be known, and the quantities of the medicinal ingredients of a mixture and the strength of the active constituents of simple preparations must be accurately given. There should be no compromise in this position; medical ethics and medical practice demand it, medical literature and pharmaceutical practice require it. The identity of the medicinal agent must be certain so that its properties may be disclosed; the strength of the preparation must be known in order that uniformity in effects may be fairly secured and that dosage may be determined.

THE FORMULA PRIVILEGES.

In solutions, liquid mixtures and extractive preparations, the selection of the particular solvents, vehicles and menstrua respectively employed in their preparation is based almost entirely on pharmaceutical considerations. The stability of the solutions, for example, the eligibility or palatability of the mixtures and the permanence of the liquid extractive preparations are the chief desiderata. In official preparations these

qualities are secured through the reported researches of practicing pharmacists, and consequently are constantly undergoing improvement. These processes are no more perfect than many a process in operative surgery; the tendency is toward perfection—apparently often attained, but more often only prospective.

The question that now arises is this: If a pharmacist, through his greater experience, skill and integrity, succeeds in producing a more stable, palatable, or otherwise more eligible preparation than has usually been afforded from the same mixture or drug, should he simply make such a working formula public for the benefit of pharmaceutical literature, or should he be permitted to seek such advantage, through exploitation of the superiority of the preparation to the medical profession, to which he may consider himself entitled as a recompense for his labors?

No doubt from a purely ethical standpoint he should be satisfied with the first course, but there is another side to the question; if he has really made an improvement he might be afforded some protection for a limited period, as is done in France, where the National Academy of Medicine is made censor of medical preparations, and decides which shall be awarded protection. In the same way the AMERICAN MEDICAL ASSOCIATION, possibly in conjunction with the American Pharmaceutical Association or the Committee on Revision of the Pharmacopœia, might form a committee whose annual reports should determine the status of these medicinal articles. A formula may be ever so complete in detail and yet not produce satisfactory results at the hands of different workers. The personal equation must be considered, i. e., the experience, skill and integrity of the pharmacist.

LIMITATIONS IN PRACTICE.

Like some other branches of medical service, pharmacy is yet in its formative stage. With the practice regulated by law in forty-five states, in no state is it required that a pharmacist shall have graduated from a college or attended a school of pharmacy as a condition for examination and license by the state board. The result is that while there is no lack of good schools, these are poorly supported, since the vast majority of young pharmacists find that they can, as a rule, easily pass the necessary examination without attending college; the comparatively small proportion who attend school are forced into competition with the non-graduates, but licensed pharmacists, with the inevitable result of reducing them to the irresistible commercial level. They are also still in competition with the hold-overs who were engaged in the drug business some fifteen or twenty years ago, when the pharmacy laws were first enacted; many young pharmacists, well educated, finding little opportunity to practice pharmacy, begin to lose heart and soon fall into a "rut." This is practically the condition of pharmacy throughout the United States to-day.

A formula is a formula—nothing more; it is incomplete without the *secundum artem*, as in all other technical operations from culinary to music. With the official preparations, the methods of manufacture are detailed with great exactness, and it must be assumed that every licensed pharmacist is competent to carry out the directions, yet many can not prepare a perfect "Griffith's mixture." Some may know how but are careless in the selection of the ingredients, do not "expend the necessary synovial fluid," and do not strictly observe the order of adding the many various ingredients. How many pharmacists can make a perfect turpentine-oil emulsion? Some can not even make a perfect one of cod-liver oil. Such a condition should not exist, but it does. So long as a better standard of pharmaceutical service can not be relied on uniformly, the physician must necessarily either pass by the pharmacist by prescribing ready-made medicines, or discriminate in favor of those who are regularly educated and have demonstrated their ability and integrity.

LACK OF STANDARD IN PHARMACEUTIC SERVICE.

It may be said that there are many competent pharmacists in the large cities and sometimes in smaller places, and they are easily discovered. The simplest and most effective method

* The fourth of a series of articles to appear weekly in THE JOURNAL, designed to correct the abuses from advertising and patronizing pharmaceutical specialties.

by which a physician can distinguish the true pharmacist from the pseudopharmacist or "druggist" is to engage him to make a preparation, for example, one of those mentioned above, or one that requires special skill.

It should be remembered that a license is simply a testimonial that the holder has a fair knowledge of drugs and medicines, and can differentiate them and thus prevent error in dispensing and compounding; that he can make the simpler official preparations, waters, solutions, tinctures, etc.; but not necessarily that he has the skill or ability required for any work outside the ordinary routine. If physicians would interest themselves a little more in the younger graduates in pharmacy, and give them opportunities to practice their art whenever possible, these young men would soon be imbued with a professional spirit, realize that pharmacy is a profession—a specialty in medicine—and become better qualified; counter-prescribing and many other evils would cease.

It is not alone in these compound preparations and mixtures that the formula is not always the *sine qua non*. While occultism in medicine belongs to the past, there are many brands of official preparations and even chemicals that maintain the preference of medical men. A considerable number of the older practitioners insist on using one special make of fluid extract of ergot, and this may be said in a still greater degree of one brand of chloroform for use in anesthesia. Until comparatively recently, one special brand of quinin sulphate was the only one that many physicians would use, and in some of the Southern states no other could be sold at all. These discriminations may not have a scientific basis, yet they exist.

The above observations have been made in order to set forth the status of the protective medicines as completely as possible, and to serve as a guide in determining the often-complicated questions involved in their relations to medicine and the medical profession.

In the article in THE JOURNAL two weeks ago, these medicines were classified as follows: 5. Proprietary pharmaceuticals, secret. 6. Proprietary pharmaceuticals, non-secret. 7. Pharmaceutical specialties, mixtures. 8. Pharmaceutical specialties, simples. These will be taken up in their order.

SECRET PROPRIETARY PHARMACEUTICALS.

These are preparations of secret composition—for internal use—protected by trade-marks or copyrighted names, offered for medical prescription. From the fact that they are secret and are sooner or later exploited to the laity, they should never receive medical patronage. They range in degree of secrecy from mixtures of fairly descriptive and therapeutically suggestive names, such as, "Antikammnia" and "Melachol," to the most bare-faced swindles that have ever been perpetuated since Cagliostro replenished the exchequer of Louis XV with gold bricks made by transmutation of the base metals from the proceeds of the bandits who, in his employ, were holding up the nobility and gentry in the Italian mountain passes, on their way to Rome.

A few examples will suffice: "Essence of Oats," some ten years ago, vaunted as a most wonderful restorative, was found to be a preparation of morphin. More recently a preparation made from a plant discovered by a Texas physician, growing in the everglades in Florida and only collected at the risk of sacrificing human life, was recommended in a New York medical journal as a cure for the opium and morphin habit, but was found on analysis, to be a preparation of opium. "Gleditsopine," an alkaloid alleged to have been obtained from the plant *Gleditsia triacanthos*, and exploited by a prominent house, was a mixture of morphin and atropin. "Flora-China," introduced by a concern in Florida, as identical with quinin in all properties save that it was tasteless, on examination proved to be calcium sulphate, gypsum or plaster-of-Paris. These articles were advertised to physicians, and many not only used them, but gave testimonials extolling their virtues.

Besides these examples of rank frauds there are all grades of deceptive articles until a class of mixtures which have suggestive trade-marked names, sometimes associated with a more or less correct definition of their derivation, is reached. One of the earliest and most successful of this class was

"Antikammnia," claimed to be a "combination of coal-tar derivatives," and to possess antipyretic and analgesic properties. It proved to be a mixture of acetanilid and caffeine with sodium bicarbonate and a little tartaric acid—a combination early adopted by medical men to insure more uniformity in the action of the acetanilid and to modify its effect on the heart. This soon had many imitations and paved the way for the introduction of the various "headache-cures" and "remedies" which, in the form of powders, wafers, capsules and tablets, disgrace the show-cases of the drug stores throughout the land, and, it may be mentioned incidentally, have been furnishing plenty of work for the undertakers. Being extensively employed, they were introduced into the revised edition of the National Formulary, in 1895, as: pulvis acetanilidi compositus—compound powder of acetanilid—"Kamma Fuga"—acetanilid, 50 grams; caffeine, 2 grams; tartaric acid, 3 grams; sodium bicarbonate, 45 grams (reduce the ingredients separately to a fine powder and mix them thoroughly).

Other mixtures of similar composition are "Ammonol" and "Phenalgin" or ammoniated phenylacetamid, etc. In these two the sodium bicarbonate is replaced by ammonium carbonate. "Melachol," composition or formula not given, is asserted to be a bulwark against all diseases of the liver that may be caused by candies, rich foods, liquors, or neglect of exercise. To restore and permanently establish vigor of manhood it is "superior to any other known remedy;" "as a tonic, half a teaspoonful in water about meal-time; to move the bowels, one tablespoonful in a glass of water." This preparation is a colorless solution of citrophosphate of sodium and, according to analysis, the following furnishes a similar preparation: sodium phosphate, 100 grams; sodium nitrate, 2 grams; citric acid, 13 grams; water to make 100 c.c. On trituration of the salts with the acid, the new compound is formed and dissolves in the water of crystallization, thus forming a 100 per cent. solution.

The "Formula-preparations" will next be considered.

Therapeutics.

Treatment of Chronic Nervous Diarrhea.

At the recent Congress of Balneology, held at Frankfort-on-the-Main, Pariser (*Berliner Klin. Woch.*, April 2, p. 309) divided cases of chronic nervous diarrhea into several groups. The first includes those dependent on organic disease of the nervous system, such as tabes dorsalis, as well as those attending exophthalmic goiter, and rarely also diabetes. The remaining cases are instances of neurasthenic diarrhea, but here further subdivision must be made for etiologic, diagnostic and therapeutic reasons. The second group includes the cases of toxic diarrhea in which the neurasthenia is only secondarily the result of the intoxication. Toxic nervous chronic diarrhea occurs in consequence of intoxication by dying tenia, and abuse of nicotine and morphin. The third group includes nervous diarrhea induced by reflex influences. The reflex may arise from the male and female genitalia, the stomach and the duodenum and through parasites. It has also been observed from a hernia of the linea alba and from enteroptosis. Also the obstinate diarrhea not rarely observed in cases of chronic gastritis is considered of reflex nervous origin. Here the irritation consists in the ingesta insufficiently prepared for intestinal digestion. The fourth group includes the cases of simple neurasthenic diarrhea. The condition is often one of a central phobia. Patients thus affected are often attacked with diarrhea, especially when influenced by the thought of being unable to reach a place of refuge. Further, chronic nervous diarrhea also occurs in conjunction with hysteria. The last group constitutes the mixed form of neurosis and intestinal catarrh. The mixed form of neurosis with isolated catarrh of the small intestines is especially obstinate and the prognosis is unfavorable. The latter is better in cases complicated with catarrh of the large and the small intestine or of the large intestine alone. The stools never contain mucus in cases of pure chronic nervous diarrhea. In the cases of toxic and

reflex diarrhea the treatment should primarily be causal and local. In these, besides, an antineurasthenic régime should be observed, and in the purely neurasthenic cases this is of paramount importance. Isolation, that is, removal from previous surroundings, is especially desirable. In severe cases rest in bed and applications of heat are unconditionally required. The diet in all cases of chronic nervous diarrhea should be bland. As opposed to the opinion sometimes expressed, that no particular importance need be attached to the diet in these cases of mixed form of catarrh, the treatment must first be directed to the catarrhal state without neglecting the neurasthenia. Among drugs bromids are particularly valuable.

Urotropin as a Urinary Antiseptic.

At a recent meeting of the Leeds and West Riding Medico-Chirurgical Society, Cammidge (*British Med. Jour.*, March 17, p. 641), after briefly referring to a case of cystitis complicating enteric fever in which urotropin had proved beneficial, gave details of investigations that he had carried out with regard to the action of urotropin on the urine from patients who had taken it, on the bacillus typhosus, the bacillus coli communis and the staphylococcus pyogenes aureus under various conditions. He also described some chemical experiments designed to determine the mode of excretion of the drug in the urine, and the cause of its marked antiseptic and inhibitory powers over the growth of micro-organisms possessed by such urine. The result of these experiments seemed to show that although this action is in part probably due to the urotropin itself, excreted unchanged in the urine, another and more powerfully inhibitory substance is present. This was not thought to be free formaldehyde, but possibly a sodium compound of this substance. There is both clinical and experimental evidence tending to show that one condition necessary for success in using the drug as a urinary antiseptic is that the urine should be acid in reaction, as it is secreted in the kidney. Stress was laid on the marked inhibitory action of urotropin and still more of urine containing urotropin on the typhoid bacillus, and it was pointed out that there is a wide field of usefulness for this drug, both in the treatment of cystitis and other conditions liable to complicate enteric fever and as a preventive against the dissemination of typhoid bacilli by the urine. It was suggested that all patients suffering from enteric fever should receive 10 grains three times a day from the end of the second week on, during convalescence. Reference was also made to the usefulness of the drug in the cystitis accompanying enlarged prostate and stone, as well as the benefits to be derived from its administration in the presence of bacteriuria, some cases of nocturnal enuresis in children and as a preparation for operations on the urinary tract.

Treatment of Inguinal Hernia by Injection.

Scully (*Medicine*, April, p. 265) recommends the following formula as an injection in the treatment of inguinal hernia:

R. Fluid extract of quercus alba.....	ʒiiss
Solid extract of quercus alba.....	ʒiiss
Carbolic acid crystals.....	ʒiii
Iodin resublimed.....	ʒiii
Morphin sulphate.....	gr. x

Mix the carbolic acid and the iodine thoroughly in a mortar, and the other ingredients and triturate slowly. Twenty minims of this solution constitute the maximum quantity for a single injection. Before the injection is made, a truss that will retain the hernia in any position the patient may assume should first be fitted. After the parts have been prepared aseptically, the patient should be placed in the recumbent posture, the hernia reduced, and the index finger placed in the inguinal canal by invaginating the skin over the external ring and pushing the finger up the canal until the tip reaches the internal ring. The needle, which should be a stout one, from 1½ to 2 inches long, should be inserted directly over the finger tip and pushed down quickly until it passes the end of the finger. From 3 to 5 minims should then be injected slowly and, as the finger is withdrawn slowly, the needle is made to follow it for about half an inch. During this time the fluid is still injected slowly, and when the 20 minims have been in-

jected the needle should be withdrawn suddenly to avoid depositing any of the fluid in the subcutaneous tissue. The truss should be placed in position immediately, and the patient lie down for about half an hour. Should pain follow, relief will be afforded by the application of a hot-water bag. The injections should be repeated once a week for three or four weeks, when, if the hernia does not come down on removal of the truss and after testing it by having the patient cough or stoop, no further injections need be given. The truss ought to be worn for at least four weeks more, when, if the patient desires, it may be left off. In most cases it is well to advise the wearing of the truss for from four to six months, and one with a large soft pad is preferable.

Treatment of Eclampsia with Saline Infusions.

At a recent meeting of the Edinburgh Obstetrical Society, Jardine (*The Lancet*, March 31, p. 938) reported 5 cases of eclampsia, in addition to 17 previously reported, treated with saline infusions, in which the diuretic effect had been prompt and marked. The solution used consisted of one dram each of sodium chlorid and sodium acetate to the pint of sterile water. From 2 to 3 pints were injected underneath the breasts, between them and the chest wall, or, if required, into the loose abdominal subcutaneous tissue. If necessary the injections are repeated. Besides, a saline purge is administered, sometimes with bromid and chloral and ten minims of tincture of veratrum viride by hypodermic injection. Of the 22 patients, 6 died, 1 from perforating duodenal ulcer. One was treated with ordinary saline solutions. This result compares favorably with that yielded by other lines of treatment for eclampsia, especially in view of the fact that many of the patients had been seized with convulsions for several hours before coming under observation, and the cases of some even had been considered hopeless. No risk attends the infusion and not a single abscess followed not less than 200 injections. Strict aseptic precautions must be observed.

Evaporating Lotion for Wounds.

Reed (*Annals of Surgery*, April, p. 431) recommends the following formula as an evaporating lotion for the saturation of gauze and application to wounds:

R. Boric acid solution, 3 per cent.....	ʒo parts
Alcohol.....	ʒo parts
Glycerin.....	ʒo parts

The addition of 8 drops of a saturated solution of mercuric chlorid (mercuric chlorid 2 ounces, alcohol 2 ounces, glycerin 6 ounces) to a pint of the foregoing makes a solution of about 1 to 3500.

Diarrhea of Infants.

Cattaneo (*Pediatrics: Phila. Med. Jour.*) calls attention to the value of tincture of iodine in the gastrointestinal infections of infants. This remedy has also been praised by Grosch and Stahan. The following combination is recommended:

R. Tinct. iodini.....	gt. v to xv
Aque dest.....	ʒv
Syrupi.....	ʒvi

M. Sig. A teaspoonful every two hours. It is well to administer a purgative dose of castor-oil or of calomel before using the iodine. This combination of a purgative with the tincture of iodine gives excellent and speedy results.

Diaphoretic.

R. Camphoræ.....	gr. xxx
Pulv. opii.....	gr. ʒ
Potassii nitratiss.....	gr. iiii
Sacch. alb.....	ʒiii

M. Sig. Take in a cup of tea before retiring.

—Von Graeffe, *Med. Record*.

Diuretic Pills.

R. Pulv. seillæ.....	gr. xxx
Pulv. digitalis.....	gr. ʒ
Caffeina, aa.....	gr. xxx
Hydrag. chloridi mitis.....	gr. v

M. ft. in pil. No. xxx. Sig. Give one three times a day after meals.

—Practitioner.

Medicolegal.

Not Necessary to Prove Mental Suffering.—In the case of the Missouri, Kansas & Texas Railway Company of Texas vs. Cox, which the latter party brought to recover damages for injuries sustained by being thrown from the top of the caboose of a freight train, the Court of Civil Appeals of Texas holds that it was not necessary for him to prove that he sustained mental suffering, as the jury was permitted to consider that element of damage as arising from the physical injuries sustained, as shown by the evidence.

Requiring Physical Examination of Daughter.—The Supreme Court of Georgia thinks that it would be going a great length to hold that an action by a father for the loss of services of his minor daughter should be defeated by the refusal of the daughter, who, though not quite 21 years old, was practically a grown woman, to submit her person to a physician for physical examination. Certainly, if, as was alleged in the case of Bagwell vs. the Atlanta Consolidated Street Railway Company, the physician, though eminent in his profession and a thorough gentleman, was distasteful to the daughter, the court says it would be placing on the father, even if she were still under his control, a great and painful burden to require him to coerce her to undergo an examination, or else give up his cause of action. But that was not the case here, for the record showed that the refusal on which the judge's order of dismissal was based was made by the daughter after she had become of age. At that time, the supreme court holds, her father had no right or authority to control her person or her movements. His conduct would have been indefensible, if not criminal, if he had undertaken to compel her, against her will, to allow a physician to examine her. It might be that, if he really desired the examination to take place, he might, by perfectly proper means have induced his daughter to consent to it. But be that as it may, the supreme court goes on to say that it is not prepared to hold that he was in any event bound to pursue such a course. On the contrary, it declares that it has no hesitation in holding that a case should not be thrown out of court because of the conduct of one not a party to it, and who was neither legally bound to obey the plaintiff's orders, nor subject to his custody or control; and so it holds that this case was improperly dismissed. In other words, it holds that an action by a father for the loss of the services of his minor daughter, occasioned by personal injuries, should not be dismissed because she, after reaching her majority, refuses to obey an order of the court in which the action is pending, requiring her to submit to a physical examination of her person by a physician.

Test of Testamentary Capacity.—In the Lawrence will case the appellate division, first department, of the Supreme Court of New York says that there was no question but that the testator was insane in the month of October. The substance of the testimony of the experts in the case was that the testator, on October 16, was in a condition of acute melancholia, with delusions; that the onset of that disease had been of a slow and steady character; and that the condition that he was in at that time was the culmination of a progressive disease, which had continued from four to six months. He made his will May 9. And with only this testimony from which testamentary incapacity could be inferred, the court does not consider that it was shown. It holds that the test was, not whether the testator at the time of the execution of this will was suffering from the disease from which he became insane in October, but whether at the date of the execution of the will the disease had so far progressed that he had not sufficient memory to collect in his mind without prompting, the particulars or elements of the business to be transacted, and to hold them in his mind a sufficient length of time to perceive at least their obvious relations to each other, and be able to form some rational judgment in relation to them, and whether he did intelligently determine to make the testamentary disposition in question, and to execute that intention. Wherefore, being satisfied from the whole evidence that at the time the testator made this will he was able to form an intelligent

and rational judgment, and that the will was the result of this intelligent, rational judgment, and carried out his intelligent and rational desire, it holds that the will was properly admitted to probate. Another thing: the court says that the testator, who was at the time of executing the will about 57 years of age, desired very much to be married, but it holds that that certainly was not evidence of insanity or lack of testamentary capacity.

Mental Injury Amounting to Total Disability.—On rehearing, the Court of Civil Appeals of Texas takes a broader view, in the case of the Fidelity & Casualty Company vs. Getzender, than it did before, of what mental injury will constitute a total disability, within the terms of an accident policy of insurance which provides for indemnity for such injuries as, independently of other causes, shall immediately and wholly disable the assured from performing any and every kind of duty pertaining to his occupation. It now believes that it was in error in condemning a charge wherein the jury was told that if the injury in question, which was one to the brain, and, as resulting therefrom, unsoundness of mind, immediately and continuously disabled and prevented the assured from performing any and every kind of duty which was materially essential to his occupation in a manner reasonably as effective as it believed the same would have been performed if he had not sustained the injury, then it should find that he had been totally disabled within the terms of such a policy as the above. As it now construes it, such a clause in a policy does not mean that one must be killed, or become totally insane immediately, or totally paralyzed or collapsed, in order to be entitled to the indemnity but only disabled in some manner to the extent that he can not perform some essential duty in the line of his occupation or profession in a reasonably safe, efficient, and profitable manner. And this question of the extent of the disability must always be left to the jury to determine. The occupation of the assured in this case was that of visiting yards and ranches and buying and selling cattle—one in which sound memory and clear, good judgment were essential. So, if the injury to his brain and mind was such as to prevent him from exercising good judgment and drawing correct mental conclusions, in a manner reasonably as effective as he could have done if he had not received the injury, then, the court now holds, he was "wholly disabled," within the meaning of the contract, because upon these qualities of the mind depends the successful performance of the duties of his occupation. If he could not perform these mental functions as well as he did before, but substantially or reasonably as well, then, the court holds, his disability would be only partial, and he could not recover the indemnity. But if he could perform them, though not substantially or reasonably as effective who, it asks, can say that he could perform them rightly and correctly at all. To illustrate further the principle involved, the court asks, among other questions if a doctor's mental balance is lost, and it becomes known that he is not reasonably as accurate and skillful as he once was, though he may be able to visit patients, write prescriptions and diagnose cases with grave and serious men in the mysterious, technical nomenclature of his profession yet who suspecting his mental disorder, would take his medicine? He would be, it declares, wholly disabled in his profession. Nor does the court find itself alone in the position it thus takes with regard to what constitutes total disability under contracts of insurance. It cites sufficient cases to show the trend of judicial decisions, and, as it expresses it, while the companies have all the time contended for a literal construction, the courts have uniformly adopted a liberal and reasonable one. So it now seems to feel perfectly justified in holding that, as it recapitulates it, if a person is injured mentally to the extent and character that he can not perform some of the essential duties pertaining to his occupation or profession under which he is insured which requires the exercise of a sound mind and good judgment, in a manner substantially or reasonably as effective as he could have done but for the injury then he is wholly disabled, within the meaning of such a contract as this one was, and is entitled to recover the indemnity stipulated for in the policy.

AMERICAN.

1. **Histopathology of Epidermolysis Bullosa.**—In this conclusion of his memoir, Elliot reports histologic findings of skin taken from apparently healthy as well as diseased portions. The morbid changes are illustrated. The process seems to be a degeneration of the cells in certain portions of the epidermis, resulting in a molecular death of the nucleus and protoplasm of the cell body. The individual is born with a congenital irritability of the vascular supply of the skin, which responds abnormally to irritation and produces these degenerative changes. Whether there is also a congenital instability of the cells themselves, he is not prepared to say. His older view as to the condition being a dermatitis, he now rejects, and he believes that the prime feature in the process is an acquired or hereditarily exaggerated irritability of the cutaneous vascular system.

2. **Nitrous Oxid, Ether, Chloroform.**—Goldan describes the requirements of an ether inhaler, and criticises the ordinary method of administering. The inhaler should be simple, easily cleaned, capable of being used as an open or closed one, inexpensive, so fashioned as to use the smallest quantity

consistent with perfect anesthesia, with no sponges, but fresh gauze for each case; it should have large air-passages, so as not to impede the respiration, no useless complicated ether and air contrivances, and a rubber bag of the fullest respiratory capacity. He describes and illustrates the one he thinks meets these requirements and lays down the rules for its use. The patient should be encouraged to breathe deeply, and the head should be slightly extended on a direct line with the body, and turned fully to one side, which position has the advantage of affording better drainage for the mucus and saliva, while the tongue will fall to one side instead of backward or on the epiglottis. The head correctly placed, should remain so through the operation. There should be no forcing of the inhaler on the patient, but it should be gently applied, removed, and reapplied, impressing on the patient at the time that it is perfectly safe. After anesthesia is complete, it should be removed, but there is no absolute rule as to the length of time the patient's face should be uncovered; this varies for each case. For chloroformization, he would have a rearrangement of the parts of the inhaler; the important point is that there should be a free mixture of air, the patient should not be encouraged to breathe deeply, and the chloroform should be begun drop by drop, at first very slowly. Chloroform vapor is heavy and falls, and the old practice of pouring 5i to ʒi on a mask and encouraging the patient to breathe deeply is probably responsible for many deaths. The degrees of anesthesia are described, and the various reflexes in the order of their disappearance: the ciliary, corneal and conjunctival reflexes, deglutition, pharyngeal and laryngeal reflexes, vomiting, the anal, the vaginal, and the uterine reflex. His practice is to keep the finger on the pulse throughout the narcosis, preferably on the temporal artery, and the possible anomalous conditions should be kept in mind. The pupil dilates at the commencement and contracts when anesthesia progresses or is moderately dilated. Its sudden dilatation may indicate dangerous or incomplete anesthesia. The pupil is not always a reliable guide; other symptoms should be watched in addition. The condition of the skin, the respiration, etc., must be watched.

3. **Antitoxin.**—Herman replies to a recent paper by Dr. A. Robin, who criticised his former articles which endeavored to show, by statistics, that antitoxin is a failure.

4. **Indicanuria.**—The relation of hydrochloric acid secretion to indicanuria is discussed by Jones, who analyzes a series of cases which he divides into four classes: 1. Those showing free hydrochloric acid with no indican present. 2. Those showing both present. 3. Those showing neither present. 4. Those showing no free hydrochloric acid but indican present in the urine. From an analysis of these cases and consideration of the facts in regard to the stomach secretion, he concludes that other means than free hydrochloric acid must be depended on to prevent formation of indican in the intestine. It would appear that so long as sufficient hydrochloric acid is secreted by the stomach to satisfy the nitrogenous elements and allow them to pass through the various steps of the cleavage in pepsin-hydrochloric acid digestion, excessive putrefaction is not likely to arise, even if sufficient hydrochloric acid is not secreted in a free state, that is in a normal or almost normal acidity of the gastric contents. When the total acidity is gradually reduced, putrefaction is likely to occur. He finds that excessive indican is more apt to be associated with obstruction in the small intestine than in the large, and it is also found with gastric ulcer where there is a great amount of free hydrochloric acid in the stomach. It has been associated more particularly with inflammatory states of the intestine. If the albuminous constituents of the food undergo digestion in the intestine, they do not putrefy, and in many cases indicanuria must be looked on as an index to the adequacy of intestinal digestion without regard to the state of the stomach.

5. **Ethylie Bromid.**—The use of ethylie bromid—C₂H₅Br—as a preliminary to ether anesthesia is recommended by Fowler, who reports a case. He places ʒi to ʒij of ethylie bromid on the inhaler, and in from thirty to forty-five seconds, according to the freedom with which the patient breathes, the administration of the sulphuric ether is begun,

without changing the inhaler, and proceeded with as in ordinary ether anesthetization.

6. **Diagnosis of Hysteria.**—The practical importance of the diagnosis of hysteria from organic disease of the nervous system is self-evident, both for the physician and the patient. The leading points are given by Burr: The diagnosis is necessarily by exclusion, and the negative elements are as important as the positive. The mode of onset and combination of symptoms are to be noted. Sometimes the nature of the symptom itself may indicate the real nature, and anesthesia is important in this regard. It, however, is not always present; there is no one pathognomonic symptom of hysteria. There may be hyperesthesia, and he points out some conditions in which it may occur. The diagnosis of the fit may be difficult or easy. Palsy, which seems to follow it, is not of diagnostic value. There is one type of flaccid palsy which is seen only in hysteria. In this, though there may be complete loss of voluntary movement, the patient is able to keep the palsied extremity in any position in which it is passively put. The other symptoms of diagnostic value are noted. One symptom is important as distinguishing hysterical paraplegia with contracture from organic disease. In the latter the muscular spasm is extensor and lessens with flexion.

7. **Bottini's Operation.**—Meyer gives the details as to the preparation of the patient, the instruments employed, the *modus operandi* and the after-treatment. He favors filling of the bladder with sterilized boric acid water, and believes that the Lewin experiments indicate the dangers of dilatation by air. The length of the incision, indications, etc., are also fully discussed. The paper appears to be a very complete handling of its subject, and is to be concluded in a subsequent issue.

9. **Progressive Pernicious Anemia and Malignant Disease of the Stomach.**—After reporting two cases, Abrams formulates the following conclusions: 1. Arsenic is a true specific in pernicious anemia, and is as certain in its immediate results as is mercury in syphilis, quinin in malaria, or iron in chlorosis. The specificity of arsenic is so great that in no case of grave anemia are we justified in excluding the progressive pernicious variety, even though the blood-examination is negative, without a heroic trial of arsenic. Like the other specifics, it produces relative cures and can not be regarded as a prophylactic, owing to the frequent relapses. It may be given as Fowler's solution, beginning with three-minim doses well diluted after each meal, and increased by one or two minims daily according to the urgency of the case, until twenty-five or thirty minims are taken three times a day. A safer rule is to push it to the point of toleration and maintain it at this point until the blood examination shows the results desired. The appearance of its physiologic effects—edema and itching of the eyelids, gastro-intestinal irritation, etc.—is a signal for its temporary discontinuance. When arsenic can not be given by the stomach, it may be administered subcutaneously or even by the rectum. 2. In association with arsenic, assimilable food and rest are indispensable. 3. The use of intestinal antiseptics in this as well as in other diseases is a mere therapeutic refinement not sanctioned by bacteriologic reasons, and they ought, therefore, not to be employed as a routine measure. In the Italian literature one finds some authentic evidence of the good effects from thymol, its administration being suggested by the theory that pernicious anemia is caused by intestinal absorption of products which are destructive to the red blood-corpuscles. 4. Iron is not only useless but is apt to create digestive disturbances. 5. Bone-marrow is said to be curative, but it induces nausea and aggravates existing gastro-intestinal troubles. 6. Gastric disturbances suggest stomach lavage. The character of the food ingested must be determined by the results of a chemical analysis of the stomach contents. 7. To counteract the great reduction in the quantity of blood weak saline solutions may be given by the colon or preferably in the subcutaneous tissue. 8. Relapses are best prevented by minute attention to dietetic and hygienic details.

10. **Infection Through the Tonsils.**—In continuing his article (see last week's JOURNAL, ¶ 2, p. 1120), Packard re-

views the literature as to the possibility of chorea, nephritis, abscess, rheumatism, etc., originating from tonsillar infection. The paper concludes with an extensive bibliography of the past ten years.

11. **Rectal Valves.**—Cooke first gives the history of the discovery and recognition of these valves, and states, as his own opinion, that he is prepared to fully endorse Martin's conclusions as to their existence. He points out the possible fallacies in examination for them. Their action in the production of disease is next discussed, and he considers that they are responsible for a considerable proportion of chronic obstipation, or obstruction of the bowels in the lower section, as distinguished from constipation. The treatment is almost invariably operative, as the condition is rarely diagnosed in its early stages. The radical operation consists in incising the valves' free margin down to the muscular coat. He cautions as regards the operation; though apparently easily borne if properly performed, it is one of the most delicate operations in surgery. The part they play in strictures and rectitis is also discussed, and he reports five cases illustrating the value of the proctoscope and the more common forms of lesions of these valves.

12. **Shortening of Round Ligaments.**—Goelet describes a method of shortening which he considers has special advantages. The technique is described in full.

13. **Exophthalmic Goiter.**—Four cases, uncomplicated and with special complications, are reported by Bartholow. He calls attention to the purely functional character of some of the similar types. As regards the treatment, he thinks galvano-faradism is the most efficient agent. He has usually applied the descending stable current so as to include within the circuit the pneumogastric and cervical sympathetic nerves, and in cardiac cases much good is derived from spartein sulphate and picrotoxin, which may be combined with sulphates of iron and manganese. In more chronic cases with valvular lesions and degeneration of the thyroid and the skin pigmented, the best results are had from the combined solution of iodid and bromid of sodium and arseniate of sodium. As to hygienic management, he recommends non-exhaustive systematic exercise, moderate mental occupation, and thinks close confinement, as in the rest cure, is damaging.

14. **Obstetric Notes.**—The three points considered are preparation of the patient for labor, in which Stuart suggests careful examination in the later months, also uranalysis and instruction as to asepsis. The time to use forceps may vary, but should usually be early in cases where there is exhaustion of the uterine muscle or disproportion preventing molding and adjustment and persistent occipito-posterior position. As to repair of the injuries, he has found it of advantage to postpone it until a convenient hour in the first or second day after the operation. For intestinal sutures he would use small-sized catgut, and be sure to include enough tissue in the grasp of the sutures. For external sutures, silkworm gut, iron-dyed, is preferred.

15. **Tuberculosis.**—An early sign referred to by Harrington is a widely dilated state of the pupils, not paralytic but apparently due to some irritation, possibly systemic. He has come to associate this with early tuberculosis.

16. **Nasal Disease.**—Rice reviews the conditions of nasal disease, in which formerly a lesser degree of conservatism prevailed as regards operative interference than is now coming to be the rule; he also shows how we are learning to distinguish between the need of operation and the utilizing of the facts for the benefit of the patient. The one thing that he thinks would justify his paper is that we are beginning to recognize the influence of alcohol and tobacco.

17. **Cancer of Breast.**—A summary of the analysis of 100 cases of this affection is given by McWilliams. Trauma was present in 44.6 per cent. of the patients, 74 per cent. were married; 60.6 per cent. had borne children, the average number to each, 5; pain was present in 56.2 per cent.; nipple retracted in 45.2 per cent.; right breast involved in 51 cases, left in 49; axillary glands palpable in 48.9 per cent., cancerous by the microscope in 78.6 per cent. The average age was 49 years, 6 months, 26 days. The mortality of operation was 4 per

cent.; average length of time in hospital, 20 days; prolongation of life for one year resulted in 59 per cent., for two years in 36 per cent., and the cured—no recurrence at end of three years—34 per cent. Recurrence took place in one year in 21, in two years in 28, locally in 15, in the lung in 6. The average length of time in recurrent cases from operation to death was 1 year, 2 months 20 days, that from the period of recurrence to death, 5 months.

18. **Cancer Occurring in Acid Parts of Body.**—The relative frequency of primary cancer of the stomach as compared with that of the bowels and certain portions of the latter as compared with the mass is significant. Benedict has studied the subject and finds that a great majority of cancers develop in the acid media of the body. He points out that the localities where the natural secretions are acid are elective points for the affection, e. g., the stomach or uterus, and that in other regions where it is liable to occur, the abnormal acidity is possible and frequent. Whether the reaction is the determining factor or not, he does not pretend to state.

19. **Tenotomy.**—The after-treatment of tenotomy, preferred by Duane, is to utilize the directive force of the eyes themselves, and if necessary, by suitable exercises, to gradually substitute a more accurate correction for the approximate one produced by operation. He gives details of treatment advocated, and is so convinced of the value of the results that he regards the technique of the operation of subordinate importance. By the latter we can set the eyes fairly straight and in a position in which, being left free to move, they themselves will work toward an absolute correction. Therefore it makes little difference how we do a tenotomy, but much how we treat the eyes afterward.

22. **Splenic Pseudoleukemia.**—Cabot suggests that we should either abandon the term "splenic anemia," or else take up that of "lymphatic anemia," as applied to the association of lymphatic enlargement with impoverished blood. Or if we agree with Osler that there is no relation between enlargement with the same condition, we ought to make a sharp distinction between the two varieties of leukemia. In going over the literature, it is difficult to separate the forms here considered and those cases due to malaria, syphilis, etc. He gives the diagnostic points. The prognosis, according to Osler, seems to be relatively favorable, though writers differ on the subject. The operation of splenectomy is rational and seems to have been of advantage in one of Osler's cases.

23, 24 and 25. **Splenic Anemia.**—Morse reports two cases with the findings from blood examination, in one the disease may have been of syphilitic origin; the other was probably a relic of some infantile condition, as anemia with splenic enlargement is not uncommon in infants and especially common in rickets. Henry Jackson reports on the only case found in the Boston City Hospital, and he thinks very few if any patients with splenic anemia have entered it. He suggests more careful observation on this point. Another case is reported by J. M. Jackson and Hill, from the out-patient department of the Massachusetts General Hospital.

26. **Danger From Leprosy.**—According to Goodhue, the danger from leprosy in this country is to be found in the general neglect to watch for and isolate patients. It is therefore greater from our home foci in Minnesota and Louisiana, and from over the border in Mexico and Canada, as well as from tropical regions generally, than it is from our new possessions, especially Hawaii, where it is under close observation and well guarded against. If the fancied danger from leprosy from Hawaii is going to arouse us to the real danger of leprosy in our midst, it would be another of the many advantages of annexing the islands.

27.—See abstract in THE JOURNAL of April 7, p. 873.

29. **Roentgen Rays in Skin Disease.**—Pusey calls attention to the value of the Roentgen rays for the purpose of epilation and in the treatment of eczema, lupus, etc. The practical points to be noticed are to avoid too great strength or tension of current, too long or frequent exposures or too close proximity to the skin. At the beginning the sittings are not longer than five minutes, and the distance not less than 12 cm. The current, not more than 1.5 amperes and 12 volt strength,

should be employed. The ordinary skiagraphic currents are not desirable. Suitable lead masks for protecting contiguous surfaces should be used, and the personal idiosyncrasy must be looked after. The evidence that exposures have been carried far enough are: 1. Appearance of erythema and pigmentation. 2. Blanching of the hair. 3. Loosening of the hair. In the treatment of hypertrichosis great care should be used to avoid irritation and, in inflammatory disorders this is not so important, as a slight degree of inflammatory reaction is desirable, but it should be held at this point and not be carried to a painful degree.

30. **Some Therapeutic Observations.**—Belfield reports three cases of the use of gelatin as a hemostatic in persistent hemorrhages, in two of which there was complete success, in the third unequivocal failure. He would, in view of Bauermeister's experiments, refrain from using these injections in extensive nephritis. He also reports two cases of tumor of the breast due to syphilis, which was diagnosed as carcinoma, and he would impress on all his patients the idea that syphilis is not curable as a rule, and that subsequent, obscure or refractory disease should have specific treatment. He also mentions a case of the successful use of carbolic acid in a case of tetanus.

34. **Ophthalmic Memoranda.**—DeBeck reports several cases of eye trouble, among them one of gouging in a fight where he inserted a glass ball in the empty eye socket for cosmetic purposes, with good results. The patient afterward wore an artificial eye with the most satisfactory deceptive effect. He thinks it the only case in which an artificial vitreous has been inserted in a traumatic case twenty-four hours after injury, with success. Another instance reported is that of complete enucleation of the eye by a jet of water from a nozzle connected with two lines of hose by a Siamese coupling. The nozzle got away from those handling it, and the jet struck the man squarely in the face, at a distance of three or four feet, and no trace of the eyeball could be found. It was completely enucleated by the water. The patient made a satisfactory recovery. He also reports other cases of interest.

46. **Dermoid Cystoma.**—A case of dermoid cystoma is reported by Beyea, who gives a very thorough discussion of the subject. In his case he finds it in no way associated with the ovary. The literature of the condition is thoroughly worked up.

47. **Acute Septic Metritis and Peritonitis.**—Grandin finds that while a great majority of patients with puerperal infection recover with minor operation, about 1 per cent. die, notwithstanding operative treatment, unless it is employed early. The importance of early diagnosis, therefore, is clear. When septic symptoms appear in the puerperium, the patient should be most thoroughly examined, preferably under anesthesia, to differentiate saprophytic and streptococcal infection. Sæpemia yields to local operative treatment, unless too long delayed or complicated by streptococcal infection. When the clinical phenomena are of low grade, and the pulse rapid in proportion to the temperature, it is a warning of general systemic infection. Sæpemia having usually been ruled out and other disturbances such as pneumonia, urinary toxemia, etc., being excluded, exploratory abdominal section is indicated for positive diagnosis. By this it is possible to remove the infectious foci, before the system has been involved and the case become hopeless. The streptococcus infection, however, is so rare that it is only exceptionally that abdominal section is required.

50. **Surgery of the Ureter.**—Pryor describes a case of tubercular dermatitis and nephritis in which he had to remove the right kidney, and after enucleating the ureter, he inverted it into the bladder as is sometimes done with the appendix in the bowel. This was done by passing a long surgical probe into the bladder and through the ureter, suturing it to the end of the severed ureter. It was then drawn back into the bladder, inverting the tube. The ureter sloughed off and the probe was withdrawn the third week. Cystoscopy repeatedly showed all traces gone except a slight elevation at the site of the ureter. The convalescence was normal.

51. **External Palpation Versus Vaginal Examination.**

—Sprigg reviews the conditions of labor and mentions that to conduct a case ideally, having previously excluded the existence of deformity and abnormalities, the progress of labor must be observed by extravaginal methods, and after delivery nothing must be permitted to enter the vagina.

52. **Prolapsus Uteri.**—Deaver condemns the Alexander operation and intra-abdominal shortening of the round ligaments and vaginal hysterectomy unless there is a pathologic lesion warranting it; he advises ventral fixation. When the prolapse is complete, anterior or posterior colporrhaphy, or both may be necessary. "The cystocele is corrected by the removal of a sufficiently large oval flap, denuding the mucous membrane and submucous tissue, by which the muscular coat of the bladder is exposed. The incision extends from immediately behind the meatus urinarius to the cervix uteri. Two rows of catgut sutures appose the edges of the incision, the deeper taking the submucous and the muscular coats of the bladder, and the superficial the mucous membrane. The denudation of the anterior vaginal wall in the correction of the cystocele, and of the posterior vaginal wall in the repair of the torn or reflexed pelvic floor, is made with a scalpel. The repair of the anterior vaginal wall is the first step in the operative technique; when this is accomplished the rubber gloves worn are discarded and a new pair, previously sterilized, put on. The next step is the ventrofixation, and, lastly, the perineum is restored.

55. **After-Treatment of Peritoneal Section.**—The after-treatment recommended by Byford consists of the use of 4 drams of fluid extract of cascara, or some equivalent, two hours before operation, and dram doses of sulphate of magnesia every hour after the patient awakes from the anesthesia; a high glycerin and water enema— $\bar{3}$ ij to iv—every two hours after. A high glycerin enema was given before the patient left the table after operations in which the adhesions were separated and raw surface left. A prompt movement of the bowels and free passage of flatus not unfrequently resulted before the others were given, hence he began to give it as a routine practice. As he stated in a former paper, this treatment must as a rule not be discontinued until the patient passes flatus, not only with the enemata but also frequently between them, i. e., efficient peristaltic action should continue at intervals. Means should also be taken to maintain frequent peristalsis and a daily evacuation of the bowels after the first day, and he frequently gives two drams of sulphate of magnesia or two or three ounces of Hunyadi water night and morning for two weeks, regulating the doses according to the effects.

56. **Mortality From Abdominal Section.**—Stone concludes his article as follows: 1. The abdominal route may be selected in the vast majority of "real pus cases," because it not only gives a better opportunity to deal with diseased pelvic structures, but also facilitates the inspection of the abdominal viscera and the relief of any pathologic condition of these organs. 2. The vaginal route is still used by the writer as occasion demands, as when a "pelvic" abscess is pointing in the vaginal vault. 3. In the majority of cases, then, abdominal section is advised; still, in a certain small number, vaginal puncture, and in a third class, when the abscess is large and situated "high" in the pelvis, it is reached through the abdomen, evacuated and drained without attempting "enucleation" if the patient is evidently too much exhausted to bear a radical operation. In short, pus should be sought for and evacuated from that quarter which gives the easiest approach and speediest and safest exit consistent with the present condition of the patient, and having in view her permanent restoration to health.

58. **Cranio-Rhachischisis.**—Under this head Lewis describes a number of interesting cases of the defective closure of the cranium, with illustrations.

68. **Guaiaecol in Malaria.**—Whalen reports the subsequent history of some cases previously reported, with several additional ones. In all his ideas in regard to the benefit of the drug, in cases where quinin fails, as expressed in an article abstracted before (see THE JOURNAL of March 10, ¶ 47, p. 356) are confirmed by these later experiences.

70.—This paper has appeared elsewhere. See THE JOURNAL of April 14, title 41, p. 924.

71. **Have We a True Nerve Tonic?**—Williams gives the results of his experience with various drugs as nerve tonics, and concludes as follows: 1. For long-continued use in conditions of weakened nerve power, strychnin, arsenic, phosphorus, and the hypophosphites are unsuitable on account of the ultimate depressant effect which their continued use may occasion. 2. In the glycerophosphates we have preparations so nearly identical with the natural phosphorus compound of nerve substance as to be more readily appropriated by depressed nerve tissue than any other phosphorus preparations. 3. This near identity of the glycerophosphates with lecithin, and the absence of nerve stimulation produced by their administration, render them true nerve tonics. 4. The success of those of the profession who have used these preparations entitles them to trial by the profession generally.

73. **Peroxid of Hydrogen.**—The use of this is recommended by Beadles in the following conditions: eczema, which may be sometimes aborted by prompt treatment; impetigo contagiosa; lichen planus, in which no other drug gives such good results; tinea versicolor; tinea circinata; chloasma; freckles and bromidrosis.

75. **Appendicitis.**—Young gives a review of the general literature of appendicitis and of the opinions of surgeons in regard to the question it involves. There is a general agreement as to the mortality of the severe, acute cases and the successful outcome of mild ones without treatment, the safety of operation during intervals, and the frequency of relapses, but on other points there seems to be a large range of opinion. The general tendency, however, on the whole, would appear to us to be more conservative than radical, as opinions go on this subject. There is need, as he points out, of exhaustive statistics on these points. The paper is followed by a symposium of communications from various physicians and surgeons in regard to the indications for operation and its favorable moment.

78. **Obstipation.**—The chief symptoms of obstruction and abnormal conditions of the rectal valves are difficult and unsatisfactory straining at stool, with occasional diarrhea and flatulence and borborygmus, and later attacks of intestinal intoxication and neurosthenia. The pathogenesis may be a normal increase of fibroid tissue from any cause. The diagnosis is easily made with the proctoscope. The operation is described and the amount of incision of the valves is estimated by inserting the hook beyond it and drawing it down toward the operator until the presence of the end of the hook shows in the form of a blanched eminence; and in the operation of division the valve should be transfixed at a point considerably nearer the free margin than the estimated position of the eminence. The valve should then be seized by a tenaculum on either side of the point selected for the section, the knife made to transfix the fibrous border of the valve and divide a few fibers of this tissue and the mucous membrane covering it, by cutting its way through the free border of the valve. This should be transfixed with the bistoury at a moment when the valve is situated at a right angle to the wall of the intestine. If the valve be pulled downward by means of the tenaculum, so that it presents an inclined plane toward the operator at a moment when the bistoury is made to transfix the conjoined tendon, the superior dense fibrous lamina will have a tendency to force the knife outward and through the wall; hence the necessity of a proctoscope of a special length for each valve, that its end may be carried to the valve instead of the latter being pulled down to the proctoscope. But a few fibers of the conjoined tendon are to be divided by this bistoury. After the incision is thus started a scalpel-like knife, provided with a similarly built handle, should be used to deepen the incision. In some cases the valve should be cut in two places. The instant the conjoined tendon is divided a gaping wound will be presented to the eye. This wound-cavity is irregularly pyramidal and open at its apex; the two walls running away from the apex consist of the fibrous lamina of the valve; the base is made up of the uncut circular muscular fibers; external to the circular muscular fibers are the longitudinal muscular and peritoneal coats of the rectum, which this technique fortifies against accidental injury.

83.—*Ibid.*, Dec. 2, 1899, p. 1421.

85.—*Ibid.*, p. 1420.

89. **Empyema.**—The contrary views as to the value of drainage and irrigation in empyema are noticed by Andrews, who tabulates the authorities as they have expressed their views in favor of incision, drainage, irrigation and resection of ribs. He considers intercostal incision safer than resection in most cases, especially in children, but not sufficient for every sort of case. As regards irrigation, his experience has been that by avoiding toxic substances, using only warm boric acid solution, small and weak at first and gradually increased, poisoning and shock can be avoided and bronchial fistula discovered before dangerous flooding has taken place if care is used with small quantities at first. The most frequent necessity for resection is in case of old cavities with strong cicatrices, preventing expansion of lungs and whose granulations are not strong enough to fill the space. In these cases we should sacrifice the ribs to let the thoracic walls fall in and fill the cavity. In cases where there is a pseudomembranous lining of the pleura it can be eventually washed out mechanically if a large tube is used.

99.—*Ibid.*, p. 751.

103.—See abstract in *THE JOURNAL* of March 31, p. 815.

105. **Congenital Dislocation of Hip.**—After giving ten cases illustrating the diagnosis of this condition, Wirt describes the methods of treatment, which he narrows down to two, viz., the bloodless method of Lorenz and the cutting operation by Hoffa, modified by Lorenz and Whitman. Four cases are reported that were treated with more or less success. He finds that the non-cutting reduction method is rarely effective after the age of 4 or 5, and when it fails the other should be employed up to the age of 8 or 9. Above this it is not worth while to attempt it, on account of the marked anatomic changes which have taken place. In his own method, he does not cut the short muscles as advised by Lorenz, or the long as Whitman advises, but uses considerable force to bring the head of the bone to its normal site.

106. **Brain Syphilis.**—The "fragmentary observations given by Aldrich refer especially to the accurate diagnosis of cerebral syphilis, the limited application of the general laws of prognosis in the specific lesions, the tendency to relapses, the importance of giving attention to the age, sex, social status, alcoholism, cachexia, etc., in each case, and the constant danger of pathologic accident in syphilitic individuals. Later he notices the favorable influence of specific treatment in these cases as compared with similar clinical conditions of non-specific origin.

110. **Rectocele.**—Lott describes a method of operating which he thinks has certain advantages over others, though not widely differing from them. It consists in making a triangular flap on the vaginal wall at the highest point on the rectocele, from the base of which two cuts are carried down to the point on each labium where apposition will re-establish the normal perineum. The space between these, excepting the triangular space mentioned, is denuded and the edges of the outer incision brought together by buried sutures fastened by perforated shot, making altogether a sort of a Y-shaped line of sutures. He thinks this the means of attaining the four cardinal wants of the case, viz., repair of the perineum, taking the slack from the lateral walls, removing the rectocele, and supplying in its stead, in the posterior wall, a contracted, cicatricial column, with prong projections into the vaginal fornix, which most nearly restores the parts to their normal function and gives support to the organs above.

112. **Cough and Its Treatment.**—The reflex origin of cough is especially emphasized by Porcher, who points out the localities from which it may arise, viz., nasal and nasopharyngeal cavities, pharynx and laryngeal tonsil, the larynx and ear. A purely neurotic one is also mentioned and affords some of the most brilliant successes of the physician. In cough we should find the cause and treat that. He finds that the C. and C. mixture of chloroform, codia and hydrocyanic

acid has an excellent effect on pharyngeal irritability. Where there has been much nasopharyngeal catarrh, he has had benefit from the use of a gargle consisting of carbolic acid and glycerin, bichlorate of soda and tannic acid. In tubercular cough nothing is so good as absolute rest of the throat; the gouty and lithemic one requires treatment for that condition, and he has met with cough where specific treatment only was effective. In order to stop the nervous form, the mental impression is a requisite and both constitutional and local treatment are useful. The former may consist of a sharp cathartic for its revulsive effect. He usually makes an application of the galvanocautery to the lingual tonsil, because the explosive effect of the cough is chiefly against that gland, and if it is made a little sore the patient will take more pains to control it. Cough medicine is hardly necessary in these cases, but the above C. and C. mixture may be soothing. It is hard to say just what effects hypnotic suggestion has in these cases, but there is no question that it goes a long way.

FOREIGN.

British Medical Journal, April 21.

"**Riding Fragment**" in **Fractured Leg**. C. H. GOLDING-BIRD.—Fracture, especially of the tibia, is noticed at length with special reference to the coaptation of the fractured ends. In the beginning the author calls attention to the real test of the value of any method of treatment, and the tendency of late years to authorize cutting down on the simple fractures to insure very direct apposition. One of the first things is to have the injury repaired at the earliest possible moment. He thinks operation for simple fractures has been carried to extremes. There is a possible danger in skiagraphy; the patient may have a skiagram taken after the fracture has been treated and find a certain deformity and on this may base a claim of improper treatment. If the utility of the limb is perfect, though there may be a remnant visible in the skiagraph, he doubts whether the success of the treatment has been in any way impeded and it is not advisable to incise simple fractures simply to meet the demands of the skiagrapher. The special subject of the lecture, however, is the "riding fragment," and the main point made is that the most frequent fracture is not the oblique, as is commonly supposed, but is rather what is called the spiral type, and for this reason the continuous retention of the bone in place is more difficult. If the tibia is intact it itself acts as a splint, but the more usual rule is for it to be a great opponent to restoration, and the arrangement of the muscles of the two bones causes a spring action, the fibula pulling the muscles of the tibia apart. We have to suppose that jagged ends of the broken fibula have been driven into the surrounding fibrous connections and firmly held there in a false position, to understand how a rotary action applied to the tibia to lock the spiral would, for anatomic reasons, give an equally rotary reaction to the fibula, the fracture of which bone not being spiral would not be similarly influenced. Hence the fractured ends of the fibula, thus twisted, act as springs until the force is removed, or continue their spring action until they unlock the adapted spiral. Golding-Bird does not claim this idea to be altogether new, but he believes the fibula to be the main cause of the trouble constantly found in setting fractures of any portion of the shaft of the tibia, hence the usefulness of operation in these cases.

Calculi Impacted in the Ureters. DAVID NEWMAN.—Newman describes the pathology, symptoms, and surgical treatment of impacted calculus in the ureter, and the symptoms produced by retention of urine in this way are quite fully discussed. The methods of diagnosis are pointed out and illustrated. Much can be done by palpation through the abdominal parietes, provided the walls are flaccid and the patient thin and the stone situated above the brim of the pelvis, but if the patient is corpulent and the muscles rigid this may not be of much use. When the stone has passed the lower third

of the ureter. examination with the finger in the rectum and vagina may lead to its detection. Cystoscopic examination may be of great value. Sometimes the calculus is arrested at the outlet of the ureter and forms a tumor in the bladder, which can be treated immediately through this organ. The Roentgen rays have not been of much value. The distinction from other obstructions, such as tumors and displacements of the pelvic organs, adhesions, etc., is sometimes a little difficult, but the usual suddenness of the obstruction is a characteristic in most cases, and other disease causing pressure of the ureters is generally so prominent as to be recognizable. The adjustment to such cases, however, does not include the calculus. The most important cases to distinguish from calculus obstruction are such as kinking of the ureter, as may happen with movable kidney, or where the impediment arises from angular insertion of the ureter. The treatment depends on a thorough understanding of the conditions. If there is reason to think only one side is affected, it is advisable to await the course of events, and frequently the obstruction is spontaneously relieved and no permanent harm results. Sometimes massage, shampooing and fomentations, etc., are useful. Opium to relieve pain should be used with great care, as even small doses may have serious effects when the kidneys are obstructed; it is better to use other methods, as hot fomentations, baths, or even an anesthetic, which may so relieve the spasm as to facilitate the passage of the calculus. Change of position may have some effect. When the ureter of the only working kidney is affected, operation is necessary, and when it can not be felt with the finger, it will have to be reached through the abdominal parietes. The methods of operation are described. If the stone can be pushed backward into the kidney and removed by nephrectomy, this is probably the best method and the sound should be passed down the ureter to be sure no further obstruction exists. If it is firmly fixed in the ureter, incision should be made, and this can afterward be closed by sutures.

The Lancet, April 21.

Coxa Vara. C. B. KEETLEY.—Coxa vara—a deformation of the femur in which the head sinks to a lower level than the normal, sometimes almost touching the lesser trochanter—is a sequence of rickets. Keetley thinks in many cases of genu valgum the knee deformity is a compensatory curve to a certain degree of coxa vara. He mentions a characteristic alteration of bones of the face and forehead, a sort of expansion and an appearance of thinness in the orbital and nasal regions. Pain is the first symptom and later there is even limitation of the movements and lameness. In diagnosis it should be differentiated from dislocation by the absence of looseness of the limb, and from hip disease by the absence of pain on pressure and movement and its relief by rest, and the lack of startings at night, and the less wasting of the thigh, etc. The disease, at first progressive, usually comes to a stop with a certain amount of deformity and the treatment is to restore the shape of the bone, as far as possible, by osteotomy, and to relieve the pain by rest; the latter is only palliative. The author suggests an operation which he thinks practicable, but not liable to be popular, for, if carelessly and awkwardly done, it may produce imperfect results. It consists in dividing the bone a little above the upper trochanter, then cutting—obliquely, again from the outer surface of the fragment—a portion with the muscular attachment and re-setting the bone on this last surface, fastening it with pins or wires. He thinks this would be more effective than simple osteotomy, and closes with a claim to priority in the recognition of the nature of the disorder, his paper having been published prior to Müller's, in a journal which only lived a couple of years, and has therefore not been largely quoted.

Causation of Nervous Symptoms in Typhoid Fever. ALEXANDER G. R. FOULERTON and E. CAMPBELL THOMSON.—The authors say that the probabilities of finding pure typhoid toxins are likely to be confined to the early stages of the disease as later other complicating infections may occur and involve the nerves and nerve-centers. They report two cases, with post-mortems, of cerebrospinal implication in which they think that the meningeal complication was due to typhoid

toxin. From studies of the cortex in these cases and the findings in the literature they do not learn of any marked changes in the ganglion cells that are characteristic. Experimental researches on the lower animals confirm this, and it appears from other observations that there is nothing to warrant the conclusion that typhoid toxin causes definite alterations in the ganglion cells of the central nervous system. This does not prove, however, that nervous symptoms are not produced by the pure toxins or that they do not act on other portions of the neuron.

Production of Local Anesthesia in Ear. ALBERT A. GRAY.—After experimenting with various vehicles Gray finds that anilin oil with rectified spirit, as a solvent for cocain, has special advantages in producing a specially beneficial effect on suppurating, causing it to diminish or cease. Anilin oil is of benefit also in rendering the drum membrane transparent. The effect on suppurating is probably due to the power of the oil in extracting the water from the tissue, which is also a quality of the rectified spirit. This method of producing local anesthesia may also be employed on other mucous surfaces. He has used it some for throat work. For the latter a 5 per cent. solution is employed; for the ear, he has used as much as 10 per cent.

Backache as a Symptom of Rectal Disorder. E. HARDING FREELAND.—The symptom of backache is usually associated with uterine disorder, but Freeland finds it by no means constant. It is frequently due to reflex irritation, having its origin in the irritation of the rectum, which, even though it is associated with symptoms referable to other pelvic organs, will not infrequently be found to be the cause. He reports several cases and in conclusion says that: 1. Backache is not only a common but a very important symptom. 2. Whether it be practically the only symptom present or whether it be associated with other more or less definite ones it is worthy of a careful and searching investigation. 3. No investigation should be considered complete until the condition of the rectum has been ascertained.

Bulletin de l'Academie de Medecine (Paris), April 3 and 10

Mortality and Disinfection. E. VALLIN.—Grancher recently pointed out, at the Academie, that isolation in measles is ineffectual, for when the disease is recognized it is already too late to prevent contagion; that disinfection is superfluous against the germ, as its virulence is extremely short-lived, but it is necessary to prevent the secondary infections, e. g., measles bronchopneumonia, etc. Vallin now brings evidence from military barracks, to show that the virulence of the germ of measles is not so transient as is asserted by city physicians, for when the disease appears in the barracks the epidemic may drag along for many months. He thinks it probable that the germs revive and thus occasion new cases and cites an instance in which the floors of some rooms in the barracks where there had been measles a year before, were torn up and the dust permeated the entire building; there had been no cases for a year, either in the barracks or in the adjoining small town, but after the floors were torn up several appeared among men who had not been away from the station for a long time. Transmission by a healthy third person is possible and frequent, but in this case no outside source for the infection could be discovered. Vallin therefore heartily approves of disinfection during measles.

Serofula and Adenoid Vegetations. P. GALLOIS.—Gallois seeks to establish that the swelling of the ganglia in the neck is secondary to a primary lesion located in some of the air cavities of the face, usually adenoid vegetations. He considers them the chief cause of cervical adenitis, of otitis and serofulous ophthalmia. They may also lead to cutaneous infections and osteo-articular tuberculosis. By disinfection of the air cavities of the face, numbers of children would be saved from so-called serofulous manifestations. He does not deny the influence of the "soil," but demonstrates that this is not the only factor in serofula.

Appendicular Pleurisy. DIEULAFOY.—In the presence of a fetid and putrid pleurisy of the right side, the possibility of an appendicitis as the origin must always be borne in mind, and by reviewing the history of the case it can usually be dis-

covered six to ten days before the phrenico-pleural stage. Dieulafoy reports several observations, and shows that the ascending infection from the appendix may reach the diaphragm and pass through it in the lymph spaces or by perforation. The fluid of the pleuritic effusion is usually turbid and fetid, but occasionally, in the rapidly recovering patients, it is clear. He still advises prompt surgical intervention in appendicitis, and in case of complicating pleurisy, the operation must be dual, attacking both the pleura and the appendix; or better still, before the appendicular infection has had time to ascend to the pleura.

Rapid Diagnosis of Rabies by Microscopic Examination of Medulla of Suspected Dog. V. BABES.—During the last nine years Babes has been making a special study of this subject, and states that out of the 487 dogs suspected of rabies which he has examined he found 35 with normal medulla, and they all proved free from the disease, as he had anticipated. Microscopic examination of the medulla is therefore one of the best means of rapid diagnosis of rabies at our disposal. The alterations noted consist in a peculiar displacement of the chromatic substance of the cell protoplasm toward the center or periphery, vacuolar degeneration, total disappearance of the chromatic elements, loss of the prolongations, modification of the nucleus until it vanishes, dilatation of the pericellular space and invasion of this space and also of the nerve-cell by embryonal elements and also by peculiar small hyaline, brownish corpuscles, partially metachromatic surrounded by a pale zone. Certain nerve-cells are surrounded by a wide zone of embryonal cells forming nodules which he calls "rabie nodules." The vessels in the medulla are always dilated, and obliterated in places by thrombi formed of leucocytes, but always containing small brown metachromatic, hyaline corpuscles, arranged in heaps, stars or crowns by free granulations and fibrin. These thrombosed vessels occasion hemorrhages. They are also surrounded by wide zones of embryonal elements which are also noted in the gray matter, where the infiltration sometimes amounts to an actual inflammation. The histologic findings are always confirmed by inoculation.

Presse Medicale (Paris), April 7, 14 and 18.

Present Conceptions of Neuron and Nerve Network. A. SICARD.—The recent attempts to dethrone the neuron theory, by Apathy and Bethe, have not succeeded in overthrowing the results of long and careful observation on which it is founded. Apathy considers the nerve-cell and its prolongations a distinct entity enclosed in, but not in contact with, a continuous nerve network which extends uninterruptedly from the sensory periphery to the motor periphery. Bethe goes still further and asserts that the nerve-cell is independent of all the conducting nerve-fibrils, sensory or motor. They converge to a "neuropile" in the center of the ganglion, and he is still uncertain as to whether or not they connect. Sicard concludes that even if the fact is established that the elementary fibrils pass from one nerve unit into another, the neuron theory may have to be slightly modified, but it would still maintain its value and importance.

Glomerulitis. V. CORNIL.—By means of colored plates, Cornil shows the various changes in the glomerulus, whether of the capsule, of the cellular coat of the vascular loops, or of the intraglomerular connective tissue, all leading to the thickening of the walls of the capillaries and a fibrous atrophy of the glomerulus. This last lesion entails the absolute functional loss of the glomerulus, which is transformed into a small fibrous nodule. This fibrous atrophy is very common in the superficial portions of the kidney and under the capsule, in subacute and chronic nephritis. In the latter a calcareous degeneration may occur or a cystic dilation or amyloid degeneration. The glomerulitis may be due to the invasion of bacteria, obstructing the lumen of the capillaries until an abscess is formed.

Painful Polymorphous Dermatitis. L. BROQUÉ.—Corlett described an observation of this affection, at the meeting of the American Dermatological Association in 1898. Another was described in France in 1896, and Broqué now presents the third. He proposes the above name for the group of symptoms in-

cluding pains of variable intensity, usually intense and out of all proportion to the extent of the eruptive phenomena, which are polymorphous, erythematous-vesicular, bullous, urticarial, papulous or pustulous, sometimes herpetiform, more often grouped, but also disseminated. There is a marked tendency to progress by successive "pushes." The general health seems very little affected. In the observation described and illustrated, the eruptive process was limited to each side of the face, extending from the neck in a strip over the forehead, with remarkable production of cicatrices and epidermic cysts in the affected regions, on which it recurred again and again and to which it remained limited, causing absolute alopecia. The patient was a man of 71, otherwise in good health. The affection had commenced a year and a half before, after a severe mental strain.

Cure of Harelip. E. JUVARA.—Severeanou has been much pleased with the results of his method of operating on harelip. No tissue is wasted; the needed raw surfaces are obtained by blunt dissection of the mucous membrane layer of the lip from the cutaneous muscular in front. Each layer is then sutured, the inner over and over, brought up to form the lip, and the cutaneous muscular flap with a special zigzag suture. The needle is inserted from side to side and follows a zigzag path through the tissues; each time it emerges on the skin it is reinserted in the same hole, but slanting at quite an angle from its path to the hole. Drawing the thread with a knot at the end, the lips of the wound are coapted with no dead space, and no signs of the thread except the two knotted ends and a row of tiny holes on each side of the wound, located alternately. If there is a considerable defect to be filled a small flap can be taken from the thickness of the lip with its base toward the exterior. He usually prefers general narcosis but cocaine will answer; and he has even removed a small cancer from the lip in this way, concluding the operation as above.

Prolapsus of Rectum. G. MARCHANT.—The rectovesical peritoneal pouch descends almost to the perineum in the embryo, and later frequently contains loops of intestines. If from any cause, such as relaxation of the rectal wall at this point, repeated efforts at defecation, possibly some congenital malformation of this pouch, the rectal wall yields, the intestine in the pouch will invaginate into the rectum, forming a primary perineal hernia into the rectum. This hernial sac drags the loosely fastened side and rear walls down with it, and the prolapsus of the rectum is complete. This is the explanation of the etiology of prolapsus as advanced by Ludlow last year and endorsed by Marchant. The question arises whether or not this hernial sac can not be operated on and the prolapsus be cured. The best method of treatment is not the usual resection with its frequent relapses, dangers of infection, etc., but recto-coecopyxy, suspending the rectal ampulla from a stable support, the stitches taken well around on the lateral as well as in the rear wall.

Pains in the Side in Habitual Drinkers. G. MILLAN.—Hepatalgia, epigastralgia or intercostal neuralgia, simulating an acute pulmonary affection, are frequently the first symptoms to call the attention of the habitual drinker to his chronic intoxication. Local revulsion, purgatives, opium and diuretics are the means to be employed in treatment, "with a moral purgation of the patient."

Revue de Chirurgie (Paris), April.

Epithelioma of Both Nipples with Secondary Dermic Nodules. A. LE DENTU.—This puzzling case was complicated with tuberculous peritonitis, but no tuberculous lesions were found in the breasts. The patient was a young woman in poor circumstances and, aside from menstrual troubles and syphilis, had never been ill. Suddenly both breasts became enormously tumefied, with acute total mastitis, followed by a stage in which the lesions assumed a nodular aspect, with the simultaneous appearance of ascitic peritonitis. Then ensued a phase of absorption and apparent recovery from the abdominal lesion after laparotomy, followed by a fourth and last phase in the cutaneous neoplastic invasion. Each breast was the seat of a cylindrical epithelioma. The mammary affection subsided to a torpid course at last, and death was due to the progress of

the peritonitis, sixteen months after first indications of the mammary affection.

Total Ablation of Scapula with Retention of Member. L. PICQUE and DARTIGUES.—A myeloid sarcoma in the scapula necessitated the total removal of the bone. The cuts of the patient, a robust young woman, taken a year after operation, showed that with the exception of the lowering of the shoulder, the results had been absolutely satisfactory. A simple brace devised by Picqué restored the shoulder nearly to normal position, and the patient pursues her occupations without inconvenience, and is stronger than before. The partial and total operations of the kind on record are reviewed in tabulated form, including three by Americans at an early day: 34 total; 27 partial, and 6 with resection of the head of the humerus. The mortality was 18 per cent. Recurrence was noted in 7 of the 34 total ablations, but 13 were eminently satisfactory in the ultimate results. Statistics are defective in regard to recurrence in regard to most of the rest. Picqué explains and illustrates the various steps of the operation, opening the capsule of the joint and luxating the head of the humerus, resecting the outer third of the clavicle and severing, as the final step, the last muscles holding the scapula and twisting it around its spinal end as on a hinge, concluding with fixation of the head of the humerus slightly backward, careful hemostasis and drainage.

Uterine Fibroma with Multiple Pedicles. F. TERRIER and E. REYMOND.—Investigation through the cervix, in a case of fibroma described, might easily have led to error, as the fibroma seemed small and the pedicle near the orifice could be readily distinguished. But in reality the neoplasm was extensive and the true pedicle was in the roof of the fundus where it would have been impossible to reach it by vaginal operation. There were two other so-called pedicles, but the writers establish that they were merely secondary adhesions, as the fibrous polyp in its growth came in contact with a portion of the uterine wall and pressed against it, thus forming a depression in which it rested, with loss of epithelium on both the surface of the uterine wall and the polyp, entailing ulceration. As the lobe of the polyp was imprisoned in the ulcerated cul-de-sac, the muscular tissue of the uterus became continuous with that of the tumor, forming a solid secondary pedicle without interposition of cicatricial tissue, and with blood circulating through it. Cysts were noted in the fibroma, but not in the central portion nor in the primary pedicle. An explanation advanced, based on the histologic characters of the cysts, especially their cylindrical epithelium lining, is that while the mucous surfaces of the uterine wall and the encroaching lobe of the tumor were in contact and became continuous, the lower end of the cul-de-sac or pocket thus formed still persisted and became surrounded by the growth of the pedicle, remaining as a closed cavity which increased in size and became a cyst visible to the naked eye.

Anterior Opening for Certain Resections of Hip-Joint. ROCHET.—Comparing the ultimate results in patients operated on directly from the front with those in which the joint was reached more from the rear, Rochet finds that ankylosis in a good position is attained more rapidly and more easily by the former than by the latter method. The dressings are much more easily applied, both for the patient and the attendant, and chances of secondary infection from the anal region are much less.

Pathologic Anatomy of Cancer of Stomach. B. CUNEO.—This author's experience renders his statements worthy of attention. He confirms the infrequency of invasion of the duodenum in case of cancer of the pylorus, and merely considers the first centimeter suspicious, as a rule, recommending resection of 2 cm. as the minimum. The propagation of the neoplasm in the submucosa, beyond the limits apparent in the mucosa, is now fully established, also the invasion of the para-stomachal ganglia, which should be removed in one mass with the tumor, the incision extending as close to the cardia as possible. He suggests that the resection would be much facilitated by preliminary ligature and division of the stem of the coronary near the main fork, and also ligature of the gastroduodenal at its origin.

Centralblatt f. Chirurgie (Leipsic), April 21.

Route to Gasserian Ganglion. F. KRAUSE.—Supplementing his former communications on the subject, Krause observes that the difficulties of the operation for resection of the Gasserian ganglion first begin with the exposure of the third branch inside the skull. From this point onward it is necessary to have the most complete supervision of the field of operation, and this can be accomplished only by elevating the temporal lobe of the brain in its dural envelope, as otherwise the field is in darkness, and complete extirpation would be impossible. Partial extirpation and the use of the sharp curette should both be rejected. But the brain should be retracted as little as possible, and, to avoid it, the side-wall of the skull should be removed down to the crista infratemporalis. It is altogether unnecessary to reset the zygomatic arch. He has tested all the methods proposed on the cadaver, but has found none that allows such ample access as his own. He has made a thorough resection of the trigeminus on twenty-two patients, and states that his method of ligating the middle meningeal artery is so reliable that he can recommend it as a typical operation. He has done it three times so far in cases of hemorrhage, with complete success. He adds that experiments on the cadaver are not equivalent to those on the living subject, as there is no venous hemorrhage from the dural veins, which in isolated cases has immeasurably enhanced the difficulties of the operation, and is much more embarrassing with a narrow opening than with ample oversight of the field. His improved technique in cutting the bone flap consists in drilling a hole at each of the upper corners of the outlined, uterus-shaped flap, after two small incisions through the skin. A Gigli saw is introduced through these holes, and the upper edge of the flap sawed through from within outward, leaving the skin untouched for a time. The two side edges of the flap are then cut with a knife, a little at a time to prevent hemorrhage, and the bone by Dahlgreen's forceps, as far down as possible. The skin-bridge across the top is then divided and the bone lifted and turned over, breaking the bottom edge of the flap across; the jagged edge always corresponds to the thinnest part of the squamous portion of the temporal bone, about 1 cm. above the zygomatic arch. It is indispensable now, to chisel away the rest of the bone down to the crista infratemporalis, after blunt dissection of the periosteum from the large sphenoidal wing and squamous portion of the temporal bone. Without resecting the zygomatic arch therefore, the flap, hanging by skin, temporal muscle and periosteum, can be turned down over the malar bone and free access to the middle cranial fossa thus be obtained.

Deutsche Medicinische Wochenschrift (Leipsic), April 10.

Reproduction of Bacteria. FEINBERG.—With the Romanowski stain, slightly modified, Feinberg has succeeded in establishing the existence of a nucleus in certain bacteria, and now announces that he has traced a series of phenomena in diphtheria, tubercle, typhus and other bacteria, which can only be interpreted as the whole process of direct cell division, from the first constriction in the nucleus to the complete division into daughter nuclei by amitosis. It is best observed in the diphtheria bacillus, in which nucleus does not so completely fill the cell as it does in some of the others.

Finding Acid-Proof Bacteria Resembling Tubercle Bacillus in Gangrene of Lungs. LYDIA RABINOWITSCH.—Several writers have reported finding "pseudo-tubercle bacilli," so-called smegma bacilli, in gangrene of the lungs, but none have succeeded in cultivating it from the sputum. This has been accomplished by the writer, from the sputa and the gangrenous focus of a patient with fetid chronic bronchitis and suspected cavity, but no indications of tuberculosis during life nor at the necropsy. The bacteria proved acid-proof and formed on glycerin-agar, in twenty-four to forty-eight hours, grayish-white, shiny, pinhead sized colonies that gradually spread into a whitish, creamy film. The film lost its shine as it grew older, and became wrinkled, yellow and finally orange-colored. On bouillon there was an indol reaction and disagreeable odor. Guinea-pigs were not affected by inoculations, but mice succumbed in about ten days and the bacilli were found in their blood and organs. The bacilli also proved

pathogenic for guinea-pigs when injected with sterile butter. In this case they produced the same lesions as those already described by the writer, caused by acid-proof bacteria isolated from butter. All the so-called acid-proof bacteria are distinguished from the tubercle bacilli by their pathogenic properties and their cultures. But they respond alike to stains to acids and alcohol, probably chiefly on account of the larger amount of fat they contain. The writer believes that the bacterium isolated in this experience is identical with those found in sputa and which are described by Zahn, Fraenkel, and Pappenheim.

Case of Isolated Paralysis of Nervus Suprascapularis. A. HOFMANN.—Traumatism preceded nearly all of the few cases on record, the rest were consecutive to neuritis of the plexus brachialis. The main symptom is the tray-shaped depression of the infraspinous fossa in consequence of the atrophy of the musculus infraspinatus, and the weakness and effort necessary to rotate the arm outward, or raise it vertically.

Case of Multiple Melanosarcomata with Peculiar Complications in Both Eyes. A. WAGENMANN.—A young man noticed small pigmented tumors on the breast and face, and one developed in the left eye, but was afterward completely absorbed. Another developed later, leaving a layer of lumps of pigment over the cornea. The right eye also became affected with a metastatic process, resembling synchysis scintillans, only the glistening points in the latter were in this case the floating, brown dots of pigment, and the membrane a compact yellow mass.

Acidophile Bacilli in Infants' Feces. H. FINKELSTEIN.—Particles of the feces sowed on .5 to 1 per cent. acetic acid bouillon, to which 2 per cent. grape-sugar had been added, showed that there are at least two and probably four different varieties of acidophile bacteria in the intestine of healthy infants. Finkelstein announces that in certain pathologic cases there is such an increase in the numbers of these acidophile, Gram-staining bacteria that they can be considered a pure culture. They sometimes resemble those found in sound intestines and again show such a difference in their cultures that a specific difference can scarcely be doubted. They are sometimes thread-like, sometimes like streptococci, sometimes slender, curved, short threads. The morbid conditions in which the last-named shapes were noted, were distinguished by infectiousness, remarkable resistance to dietetic therapy and by the preponderance of severe nervous disturbances in the syndrome. They did not prove pathogenic for the usual laboratory animals, but young goats died regularly two to three weeks after ingestion of 10 gm. of fluid feces containing bacilli from severely sick children. The animals became extremely emaciated and temperature was subnormal, but neither clinical nor anatomic alterations could be discovered. The same amount of a pure milk culture, three days old, from a fatal case, caused death in three weeks with the same symptoms, while a like amount of normal fecal matter produced only slight and transient disturbance.

Silver Wire Treatment of Prolapsus Recti. URRAN.—Several years' experience has confirmed the absolute harmlessness and efficacy of Urban's method of preventing prolapsus of the rectum. It consists in merely narrowing the orifice so that the prolapse can not occur. A silver wire is run around the rectal walls 1 cm. above the anus, and the needle inserted back in the stitch hole from which it emerges each time. The wire is drawn up and fastened, closing the lumen until the orifice will admit nothing larger than the forefinger in an adult and the little finger in a child. The wire has been usually removed after two or three months, but he is now leaving it permanently since it heals into the tissues without disturbance of any kind. All the troubles of the prolapsus vanish at once after the insertion of the wire.

Muenchener Medicinische Wochenschrift, April 17.

Diagnosis of Pulmonary Lesions Caused by Inhalation of Dust in Industrial Establishments. BAEUMLER.—Percussion sometimes shows that the upper part of the anterior margins of one or both lungs is very much retracted, and this retraction is evidence of induration and contractions in the lung

tissue. Baemler has noted it in a large number of cases, and in nearly all he could demonstrate lesions due to the inhalation of foreign particles in the dust from industrial establishments. These inhalations cause frequent bronchial catarrh, recurring at progressively shorter intervals, emphysema of the lungs, bronchopneumonia and inflammation, with participation of the interstitial tissue later and termination in the formation of indurations and contractions. Bronchiectasis is frequently the result of the bronchopneumonic processes and atelectasis in the lower lobes, but more or less extensive indurations and shriveling predominate at the apices. Tuberculosis may make its appearance sooner or later, but the alterations it finds are nearly identical with its own healing processes, and its course is liable to be much more favorable than in persons without these dust lesions. Changing to another occupation may rapidly cure persons who have for years presented evidences of serious but non-tuberculous pulmonary processes, but the remains of the former inflammatory lesions persist, and in case of a fresh catarrh or acute bronchopneumonia, may deceive the physician into the belief that he has an advanced case of tuberculosis. It is therefore of great importance in both differentiation and prognosis to determine the significance of the alterations noted. The shortening of one or both of the apices indicates shriveling, but the retraction of the anterior margins of one or both of the lungs along the upper portion is an almost infallible sign of indurations and shriveling. In an observation described and illustrated, the margins are so retracted that the anterior mediastinum is not covered by the lungs in any portion.

Improved Sediment Method for Microscopic Study of Bacteria, Especially of Tubercle Bacilli in Feces. J. STRASBURGER.—An abundant sediment can be obtained from urine or diluted feces containing bacteria, by reducing the specific gravity. This allows the bacteria to settle to the bottom by centrifugalization, while in fluids with the specific gravity of water, the bacteria remain indefinitely in suspension. Strasburger finds the specific gravity can be best reduced by diluting one part of the fluid with two parts of 96 per cent. alcohol. The bacteria will be found in the sediment with half a minute's centrifugalization. The flakes of albumin coagulated by the action of the alcohol assist in the rapid sedimentation of the bacteria. A peculiar advantage of this method is that preparations made by the sediment dry much more rapidly than usual, on account of the alcohol. Even without a centrifugalizer, sedimentation occurs in one-half hour, but would require a whole day without the alcohol. This sediment process is especially instructive in case of suspected tuberculous lesions in the intestines, and will afford information in regard to the presence of tubercle bacilli in apparently normal feces, not obtainable in any other manner.

Zeitschrift f. Orthopedische Chirurgie (Stuttgart), vii, 22.

Congenital Luxations of Knee Joint. G. DREHMANN.—To determine the relations between congenital luxation of the knee-joint and congenital genu recurvatum, which have been frequently confounded by various later writers, Drehmann describes five personal cases and reviews all he could find in the literature of both malformations—127 in all. He restricts the term genu recurvatum to an abnormally excessive extension movement, with otherwise normal flexion, without backward displacement of the condyle of the femur. True luxation consists in the dislocation of the condyle of the femur toward the rear, or a luxation of the tibia on the articulating surfaces of the patella. Later, as the child develops, the more advanced stages of the dislocation are reached, as occurs with congenital luxation of the hip-joint, which is much more frequent, and in which several stages can be distinguished. The slight displacement at birth gradually becomes more and more pronounced forward and upward. Not until later, when weight comes upon it, is the backward luxation observed. We are justified in assuming that at birth there is merely a sub-luxation in many cases. Another point in which it resembles luxation of the hip-joint is the frequent association of other malformations allied to it. Coxa vara usually occurs with luxation of the hip, and genu valgum frequently with luxation of the knee. In the cases reviewed in which the sex was men-

tioned there were 46 females to 29 males and 1 hermaphrodite. In 54 cases of forward dislocation it was restricted to one side; and in 48 it was bilateral; in 6 it was "voluntary luxation;" in 6, unilateral backward; in 3, unilateral outward; in 5, bilateral backward; and in 3, bilateral mixed (backward and forward). The etiology is possibly that in the differentiation of the joints, the knee does not become flexed, or else it gets into extension at a time when the upper portion of the limb is much larger than the lower and thus the lower portion has freer swing. If this occurs before the muscles are completely formed—which we are justified in assuming from the conduct of the patella—the leg can remain a long while in this abnormal position. The foot gets caught by the chin or in the axilla, and notwithstanding the presence of plenty of fluid, is prevented from returning to a flexed position as it has grown in length during the interval. Genu recurvatum first occurs, then pes calcaneus and then the joint surfaces slide apart. The hip or the knee joint may be affected or both together. Prognosis is more favorable for the knee than the hip, which is a much looser articulation. The results of treatment are better, the earlier it is commenced. Reposition—with narcosis for older children—is only complete when the condyle of the femur is no longer to be felt in the popliteal space and the lower portion of the leg remains flexed during narcosis; for after-treatment a circular plaster cast holding the knee at a right angle or in moderate flexion for younger children; operative treatment for older persons or rebellious cases.

Recent Progress in Treatment of Scoliosis. A. HOFFA. —In this profusely illustrated communication Hoffa describes his success in mobilizing the rigid scoliotic spinal column with suitable apparatus; the general and special gymnastic exercises by which he stimulates and restores strength to the muscles of the back, until the patient can voluntarily assume the normal position, and the apparatus which he uses to hold the spine in this normal or overcorrected position. The latter consists of an iron pad covered with leather, which is applied to the prominence on the spine and held by a leather strap over the shoulder, and a stout iron rod which screws up and down in a threefold slide at the base of the spine, modifying its position in three different directions. The slide is fastened immovably in a long corset which embraces the pelvis. The firm support afforded by this is the chief feature in the apparatus. The pressure of the pad is as much like that of the hand as possible.

Progress Medical (Paris), March 31 and April 7.

Tuberculosis of the Eye. A. PECHIN.—The arguments in favor of enucleation as the treatment of supposed primary tuberculosis of the eye are refuted by the extreme rarity of this form of tuberculosis as a primary affection. Pechin advocates very conservative measures. Even a "fungous" degeneration, with the cornea quite destroyed, has been known to heal spontaneously. Iridectomy in case of a solitary tubercle may save the eyesight, as in a few cases on record, in which there was good retention of light vision. With disseminated tuberculosis of the iris there should be no intervention, as the traumatism might develop acute accidents, while there is always a possibility of spontaneous absorption.

Societies.

COMING MEETINGS.

- AMERICAN MEDICAL ASSOCIATION, Atlantic City, N. J., June 5-8.
 Arkansas Medical Society, Jonesboro, May 14-16.
 Illinois State Medical Society, Springfield, May 15-17.
 Medical Association of State of Missouri, Mexico, May 15-17.
 Medical Association of Montana, Butte, May 16.
 Iowa State Medical Society, Des Moines, May 10-18.
 American Medico-Psychological Association, Richmond, Va., May 22-25.
 Connecticut State Medical Society, New Haven, May 23-24.
 North Dakota State Medical Society, Grand Forks, May 23-24.

- Indiana State Medical Society, Anderson, May 24-25.
 Association of Military Surgeons of the United States, New York City, May 31 to June 2.
 American Laryngological, Rhinological and Otolological Society, Philadelphia, May 31, June 1 and 2.
 New Hampshire Medical Society, Concord, May 31 and June 1.
 International Association of Railway Surgeons, Detroit, Mich., May 30 to June 1.
 Baltimore & Ohio Association of Railway Surgeons, Atlantic City, N. J., June 1-2.
 Conf. of State and Prov. Bds. of Health of N. A., Atlantic City, N. J., June 1-2.
 American Academy of Medicine, Atlantic City, N. J., June 4.
 American Medical Publishers' Association, Atlantic City, N. J., June 4.
 Association of American Medical Colleges, Washington, D.C., June 4.
 American Medical Editors' Association, Atlantic City, N. J., June 4.
 Medical Society of New Jersey, Atlantic City, N. J., June 4.
 New Mexico Medical Society, Santa Fe, June 5.
 American Association of Acting Assistant-Surgeons. U. S. Army, Atlantic City, N. J., June 6.
 Rhode Island Medical Society, Providence, June 7.
 Medical Association of Delaware, Rehoboth, June 12.
 Massachusetts Medical Society, Boston, June 12-13.
 American Association of Military Surgeons of the U. S., New York City, June 12-14.
 Oregon State Medical Society, Portland, June 12-14.
 Colorado State Medical Society, Denver, June 13.
 Maine Medical Association, Portland, June 13-15.
 South Dakota State Medical Society, Aberdeen, June 14.
 Indian Territory Medical Association, Wagoner, June 19-20.
 Wisconsin State Medical Society, Milwaukee, June 20.

Worcester North District Medical Society.—This Society's forty-second annual meeting was held in Fitchburg, Mass., April 24. C. H. Bailey was elected president for the coming year.

Greene County Medical Association.—This body met in Waynesburg, Pa., April 24, and elected officers: president, Ira D. Knotts, Davistown; vice-president, T. N. Milliken, Waynesburg.

Bucks County Medical Society.—At the spring meeting, held May 2, the following officers were elected: president, A. S. Wilson, Bristol; secretary, A. F. Myers, Blooming Glen. Prof. John Da Costa, of the Jefferson Medical College, Philadelphia, made the address.

Brainard District Medical Society.—The annual meeting of this Society was held in Springfield, Ill., April 26, and the following officers were chosen for the ensuing year: president, J. L. Lourie, Lincoln; vice-president, S. F. Hurst, Greenview; secretary, Katherine Miller, Lincoln.

Ophthalmological and Otolological Society.—At the annual meeting of this Society, held recently in Washington, D. C., the following officers were elected: president, S. O. Richey; vice-president, secretary and treasurer, Anton Coe, vice W. K. Butler, who resigned, having filled that office for the past four years.

Hunterdon County Medical Society.—The annual meeting was held in Flemington, N. J., April 24, and the following officers elected: president, E. H. Moore, White House; first vice-president, Geo. W. Barton, Three Bridges; second vice-president, H. Ward Servis, Junction; treasurer, I. S. Cramer, Flemington; secretary, O. H. Sproul, Flemington.

Suffolk District Medical Society.—The fiftieth anniversary of this Society was observed April 28, in Boston. The programme contained a history of its organization, sketches of some of its members and speeches by a few who had been with the Society since its inception. The officers elected were: president, H. L. Burrill; vice-president T. M. Rotch; secretary, H. A. Lathrop; treasurer, W. H. Prescott.

Susquehanna County Medical Society.—The fifty-second annual meeting of this Society was held in Wilkesbarre, May 3. The following officers were elected: president, R. M. Stratton, Scranton; vice-president, B. M. Crary, Wilkesbarre; recording secretary, T. W. Thomas, Wilkesbarre; treasurer, J. C. Mertz, Easton. The next meeting will be held in Williamsport.

Hudson County Medical Society.—The annual meeting of this New Jersey organization was held May 1 in Jersey City. Following are the newly elected officers: president, John Parsons; secretary, C. J. Purdy; treasurer, Henry C. Brinkerhoff. It was decided to hold two meetings a year hereafter instead of one, as has been the custom.

American Therapeutic Society.—In pursuance with a call issued by the Therapeutic Society of the District of Columbia, a meeting was held in Washington, May 1, and the organization of the American Therapeutic Society effected. It will become affiliated with the Congress of American Physicians and Surgeons, and will meet annually, next year in Washington, D. C., on May 7. The officers are: president, Horatio C. Wood, Philadelphia; first vice-president, Howard H. Barker, Washington; second vice-president, R. W. Wilcox, New York City; third vice-president, E. H. Long, Buffalo, N. Y.; secretary, Noble P. Barnes, Washington; recorder, William M. Sprigg, Washington; treasurer, John S. McLain, Washington.

Pan-American Medical Congress.—The International Executive Committee of the Pan-American Medical Congress, consisting of Drs. Albert Van Dervere, Albany, N. Y.; Chas. A. L. Reed, Cincinnati, Ohio, and H. L. E. Johnson, Washington, D. C., met in executive session at Buffalo, N. Y., April 27, to determine the place of meeting of the third Pan-American Medical Congress. The Congress should have been held in Caracas, Venezuela, but owing to the uncertain conditions, growing out of the military operations in that country, the executive committee was requested by the medical president to hold the meeting elsewhere. The committee was unable to decide just where the Congress should meet, owing to the urgent requests from several countries, so has taken the matter under advisement, and will report on the date and location later.

Congress of American Physicians and Surgeons.

Fifth Triennial Session, Washington, D. C., May 1, 2, and 3, 1900.

The President of the Congress, Dr. Henry P. Bowditch, of Boston, in the chair.

The Congress voted on a proposition for the appointment of a committee of three with full power to draw up and execute a memorial to the Congress of the United States, asking that charitable, religious, and educational institutions be relieved from such provisions of the war revenue act of 1898 as imposed taxes on the legacies left to such institutions, and to take such other action as may, in their discretion, seem desirable in securing such relief.

ADAPTATION OF PATHOGENIC BACTERIA.

PROF. THEOBALD SMITH, Boston, presented the first paper, in which he spoke of the adaptation of pathogenic bacteria to different species of animals, and discussed at length the diseases incident to, and the infectious diseases which human beings share with, animal life. He said that medical science and medical art are concerned chiefly with the phenomena of human disease. All that medical science desires to know is the series of causes antecedent leading to any given disease. Medical art wishes to know where human ingenuity may enter to modify, suppress, or eliminate portions of this series, to interfere with the progress of the disease and bring it to a standstill. By common consent, hygiene devotes itself to external phenomena; pathology to the internal. Professor Smith contended that to learn the simplest facts recourse to animal experiments has been necessary. Experiments on human subjects are not only not permissible, but as a rule sterile of results under conditions necessarily imposed. He gave a technical description of experiments made on many of the lower animals and demonstrated their value to science.

DR. SAMUEL J. SMELTZER, New York City, followed with a paper in which he dwelt on the physiologic resources of the body in its defense against bacteria and their toxic products; while Prof. Harold C. Ernst, of Boston, spoke in a technical manner of flagella and serum reactions.

BACTERIOLOGY AND CLINICAL MEDICINE.

DR. RICHARD C. CABOT, Boston, discussed the relations of bacteriology to clinical medicine. He classified the diseases whose etiology is known, such as diphtheria, anthrax, Asiatic cholera, tuberculosis, bubonic plague, gonorrhoea, glanders, tetanus, relapsing fever, influenza, erysipelas, typhoid fever, epidemic cerebrospinal meningitis, croupous pneumonia, etc. He then considered diseases whose etiology is probable, but not definitely known, and among these he mentioned meat poisoning, leprosy, epidemic and tropical dysentery, and referred to diseases whose etiology is shrouded more or less in darkness, such as whooping-cough, yellow fever, etc.

He advised examination of the sputum for the influenza bacillus, for the pneumococcus, and in tropical countries the sputum should be examined for the possible presence of the bacillus of plague. Examination of the cerebrospinal fluid enables the physician to identify the bacillus of epidemic cerebrospinal meningitis—the diplococcus intracellularis of Weichselbaum. The pneumococcus can be identified, as well as the tubercle bacillus, in the same fluid. Examining the urine for typhoid bacilli should have a wider range of use than it previously has had. That too, of the nasal discharge, sometimes influences the prognosis.

As to the use of serum reactions, he regards the Widal as established, also the tuberculin reaction, which has taken a firm hold on the profession; it can be carried out without danger, if the proper precautions are taken. The mallein reaction is also well established.

As to pneumonia, it is now known that no one organism is responsible for this disease, but that the affection is produced by many different ones, as can be clearly demonstrated by the appearances and conditions found post-mortem. One organism may cause many diseases; for instance, the tubercle bacillus acts on the brain, bone, peritoneum, etc. The finding of the influenza bacillus in coryza influences the prognosis of that disease. The finding of pneumococci in cases of empyema likewise markedly influences the prognosis of that.

BACTERIO-THERAPEUTICS WITH SPECIAL REFERENCE TO TUBERCULOSIS.

DR. EDWARD R. BALDWIN, Saranac, N. Y., followed with a paper on this subject.

He briefly considered the various uses of bacteria and serums in the prevention and treatment of disease, with a more detailed account of those in tuberculosis.

Living bacteria are little used, except in vaccination for variola and anthrax. Dead cholera, plague and typhoid bacilli are useful in prevention, but irrational in treatment.

Diphtheria and tetanus are as yet the only conspicuously antitoxic serums of practical value. Streptococcus, pneumococcus, cholera, typhoid, plague and recurrent fever serums are either bactericidal or bacteriolytic, and of greater value in immunization than treatment.

There are many extracts of tubercle bacilli under the general name of tuberculin, which the author enumerated and described. No permanent immunity is produced by any of them, though the new tuberculins have some immunizing power in animals. The method is not applicable in man, nor safe, as it is likely to produce chronic poisoning, even in healthy subjects. Research at present aims to discover and utilize the mechanism of relative immunity produced by injections of bacillus substance.

The nature of the tuberculin reaction is of importance. Of the various theories promulgated, that which assumes a ferment action chiefly produced by secretions from the leucocytes, is most in line with present knowledge. Many bacterial extracts, nucleins and digestive albumoses excite some such reaction as tuberculin produces.

Tuberculin used therapeutically has only a limited application, and as it does not immunize for any length of time, may not be better than other substances that can produce local

hyperemia. The production of local hyperemia as a therapeutic measure is rational in lupus, tuberculous peritonitis and to a limited extent in pulmonary tuberculosis.

Serums are not yet successful as to antitoxic properties. They may be bacteriolytic or bactericidal. The profession must still hope for some efficient serum or extract of tissues, though possibly not antitoxic.

ETIOLOGY OF MALARIA.

DR. WILLIAM S. THAYER, Baltimore, Md., discussed the etiology of malarial fevers, and spoke of mosquitoes as causative factors in this affection. Inoculation experiments have shown that through the bites of these insects some type of the disease can be transmitted from one individual to another.

BACTERIOLOGY OF DYSENTERY.

PROF. SIMON FLEXNER, Philadelphia, talked on this subject and presented a summary and the results of his investigations in the Philippine Islands. He said that three sets of organisms have been described by different observers, as the cause of dysentery, namely, pathogenic cocci, bacilli, and protozoa, but the specific organism has not as yet been discovered. Evidence to show that the bacillus coli commune is the cause is wanting in many particulars. The ameba coli, on the other hand, has much more evidence in its favor as a cause of dysentery, and this the speaker dwelt on at considerable length, narrating experiments, etc. A large number of observations tend to show that in the tropics the protozoa which have been found, and are said to be the cause of dysentery by some, can not be distinguished morphologically from the ameba coli which is present in the normal intestine. During a residence of three months in Manila, he had an opportunity of studying this disease among the American soldiers. He found two forms, a very acute one, which was rapidly fatal, and the chronic. The acute was unassociated with the presence of ameba coli; while the chronic showed the amebæ with greater regularity.

SOCIOLOGIC STATUS OF THE PHYSICIAN.

DR. CLARENCE J. BLAKE, Boston, discussed the sociologic status of the physician. Sociology was defined as the science of the laws of human relationships. Among other things, the Doctor said that people turn to the practitioner of medicine for advice and counsel because of his broad knowledge and thorough study of human nature and the relation of one individual to another. The education necessary to fit one for the practice of medicine is more exacting, and requires more intense and closer application than the corresponding courses which lead to a degree in law or divinity. The possession of a knowledge of human life and intimate relationships implies great responsibility.

Attention was directed to the admittance of women into hospital life, and to training schools for nurses. Since the advent of the trained nurse better service has been rendered to both the physician and patient; besides the general beneficial effect exerted on the morale of the latter.

EVOLUTION OF THE PHYSICIAN.

DR. S. WEIR MITCHELL, Philadelphia, recited a poem on the evolution of the physician. It elicited considerable applause throughout its delivery.

THE MEDICAL SCHOOL OF THE FUTURE.

PROF. HENRY P. BOWDITCH, the President of the Congress, delivered an address on this subject. He said that among the intellectual movements that have characterized the century now drawing to a close, there is perhaps none more deserving of careful study than that which is concerned with providing education for the people in the school, the academy, and the university. The importance of popular education becomes apparent in proportion as political freedom is secured for the people. For many years educators looked on their work with no little complacency. The educational systems of the various civilized countries were supposed to be well adapted to the ends in view. Education has not always been found to furnish the required safeguards for order and liberty, and highly educated men have been found singularly lacking in mental balance. Schools for the inculcation of common-sense have never yet been established. The great danger which threatens the system of popular education in America is its too close association with party politics. The office of school committeeman

in one of our large cities has been well described as "the smallest coin in which the politicians pay their debt," and as long as the education of children continues to be entrusted largely to men who consider their positions to be the lowest step of the political ladder, there is small hope of the adoption of rational methods of education.

Professor Bowditch pointed out many of the evils of the modern system of education, paying particular attention to medical colleges, and showing how he believes the faults or defects will be remedied in the future. He thinks the medical school of the future should be connected with some university, but entirely independent of university control outside of questions relating to methods of personal teaching. Such a school will afford advanced instruction in every department. Laboratory instruction will be greatly extended and students trained to get knowledge, as far as possible, by direct object study. The didactic lecture, though it will not occupy as conspicuous a place as it has heretofore, will not by any means be displaced as an educational agency. The work of students will be so arranged that their attention shall be concentrated on one particular subject at a time, and subjects will follow each other in natural order.

Chicago Medical Society and Chicago Medical Examiners' Association.

Joint Meeting, April 11, 1900.

DISEASES OF THROAT AND NOSE IN RELATION TO LIFE EXPECTANCY.

DR. WILLIAM E. CASSELBERRY read a paper on this subject. Diseases of the throat and nose have not as yet been accorded a position of any great prominence with reference to life expectancy. Many of the simpler affections, important as they are from the standpoint of the patient's comfort, show but little tendency to abbreviate existence; yet there are other and graver conditions often confused with the simpler affections, lightly passed over, or wholly unrecognized by the casual observer, which do exert a decided influence on one's expected term of years. Simple, hypertrophic, and atrophic rhinitis, when uncomplicated, have little or no influence on life expectancy, unless the case be of extraordinary severity, or occurring in one of otherwise debilitated constitution. But these unimportant catarrhal affections are liable to be confounded with more serious nasal diseases which are prone to shorten the duration of life and which the examiner therefore should seek to discover. Prominent among these the author mentioned chronic suppuration of the antrum of Highmore, or of the frontal and ethmoid sinuses.

Nasal obstruction commonly indicates only hypertrophic rhinitis or septal deformity, widespread affections which, unless extreme, may be disregarded from the standpoint of life expectancy.

The significance of nasal polypus with reference to life insurance varies with the individual case. If single or small and with little disposition to recurrence after removal, it may add but a trifling risk, but when multiple or large and persistently recurrent, a conservative custom would be to exact a thorough removal of polypi, as a condition preliminary to acceptance. Polypi are a frequent accompaniment and probably at different times both a cause and an effect of sinus empyema, so much so that to the rhinologist their presence is instantly suggestive of a possible chronic suppuration in one or more of the accessory sinuses of the nose.

Another symptom of nasal disease of which the examiner should take cognizance is fetor. When pronounced, it is common both to the *ozena* type of atrophic rhinitis and to the gummatous ulcerative or necrosing stage of nasal syphilis.

Tuberculosis of the larynx is almost invariably secondary to pulmonary tuberculosis. The primary lung disease, however, may be so slight as to escape notice in some cases; hence the importance of bearing in mind the possibility of laryngeal tuberculosis as a rapidly fatal and sometimes early complication.

Impairment of the voice is an important symptom with reference to life expectancy, one which should be the subject of minute inquiry on the part of the examiner, eliciting informa-

tion concerning its cause, mode of onset, duration, variation, disposition to recurrence, etc., and which, if not thus satisfactorily accounted for, should suggest a careful laryngoscopic examination.

DR. E. F. INGALS sent a short paper in which he estimated that less than 3 per cent. of all persons examined for life insurance are subjected to any examination of the upper air-passages. It is not believed that the insurance companies lose anything in a large percentage of the cases supposed to be normal. There is no question, however, among those who have to do with diseases of the upper air-passages that they have an important relation to various other affections which materially influence life expectancy. Sharp deflections of the nasal septum would influence the opinion of the examiner, for the reason that such deflected septa may produce epilepsy.

DR. HOMER M. THOMAS classified a list of diseases into those which are of the acute and chronic type; those which are malignant and non-malignant, and those which are irrelevant as to life expectancy, but inferentially dangerous. A long list of diseases was mentioned. He quoted Horace Green, who maintained that chronic follicular pharyngitis is an impediment for life expectancy, for the reason that this disease might ultimately lead to phthisis. Many other affections were mentioned as influencing life expectancy.

DR. J. HOMER COULTER believes that the medical directors should select younger men as examiners, because the colleges of later years have devoted more attention to life insurance examinations and physical diagnosis as a specialty than formerly, consequently the men who have graduated within the last twelve or fifteen years are better prepared to make critical examinations, when necessary. Medical colleges should establish a chair of insurance examinations. When this is done there would be a practical application of the theories advanced by Dr. Casselberry.

DR. WILLIAM L. BALLENOER said that all patients with chronic hoarseness should be subjected to a critical examination before being accepted as risks, all who have a chronic pus discharge and all with cyanotic hue of the mucous membranes of the nose and throat.

EARLY DIAGNOSIS OF PULMONARY TUBERCULOSIS.

DR. GEORGE W. WEBSTER followed with a paper on this subject. By the early recognition of this disease he means a positive diagnosis made at the earliest time that tubercle bacilli are found in the sputum, either by the aid of the microscope, or by the inoculation of animals, and a tentative probable diagnosis long before this time. He first described the clinical manifestations, including an examination of the sputum, and then other means and methods which are available and valuable, such as the use of potassium iodid, tuberculin, the X-ray, and the inoculation of animals.

The family history should be carefully investigated, for two reasons: 1. The peculiar type of chest and tissue in which resistance is diminished and tuberculosis is likely to develop is inherited. The degree of immunity is below the average. What is inherited is rather an increased vulnerability to adverse conditions of all kinds. 2. Where there has been tuberculosis in the family, the environment has been unusually favorable for the occurrence of infection.

Dr. Webster then discussed, in their order and at considerable length, personal history, age, occupation, habits, previous illnesses, symptoms, general examination, mensuration, circulatory system, palpation, percussion, auscultation.

The earliest respiratory sign of beginning tuberculosis is enfeebled breath sounds, or a slightly roughened harsh respiratory murmur, audible during expiration; or the expiratory sound slightly prolonged. This slight increase in the relative length of the expiratory murmur may be the only sign at first and may not have the slightest suspicion of a tubular quality, but is slightly increased in intensity.

Auscultation of the voice is of great value in confirming the findings of percussion and auscultation. Temperature is one of the most reliable guides. In all doubtful cases it should be carefully taken at least four times in the day and for several successive days. When the temperature is persistently above the normal, especially in the evening, it deservedly arises

above the dignity of a mere suspicion. The sputum should then be examined for tubercle bacilli.

The value of the serum test as a diagnostic aid is as yet not fully determined.

The essayist spoke of a new sign of tuberculosis to which the attention of the profession has been directed by Murat, which consists of a subjective sensation of vibration in the affected apex on loud speaking. Dr. Webster has been able to confirm this sign in cases far enough advanced to cause consolidation, this facilitating the conduction of vibrations, but at this stage it is not needed. He has failed to elicit it in the earliest cases.

The X-ray has its advocates as a valuable means of early diagnosis, but the cost of the necessary apparatus, together with the high degree of technical skill required, will serve to limit its value, which has not yet been satisfactorily demonstrated.

The iodid of potash test is one of very considerable value. In those cases in which there are very faint physical signs and an absence of even the amount of sputum necessary for a microscopic examination, or where we desire to determine the location and extent of the tuberculous process, this method offers many advantages. The author directed attention to and quoted from a paper by Dr. Edward F. Wells, read before the Chicago Society of Internal Medicine, December, 1898, and published in *THE JOURNAL*, Feb. 4, 1899, in reference to the iodid of potassium test.

He presented a mass of evidence for and against the tuberculin test. Opponents of the test allege unreliability, reaction in other diseases, notably syphilis; no reaction in cases of undoubted tuberculosis. Its advocates assert that it is safe, delicate, reliable, and that in very many cases it furnishes an absolutely safe means of making an absolute diagnosis.

Dr. Webster presented the following conclusions: 1. There seems to be no agreement or understanding as to what constitutes the "pretubercular" stage or what is meant by this term. Does it apply to that syndrome of symptoms which arise after infection has taken place; or, to that condition in which vulnerability is increased, the degree of immunity lessened, whether from hereditary predisposition or the effect of disease, unsanitary surroundings, bad habits, impaired nutrition, etc. This may seem a nice distinction, and yet such a discrimination must be made. In the former, any characteristic phenomena are symptoms of tuberculosis; and in the latter they are simply those of other diseases, types, etc., which should warn us that in these cases tuberculosis is especially likely to develop. To speak of such phenomena as pretubercular in the sense that they all make up a symptom group indicating that tuberculous infection has already occurred, is absurd. To speak of it as a "stage" of a disease before the infection has occurred is equally preposterous.

2. We should be able to recognize definitely those cases in which there is that form of chest and type of tissue, together with low vital index, lessened vital capacity, diminished respiratory expansion, perimeter below the normal, corpulence below standard, in which tuberculosis is very likely to develop. This should never be designated the pretubercular stage of tuberculosis.

3. We should also be able to recognize the probable occurrence of infection by the malaise, gradual loss of weight, sense of fatigue, upon slight exertion, digestive disturbances, hacking cough, occurrence of single or repeated hemorrhages, night sweats, increased frequency of low tension pulse, slight evening rise of temperature. In these cases the finding of a slight localized bronchitis in one apex or the slight early auscultatory signs alluded to, ought to enable us to make a correct diagnosis whether the tubercle bacilli are found in the sputum or not.

4. When the tubercle bacilli are present in the sputum there is no excuse for not making an absolute diagnosis.

5. In doubtful cases, the iodid test, and the tuberculin test, may be resorted to with confidence in their safety, efficacy and reliability.

6. But while we should and do welcome every new symptom, sign and method; and while we hail with joy every ray of new or additional light which will enable us the better to read the

symbolical language of disease aright, interpret the "hand-writing on the wall," the great need of the hour is for men well trained in correct clinical methods, and in the art and science of physical diagnosis rather than the addition of new methods.

DR. ROBERT H. BARCOCK indorses in the main what had been said by the essayist, and called attention to the persistent lightness of weight presented by individuals who have a strong tendency to tuberculosis. Individuals of spare weight, who have an inherent tuberculous tendency, are not only of light weight, but they present a peculiar narrowing of the chest, or constriction of the apices, with lightness of bone structure. The pulse of incipient tuberculosis is accelerated and one of low tension and small volume. However, in some cases he has found tuberculosis in individuals whose pulse was not accelerated. In one case the pulse was 80, yet the patient had a marked lesion of the right apex with bacilli in the sputum. A temperature suspicious of tuberculosis is one between 99.5 and 100.5 F. An important point to remember is the facility with which it becomes accelerated on exertion.

DR. EDWARD F. WELLS believes there is no pretubercular stage in tuberculosis. He laid stress on the importance of fetor. Nutritional changes occur with loss of weight. Loss of weight is most marked during febrile attacks, and it is usually not regained. In cases of diffuse miliary tuberculosis, at least in some of them, attended with a good deal of fever, there is no expectoration, or no bacilli in the sputum. The diazo reaction is of certain value. The blood-count is likewise of value in tuberculosis. He has used the sphygmograph constantly for fifteen years, and he has yet to see a case of anemia of any sort, or a case of chlorosis, in which the pulse tension is not greatly reduced.

DR. JOHN A. ROBISON said that while he believes in the majority of cases the tubercular diathesis or tubercular predisposition is inherited, there are many cases in which there is a direct transmission of the tubercle bacillus from the parent to the child. The bacillus of tuberculosis may pass through the placental circulation of the mother to the child. The tubercle bacillus is found in glands and other tissues of children and adults who are apparently healthy. An early sign of incipient tuberculosis is the prolongation of the expiratory sound, heard on auscultation; this sound is accompanied by a rise of pitch. While he does not believe there is really a pretubercular stage, there is a stage which Hare calls the stage of hyponutrition. Lack of nutritive power occurs in persons whom we denominate as those having a tubercular predisposition.

St. Louis Medical Society.

CARCINOMA OF TONGUE; TOTAL EXTIRPATION.

DR. A. H. MEISENBACH presented specimens from a patient 65 years of age, strong in appearance, of good habits, who had smoked a pipe for many years. On account of the front incisor teeth in the lower jaw being defective, he had held his pipe well down in the floor of his mouth, mostly on the left side, and last October he discovered a nodule below the lower jaw-bone about an inch to the left of the symphysis. This grew and became painful, so he shifted his pipe to the right side. The tumor kept on growing, he consulted several physicians without results, and came to St. Louis for relief.

The patient was first seen in consultation with Dr. Henry Summa, on April 1. Examination revealed a very hard mass occupying the floor of the left side of the mouth, extending backward behind the base of the tongue; on the right side the floor was also infiltrated, extending only as far as the first molar tooth. The tongue was so bound down that the patient had no control over it. The body of the tongue did not seem to be involved. At the inferior margin of the jaw-bone, on the left side, about an inch from the symphysis, there was a fistulous opening. On pressing the floor of the mouth pus could be expressed from the fistulous tract. The diagnosis of carcinoma was made and operation suggested, but without any assurance of positive cure and no recurrence.

On April 3 Dr. Meisenbach operated, at the Pius Hospital, assisted by Drs. Henry Summa, Heidemann, Auf der Heide and

Robert Hughes, Denver, Colo. Under chloroform, a preliminary tracheotomy was made, low down. An ordinary large-sized No. 4 canula was introduced. The pharynx was tightly tamponed with iodoform gauze, shutting off the upper air-passage from the field of operation. Chloroform was administered through the tracheal tube, to the completion of the operation. A combined Kocher and Sedillot operation was done, the incision of the former extending from below the mastoid process on the left side to the greater cornua of the hyoid bone and parallel with it, about 1 cm. above it to the median line. The second incision (Sedillot) began about 1 cm. below the mucous margin of the lower lip—thereby saving the coronary arteries from being cut—in the median line, going down to the bone over the symphysis, and extending downward joining the first cut at right angles. The flap thus formed on the left side was dissected up to the inferior margin of the lower jaw, tying the facial artery and vein. The mucous of the lower lip was next cut away from the alveolar process in the median line. A key-hole saw was used to divide the jaw-bone through the symphysis, and both halves were pulled aside giving free access to the floor of the mouth. The operation was continued by using the scissors, cutting through the healthy tissue, beginning at the lower part of the mass above the hyoid bone and freeing it from below upward. During the dissection the lingual artery on the left side was exposed and tied. Having freed the tissues of the floor of the mouth from the left half of the jaw, the tongue could easily be drawn down into the floor of the mouth, with the scissors the tongue was cut across as near as possible to the epiglottis, leaving a bridge of tissue on the right side, in which was the right lingual artery. This bridge was clamped and the tongue cut away. The artery was tied. The jaw-bone was drilled and two silver wires introduced, bringing it again into place, the ends were left long and sticking out of the incision, so that the wires could be removed when the bone was united. The incision was united with a running suture of fine silk. Previous to suturing the wound the packing in the pharynx was removed and replaced by a fresh one, leaving the edges protruding through the fistulous opening below the jaw, the edges of which had been freely excised by the scissors.

Dr. Meisenbach said that the operation was practically a bloodless one, and, on account of the ease with which the anesthetic could be given through the tracheal tube, the pharynx being plugged, it was robbed of many of the unpleasant features that these operations sometimes give rise to if done without preliminary tracheotomy. The canula was left in the trachea, the pharynx kept plugged and the patient kept nourished by rectal enemata. The tracheal tube was removed and feeding commenced with the stomach-tube, on April 17.

The Doctor pointed out that, barring the recurrence of the disease, there are three sources of danger in the operation: 1, hemorrhage; 2, pneumonia; 3, sepsis.

It is of the utmost importance to have full control of the operative field. This can be done by such a method as he used in this case, preliminary ligation of the lingual arteries not then being necessary. Ligation of the arteries at best is tedious work and in this case would have been difficult on account of changed anatomic relations, due to the inroads of the disease.

VAGINAL EXTIRPATION OF THE UTERUS; FIBROMYOMA.

Dr. Meisenbach also presented a specimen of this, from a patient 55 years old, seen March 14. She complained of uterine hemorrhage, irregular in character—lasting three weeks at a time, stopping a few days and then coming on profusely. She weighed 250 pounds, so manual examination was very difficult. The uterus was large, freely movable, $5\frac{1}{2}$ to 6 inches in depth. There was nothing suspicious about the os or vagina. On March 17 he made exploratory curettement. Microscopic sections revealed only endometres interstitialis. Packing and rest and hemostatics did not arrest the bleeding. Although microscopic examination was nil, this was not conclusive evidence that carcinoma could be entirely excluded.

At the menopause fibroids usually cease to give trouble, as well as hyperplasia, so the case was more or less obscure. The patient continuing to lose blood and beginning to feel its

effect, he suggested operation, which was done April 5, at the Lutheran Hospital, by the vaginal route, on account of the thick abdominal walls.

Philadelphia County Medical Society.

April 11, 1900.

Dr. J. H. Musser, President.

SYMPOSIUM ON EMPYEMA.

DR. L. SHARP spoke of a patient who suffered from this condition as a sequel of pneumonia, was operated on and the abscess cavity drained for several months. Considerable discharge continued and another operation was done, when it was found that portions of two drainage-tubes had been retained within the abscess. These were removed and, after a considerable period, the man recovered.

PLEURAL EXUDATES AND PHYSICAL SIGNS.

DR. HERMAN B. ALLYN read a paper entitled "Pleural Exudates with the Physical Signs in the Lungs." He considers the most important physical signs as diminished or absent vocal fremitus, diminished or absent vocal resonance, tubular breathing, and displaced organs. Austin Flint has reported instances of pleural exudates in which the physical signs were variable. The speaker had treated a case in which there was flatness, increased vocal fremitus and subcrepitant râles. Movable dullness, and Skodaic resonance anteriorly are also very important physical signs. Puncture with a needle is always the most certain method of determining the presence of fluid within the pleural cavity. The aid furnished by a skiagraph is very great in some cases.

ETIOLOGY AND PATHOLOGY OF EMPYEMA.

DR. JOSEPH MCFARLAND read a paper entitled "The Etiology and Pathology of Empyema." He regards the condition as an infectious inflammatory process of the pleura, due to traumatism, local disease or metastasis. As to traumatism as an exciting cause, the history in most cases would be hard to trace. As to local disease, tubercular abscesses were important. Metastasis may take place through the lymphatic channels, from an infectious process elsewhere. As to the bacteriology of the condition, in children the pneumococci, in adults the streptococci, have been most frequently present. Tuberculous empyema is not as common as generally supposed. In children the prognosis is generally favorable, while in adults it is grave. As a rule the left side is most often involved. The fluid aspirated may contain leucin, tyrosin, cholesterolin, uric acid, pus cells, and blood. The pulmonary pleura is more frequently involved than the parietal. Spontaneous rupture generally takes place in the fifth interspace.

SURGERY OF EMPYEMA.

DR. EDWARD MARTIN spoke of the surgical treatment of empyema. The most important plan of prophylaxis is aspiration as soon as the fluid becomes purulent. The technic, while simple, is often carried out in a wrong manner. The sight of the wound should be in the eighth interspace, slightly anterior to the angle of the scapula. The parts should be anesthetized and an incision should be made through the skin with a tenotome, and then the trocar and canula inserted. The needle should not be thrust through the external skin. The Doctor has practiced aspiration and drainage with advantage. In some cases it would be advantageous to resect a portion of a rib. Small cavities may be packed with gauze. In old cases frequently the only relief is a resection of a portion of the chest so as to allow collapse of the chest walls. Serous effusion is best treated by aspiration.

DR. S. SOLIS COHEN spoke of certain difficulties met with in the treatment of special cases, and also the difficulties of diagnosis. In one instance three ineffectual attempts were made to aspirate, and afterward the person was anesthetized and the abscess opened. As to the prognosis, he knew of one case in which the tubercle bacillus was the exciting cause. An incision had been made over the abscess, causing it to drain for a period of several months. Later another one opened higher up in the axilla. After a period of six years the pa-

tient is still living. In the speaker's opinion the most favorable cases are those following pneumonia.

DR. L. BRINKMANN said he generally uses the antitoxin needle half filled with normal saline solution. He believes that irrigation of the cavity would rather increase than decrease the amount of discharge. In resecting a rib the patient will often cough violently, tearing apart new adhesions, and this is a disadvantage.

DR. W. E. HUGHES stated that tubular breathing is nearly always associated with pleural effusions, and this seems to be more fully recognized by the English than the American physician. The tubular breathing in pleurisy is different from that of pneumonia, in that the former is more insistent and superficial. As a diagnostic sign he regards displaced organs as of the greatest importance. In aspirating he would not depend on a hypodermic needle, as the orifice is too fine to permit of thick pus escaping into the barrel of the syringe. He believes that all cases of empyema should be drained early, and further that all the fluid possible should be removed at the first operation.

DR. MORDECAI PRICE spoke of the condition when the abscess is sacculated. He believes in resecting a rib, washing with boric acid solution and inserting a double drainage-tube.

DR. W. L. RODMAN spoke of the case referred to by Dr. Cohen. To say that most cases of empyema and pleurisy are of tuberculous origin he regards as an error. He does not insist on resection of a rib, but has found that thoracotomy often gives relief.

DR. H. R. WHARTON agrees on early operation in these cases. He does not believe that resection of a rib is always necessary. Drainage-tubes will often accomplish the same purpose. He has changed his mind in regard to the teaching that most cases of empyema are of tuberculous origin.

ELPHANTIASIS OF LEG.

DR. DAVID RIESMAN, through Dr. Eshner, presented a case of elephantiasis of the leg, in a man of middle age, who had suffered from measles and pneumonia; eight years ago he had a severe fall down stairs. He is a foundryman, and his present illness dates back to four years ago, when he observed enlargement of the left leg, at first painful, especially during certain changes of the weather. He also suffered from pains in the abdomen. Some time after the process began in the left leg the right became much swollen, and is now the larger of the two. The skin is cold and dry, and does not pit on pressure. For relief of pain, 5-grain doses of antipyrin have been given. Several attempts have been made to detect the filaria sanguinis hominis, but without results.

Detroit Medical and Library Association.

April 23, 1900.

TWO FATAL CASES.

DR. D. M. CAMPBELL read a paper with this title. The first case was in a girl of 12, who had been in her usual health up to February 10, when her parents noticed a small pimple on her forehead. This was ruptured the next morning, by the child, and a very small quantity of pus was evacuated. Late that afternoon she had a chill followed by fever. On the following morning the family physician was called. Besides a temperature of 104 F., a pulse of 140 and the general symptoms accompanying fever, the right eyelids were swollen and there was exophthalmus. At 4 p. m. the temperature was 106 F. and the pulse 160. The other conditions were more marked. Dr. Campbell was called as consultant, and at 10 p. m. found a temperature of 105 F. (axilla), the pulse too rapid to count, the patient comatose, widely dilated pupils, enormous exophthalmus on the right side, and great puffiness on the eyelids. No pus was reached through the deep incisions made into the orbital cavity. The child died the next afternoon.

The second patient was suffering from double phlegmonous orbital cellulitis. Great quantities of pus and necrotic tissue were evacuated through free incisions made deep into the orbital cavity. In spite of this the patient died comatose, showing all the evidences of a general septic infection.

EFFECTS OF REMOVAL OF LARGE PORTIONS OF THE
DIGESTIVE TRACT.

The tolerance of the human body to surgical intervention and aseptic traumatism, without excessive hemorrhage or shock, is at times quite remarkable. Anatomic structure seems to be so organized and physiologic function so adjusted that there may be compensation for even extensive destruction or ablation of tissue. The records of surgery contain numerous instances in which large portions and even the whole of organs considered vital have been removed by accident or design and life has been preserved. Thus, the kidney, the spleen and the stomach have been removed entirely and successfully. Large portions of liver and of intestine, and considerable portions of brain have been excised with relatively little inconvenience. It can be readily understood that if excessive amounts of the digestive tract be removed death may result from inanition, although it has not been definitely determined what amount of loss can be tolerated. It has been thought that removal of more than one-third of the small intestine is dangerous to life, causing fatal marasmus after a time, although in some experimental observations on animals resection of half the small intestine was well borne. It has been found that the results of resection of the beginning of the jejunum are more serious than those of resection of more distal portions of the bowel. A not inconsiderable number of cases are on record in which more than one meter of small intestine has been removed from human beings. The operation was survived in the majority of cases, and in most digestion was not notably impaired. In a small number, more than two meters of small intestine have been removed, but in most of these digestive disorder followed. To the cases already reported Schlatter¹ adds another in which he resected about two meters of small intestine. The patient was a strongly built, well-nourished man, 23 years old, who received a stab-wound in the hypogastric region and immediately fell to the ground, the intestines protruding from the wound. With aid, the man walked a distance of 320 yards, and in a short time a temporary dressing was applied. He was received at the hospital eight hours after the infliction of the injury. After removal of the dressing, about two meters of small intestine were found lying in the right hypogastric region, the greater part of which varied in color between deep dark blue and black. The serosa was lusterless. The protruding intestine was tightly grasped within the small wound and in places undergoing necrotic change, and resection was with some

difficulty effected. The removed portion of bowel measured 92 cm. in its shortest length. The further course of the case was complicated by an attack of urticaria. The patient drank tea on the day of the operation, ate fried sausage on the seventh day, and was on a full diet on the twenty-fifth. He was permitted to stand on the thirty-first day, and was discharged cured on the fifty-ninth, having gained nearly 24¼ pounds in weight in the course of four months. A study of the digestive processes showed that while nitrogenous assimilation was not seriously interfered with, that of fats was considerably impaired. Later reports concerning the patient, some eight months after the operation, indicated that he could do but little work and this but slowly and with many intervals for rest. He lived principally on broths, soups and animal food, and was quite unable to tolerate solid food. He had lost a slight amount in weight. This case would seem to show that the process of digestion may be seriously interfered with, even in young robust patients, by the removal of more than two meters of small intestine, unless precautions are taken to secure the requisite sustenance.

PSYCHIC SARCOLOGY ET AL.

Along with the delusions of osteopathy, Weltmerism, goats' lymph, etc., we have from Missouri still another, "Psychic Sarcology," which is notable if only for its name. It would appear to be a sort of nomenclatory misfit, but it doubtless has its utility—"words of long length and thundering sound" sometimes take in more than the simple rustics. It is only one evidence, however, of the tendency to which the other medical delusions mentioned above, together with Dowieism, and the generally pervasive "Christian Science," are witnesses—the aptitude of fallen man to go after false gods in medicine, religion and efforts at social regeneration. Just at the present time this tendency seems unusually rampant, and the reason why this "eraze of quackery" exists has troubled some of our contemporaries. If we were to attempt to answer the question, we could suggest several reasons why. While science has advanced, especially in its practical applications, more during the past century than in the centuries before, the mental development of man as a species has made no such remarkable strides. We have now living no greater thinkers than those of the remote past; we have accumulated facts but do not handle them in all respects any better than did our predecessors. The universal vulgarization of science has neither made a race of philosophers nor necessarily bettered the average human power of judgment, but it has perhaps spread broadcast the little knowledge that is a dangerous thing. It is a question whether or not modern methods of education, with their intensely practical side, are really better for turning out cultured and well-balanced men and women than the old limited classical ones, which none can honestly deny had some real educational and disciplinary worth. It is said too, on every hand now, that there is a decay of faith,

¹ The Lancet, January 27, p. 217. THE JOURNAL, February 17, p. 419.

that religion has lost some of the hold it formerly had on the masses of mankind. If these things are so, and they may be to some extent, it is no great wonder that false systems prevail; when man loses his faith it is not in his nature to depend on himself, and he must therefore take up with superstition of some kind or other. Science, falsely so-called, is the most convenient idol of the day, whether it be in the form of Eddyism, Dowiesism, Ingersollism, or any other heterodoxy that is in fashion at the time. There is also a great deal of what Sir Michael Foster has called "blatant science that is worse than the superstition at which it scoffs," and its effect is too often to only prepare the way through unfaith to the most aberrant form of belief. The discontent so prevalent at the present time is another factor, though perhaps a less direct one, in bringing about the special evils here in question. It is not altogether the healthy discontent that tends toward progress, but is the destructive one based on envy and the meaner impulses that in the species reverts to savagery. Our civilization is after all only skin deep with a large proportion of the population, who only need the veneer rubbed off to fit in with and take up any fetish that may present itself. Just now there is too much useless suffering with the itch of discontent, and when, as a popular writer has said, our whole civilization begins to scratch itself it is a serious matter.

Taking all things into consideration it is not so difficult to see a possible reason why quackery should flourish at the present time, and especially why the special medicoreligious frauds of the day should exist. There is, however, no reason for pessimism as to the future, the world will not retrograde into barbarism and superstition, and we are not on the threshold of a second Dark Age. The disturbing present conditions so far as they exist are, we trust, only ephemeral, and while there will probably always be some quackery, we have for our comfort the truth enunciated by Mr. Lincoln, that it is impossible to fool all the people all the time.

THE CLASSIFICATION OF TUMORS.

The modern doctrine of tumors rests wholly on the basis of histogenesis. Some of the shortcomings and the objections to the present embryologic classification of tumors are noted by Klaatsch¹ and by Charles Powell White.² The former points out some of the inconsistencies which are creeping into our classification, and that the distinction between mesodermal and other structures of the body is in reality not as hard and fast as it is usually drawn. White emphasizes the fact that the developmental origin of some parts of the body is not yet fully explained; the present onkologic classification separates tumors that are not distinguishable histologically, such as some forms of carcinoma and endothelioma; some authors, for instance Ziegler, class tumors of epiblastic origin—the gliomas or neuro-epi-

theliomas—among the mesoblastic ones. In order to overcome these inconsistencies, and also in order to avoid all theories as to the as yet unknown etiology of tumors, White proposes a purely morphologic grouping and definition. He defines a tumor as "a mass of cells, tissues or organs, resembling those normally present in the body but arranged atypically, which grows at the expense of the organism without at the same time subserving any useful function therein." This statement seems a serviceable one. It seems to include all tumors and to exclude retention cysts, hypertrophy and hyperplasia, and also inflammation, because the inflammatory processes are held to be adaptive and useful changes. White divides all tumors into three classes, viz.: 1. Organ tumors—the teratomas of the present classification. 2. Tissue tumors, which include all so-called benign or simple tumors of epithelial or mesoblastic origin. 3. Cell tumors, i. e., the sarcomas and carcinomas. The present classification of tumors on the basis of embryologic origin may be imperfect and difficult of application in special cases, and while it in a measure involves a theory as to the origin of tumors, yet the study of their histogenesis incited by this theory has borne rich fruit, as perhaps shown more especially by the remarkable and partly quite recent developments in regard to adrenal tumors of the kidney, the adenomyomas and other tumors of the female genital structures, the neuroepitheliomas, and the embryonal adenosarcomas of the kidney. A theory which has given rise to so many important discoveries should not be too hastily discredited or abandoned.

THE LYMPHATICS OF THE LUNG.

Councilman¹ points out that the lobule of the lung constitutes a definite unit in its anatomy, normal and pathologic. The outlines of the lobules are seen most perfectly on the pleural aspect of the lung; they are triangular, the base corresponding to the pleural surface, and are separated from one another by small strands of connective-tissue which forms either a complete investment of the lobule or is in places wanting. At the apex the bronchus and the artery enter. The small areas supplied by the terminal branches of the bronchus are commonly called "acini," though Miller has designated them lobules, but the use of the term lobule in this sense can be at once seen to be confusing. The bronchial passage ends in an atrium, thoroughly described by Miller, from which the air-sacs or infundibula are given off, and from these arise the air-cells or alveoli. Councilman emphasizes the importance of this atrium because it is the starting-point of the focal pneumonias of children.

Accompanying the bronchial branches are branches of the pulmonary artery; a small amount of connective tissue accompanying the arteries, maintaining some connection with the perilobular connective tissue; veins are also found in the fibrous septa, the largest

¹ Münch. Med. Woch., Feb. 7, 1899.

² Jour. of Path. and Bact., 1899, vi, 220.

¹ Jour. Boston Soc. of Med. Sci., 1900, iv, 166.

at the periphery of the lobules. In focal pneumonia of children Councilman found the lymphatics distended so that they could be followed with ease. They are described as originating about the acini, and divided into two sets: 1. A central, running along the pulmonary arteries and emptying directly into the peribronchial glands at the root of the lungs. 2. A set which ramifies in the interacinous and interlobular septa and empties into the pleural lymphatic plexus. The second set is the more extensive; its vessels are provided with valves which point toward the pleura. When a smaller vessel enters a larger, the walls of the smaller project for some distance into the lumens of the larger, forming an effective valve. These interlobular lymphatics are important because it is probably through them that infections in the center of the lung extend to the pleura. They also play a prominent rôle in the absorption of exudates and in the removal of organisms entering the lungs.

The central lymphatics are large vessels which often become greatly distended in pathologic conditions. Small branches from the peribronchial tissues and probably also from the tissue of the acini open into them. Councilman did not find valves in the central lymphatics, but he thinks they are probably present; neither has he found any connection between the central lymphatics and the peri-arterial, but it is reasonable to suppose that such exists.

A TRAITOROUS HOSPITAL CORPS.

The *New York Medical Journal* comments with deserved severity on the treason, to the Geneva Cross, of a so-called hospital corps that went from this country to the Transvaal. No censure can be too strong for men who thus violate their voluntarily assumed obligations, nor, whatever our sympathies may be in other regards, can we justify the Boer Government for accepting them as militant recruits. It is said that the Boers as a class have a distrust of medical assistance from the outside and it is hinted, we hope unjustly, that they encouraged rather than otherwise the transformation of a hospital into a combatant force. So far as the facts have come to us there is enough to suggest greater care in those who have influence or interest in the international Red Cross movement in endorsing or recommending volunteer hospital corps for the present war, unless they go under particularly well-known and reliable auspices.

MEDICAL PRACTICE LAWS.

The efficient working of the new medical registration law of Michigan has been materially aided by a recent decision of the supreme court of the state, noted in our news columns last week. A graduate of a "fake" medical college obtained registry under the old law and has contested the right of the State Board to refuse him this under the law now in effect. The case was made a test one and the decision is that although registered under the old act he was not legally entitled to that registration, because the affidavit on which it was based did not show him to be duly qualified. It is said that about 780 so-called physicians will be ruled out by the

decision, most of them holding diplomas from the Armstrong-Bland "Independent Medical College," though there are two other similar concerns that also appear to have done a thriving business. The authorities appear to be thoroughly in earnest in enforcing the law, and this will be very much to the advantage of the profession in Michigan, though much more needs to be done to bring the state up to the standard that is the ultimate object of the best wishers of our profession. It is, however, a step in advance, and will be followed later by others. In this connection it may be remarked that in Rhode Island, the only remaining New England state that admits to practice on a diploma, legislation is now pending to bring it abreast of its neighbors in this respect.

MEDICINE AND MISSIONS.

Among the subjects of interest discussed in the recent missionary conference in New York City was that of medical missions and their advantages in aiding mission work among the heathen, noted in our columns last week. It was the unanimous testimony that in this way, often before any other is opened, a successful attack on the strongholds of heathenism can be successfully inaugurated. That this must be so is self-evident; the wonder is that mission boards were so long in adapting this for their purposes. Amongst savages and unenlightened people generally, including the degenerates who take up with "Christian Science" and Dowieism, the healing of the body and the healing of the soul go together—the shaman, the sorcerer and the priest have alike the control of health here and hereafter. The destruction of the old faith and its replacement by the new can be no better aided by purely human agency than by the introduction of scientific medicine and surgery, hence the value of medical missionaries. That they can not always overthrow error proves nothing; medical science fails in this even in the most civilized Christian countries; the mental peculiarities that even the gods strive against in vain exist everywhere. But as a material accessory to mission work medicine must always take first rank, and as a profession we should be interested to have it always thoroughly representative of our best.

THE FUTURE OF THE NEGRO.

In an address delivered before the Tri-State Medical Society of Virginia and the Carolinas, Dr. Paul B. Barringer very forcibly presents his views on the medico-sociologic aspects of the negro question in this country. He thinks the negro is, under present conditions, rapidly reverting to savagery, that the future of the country is in peril and that "unless a brake is placed on the ontogeny of this savage, the South will be uninhabitable for the whites." The picture he draws is a dismal one; we prefer to see a brighter possibility ahead, and hence are glad to be able to correct one or two of the premises on which his conclusions are based. He thinks that the negroes in the large Northern cities are not advancing as compared with those of the country districts of the same sections. It is true that they include many disreputables, but it would, we believe, be an error to say that they are retrograding, and the careful studies by students of degeneracy reveal a prevalent

type that, as far as physical stigmata are concerned, is a marked advance on the African and the southern field negro. One negro regiment recruited from these Northern negroes and officered by men of their own color made a record in service during and after the late war that ought hardly to fall under his wholesale condemnation of such organizations. The northern negro, city or country, is very far from being altogether what he ought to be, but he presents no very serious problems. In the South the vast number of the blacks renders the more serious aspects of the subject more prominent, and it is perhaps not surprising that pessimistic views are sometimes expressed. There may be in places a segregation of the blacks and some undesirable developments, but never a Hayti under properly supported Anglo-Saxon laws and institutions. The Jamaica negro is not always a pleasant individual, but he is not a Haytian. The development of the South will, we believe, bring out some interesting anthropologic evolutions that will be well worthy of study, but it does not seem that the future of the white race is in danger.

REDUCTION IN MORTALITY IN DIPHtherIA IN AUSTRALIA DUE TO USE OF ANTITOXIN.

We have had so much to say on the subject of the treatment of diphtheria with the antitoxin that we hesitate to reiterate our position in this connection, but we feel that the truth can not be too securely driven home and that even yet some lives are needlessly lost that antitoxin could save. Statistics—the brute force of figures—and personal experience alike testify most eloquently to the efficacy of this method of treatment, and the saving of life thereby accomplished must forever stand as a monument to the scientific acumen and the unselfish devotion of a profession always distinguished by high motives and noble ideals. Some additional statistics of an interesting character in this connection are presented in a recent communication by Turner,¹ who reports the results of a study of the mortality from diphtheria in the three principal Australian colonies, Queensland, New South Wales and Victoria, for fifteen years, with especial reference to the influence of the antitoxin on the death-rate. In the eleven years preceding the introduction of antitoxin—from 1884 to 1894—the number of deaths from diphtheria and croup per hundred thousand in Queensland varied between 65.3 in 1885 and 35.8 in 1894, the mean annual death-rate per hundred thousand being from 1884 to 1889, 49.2, and from 1890 to 1894, 44.1; while during the four years of antitoxin-treatment, from 1895 to 1898, the number of deaths from the same diseases per hundred thousand varied between 21.2 in 1895 to 12.9 in 1896, the mean annual death-rate per hundred thousand from 1895 to 1898 being 16.4. In New South Wales the number of deaths from diphtheria and croup per hundred thousand between 1884 and 1894 varied from 62.8 in 1885 to 27.8 in 1886, the mean annual death-rate per hundred thousand being, from 1884 to 1889, 43.2, from 1890 to 1894, 47.7 and from 1895 to 1898, 18.4. In Victoria the number of deaths from diphtheria and croup per hundred thousand varied, between 1884 and 1894, from 92.2 in 1890 to 15.6 in 1893, the mean annual death-rate per hundred thousand being,

from 1884 to 1889, 45.4, from 1890 to 1894, 39.8 and from 1895 to 1898, 19.7. In all three colonies the number of deaths per hundred thousand between 1884 and 1894 fluctuated between 72.6 in 1890 to 29.7 in 1894, the mean for the eleven years being 44.4, while the number of deaths per hundred thousand between 1895 and 1899 varied between 19.9 in 1898 and 16.4 in 1896, the mean for the four years being 18.7.

HEMISYSTOLE.

This designation has been applied to a condition in which it is supposed that there exists asynchronous action of the ventricles of the heart, so that with each contraction of one ventricle, one or more contractions of the other take place. The evidence as to the actual occurrence of such a phenomenon is, however, not conclusive. For obvious reasons the demonstration can only be made by experimental means, but the observations that have thus far been recorded in this connection are not wholly free from criticism. For these reasons Frank and Voit² undertook an investigation of the subject with the aid of specially devised apparatus. They employed a rubber manometer and made their observations on rabbits and dogs. Narcosis was induced by curare, the thorax opened in the middle line and a small, curved metallic catheter introduced through the left auricle and fastened into the left ventricle, while a straight metallic catheter with lateral fenestra was introduced through the jugular vein into the right ventricle. Both catheters were connected with rubber manometers, as was also a canula fastened in the carotid artery. In accordance with previous statements attempts were made to induce hemisystole, in part by means of suffocation and in part by means of poisoning with helleborein. Marked irregularity in the action of both ventricles, such as could be designated hemisystole, was, however, not noted in a single instance in either rabbits or dogs, although the observations were continued for long periods of time. Almost unexceptionally the pulsations of both ventricles were synchronous throughout, and each variation in the pressure curve of one ventricle was exhibited by that of the other. In some instances the carotid pulse failed, although that of the ventricles remained normal. Occasionally also there was slight disparity in the maxima of successive pulse-waves. These observations would seem to demonstrate that the condition of hemisystole does not develop under the influences to which it has been attributed, and it is thought that the designation is unjustified.

HYPERthermia AND HYPOTHERmia.

In spite of the fact that physiologists state that life can not be maintained for any length of time at temperatures above 110 or below 90 degrees, reports of both higher and lower figures are made from time to time, and often one is perplexed for an explanation. In some instances deception is obvious, and in others it can not be wholly excluded, but, even allowing for these, there still remain a number whose authenticity can not be doubted. The evidence, so far as it goes, would therefore seem to prove that extremes in either direction are possible, though, naturally only for brief periods. Hypotheses have not

¹ *Intercolonial Med. Jour. of Australasia*, January 20, p. 39.

² *Deutsches Archiv. f. Klin., B. Ixv, H. 5 u. 6, p. 580.*

been wanting to explain the mechanism of heat-regulation, but the problem is not easy of solution and the final word has not yet been said in this connection. In the familiar case of Teale, in which a lesion of the cervical spine was present, the temperature reached 122° F. Jacobi has recorded the case of a hysterical fireman in whom a temperature of 148 degrees was observed, Jones one of a girl in whom the temperature rose above 150, and Galbraith one of a young woman in whom he noted a temperature of 151; and in the same case a nurse noted one of 171. It is noteworthy that many of the cases of hyperthermia have occurred in malingerers or hysterical women or men. Not less remarkable observations of hypothermia have been recorded, a number of which are cited in a communication by Hulbert,¹ in which he reports a most remarkable case of morbid drowsiness in a man, 36 years old, in whom the rectal temperature fell as low as 81.6 degrees and on numerous occasions was under 90. Such hypothermia has been variously observed by others in connection with shock, collapse, as in cholera and pernicious malarial fever, with disease or injury of the spine or brain, with inanition, hemorrhage, chronic wasting disease, like carcinoma, with intoxication, as with alcohol, carbolic acid, uremia, with diseases of the skin as sclerema, and with heat-exhaustion.

THE IODIN REACTION OF SPERMATIC FLUID.

There are times when the determination whether spots on linen are due to seminal fluid or not may be of the highest medicolegal importance, and a method would be welcome that will permit a ready and reliable decision. Florence assumed that the seminal fluid may contain specific alkaloidal substances, and in order to determine this point undertook a study of the effect that the alkaloidal reagents would have on human spermatic fluid. Using a solution of iodine and potassium iodide he was able to obtain a reaction only when the iodine was present in amount sufficient to correspond to a solution of potassium tri-iodide. For this purpose he used 1.65 grams of iodine and 2.54 grams of potassium iodine to 30 grams of water, and added 1 drop of this solution on a glass slide to a watery extract of seminal stain. In the course of a few minutes there appeared brownish microscopic crystals, closely resembling hemin crystals and, like these, appearing in typical form as rhombic plates, together with numerous rudimentary forms. No other secretion, as well as brain-substance, alkaloids, dough, articles of food and spermin, yielded a similar reaction, but only lecithin and cholin did. It was believed that possibly the reaction was due to some previously unknown body peculiar to seminal fluid, but in view of the reaction yielded by cholin and lecithin it was deemed wise to employ the test as a preliminary one, and when it yielded a positive reaction to search for spermatozooids. Subsequent observers, however, obtained a similar reaction with spermin, muscarin, derivatives of nuclein and of uric acid, and still others attributed it to cholin and lecithin. In view of these rather radical differences of opinion Vertun² undertook a series of independent observations. A quantity of seminal fluid was

added to a mixture of alcohol and ether, the supernatant fluid decanted, the extract precipitated with an acid alcoholic solution of platinum chloride, the filtered alcoholic solution of platinum chloride, the filtered precipitate dissolved in water and permitted to crystallize obtained in this way were placed on a filter and washed with a mixture of alcohol and ether until the wash-water was colorless, for the removal of the excess of platinum chloride. The filter was then placed in a vacuum-exsiccator. In one case in which seminal fluid twelve hours old was examined crystals remained, indicating the formation of a double platinum salt of an organic base, and thus the presence of another base besides spermin. In two other cases, in which the seminal fluid was only a few hours old, no crystals remained, so that no other base and, therefore, not cholin, was present. As the reaction of Florence was present in all three cases it can be attributed to spermin, although in the one instance it may have been intensified by the presence of cholin. Inasmuch as the reaction has been yielded besides by members of the cholin group—cholin, muscarin, neurin—by spermin and by derivatives of nuclein or alloxuric bases—adenin, xanthin, hypoxanthin, guanin, carnin—it must be looked on as belonging to a group of substances and particularly a large number of organic bases. In view of these facts the development of the reaction with a watery extract from spots on linen would not indicate conclusively the presence of seminal fluid, but would necessitate microscopic examination for spermatozooids; nor would its failure to develop be sufficient to exclude the presence of seminal fluid. It was found further that the reaction was prevented in direct proportion to the albuminous concentration of the fluid tested.

URIC-ACID AUTOINTOXICATION.

Although much has been written on the subject of uric acid, it can not be said that there is universal agreement as to its influence in the causation of disease, or as to the means of affording relief from its reputed manifestations. While perhaps our present nomenclature may prove to be incorrect and current explanations inadequate, it is safe to assume that certain derangements in metabolic activity are capable of bringing about morbid manifestations of a more or less definite and sometimes even alarming character. Of this we have evidence in the development of gout, of diabetes, and of the condition or process that correctly or incorrectly, it is customary to speak of as uric-acid intoxication. Care must, however, be taken not to generalize too freely on the basis of scant knowledge of a precise character. The individual factor should never be forgotten or ignored, and a growing experience teaches that the reactions that take place in the body can not always be reproduced in the laboratory. Uric acid may appear in the urine of persons under widely different conditions—on a diet of milk, as well as on one of meat or carbohydrates; in those who abstain from, as well as in those who indulge in, alcohol; after exercise, as well as after rest—so that one is often at a loss for an explanation of its occurrence. For the present we must be satisfied with the statement that this represents an aberration in metabolism; but the patient is not so much concerned with the mechanism of

¹ The Lancet, January 13, p. 84.

² Centralbl. die Krankheiten der Harn- und Sexual-Organen, B. ix H. 1, p. 1

the process as with the treatment, or rather with its results. Some interesting observations of an original character were made in this connection in an address delivered a short time ago by Goodhart,¹ before the Reading (England) Pathological Society. He expressed the conviction that in the majority of cases of uric-acid intoxication the condition is scarcely one of diet at all, as uric acid will sometimes appear in the urine when, so far as is known, all food capable of giving rise to it has been withheld. Uric acid is considered as an ash or a final product common to the many metabolic processes that take place within the body. In one case the cause may be the visceral sluggishness that is the common outcome of nervous exhaustion; in another the hereditary condition that determines gout; in still another a great or a sudden shock or great anxiety or exhausting illness; in others some early defect in the kidney; in others it may be an indication of senility and of a failure on the part of the organism to accommodate itself rapidly to various changes in its environment. The important part in the arrangement of a dietary is first to determine the metabolic capability of the individual. Thus, under suitable conditions even sugar and fat and alcohol in one form or another may be permitted. The object of treatment should be, so far as possible, to prevent the formation of uric acid rather than its elimination. The free drinking of water is a most useful measure, not only flushing out sand in the urinary passages, but also softening and disintegrating small calculi.

Medical News.

DR. GEGENBAUER, professor of anatomy at Heidelberg, has been awarded the Vohlbrecht prize of 12,000 marks for works on natural science.

COMPOSITION OF OLEOMARGARIN.—Secretary Wilson, of the United States Department of Agriculture, is making an effort to determine the ingredients which go toward making oleomargarin. It is believed that much of what is sold as pure butter is made from a mixture of cheap fats and tallow, together with deodorizing substances and artificial coloring matters.

COMMITTEE APPOINTMENTS.—At a meeting of the American National Committee of the XIIIth International Medical Congress, held at the Cosmos Club, Washington, D. C., May 2, with Dr. W. W. Keen in the chair, the secretary read the minutes of the preceding meeting and reported that about two hundred American physicians had already joined the Congress. It was unanimously voted that the president of the American Medico-Psychological Association be added to the Committee, and that the organizations whose presidents compose the Committee be requested to contribute to the expenses of the Committee. The meeting adjourned subject to the call of the president.

INVITATION TO INTERNATIONAL DERMATOLOGICAL CONGRESS.—At the meeting of the American Dermatological Association, just held in Washington in connection with the Congress of American Physicians and Surgeons, a committee was appointed consisting of Drs. J. Nevins Hyde, of Chicago, Henry W. Stelwagon, of Philadelphia, and T. Caspar Gilchrist, of Baltimore, to represent the Association at the International Dermatological Congress which meets in Paris in August. The

committee is to extend an invitation, in the name of the Association, to the members of that Congress to hold the next international meeting in New York City. It was further instructed, in the event of the Congress giving a favorable response, to present the name, and urge the election, of Prof. James C. White, of Boston, the first president of the American Dermatological Association, and an honorary member of the French and Italian Dermatological societies, for the presidency of that Congress.

PROGRESS OF THE PLAGUE.—Having one of the best harbors in the world, Sydney, N. S. W., acts as a shipping center for the South Sea Islands, and a correspondent writes that the plague is thus thought to have gained entrance from one of the New Caledonia group. Up to the date of writing (April 11), 94 cases were reported, with 31 deaths. All cases, with one exception, were in English-speaking people, the exception being in a Chinaman, and all but one can be traced to the original plague center around the wharves. Among other sanitary measures in progress, 28,600 rats were destroyed. It has also been demonstrated that the flea acts as a means of inoculation, and 4 cases are reported, all showing blebs, the result of flea bites. In three the blebs were broken before examinations could be made, but those from the other patient showed the bacilli of plague present. Plague serum has been used in about 1200 contacts. Cases of plague are also present in Melbourne, Perth West and Brisbane. According to the *British Medical Journal* (April 28), the deaths from plague in Bombay city showed an increase for the first week in April over the last week in March. For the first 4 days in April, in Karachi, the new cases were, respectively, 49, 31, 54 and 60, and the deaths, 34, 28, 33 and 42. For the same dates, in Calcutta, they were, 111, 109, 93 and 103, and the deaths, 99, 109, 104 and 89. One new case was reported in Mauritius for the week ending April 19.

MEDICAL SERVICE IN TRANSVAAL WAR.—S. Osborn, chief surgeon of the Metropolitan Corps of the St. John Ambulance Brigade, speaking of the hospital arrangements in South Africa (*The Lancet*, April 21), says that the war has upset many of their former ideas as to military surgery, because many seriously wounded men, suffering from injuries which would, ordinarily, have demanded operative measures, have recovered without surgical interference. While this might have been due either to the excellent antiseptic dressings adopted as first aid on the field, or to the nature of the projectile, he is inclined to think it is because of the antiseptic precautions. The ambulance and nursing organizations, in point of comprehensiveness and efficiency, he considers far beyond anything of the kind previously seen; and though he served in the Franco-German War, in the wars between Russia and Turkey and between Turkey and Greece, he says that never was the effort to save the lives and limbs of the wounded made on anything like the extensive scale found in South Africa to-day. In regard to the rescue of the wounded, the devotion shown by the ambulance section of the British army, and the completeness of the machinery by which the efforts have been aided, is most admirable, since every engagement has witnessed scenes of heroism in which the officers of the Royal Army Medical Corps and their helpers have themselves suffered wounds and death in the discharge of their duties. As to enteric fever, at Modder River 6 per 1000 of those inoculated and 9 per 1000 of the non-inoculated suffered from the disease, and the prevalency of this he considers the saddest feature of the situation.

¹ *The Lancet*, January 6, p. 1; *THE JOURNAL*, January 27, p. 225.

NEW YORK.

THE SIXTY-NINTH commencement of the Albany Medical College was held May 2. The class numbered twenty-five and is the last to be graduated under the three-year course. The address was made by Dr. Jas. H. Canfield, librarian of Columbia University, and Rev. Dr. Raymond, president of Union University, conferred the degrees.

New York City.

REV. GEORGE F. CLOVER, who has been connected for a number of years with St. Luke's Hospital, has been appointed pastor and superintendent to fill the vacancy caused by the retirement of the Rev. George S. Baker, previously noted in THE JOURNAL.

A FIRE in the industrial school on Randall's Island recently caused a panic among the inmates of the Children's Hospital and neighboring institutions. The school, which was a one-story frame building, was burned to the ground, but the fire did not spread to the adjoining buildings.

NURSES' CONVENTION.

About one hundred superintendents of training schools for nurses have just held a convention in this city, and during the three days they were in session discussed various topics connected with the training of nurses. Special attention was given to a consideration of the advisability of increasing the course of study to three years, fifty schools having already done so. They also adopted the following resolution:

Resolved, That this society strongly indorses the principles set forth in the Army Nursing bill recently brought before Congress, and pledges itself to use every effort to further the objects therein set forth.

HONOR DR. JACOBI.

A complimentary dinner was given to Dr. A. Jacobi on the evening of May 5, in commemoration of his 70th birthday. Dr. Joseph D. Bryant presided, and among those who responded to toasts were Carl Schurz; Seth Low, president of Columbia University; Dr. William H. Thomson, president of the Academy of Medicine; and Dr. William Osler, of the John Hopkins University. A notable feature of the evening was the presentation of the "Festschrift," a volume of 500 pages entitled "International Contributions to Medical Literature." This book is modeled after those annually presented to European scientists on similar occasions. For many years Dr. Jacobi has been widely known as an authority on the diseases of children, but particularly since 1870, when he became clinical professor in that department of the College of Physicians and Surgeons.

PENNSYLVANIA.

ELEVEN COWS near Spring City were recently declared infected with tuberculosis and ordered killed.

LAND VALUED at \$25,000 has been left to the Sisters of St. Francis, for the establishment of a hospital for convalescents on the hills adjacent to Bridgeport. The proposed building will be constructed of gray stone, and when finished will cost in the neighborhood of \$75,000.

PREVENTION OF INFECTIOUS DISEASES.

The annual report of Dr. Leonard Pearson, state veterinarian, and of the State Live Stock Sanitary Board, has been submitted to the Secretary of Agriculture. Of the \$40,000 allowed the Board, \$26,992.98 was paid for the destruction of tuberculous cattle; \$233.50 for horses and mules suffering from glanders; \$5692.03 for tuberculin tests and inspection of animals; \$2906 for inspections, vaccinations, etc.; \$3286.46 for animals afflicted with other diseases than glanders and tuberculosis, and \$889.48 for special services in connection with the enforcement of the law regarding the prevention of diseases among cattle. There were 9 cases of glanders reported during the year. Anthrax occurred in the following counties: Bradford, Cambria, Chester, Delaware, Franklin, Jefferson, Monroe, Philadelphia, Pike, Potter, Susquehanna and Warren, with 236 deaths from the disease. Rabies was reported from 12 counties: Allegheny, Berks, Blair, Center, Chester, Clearfield, Clinton, Delaware, Erie, Montgomery, Philadelphia and Union. The number of tubercular cattle found was 1187. They were paid for at \$22.30 a head.

Philadelphia.

DR. JOSEPH GOLDBERGER has been appointed assistant to Dr. T. F. Richardson, medical officer in command at the Reedy Island Quarantine Station of this city.

DURING commencement week, a well-designed bust of the late Dr. George B. Wood, formerly professor of the practice of medicine in the University of Pennsylvania, will be presented to the University.

SUIT FOR \$25,000 has been entered against Dr. Charles W. Dulles, to recover damages for illegally declaring the plaintiff insane. It is stated that the Doctor has a complete defense to all the charges made.

THE COMMITTEES on elementary schools and hygiene, of the Board of Education, recently adopted a resolution recommending that regular instruction be given in physical culture in the elementary schools and that a teacher be appointed to take charge of such work at a salary of \$1200 a year, beginning next September.

MARYLAND.

DR. GEO. W. SIMMONS has been appointed physician to Kent County Jail, at Chestertown.

DR. JAMES V. URIC has been appointed health officer of Kent County, vice Dr. W. Frank Hines.

DR. J. L. NOBLE has been reappointed health officer of Caroline County.

Baltimore.

DR. WM. OSLER has been called to Canada to see his brother, who is ill.

DR. LEWIS W. ARMSTRONG has been appointed first assistant in the insane hospital at Bayview.

DR. ST. CLAIR SPRULL has resigned the post of superintendent of University Hospital.

DR. N. G. KEITLER, JR., has been appointed resident physician to Bayview Hospital, etc., and Drs. C. Howard Lewis, Frederick Crawford and J. L. McKnight assistant physicians in the same institution.

DR. WILLIAM R. STOVER was formally installed as resident physician in the Baltimore University Hospital. April 30. Dr. William D. Bacon was made assistant.

DR. JOSEPH CLEMENT CLARKE has been elected professor of psychiatry in the Woman's Medical College of Baltimore, vice Dr. Edwin A. Brush, resigned. Dr. Clarke is a graduate of the University of Maryland and superintendent of Springfield Asylum for the Insane, Sykesville.

A complimentary dinner was tendered to Prof. Wm. H. Welch, of the Johns Hopkins Medical School, May 4, by those who have carried on investigations in his laboratory in past years. On this occasion the "Festschrift," containing the work of his pupils and associates, was presented to him as a testimonial of affection and esteem and to mark the twenty-fifth anniversary of his professional career.

THE THOMAS WILSON Sanitarium for sick children was opened May 1. The hospital is eight miles from the city, on a hill six hundred feet above sea-level; there are three wards, each accommodating about thirty. The mothers of the children are allowed to come, their transportation being paid for them.

THE SCOPE of work in Johns Hopkins Hospital and Medical School has again been broadened. The hospital will offer special courses of instruction for graduates during May and June. This is intended to meet the requirements of practitioners of medicine and is almost wholly of a practical character.

OHIO.

SEVERAL CASES of malignant diphtheria having been found in Mansfield, the health officer caused an investigation to be made. A sick cat, with which the children had been playing, was found to have diphtheria germs in its throat.

APPROPRIATIONS.

The seventy-fourth general assembly of the State of Ohio, just adjourned, appropriated \$180,400 for the Ohio Hospital for Epileptics at Galipolis, for the fiscal years 1900 and 1901. For construction the sum of \$125,000 is available, and the items are a general hospital (\$35,000), administration building (\$50,-

000), and two new cottages for patients (\$40,000). The purchase of more land, including a considerable addition to the colony farm, is also authorized. Funds are provided for the continuation of the work in the pathologic laboratory, and a special appropriation has been made expressly to enable this laboratory to participate in the pathologic exhibit of the AMERICAN MEDICAL ASSOCIATION.

THE OHIO LAW.

The new medical practice act enacted April 14, 1900, by the Ohio Legislature is of more than local interest, and now that a copy of the measure has come to hand a satisfactory review of its provisions can be made. The number and character of the Board of Medical Registration and Examination was not changed, and the Board will consist, as formerly, of seven members, of whom three are "regulars." The new portions of the law will take effect on July 1, with the exception that students who were matriculated in Ohio medical colleges on Jan. 1, 1900, and who shall graduate from their respective schools and present their diplomas to the Board prior to July 1, 1904, shall be entitled to have their diplomas simply registered as provided by the existing statute. This concession to the students was necessary in order to silence their opposition to the bill as a whole, and it is not in any way unjust, for present students matriculated at Ohio colleges with the implied understanding that their diplomas when received would entitle them to a State license.

With this exception, all applicants to practice medicine in Ohio must pass a satisfactory examination before the State Board in the future in all branches of medicine; and more important still, shall present, as a necessary preliminary to their admission to the examination, certain specified evidences of previous education. In this respect the Ohio law is now second to none; for in addition to having a medical diploma granted after four years of study in a medical college which is recognized by the Board as in good standing, the applicant must show either that he has obtained the degree of A. B., B.S., or its equivalent from a reputable college; or a diploma from a normal school, high school or seminary, issued after four years of study; or a teacher's permanent or life certificate; or a student's certificate of examination for admission to the freshman class of a reputable college; or a certificate of his having passed an examination conducted by the Board itself.

From this it will be seen that the State of Ohio is no longer behind in the matter of medical legislation, but possesses a statute second to none in its standard of educational qualification.

The Board has always had some difficulty in adjudicating questions that arose from the presentation of diplomas which under terms of the former law in regard to various forms of foreign certificates, entitled the holder at home to practice a certain branch of his profession. This has been fully met in the new statute by a plain statement that the certificate must have conferred the full right to practice all branches of medicine or surgery in some foreign country. Another important provision is the one permitting the Board to arrange for reciprocity in registering certificates which have been acquired from state boards after examination when the other states have laws demanding an equal grade of qualifications. This is one of the first direct legal enactments toward arranging for reciprocity in registration, something in which so many medical societies are now interested.

While under the existing law midwives were required simply to produce evidence of some experience in order to secure a license, the new statute compels them to appear before the Board and take such examination as it shall require. Because many loopholes had been found by lawyers, in the section of the former law that defined the practice of medicine, a new one has now been enacted which will prove much more difficult of evasion, and even the Supreme Court of Ohio, which not long since held that osteopathy was not "an agency for the treatment, cure or relief of any bodily injury, infirmity or disease," will probably not be able to nullify this revised section. It will not be so difficult in the future to secure proof of the illegal practice of medicine. This section being of some general interest, it is given in full, as follows:

Any person shall be regarded as practicing medicine or surgery within the meaning of this act, who shall use the words or letters "Dr.," "Doctor," "Professor," "M.D.," "M.B.," or any other title in connection with his name which in any way represents him as engaged in the practice of medicine or surgery or midwifery, in any of its branches, or who shall prescribe or who shall recommend for a fee for like use any drug or medicine, appliance, application, operation or treatment of whatever nature, for the cure or relief of any wound, fracture or bodily injury, infirmity or disease. The use of any of the above-mentioned words or letters or titles in such connection and under such circumstances as to induce the belief that the person who uses them is engaged in the practice of medicine or surgery or midwifery or any of its branches, shall be deemed and accepted as prima facie proof of an intent on the part of such person to represent himself as engaged in the practice of medicine or surgery or midwifery.

The osteopaths having developed strength, largely through the influence of Senator J. B. Foraker, some recognition of them became necessary to the enactment of the law. Even then they almost succeeded in getting a law of their own passed, that would have nullified all restrictions governing the practice of medicine, and this measure was openly lobbied for by two judges of the Supreme Court of Ohio. The law, as passed, provides that an osteopath must have a diploma from a legal school of osteopathy which requires four years of study of at least five months, each taken in four separate years; and that he must pass a satisfactory examination before the state board, in anatomy, physiology, chemistry and physical diagnosis. It is also provided that osteopaths "shall not be granted the privilege of administering drugs, or of performing major or operative surgery."

The passage of this amended law is the full fruition of the dreams for many years of the leading members of the Ohio profession, and it required the most assiduous and most self-sacrificing labor on the part of the legislative committee of the State Medical Society assisted by committees of some of the local societies. The result, however, clearly demonstrates that when the medical profession shows itself to be determined in its requests to the politicians it can overcome all opposition. Because the new Ohio statute is to be administered by but one board for all the so-called schools of medicine, in addition to the commendable points above enumerated, it possesses features of superiority over any medical law in America, and it will no doubt for many years be a model after which other states will pattern. The politicians can not attempt to disturb it for two years at least.

Cincinnati.

AT THE commencement exercises of the Cincinnati College of Medicine and Surgery, May 2, diplomas were granted to thirteen young men and women.

TWENTY-SEVEN young men were graduated, May 1, from the Miami Medical College. The alumni banquet was attended by two hundred members.

A CITIZENS' committee visited the city council recently and secured the repeal of the compulsory vaccination ordinance.

ILLINOIS.

THE LADIES of the hospital board at Galesburg gave a benefit bazaar and concert May 1 and cleared \$500.

Chicago.

DR. ARTHUR R. EDWARDS has returned from an extended European trip.

DR. JAMES B. HERRICK announces that he will hereafter limit himself to office and consultation practice.

LAST WEEK the donations to the fund for the hospital for consumptives were \$1186, bringing the total up to \$18,333. The committee awaits only the settlement of the labor trouble to begin building.

EXAMINATION of candidates for license to practice medicine was held May 3. There were 105 applicants.

KANSAS.

SIX ACRES of ground had been transferred to the Bethany Hospital Association at Kansas City for the consideration of \$12,500, and on this site will be built a new \$100,000 hospital.

Rev. J. H. James, of Oakley, Kan., has given \$60,000 of this, and work will be commenced soon.

DISTRICT OF COLUMBIA.

BILL FOR INCREASE OF MEDICAL DEPARTMENT OF ARMY.

Be it enacted by the Senate and House of Representatives of the United States of America in Congress assembled,

Sec. 1.—That there shall be added to the number of medical officers of the army now authorized by law, four assistant surgeons-general with the rank of colonel, thirty surgeons with the rank of lieutenant-colonel, thirty surgeons with the rank of major, and eighty assistant-surgeons with the rank of first lieutenant who shall have the rank of captain at the expiration of five years' service as now provided by law. Provided that the original vacancies created by this act in the grade of colonel, lieutenant-colonel and major shall be filled by seniority promotion in accordance with established laws and regulations.

Sec. 2.—Hereafter candidates for appointment in the medical corps of the army who pass a medical examining board in compliance with existing regulations, shall be appointed acting assistant-surgeons for a probationary period of six months; during this probationary period they shall attend the army medical school established at the army medical museum in the city of Washington, and the faculty of the army medical school shall report to the Secretary of War at the end of the prescribed course of instruction upon the fitness and relative standing of the probationary candidates; those who are recommended by the faculty may then be commissioned by the President to fill existing vacancies in the medical corps of the army.

Sec. 3.—Acting assistant-surgeons appointed in accordance with the provisions of Section 2 shall be paid \$100.00 per month and shall not be entitled to any allowance or to mileage in reporting for the prescribed course of instruction, or in returning to their homes if they are not recommended for a commission.

Sec. 4.—The number of acting assistant-surgeons appointed in accordance with the provision of Section 2 shall not exceed the number of vacancies existing or to result from retirements during the probationary period.

Sec. 5.—Candidates who have rendered satisfactory service as acting assistant-surgeons or as commissioned medical officers in the volunteer army of the United States for a period of six months or more, shall be exempted from this period of probation and may be commissioned at once if vacancies exist and they pass a satisfactory examination as to their physical, moral and professional qualifications.

DELAWARE.

THE GOVERNOR has appointed the following trustees of the State Insane Asylum: Drs. J. J. Black of Newcastle, J. H. Wilson of Dover, and H. W. Baker of Seaford.

THE FOLLOWING members of the Wilmington Board of Health have recently been elected: president, George B. Ward; treasurer, James H. Morgan; secretary, Andrew A. Cahill; executive officers, Harry Graham, Thomas Garvey, George Spath and Thomas Welsh.

LOUISIANA.

THE SIXTH annual session of the Charity Hospital Alumni Association was held in New Orleans the 18th ult.

A LARGE CLASS was graduated from the medical department of Tulane University, May 2. The total number of students this year was 426, the largest in the history of the college.

NEBRASKA.

AT THE commencement exercises of Creighton Medical College, held in Omaha, April 27, a class of twenty-two received diplomas. Prof. J. L. Greene, of Lincoln, who is a member of the faculty, delivered the doctorate address, and Rev. M. P. Dowling, president of Creighton University, conferred the degrees and presented the prizes.

IOWA.

AT CEDAR RAPIDS, the Sisters of Mercy cleared over \$1300 through a bazaar given to raise money for furnishing and equipping a hospital.

THE NEW ST. Joseph's Hospital buildings were dedicated in Sioux City, May 6. The institution was founded about ten years ago, but the improvements and enlargements made recently have cost \$150,000.

MISSOURI.

THE SUM of \$3000 has been subscribed for the erection of a chemical laboratory at Westminster College, at Fulton. The building when completed will cost \$5000.

THE COMMENCEMENT exercises of the Marion-Sims College of Medicine in St. Louis occurred April 27, and fifteen received diplomas from the medical department. Rev. J. W. Day addressed the graduates and Dr. Y. H. Bond conferred the degrees.

WASHINGTON.

A NEW WARD will be added to the Medical Lake Hospital for Insane; \$4000 has been appropriated for the purpose and the plans are now being drawn.

SPOKANE is to have a new Protestant Hospital. John A. Finch has donated a site and about \$15,000 has already been pledged. The cost will be about \$50,000. It will be incorporated as St. Luke's Hospital, under the auspices of the Protestant Episcopal Church.

CANADA.

DR. G. A. B. ADDY, St. John, N.B., has gone to England to study pathology under Dr. Sims Woodhead.

DR. J. W. DANIEL has just been elected mayor of St. John by over 600 majority.

THE MEDICAL health officer of Toronto, accompanied by the city engineer, will go to Europe soon for information regarding the construction of sewers.

EIGHTEEN medical students from McGill University are making their way to the Paris Exposition by taking care of cattle on the *Lake Huron*.

THE MCKAY bill, previously discussed in these columns, has been withdrawn from the local legislature.

DR. P. A. MCLENNAN, Nelson, B. C., has been appointed public vaccinator for the Kootenay districts, with power to perform vaccination on all school children.

THE SMALLPOX outbreak in Winnipeg has extended to twelve cases. Four nurses of the General Hospital are down with the disease and another death has occurred.

AT THE coming meeting of the Ontario Medical Association, June 6 and 7, Dr. Lowellyn Barker, of Chicago, will deliver the address in medicine, and Dr. Luke Teskey, the address in surgery.

THE PROVINCIAL Board of Health of Manitoba has issued a circular letter to the press dealing with the benefits of vaccination. The city officer of Montreal has also had published a decision of a U. S. judge on the same question.

DR. FARRELL, Halifax, has issued a warning to the citizens of that city who are moving at this time of the year, to the effect that tenants should see that all apartment houses and other residences have been thoroughly disinfected and especially should this precaution be taken where consumptives have been the previous occupants.

MEDICAL ALLIANCE OF AMERICA.

THE *Canada Gazette* contains the notice of the incorporation of this institution. It emanates from Montreal and is composed of citizens of that city. Full particulars appeared in THE JOURNAL early last fall, but this may be given as additional information. The company is a limited one with a capital of \$100,000, in \$10 shares. Among other powers bestowed, the following is granted: "To negotiate and arrange agreements and contracts between physicians, surgeons, pharmacists, nurses and the like, whose profession or calling is to care for and attend the sick, injured or infirm on the one hand, and such persons as desire these services on the other hand, whereby the latter shall be attended, treated and cared for by the former in return for a fixed fee or subscription, payable weekly or otherwise, to be collected and paid by said proposed corporation."

TRAUMATIC ORIGIN OF CANCERS—A MEDICOLEGAL CASE.

A case which has caused much talk among the profession in Toronto has just been concluded here in the courts of law. About the middle of last December, a traveler was walking to his home and carrying two heavy valises. He slipped, and in the attempt to recover himself, it is alleged that one of the

valises was thrown against the region of his liver with some violence. About the beginning of January the man went on a business trip to the maritime provinces, not having suffered much from the accident, but still not being in good health. He returned early in February, when his physician counseled an exploratory incision. This was performed, and it was found that he was suffering from a severe cancer of the liver. The incision was immediately closed, and two days later the man died. Dr. H. B. Anderson performed a post-mortem and found that the liver was greatly involved with cancer, and that there was also a nodule in the head of the pancreas. Nothing was found in any other part of the body. The traveler carried an insurance (accident) policy for \$5000, and the company refusing to entertain the claim; suit was brought for the recovery thereof, and a goodly number of the city physicians were summoned to give expert evidence, *pro* and *con*. It turned out that that part of the liver adjacent to the supposed injury was entirely free from the disease, and also that a doctor out of town had examined the man two or three months before the alleged injury and had diagnosed cancer of the liver. The action was dismissed.

ASSOCIATION OF TRAINED NURSES.

A bill was recently introduced into the Dominion Parliament by Dr. Roddick, on behalf of nurses of Montreal, who sought to obtain legislation toward the formation of a Canadian nurses' association. Opposition developed which was ultimately successful in forcing the withdrawal of the measure. The powers sought by this "association" were both extensive and unlimited so far as the Dominion was concerned, and the latter was the chief, though not the only, objection to the bill. J. Ross Robertson, M. P., chairman of the Board of Trustees of the Victoria Hospital for Sick Children, Toronto, took an active part in opposing the measure, and it was through his energy and representations to Dr. Roddick that the latter concluded to withdraw the bill. The introduction of the measure has, however, accomplished good, for it has laid the foundation for the formation of a trained nurses' association for the entire Dominion. The membership of this will include the woman superintendents of all the hospitals of Canada, together with the alumnae of each training school. The hospital authorities of the following cities have already given their support to the scheme: Vancouver, Winnipeg, London, Hamilton, Toronto, Kingston, Montreal, Ottawa, St. John and Halifax. It is understood that in the formation of this society Dr. Roddick will give hearty co-operation.

SAMARITAN HOSPITAL, MONTREAL.

The annual meeting of the above institution for women was held last week and the results show that the hospital is in a very satisfactory condition. The surgeon-in-chief, Dr. A. Laphorn Smith, read his report for the year. During the 5½ years since the hospital was founded, there has been each year a very substantial growth, while the past one has been the most active in the whole history of the institution: 124 patients have been under treatment, as compared with 101 last year, an increase of 23 per cent.; 41 of this number suffered from tumors or other forms of abdominal disease, requiring abdominal section for their cure. Of these 41 women, none died in the hospital, but 2 with hopeless cases of cancer died two weeks after return to their homes. There were 95 other gynecologic operations for inflammations, lacerations, cancer, etc., and 24 received only medical treatment. Three deaths occurred in the hospital during the year, but not one from the 41 major operations. In addition, in the out-door department, 150 patients were treated, 23 of these were admitted to the wards. Thus 274 patients have been cared for during the year, and 1310 since the hospital began its work. The receipts for the year amounted to \$3086 and the disbursements \$2696. It is altogether likely that a new building will shortly be erected. Dr. A. Laphorn Smith was re-elected surgeon-in-chief, and Sir Wm. Hingston consulting surgeon. Sir James Grant and Dr. F. W. Campbell were elected consulting physicians.

RECENT MEDICAL LEGISLATION IN NOVA SCOTIA.

Three acts of importance to the medical profession in the province of Nova Scotia passed the legislature at its recent sitting: An act to amend the public health act; one to establish

a provincial sanatorium for the treatment and care of persons suffering from tubercular disease of the lungs, and a third, introduced by Dr. Kendall, which aimed to remedy the abuses associated with medical attendance on employees of collieries and manufacturing companies. The act regarding the public health of the province provides for the appointment of county medical health officers, who shall be duly qualified practitioners. As noted in THE JOURNAL last fall, Nova Scotia was far behind the times in this respect. These appointments are to be for one year, the appointee to be paid a salary of not less than \$100. The act also sets forth at considerable length the duties required of these officers. Nova Scotia is the first province in the Dominion to set apart an allowance for the erection of a state sanatorium for consumptives; and the \$15,000 provided for this purpose speaks well, when it is remembered that the Ontario legislators voted, at their recent session, only \$4000, to enable municipalities to carry on this work. Clause (h) of the act is: "To pay to any municipal or civic body, corporation, private person or benevolent organization maintaining and conducting a sanatorium within the province for the treatment and care of persons suffering from tubercular disease of the lungs, a sum not to exceed 30 cents per day for not more than 100 days that each patient may be in actual attendance and under treatment at such sanatorium."

Correspondence.

Medicine in the Far East.

VIENNA, AUSTRIA, April 13, 1900.

LUCKNOW.

To the Editor: I found rather "short picking" as far as medicine is concerned, in Lucknow. There is a special hospital there for lying-in and gynecologic cases, but as everywhere in India women have a deep-rooted prejudice against allowing men to examine or treat them; they are very generally cared for by an inexperienced female.

By a visit to King's Hospital, I made the acquaintance of Dr. Raham Khan Bahadur, a native physician of wide reputation, and especially noted as an operator for cataract. The Doctor has done over 7000 operations of this kind, after a manner that he claims is practiced only by himself. He uses pure cocaine in powder, to render the eye insensible. He makes the usual incision before his extraction, but uses no eye speculum, and does not fix the eye with forceps while operating. After the incision is made, he uses a small ring-shaped instrument to press out the lens, but makes his pressure on the outside of the eyelid. The room that he operated in opened out on a dirty street; the air was full of dust, and he failed to wash his hands before beginning to operate, though he took the precaution to dip his instruments into hot water before using them. In spite of all this his results seemed to be excellent. The Doctor, like the other physicians whom I met in India, has a general practice. I saw a few patients with typhoid fever in his wards, all white men; in fact, every white man he had in his service had this disease, while among the natives, who outnumbered the whites twenty to one, there was not a case. In the management of enteric fever the Doctor has a hobby, i. e., the restriction of the diet of his patients. He claims that overfeeding is responsible for a large amount of the mortality in this complaint. He gives his patients only sterilized milk, and limits the quantity of this to from 1½ to 2 pints in the twenty-four hours. As to medication, he is entirely indifferent, but washes out the entire lower bowel by free injections of tepid water once in twenty-four hours.

AGRA.

I visited the Civil Hospital of this place, under the charge of Dr. Anderson, in whom I found one of the best all-around men.

He is a living refutation of the idea that for thorough efficiency in the practice of medicine it is necessary to divide it into an infinite number of specialties. I saw him do, in one forenoon, a half dozen cataract operations, with marked skill, and he crushed a stone in the bladder with a dexterity that I have seldom seen excelled. He also operated for hemor-

rhdoid and amputated a forearm in a manner that would do credit to any general surgeon. Besides all this, I visited, with him, his wards that contained nonsurgical cases, and he examined and prescribed for these in a manner that showed him to be well up in internal medicine. The patients in this hospital were all natives, and bowel troubles and malarial complaints were the most widely prevalent diseases among them.

I saw swarms of rats running over the patients' beds and chasing each other about the floor. On asking the Doctor why he did not exterminate these pests, he told me that if he should kill or poison a single one every patient who could walk would abandon the ward at once. "These people," he said, "would divide their last grain of rice with a rat," and these little beasts were as tame as cats.

I visited also the prison hospital, where 2000 prisoners are confined, and the attending physician told me that during a service of ten years he had never had a case of typhoid fever under his care. Such is the willingness of the British authorities to pander to the religious prejudices of its Indian subjects, that three cooks are employed in this institution to prepare the food for the different sects into which the inmates are divided.

DELHI.

In this remote city of the Far East, I was surprised to find the table in the reading-room of my hotel covered with numbers of Dowie's *Leaves of Healing*. I looked these over with considerable interest, for the success of this man illustrates a phase of humanity that I have always studied with interest. This periodical, and the doctrines that it teaches, show into what absurdities mankind will drift in search of a religion to save their souls, or some therapeutic agent to heal their bodies. It most thoroughly illustrates "What fools we mortals be." Platform orators and writers for the press are wont to paint, in glowing terms, the intellectual progress that the race has made during the century just closed. Let, however, any cultivated man or woman, with a well-balanced mind, read this sheet of Dowie, study the absurd pretensions of the man, and consider the success that he has achieved in that great center of modern progress, Chicago, and I think he or she will lay it down with a mind full of pessimistic reflections, and a firm conviction that our race has a long journey yet before it ere it will have shaken off the shackles of ignorant fanaticism and freed itself from the power of designing mountebanks. In a single article in this periodical the term stinkpot is used a score of times. Yet this man who revels in such slang is looked upon by his followers as so near approaching the Divine that a god who is deaf to the entreaties of the noblest of our race hears him and does his bidding. In conversation with a prominent western lawyer, in regard to Dowie and his work, he said: "I had always been inclined to be a little agnostic, but had never settled down into an attitude of absolute unbelief. Being in Chicago over Sunday I went to hear Dowie, and after listening to him for an hour and a half, I left the hall where he spoke fuller of doubts than I had ever been before in my life, and I have ever since been a firmer believer in agnosticism than I had ever been before." Ingersoll is dead, Dowie is the best man living for the propagation of his tenets, and the confirmation of thinking men in their doubts as to the Divine authenticity of the Bible.

JEYPORE.

I visited the Mayo Hospital, in this city, an institution containing 200 beds, under the charge of Dr. Pank, an up-to-date Englishman. Like Dr. Anderson of Agra, I found him doing all kinds of work, and that, too, in a most satisfactory manner. Jeypore is the capital of the native state of Rajputana, and the ruling Maharaja is a liberal-minded ruler, and furnishes Dr. Pank with unlimited funds to keep up this hospital.

The patients in the wards devoted to internal medicine were largely those in whom malaria and its complications played the most important role. I saw a large number with spleens that filled the entire abdominal cavity. Dr. P. told me that this disease kills more people in India than all others combined, the plague and cholera not excepted. He treats these cases by the administration of large doses of the iodid of arsenic,

together with 3 grains of quinin three times a day. I traveled 2000 miles over the dry plains of India, where for nearly two years not a drop of rain had fallen, and where men and beasts were dying by the thousands on account of this drouth, yet if this dry crust of earth on top be disturbed and the underlying soil exposed there emanates from it a malarial poison, the influence of which the oldest resident can not withstand. Dr. Pank confirmed the opinion I have so often heard expressed by physicians in India, that the natives never have typhoid fever. Pneumonia is very prevalent in Jeypore during the winter months, and the natives, who are nearly all illy nourished, fall ready victims to its ravages; 60 per cent. of those attacked die.

It seems that at Colombo, Madras, Calcutta and Bombay, each of which is located near the sea-level, and where the temperature is nearly uniform during the entire year, pneumonia scarcely ever prevails and articular rheumatism is a rarity. However, at Jeypore, where the altitude is considerable and where the nights are cool, the former disease is very prevalent. Its treatment is entirely of a supportive character, consisting of the administration of the tincture of bark and the carbonate of ammonia. I saw the Doctor treat several cases of lupus, by first curetting the diseased surface and then sprinkling antipyrin over it in the form of a powder, and applying over this an adhesive strap to keep it in place. He claims that in his hands this treatment has been eminently satisfactory.

At my first visit to the Mayo Hospital Dr. Pank began his forenoon's surgical work by operating on four patients for cataract, and two for stone in the bladder. In operating for stone the Doctor crushes everything. If the stone be too large to be caught in the jaws of the lithotrite, or too hard to be crushed by that instrument, he makes a perineal incision, not for the purpose of removing the stone in its entirety, but to introduce a powerful crusher, and after the stone is crushed, the fragments are washed out, both by the perineal opening and by the urethra.

The earth-closet system of the disposition of the excreta of the patients in the hospitals in the interior of India is the one generally adopted, and as the dry earth is abundant, and is changed often, the system seems to work well. Jeypore was the first great famine center that I struck in my tour through India. In the Mayo Hospital grounds long rows of temporary rice-straw sheds were erected, where nearly a thousand women and children were being housed and fed, their husbands and fathers working on public works in the vicinity. Many of these, especially the children, presented a most sorrowful aspect. Starvation among them carried with it a train of morbid phenomena to which many of these poor creatures succumb, even after they have an abundant supply of food. A catarrh of the whole alimentary tract affected a good many of the children, and in their emaciated condition nothing seemed to arrest it. Two score years devoted to the practice of medicine ought to school a man to the sight of human misery and suffering, yet in famine-stricken Jeypore I witnessed scenes against which my blunted sensibilities turned away with horror and disgust. For instance, a woman with a child just born, naked and unwashed, paraded herself before me, exhibited her withered, skinny breast, telling me that as she had no food to eat, she could not give milk to nourish her child. Then came a nearly nude skeleton of a man carrying in his arms a dead child, and he recounted with tears in his eyes that the infant he carried was the last of his family to die of starvation, and he would soon follow them to the grave unless I gave him money to buy food.

M. S. CALDWELL, M.D.

The Mad Stone.

PHILADELPHIA, April 11, 1900.

To the Editor:—A question in regard to the so-called "mad-stone," in THE JOURNAL of April 7, 1900, prompts me to reproduce from my notes on hydrophobia some facts in regard to this subject, as it is one about which much uncertainty prevails.

One of the earliest descriptions of such a thing is that attributed to Abbé Grosier, in his "Description of the Chinese." He there gives an account of the use of a stone called the ser-

pent-stone in "Tang-King." This was applied, stuck fast, absorbed the poison, dropped off, and the patient was freed. The stone was washed in lime-water, dried and could then be used again.

In a work on hydrophobia, published in 1812, Dr. Thacher says: "There prevails a fanciful opinion among a certain class of people, that a celebrated substance, known by the name of snake-stone, possesses, intrinsically, the power of extracting the poison of a snake or mad dog from the human body; that when applied, the stone will adhere like a leech to the bitten part, nor loose its hold till its numerous pores are literally glutted with the liquid poison. A case intended to corroborate this doctrine is recorded by Mr. William H. Harding in the *Medical Repository*, Vol. 4, hex. 2. He relates that his child received a bite from a dog supposed to be affected with rabies. The snake-stone was applied (in due form and full faith no doubt) by which every particle of poison was extracted, and no ill consequences resulted from the accident. Dr. Mease has, in the *Medical Museum* (Vol. 5, p. 1) with his usual freedom and good sense, animadverted upon the unreasonable prejudice in favor of this popular but fallacious expedient. He informs us that in India such stones are very common, and the credulous natives believe, most firmly, in their preservative powers against the effects of the bites of venomous snakes. The author of the 'Wonders of Nature and Art,' says Dr. Mease, thus notices these stones in the account of Tonquin. 'Persons who happen to be bitten by serpents, press out the blood, and apply a small stone, called the serpent-stone, which is said to possess the miraculous power of drawing out the poison. When impregnated with the venom it drops off like a leech. It is then carefully washed with milk and water in which lime has been diluted, and on a second application to the wound, it exhales all the virus so completely, that in less than an hour, the patient becomes perfectly free from pain.' 'Two of these stones,' adds Dr. M. 'are in the cabinet of the Philosophical Society, and another one is in my possession, all of which were brought last year by a gentleman from India. They are rather more than an inch long, and about five-sixteenths of an inch broad, of a bluish or slaty color and flatish shape.'" [Pp. 204-206.]

In 1801 Dr. Samuel Davis, of Petersburg, Va., wrote a letter to Dr. Benjamin Rush, which has never been published, but which is preserved in the Ridgway Branch of the Philadelphia Library. In this letter he describes a mad-stone which emitted bubbles when put in water after the application, and this was taken to be evidence that it had extracted the poison from the bite. The owner of this stone refused an offer of 300 guineas for it, a very large sum of money at that time. It was yellow, light and had many black pores. It had been given to the owner by a stranger who had been sick and cared for. It was wrapped in a printed paper, which declared "Francis Torres, a Native of France, is in possession of a chymical preparation, called a Chinese snake-stone, which will extract the poison of the bite of snakes, spiders, and of a mad dog and will cure cancers, which are sold at half a Guinea for the small and a Guinea for the large ones." This was dated Charlestown, S. C., 1740.

Mad-stones seem to be of two sorts: 1, some porous form of calcareous rock, or, 2, a concretion found in the intestinal canal of herbivorous animals, in this being like the Bezoar stone which figured so largely in the pharmacopoeias of one hundred and fifty or two hundred years ago; in fact, it seems as though the mad-stone was indeed in many cases the Bezoar stone, which, when it ceased to be used in internal medication, came to be applied externally. There have been a number of so-called mad-stones in different parts of this country, most of them in the South and Southwest. In one case, in Virginia, the owner of a mad-stone in 1885 believed that it was the "talisman" sent by the Sultan as a wedding present on the occasion of the marriage of the Earl of Huntington to Edith Plantagenet.

Serious writers usually treat the mad-stone as having no specific virtue, but serving as a means to calm the apprehensions of those who have been bitten by rabid animals. I quite agree in this opinion, but am assured from my long-continued investigations of the subject of hydrophobia that in this re-

spect it is not really inferior to some other modes of preventive treatment which have obtained the approval and support of men whose distinction in medicine is far greater than their industry in critically investigating the real worth of prophylactic measures which present themselves, with a pretentious air of scientific accuracy.

CHARLES W. DULLES, M.D.

4101 Walnut Street.

Division of Fees.

CHICAGO, April 29, 1900.

To the Editor:—For some time the surgeon and specialist have been giving their opinions as to the demands for fees and their division between the general practitioner and the operator. The view taken by the majority of specialists, that division of fees is dishonest and does the patient an injustice looks well in print and reads as though it were necessary for the specialist to guide the physician and correct his dishonest, grasping hand.

This controversy has been one-sided. And to show where the corruption is to be found I will state my own personal experience with the specialist. Within the last three years I have been approached by no less than three of the prominent and leading surgeons of Chicago who, openly and of their own free will, made these propositions to me: One said he would be pleased to do all my surgical work and give me 50 per cent. of his fees from all patients I sent him. Another said he would do the square thing and give me 33 per cent. The third, and not the least, so far as his reputation as an operator and writer, offered me 50 per cent. of all fees. These same specialists have given their opinion freely at medical meetings, denounced the general practitioner and placed him alongside the crook. If all surgeons and specialists who have been so free to denounce the practice are playing the double game it is time to correct the would-be honest surgeon and place him where he should be. For my part I think he has played the part of the wolf long enough. I feel sure that I am not the only physician doing general work who has had such propositions.

LEWIS S. EASTLAKE, M.D.

Castor-Oil in Neuralgia.

NEW YORK CITY, April 26, 1900.

To the Editor:—In the discussion on castor-oil in the treatment of neuralgia, I note (see THE JOURNAL of April 21, p. 982) that Dr. Paddock is troubled to know how the oil can be given, while Dr. Fütterer tells of giving it with alcoholics that may in some degree interfere with its usefulness; and Dr. Hirst is quoted as advising that it be given in warm milk, while the question is raised as to how warm milk disguises the taste of the oil.

Some fifteen years ago I not only gave to the profession the fact that cold milk is the best of all vehicles in which to administer both castor-oil and cod-liver oil, but also pointed out the method of administration with the reasons for the method used.

Milk, like these two oils, is an oil or, more properly speaking, an emulsion—and just here let me say that it is Nature's emulsion and, in a very short time, when allowed to stand, it separates, hence the uselessness of all emulsions made by men, for all separate and are a snare and a delusion. Few if any of the emulsions contain the amount of oil that is claimed for them, hence the stomach tolerates the supposed amount of oil better than the amount given when we measure out the oil ourselves.

The method I gave is this: fill the mouth with milk and hold it there; dip up a tablespoonful of milk and pour into this spoon—already full of milk—about a teaspoonful of oil; whether cod-liver oil or castor-oil, you will see that it displaces milk to the extent of its bulk, as any other liquid would do, but the globules of either of these oils, being different from the globules in milk, do not mix with the latter, and the oil will be in a round ball, not touching the spoon. As you swallow the milk that has been held in the mouth, take the spoonful of milk in the mouth and at once begin to drink milk from a cup at hand. I have never yet found the person who, if the procedure

was carried through in this manner, could tell whether he had taken castor-oil or cod-liver oil, or taken none at all. There is absolutely no contact with the mouth or throat, of any particle of the oil, nor can it be smelled on the spoon. All this implies taking immediately, but not with undue haste.

The oils as well as the milk must be cold and the colder the better. The quantity can be increased by degrees as the stomach will stand the oil desired, but if a large dose of castor-oil is desired, it can be given better by repeating the procedure than by attempting to swallow too much at one time.

This procedure has given me and so many of my patients, especially parents when administering oils to children, so much comfort that I repeat what I wrote over fifteen years ago, hoping others who do not seem to have heard of it in detail may also find relief from the nauseous taste that so many dread.

Yours respectfully,
WICKES WASHBURN, M.D.

Association News.

The Official Program.—In order to avoid misunderstandings and to protect the interests of advertisers, attention is called to the fact that there is but one official program. This program is copyrighted by the Board of Trustees and contains no advertising matter.

Delegates to the Meeting of the American Medical Association.—Secretaries of societies are requested to forward the names of delegates as soon as possible after these are appointed or elected. George H. Simmons, M.D., Secretary, 61 Market St., Chicago.

General Business Committee.—The first meeting of the General Business Committee of the AMERICAN MEDICAL ASSOCIATION will be held at the Hotel Dennis, Atlantic City, N.J., on Monday afternoon, June 4, at 4:30 o'clock. Subsequent meetings of the Committee will be held at the same place and hour, every afternoon, during the meeting of the ASSOCIATION, unless otherwise directed by the Committee. In order that the business of the ASSOCIATION may be effectively transacted, it is very important that all the members of the Committee should attend all its meetings. L. DUNCAN BULKLEY, Acting Secretary.

Entertainment of Members of the Association.—The Directors of the Philadelphia County Medical Society, aware of the large number of physicians who will pass through Philadelphia on their way to and from the meeting of the AMERICAN MEDICAL ASSOCIATION, to be held at Atlantic City, N. J., June 5 to 8, and desirous of affording them an opportunity to visit the various hospitals and scientific institutions of Philadelphia, and to witness operations, etc., will establish a bureau of information for the furtherance of these objects. This will be at the College of Physicians of Philadelphia, northeast corner of Thirteenth and Locust Streets, the College having kindly placed a room in its hall at the disposal of the Philadelphia County Medical Society. This room will be in charge of a competent physician, and open from 10 a.m. until 5 p.m., daily except Sunday, from Monday, June 2, to Monday, June 11. Physicians are invited to make free use of the bureau, where they may obtain full information relative to the situation of the various hospitals, medical colleges, and other scientific institutions of Philadelphia, and to the time of operations and clinics at the different hospitals throughout the city. Information will be secured and tabulated daily, showing the leading attractions for that day. The College of Physicians of Philadelphia has also voted to extend to the members of the AMERICAN MEDICAL ASSOCIATION the courtesies of the library and of the Mütter museum. The library, which was founded in 1788, is, with the single exception of that of the surgeon-general's office in Washington, D. C., the largest collection of medical books in this country. The Mütter museum, which was endowed in 1856, by the late Prof. Thomas D. Mütter, contains about 4000 specimens of normal and pathologic anatomy, besides valuable models, casts, and illustrated anatomic works. Both the library and the museum will also be open from 10 a.m. to 5 p.m., daily except Sunday. Additional information may be secured

by addressing the Bureau of Information, at the address above, from June 2 to 11, and prior to that time by addressing any of the directors of the Philadelphia County Medical Society, as follows: Drs. A. O. J. Kelly, Chairman, No. 1911 Pine Street, Chas. A. Oliver, John G. Clark, Addinell Hewson, or Emma Musson.

Deaths and Obituaries.

S. G. PLUMMER, M.D., Rock Island, Ill., died April 29, aged 79 years. He was born in Pennsylvania, received his early education in the Greenville (Pa.) Academy, and the Western Reserve College in Ohio. In 1856 he was graduated from the Cleveland Medical College, and in 1861 was made surgeon of the Thirteenth Ill. Vol. Inf., later appointed medical director of the First Division, Fifteenth Army Corps, and made its surgeon. Since the Civil War, he had practiced medicine in Rock Island, where he served on the medical staff of St. Anthony's Hospital. He was a member of the AMERICAN MEDICAL ASSOCIATION, the Illinois State Medical Society, and the Iowa and Illinois Central Medical Association.

M. M. BAGG, M.D., died May 2, in Utica, N. Y., aged 89 years. He studied in Hamilton College; in 1833 went to Yale, where he was graduated four years later; and in 1842 received his degree in medicine from the Geneva Medical College. After a year spent in Paris, he returned to Utica, where he had since practiced. He was a trustee of Paxton Hospital and a member of its board of physicians, was also on the consulting staff of St. Luke's Hospital and one of the visiting physicians to the Utica Orphan Asylum.

LEANDER H. BAKER, M.D., Louisville, (Ky.) Medical College, died May 4, of bronchitis, at his home in Oak Park, Ill. He practiced medicine in St. Louis, Mo., until the breaking out of the Civil War, when he was appointed surgeon of the Twenty-fourth Mo. Vol. Inf. In 1864 he located in Quincy, Ill., and from there went to Payson, Ill., thence to Oak Park.

JOHN STOCKTON HOUGH, M.D., a retired physician, died at his home in Ewing, near Trenton, N. J., May 6, aged 54 years. He was graduated from the Pennsylvania University's medical department, and had traveled extensively in Europe in the interest of his profession. He was also one of the best known men in New Jersey, a bibliographer possessed of a large library, and of late years was active in the movements for good roads. His death resulted from injuries received by having been thrown from his carriage a week previously.

RICHARD H. KEALHOFFER, M.D., aged 50, died suddenly of heart disease, in Philadelphia, May 1. He was a resident of Hagerstown, Md., and had been on a trip to Atlantic City. Dr. Kealhofer was educated at Franklin and Marshall College, studied medicine with Dr. J. McPherson Scott, of Hagerstown, and received his degree at the University of Maryland in 1866. He practiced for a time in St. Louis, Mo.

BENJAMIN GERET, M.D., St. Charles, Mo., died May 3, aged 58 years. He was a native of Bavaria, and in 1868 was graduated from the Royal College of Medicine at Erlangen; later he was appointed a major-surgeon in the German army, and was decorated with high honors by both the king of Bavaria and the emperor of Germany.

G. R. C. TODD, M.D., a brother-in-law of Abraham Lincoln, and a surgeon in the Confederate Army during the Civil War, died at his home in Barnwell, S. C., April 25. He was graduated from the medical department of the Transylvania University, Lexington, Ky., in 1850.

CHARLES H. MESEREAU, M.D., College of Physicians and Surgeons, New York City, 1884, died of cardiac disease at his home in New York City, May 4, aged 37 years. For two years he was a house-surgeon in the Hartford (Conn.) Hospital, and was for several years a sanitary inspector of the New York Health Board.

JOHN P. LANDON, M.D., died at his home in Tilleride, Colo., recently. He was graduated from the Bellevue Hospital Medical College, New York City, in 1875, and practiced in Sterling, Ill., for a number of years before going West.

DAVID STOVEL, M.D., Detroit, Mich., died May 1, aged 61 years. He was born in Mount Forest, Ont., and graduated first from the Toronto College of Medicine, then from the Detroit College of Medicine.

EDWARD LYON, M.D., a graduate of the medical department of the University of Pennsylvania, class of 1867, died recently at his home in Williamsport, Pa.

W. N. ROGERS, M.D., of Waco, Texas, died May 1. He graduated from the Louisville Medical College in 1878, and practiced in Belton, Texas, until four years ago.

GEORGE FULMER, M.D., Jefferson Medical College, 1853, died in Mechanicsburg, Pa., May 1. He was a member of the AMERICAN MEDICAL ASSOCIATION and of the Medical Society of the State of Pennsylvania.

EDWARD PAYSON WILLIAMS, M.D., Atlantic City, N. J., died there April 29, aged 69 years. He was graduated in 1875, from the College of Physicians and Surgeons, New York City.

WM. E. H. BROWN, M.D., of Algiers, La., died April 23, aged 70 years.

Miscellany.

Food Poisoning at San Juan, Porto Rico.—On March 25, 1900, out of a company of ninety-four men of the Eleventh United States Infantry, forming part of the garrison of San Juan, P. R., 57 were admitted to hospital and 10 became slightly sick, but did not apply for treatment. The symptoms were persistent vomiting, severe cramps in the stomach, purging, great prostration, dilatation of the pupils, headache, clammy perspiration, chilliness and great thirst. The stomach in each case was washed out by means of the stomach-tube. In some cases the stomach was empty and nothing but water and mucus came away; in others the washings were tinged with bile, and in others again a moderate amount of food that had been eaten for breakfast was washed out, but in no case was the stomach overdistended or even full. The vomiting was controlled in several instances by the washing out of the stomach, but in many it persisted for several hours afterward. The prostration was so great that some of the patients fainted before reaching the ward. A large number vomited blood in small clots, in most instances mixed with nothing but mucus, showing that the hemorrhage had not taken place until after the contents of the stomach had been expelled. Purging began in most before the vomiting had ceased, and continued for twelve to fifteen hours. At first the stools were natural, soon watery, afterward becoming mucous and blood-tinged. Cramps in the voluntary muscles were mild in some, but other patients writhed in agony, their sufferings being relieved only after thorough kneading and massage by the hospital attendants. Forty were discharged on the following morning; the others from day to day until the fifth morning, when all were returned to duty.

A careful study of the food eaten that morning led the surgeon in charge, Captain George M. Wells, assistant-surgeon, U. S. A., to refer this general attack to the milk used with the mush furnished for breakfast. This meal consisted of hash made from meat and potatoes, which had been baked in the oven for two hours prior to being served; mush made from the corn-meal of the subsistence department and served with diluted condensed milk of the Eagle brand; bread, coffee and sugar, but no cream. The evidence seemed to point to the condensed milk as the ingredient of the food containing the poison.

Sanitary Progress in Porto Rico.—General Orders, No. 69, April 2, 1900, Headquarters Department of Porto Rico, prescribes regulation for the establishment and care of cemeteries, public and private. So far as relates to public cemeteries, it is required that on or before June 30, 1900, each municipality shall provide within its limits at least one civil cemetery, which shall be available for the burial of all who die in the municipality. Graves or lots in such cemeteries may be sold for the interment of the remains of individuals or families, but a sufficient area must be set apart for the free and proper burial of the remains of the poor and friendless.

All interments in, or disturbance of, the soil of any cemetery now in use, after the above-mentioned date, are prohibited, provided, however, that the alcalde of any municipality may submit evidence to show, as respects any cemetery in his municipal district, that there is a space in a designated one available for burials, and that interments may be made in such space without disturbing the remains of others previously buried therein. This proof will be forwarded to the military governor, and if, after investigation by the Superior Board of Health, the facts as claimed shall be established a special exception will be made in the case of the cemetery in question.

General Orders, No. 74, April 7, 1900, establishes a board of charities in each municipality, to consist of three members to be selected by the alcalde, with the approval of the municipal council, on account of their special fitness for organizing and supervising charitable work. All matters respecting municipal charitable institutions, including homes, asylums and hospitals wholly maintained from public funds and intended for the care of the destitute, sick or incurables, the nomination of destitute children for admission to the insular charity schools, and matters relating to the improvement of the state of the poor and distressed in general are submitted to this board.

Again, No. 78 of the series of General Orders, dated April 10, 1900, provides for the appointment in each municipality of a competent inspector of cattle and meat, to be appointed by the municipal council and paid from the municipal funds. When sick animals or those suffering from sores or wounds are offered for slaughter, for human consumption, the inspector will forbid the slaughter. Meat which has not been inspected, approved and duly tagged by the authorized inspector will not be sold for human food. The flesh of animals suffering from tuberculosis, fever, actinomycosis, glanders, cancer, hydrophobia, eruptive skin disease, measles and cholera (in hogs), and of those which have died natural deaths, is especially unfit for human food and must be condemned. No animal over six months pregnant shall be slaughtered for food, and the number of cows shall not exceed one-fourth of the total number of cattle butchered. The district courts have jurisdiction in cases of violation of the provisions of this order.

Lastly, Circular No. 16, dated April 9, from the same headquarters, publishes rules and regulations respecting burials, disinterments and transportation of human bodies.

The Prognosis of Appendicitis.—For a time discussion raged warmly around the question as to the indications for operation in cases of appendicitis, and while it can not be said that a final decision has been reached, there is a growing tendency to operate early and to operate often. There are not many who to-day consider appendicitis a medical disorder exclusively, but the condition is rather looked upon as a borderline affection in whose management the surgeon should be consulted from the outset, in order that, should his opinion be desired, he can give it intelligently, and should operation be required, he can perform it promptly. The general proposition that successful treatment demands early and accurate diagnosis is especially applicable here, but even under the most favorable circumstances it will be difficult, if at all possible, to determine the character of the disease, the nature of the infection, the intensity of the morbid process, and the quality and the extent of the lesions. The prognosis will depend on all of these factors and this aspect of the subject is given careful consideration in a recent communication by Caley (*The Lancet*, February 10, p. 378), based on observation of 200 cases of appendicitis. Of this number 98 were treated in the medical wards, with 3 deaths, and 102 in the surgical, with 22 deaths. The low mortality among the medical cases is attributed to the large proportion of simple ones and the high mortality among the surgical to the large proportion with general peritonitis.

The cases were divided into five groups: 1, simple appendicitis and perityphlitis, in which the inflammation was limited to the walls of the appendix or localized non-suppurative adhesive peritonitis developed; 2, appendicitis with localized suppuration; 3, appendicitis with diffuse peritonitis; 4, chronic and relapsing peritonitis; 5, appendicitis with special compli-

eations, such as intestinal obstruction, fecal fistula, suppurative pyelophlebitis with portal or general pyemia, hepatic or subphrenic abscess, thrombosis of the iliac veins, pleurisy, pneumonia, parotitis and secondary hemorrhage.

From a pathologic point of view the prognosis will depend principally on the extent and the nature of the peritoneal infection—whether local or diffuse, suppurative or non-suppurative, of a mild or of a severe degree of virulence—and in less degree on the nature and the course of the lesion of the appendix—whether mild or severe, as measured by its infectivity. No certain data are available for determining the virulence of the infective micro-organisms, but the lesions may be considered as severe or mild accordingly as one or another of the following phenomena are present: Severe—1, perforation, whether from concretion, ulceration or gangrene; 2, gangrene, whether from interference with the blood-supply or from intense infectivity of the inflammation; 3, ulceration due to specific infections, e. g., tuberculosis, typhoid fever, dysentery or actinomycosis, the presence of concretions, or the result of intense inflammation; 4, concretion; and 5, suppuration within the appendix itself. Mild—1, simple inflammation—catarrhal or more correctly, "parietal" appendicitis—acute or chronic; 2, stenosis or obliteration of the lumen, which is frequently associated with; 3, cystic dilatation of the distal portion; 4, concretion without ulceration; 5, superficial ulceration, and 6, kinking, adhesion, volvulus or hypertrophy of the mucosa.

From the clinical point of view the prognosis depends on: 1, the local symptoms; 2, the general symptoms; 3, the local signs; and 4, the progress of the case. Of the local symptoms pain is one of the most constant, and its distribution, severity and character are of much significance. In mild cases it is localized to the right iliac fossa, whereas in perforative ones it is usually more sudden, more severe and more generalized. When associated with definite collapse it suggests perforation, rupture of adhesions or rapidly spreading peritoneal infection. It may at first be dull and aching or slight and colicky—from inflammation of the appendix—and followed by a sudden increase in severity, with vomiting and general disturbance—from inflammation of the surrounding peritoneum, or extension of peritonitis, or rupture of an encysted abscess. In mild cases the pain tends soon to become localized and less intense. If persistent and severe it generally indicates a severe lesion. If it is also radiating it indicates extension of peritonitis; if persistent, severe and local, it is indicative of a concretion; if increased by deep respiration, it indicates considerable local peritonitis; as does also pain or difficulty in micturition. It should not be forgotten, however, that a severe lesion may be attended with little pain.

Vomiting, if present, usually accompanies or follows the pain, although it sometimes precedes. If frequent and severe, and especially if persistent, it indicates a severe lesion, as it does also when it occurs after a period of comparative repose. If it is stereocaceous or coffee-grounds in character, it is of serious import. Absence of vomiting, however, is inconclusive. Other things being equal, natural action of the bowels is a favorable sign. Hiccough, especially if persistent, is of unfavorable omen.

Among the general symptoms the temperature, pulse and respiration conjointly and the aspect and the general condition of the patient with especial reference to collapse or anything approaching it, restlessness or general distress, are reliable guides in determining the effect of the local lesion on the organism as a whole. The temperature may be subnormal in the initial collapse of acute perforative or gangrenous appendicitis, fully developed septic peritonitis, localized circumscribed suppuration, mild appendicitis without appreciable local peritonitis. High fever of a continued type in the first two or three days is generally indicative of a severely infective lesion. A decline in temperature with a reduction in pulse, frequency and improvement in the general condition is usually reassuring. A secondary rise of temperature after the first few days is indicative of spreading peritonitis, suppuration or intercurrent complication, while fever persisting after eight or ten days is generally indicative of local abscess. A high pulse-rate is sug-

gestive of a severe lesion, and in particular diffuse peritoneal infection, especially if the pulse-frequency is disproportionate to the temperature. Frequent and shallow respiration of costal type, with low temperature and pulse-rate, suggests grave peritoneal implication.

A pinched and anxious expression, restlessness, obvious distress and collapse indicate peritoneal shock or general peritonitis. The initial collapse that marks the onset of perforative appendicitis is significant. More or less persistent collapse is of the worst possible omen.

The local signs include impaired mobility during respiration and distension, tenderness, muscular rigidity, tumor or deep-seated resistance. Local immobility is the rule in cases of appendicitis with localized peritonitis. General immobility, except of diaphragmatic origin, is indicative of diffuse peritonitis. The area of local tenderness is proportionate to the extent of the local inflammation. Muscular rigidity corresponds with cutaneous hyperesthesia and tenderness. Local tumor or deep-seated resistance and dullness on percussion are common but not invariable. Their absence may be of serious prognostic significance and their presence reassuring.

The progress of the case during twenty-four, thirty-six and forty-eight hours may furnish a needed indication in prognosis and treatment. In mild cases the symptoms recede or become localized, while in severe ones the symptoms persist or become intensified.

Recurrence may be expected in about one-third of all patients, usually within two years, and most commonly within one year of the first attack. In the presence of local suppuration the probability of recurrence is relatively slight. A mild first attack is frequently followed by recurrence. If the condition clears up slowly and local pain, tenderness or swelling persists for some time, the probability of a relapse sooner or later is great. If in the interval between attacks there is occasional pain or discomfort, with irregularity of the bowels and definite local tenderness or resistance, a chronic appendicitis probably exists, recognizable on palpation, with a chronic tendency to relapse so long as the appendicitis remains.

EXAMINATION QUESTIONS.

The Michigan State Board of Registration in Medicine, presented the following questions at a recent examination in the several subjects noted.

PUBLIC HEALTH LAWS AND HYGIENE.

1. Name the diseases dangerous to public health that must be reported to the Board of Health. 2. What restrictive measures should be adopted in an outbreak of smallpox? 3. Describe method of disinfection during and following a case of scarlet fever. 4. Nuisances: What constitutes a nuisance? How abated? 5. Milk: Dangers from impure milk? How adulterated? What is the legal standard in Michigan? 6. What preventive measures should be adopted in typhoid fever? 7. Number of cubic feet of air that should be provided in schools for each pupil. 8. Name some of the impurities in drinking water. 9. State Board of Health: Number of? How appointed? Their powers? 10. Local Boards of Health: Who are they under? The general law in townships? in cities and villages?

OBSTETRICS.

1. Name four of the most important signs or symptoms of pregnancy. 2. What are the disorders resulting from the mechanical interference of the gravid uterus. 3. Give causes and symptoms of puerperal eclampsia. 4. Define the terms abortion, miscarriage and premature labor. 5. Define accidental hemorrhage. 6. Placenta previa—diagnosis and prognosis. 7. Describe the stages of labor. 8. Describe the terms presentation and position. 9. What should an obstetric bag contain.

MINOR SURGERY.

1. Describe the process of applying a plaster of paris jacket. 2. Name ten important agents used as germicides. 3. Describe preparation for aseptic operation: a. Surgeon and assistants; b. patient; c. instrument. 4. Define anesthesia and name two local anesthetics. 5. Give principal differences in effects of chloroform and ether. 6. What is an aneurysm? 7. Give eight methods of controlling hemorrhage. 8. Describe: 1, compound fracture; 2, simple; 3, comminuted. 9. Describe Colles' fracture, and how would you dress it? 10. Describe Pott's fracture.

EYE AND EAR.

1. Briefly describe the anatomy of the eye. 2. What symptoms are diagnostic of conjunctivitis? 3. Describe keratitis, and state in a general way its treatment. 4. How would you diagnose cataract? 5. What do you understand by the terms hypermetropia, myopia, astigmatism. 6. What treatment do you recommend in cases of ophthalmia neonatorum—in what way can you prevent its occurrence? 7. What is the treatment for acute peristitis of the mastoid process? 8. In what way is air admitted to the middle ear? 9. Are growths and obstructions within the nose apt to cause deafness? If so, how? 10. How would you remove foreign bodies from the auditory canal?

The Public Service.

ARMY CHANGES.

Movements of Army Medical Officers under orders from the Adjutant-General's Office, Washington, D. C., April 28 to May 4, 1900, inclusive:

Charles H. Alden, colonel and asst.-surgeon-general, U. S. A., retired from active service April 28, 1900, by operation of law, under the provisions of an act of Congress, approved June 30, 1882.

James A. Alexander, acting asst.-surgeon, from Fort Fremont, S. C., to Tampa, Fla., and thence to Havana, Cuba, for duty in the Division of Cuba.

H. Eugene Allen, acting asst.-surgeon, from Chicago, Ill., to duty in the Department of Texas.

Charles Brunning, acting asst.-surgeon, from New Orleans, La., to Tampa, Fla., and thence to Havana, Cuba, for assignment to duty.

August von Clossman, acting asst.-surgeon, from St. Louis, Mo., to duty at Jefferson Barracks, Mo.

Edward Everts, captain and asst.-surgeon, U. S. A., retired from active service as a major, April 28, 1900, having been found physically disqualified by reason of disability incident to the service.

Robert J. Gibson, major and surgeon, U. S. A., from the hospital ship *Missouri* to temporary duty in the Department of California.

William C. Gorgas, major and surgeon, U. S. A., from the department of Havana and Pinar del Rio, Cuba, to duty as chief surgeon, Division of Cuba.

Randell C. Stoney, acting asst.-surgeon, from temporary duty at the Presidio of San Francisco to duty in the Department of California.

Harrison W. Stuckey, acting asst.-surgeon, former orders, requiring him to accompany troops to Manila and report for duty in the Division of the Philippines, revoked.

Hedley V. Tweedy, acting asst.-surgeon, from Jackman, Me., to Seattle, Wash., for duty at Fort Egbert, Alaska, or other post, if deemed advisable.

Benjamin B. Warriner, acting asst.-surgeon, from Crewe, Va., to Fort Fremont, S. C., for post duty.

NAVY CHANGES.

Changes in the Medical Corps of the U. S. Navy for the week ended April 28, 1900.

P. A. Surgeon L. Morris detached from the *Brooklyn* and ordered to the *Baltimore*.

P. A. Surgeon J. Stoughton, detached from the *Bennington* and ordered to the *Cass*.

Asst.-Surgeon T. M. Lippitt, detached from the *Baltimore* and ordered to the *Oregon*.

Asst.-Surgeon J. C. Thompson, detached from the *Castine* and ordered to the *Bennington*.

Asst.-Surgeon A. G. Grunwell, detached from the *Yosemite* and ordered to the *Brooklyn*.

P. A. Surgeon J. F. Leys, detached from the *Essex* on reporting of relief, and ordered home and to wait orders.

Asst.-Surgeon C. H. Delancy, detached from the *Amphitrite* and ordered to the *Essex*.

Asst.-Surgeon J. C. Thompson will return to the United States by the *Bennington*.

P. A. Surgeon A. Farenholt will return to the United States by the *Concord*.

P. A. Surgeon M. R. Piggott, from the naval academy and ordered to the *Chesapeake* same day.

Asst.-Surgeon K. C. Ohnesorg, detached from the naval academy and ordered to the *Scipio* same day.

MARINE-HOSPITAL CHANGES.

Official list of the chances of station and duties of commissioned and non-commissioned officers of the U. S. Marine-Hospital Service for the seven days ended April 26, 1900.

Surgeon J. M. Gassaway leave of absence for 5 days from April 23, 1900, under the provisions of Par. 179, Regulations, M. H. S.

P. A. Surgeon C. P. Wertebaker, detailed to represent the service at the meeting of the Association of Military Surgeons of the United States at New York City, May 31 to June 2, 1900.

P. A. Surgeon W. G. Stimpson, granted leave of absence for ten days from April 28, 1900.

Asst.-Surgeon John McMullen, granted leave of absence for seven days; upon expiration of leave of absence to proceed to the Gulf Quarantine Station, Miss., and report to medical officer in command for temporary duty.

Asst.-Surgeon Joseph Goldberger, upon being relieved from duty at the Immigration Depot, New York City, to proceed to the Reedy Island Quarantine, Del., and report to the medical officer in command for duty and assignment to quarters.

Acting Asst.-Surgeon J. B. Engelson, granted leave of absence for three days from May 8, 1900.

Acting Asst.-Surgeon J. C. Rodman granted leave of absence for four days from April 23, 1900.

Hospital Steward E. T. Olson, upon being relieved from duty at Wilmington, N. C., to proceed to Mullet Key Detention Camp, Fla., for duty.

Hospital Steward C. F. Crowley, to proceed to Wilmington, N. C., and report to the medical officer in command for duty and assignment to quarters.

PROMOTIONS.

P. A. Surgeons T. B. Perry, R. M. Woodward and G. T. Vaughan, commissioned as surgeons.

APPOINTMENTS.

Charles F. Crowley, of Nebraska, appointed junior hospital steward.

HEALTH REPORTS.

The following cases of smother yellow fever, cholera and plague have been reported to the Surgeon-General, U. S. Marine-Hospital Service, during the week ended May 5, 1900.

SMALLPOX—UNITED STATES.

Alabama: Mobile, April 14 to 28, 14 cases.
District of Columbia: Washington, April 21 to 28, 1 case.
Illinois: Chicago, April 21 to 28, 11 cases.
Kansas: Wichita, April 21 to 28, 5 cases.

Indiana: Evansville, April 21 to 28, 2 cases; Indianapolis, April 21 to 28, 7 cases.

Kentucky: Covington, April 21 to 28, 6 cases; Lexington, April 21 to 28, 1 case.

Louisiana: New Orleans, April 21 to 28, 43 cases, 25 deaths. Massachusetts: Boston, April 21 to 28, 1 case.

Michigan: Detroit, April 21 to 28, 1 case; Grand Rapids, April 7 to 28, 1 case, 1 death.

Minnesota: Minneapolis, April 14 to 28, 47 cases, 1 death.

New York: New York, April 21 to 28, 2 cases.
Ohio: Cleveland, April 21 to 28, 12 cases.

Utah: Salt Lake City, April 21 to 28, 1 case.

SMALLPOX—FOREIGN.

Austria: Prague, April 1 to 7, 2 cases.

Belgium: Ghent, April 7 to 14, 2 cases.

Brazil: Rio de Janeiro, March 2 to 28, 42 deaths.

China: Hongkong, March 10 to 31, 10 cases, 5 deaths.

England: Liverpool, April 7 to 14, 9 cases, 2 deaths; London, April 7 to 14, 2 deaths.

Gibraltar: April 8 to 15, 4 cases.

Greece: Athens, April 7 to 14, 5 cases, 1 death.

India: Bombay, March 27 to April 3, 120 deaths; Calcutta, May 3 to 10, 10 deaths; Kurrachee, March 24 to April 1, 27 cases, 6 deaths.

Japan: Nagasaki, March 21 to 31, 1 case; Tamsui, February 22 to 28, 87 cases.

Mexico: Chihuahua, April 14 to 21, 2 deaths; Guadalajara, April 21, epidemic.

Russia: St. Petersburg, March 24 to April 17, 80 cases, 24 deaths.

Scotland: Glasgow, April 7 to 14, 1 case.

Spain: Madrid, April 1 to 7, 10 deaths; Valencia, April 14, 1 case and 1 death.

Straits Settlement: Singapore, March 19 to 26, 7 deaths.

YELLOW FEVER.

Brazil: Rio de Janeiro March 2 to 23, 104 cases, 50 deaths.

Colombia: Panama, April 10 to 24, 4 cases.

Costa Rica: Port Limon, April 21, 1 death.

Cuba: Neivitas, April 24, 1 case.

Mexico: Vera Cruz, April 14 to 21, 3 deaths.

San Salvador: Livingston, April 11, epidemic.

CHOLERA.

India: Bombay, March 27 to April 3, 7 deaths; Calcutta, March 3 to 10, 74 deaths.

PLAGUE.

India: Bombay, March 27 to April 3, 685 deaths; Calcutta, March 3 to 10, 601 deaths; Kurrachee, March 24 to April 1, 248 cases, 162 deaths.

Japan: Tamsui, February 1 to 28, 47 cases, 38 deaths.

CHANGE OF ADDRESS.

Brown, G. R., from 49 W 5th St., Cincinnati, Ohio, to Pleasant Valley, Ky.

Breebault, J. C., from Kansas City, Mo., to Pucklin, Kan.

Binkley, J. T., from 452 E. 49th St., to Windemere Hotel, Chicago, Ill.

Caldwell, W. S., from Vienna, Austria, to 7 Rue Scribe, Paris, France.

Carr, C. W. of Moore & Co.

Chesmore, H. P., from St. Joseph, to Nowaday, Mo.

Campbell, W. L., from 504 Olive St. to 123 Brooklyn St., Kansas City, Mo.

Anderson, C. L., from 2400 Chestnut Ave. to 2316 Agnes St., Kansas City, Mo.

Dunn, B. S., from Whitestone, N. Y., to Ardsley on Hudson.

Devine, G. C., from Chetek to Mason, Wis.

Dye, J. S., from Little Rock, Ark., to Chattanooga, Tenn.

Groffness, W. O., from Wauwatosa to Ixonia, Wis.

George, L. C., from Alexandria to Shreveport, La.

Hunter, R. B., from Winchester, Ky., to 904 South St., Springfield, Mo.

Hering, E. R., from Manawa to Cross Plains, Wis.

Hutchins, S. E., from Arcadia to Whitehall, Wis.

Halstead, A. E., from 844 Warreu Ave. to 2037 Indiana Ave., Chicago, Ill.

Harold, A. W., from Iowa City to Ackley, Iowa.

Hills, W. A., from 618 Kansas Ave., Topeka, to Delphos, Kan.

Hemingway, W. C., from Rome to Lambert, S. C.

Heminger, V. J., from Union City to Ohlen, Tenn.

Johnson, I. E., from Lebanon to Lebanon Junction, Ky.

Kee, H. D., from New Orleans, La., to Gonzales, Tex.

Kirby, E. G., from Salem to Elgin, Ore.

Lehman, C. A., from 2009 Market St., to Gill & League Bldg., Room 13, Galveston, Texas.

La Rue, H. M., from 511 E. 8th St., to Savoy Hotel, Kansas City, Mo.

Lamerton, E. W., from Chicago, Ill., to Wymong, Iowa.

Litzinger, G. H., from Kansas City, Mo., to Milford, Kans.

Miller, E. E., from Omaha to Surprise, Neb.

McClough, S. S., from Itasca, Texas, to Ramsay, Miss.

Medringhaus, R. E., from St. Louis to Eagle, Mo.

Le Moyné, P., from Pittsburg, Pa., to Melvale, Md.

Major, C., from Salt Lake City, Utah, to Denison, Iowa.

McGill, J. M., from 42 Laflin St., Chicago, to Pontiac, Ill.

Morcom, D. W., from 618 W. Monroe St. to 165 Wood St., Chicago, Ill.

Murtagh, A., from Delaware to Monticello, Iowa.

Maxey, W. E., from Caldwell, Idaho, to Johns Hopkins Medical College, Baltimore, Md.

Miller, J. H., from Pana, Ill., to 1901 Jefferson St., Baltimore, Md.

Pettyjohn, E. S., from Alma, Mich., to Stewart Bldg., Chicago.

Posh, F., from Ives Grove, to Western Union Junction, Wis.

Plant, J. J., from Pembina, N. D., to Arcadia, St. Paul, Minn.

Riley, B. M., from 518 N. 19th St. to St. Joseph's Hospital, Omaha, Neb.

Reitz, W. M., from Waterville to Bremen, Kan.

Snow, H. O., from Abbeville to Douglas, Ga.

Smith, E. A., from 1928 Archer Ave., to 1910 State St., Chicago.

Speelman, G. T., from Kelly, Ga., to Hamilton, Texas.

Thill, D. P., from 705 Smith St. to 1101 North Ave., Milwaukee, Wis.

Waller, E. E., from Alleghen to Markleton, Pa.

THE PRESENT STATUS OF OPERATIONS FOR CANCEROUS UTERI.*

BY HOWARD A. KELLY, M.D.

BALTIMORE, MD.

We are one and all curious creatures of habit and victims of fancy. For example, if a little epidemic of smallpox claims a dozen victims or so, everybody is horror-stricken and large numbers of people are vaccinated as a precautionary measure. This is because smallpox is associated with a horrible disfiguring eruption. Thousands of victims die year by year of typhoid fever, in many of our large cities—notably in Philadelphia, through a long series of years—at a time in the world's history when it has long been shown that about one in a hundred thousand is what may be considered an average death-rate in well-regulated communities, and the most public interest that can be aroused is an occasional little spasmodic flutter in the newspapers. And this goes on indefinitely when every child knows that pure water will stop the disease, and when the pure water is within reach. The same is true of the awful scourge, tuberculosis, when we know that clean streets and good sanitation, all within easy reach of communities already spending sums vastly in excess of those abroad of equal size, will largely tend to check the disease. Let us not blame the politicians, degraded as most of them are, but let us blame the low moral standard of the whole body politic of which we are a component part and in which we ourselves bear our due share of the odium. The same is true of that terrible scourge, cancer. What systematic, thorough-going, persistent efforts are we making to get at the root of the matter, to make a notable reduction in the number of its victims? Are we not all of us simply treating the few cases that come into our hands without reference to the enormous crop which goes on increasing year by year.

Welch has collected statistics which show the frightful prevalence of cancer in civilized countries. He gives these data:

PRIMARY CANCERS.	STOMACH.	UTERUS.
11,131 in Vienna.....	10 per cent.	31 per cent.
7,150 in New York.....	25.7 per cent.	24.2 per cent.
9,118 in Paris (Tanchou).....	25.2 per cent.	32.8 per cent.
1,378 in Paris (Salle).....	31.9 per cent.	32 per cent.
587 in Berlin.....	35.8 per cent.	25 per cent.
183 in Wurzburg.....	34.9 per cent.	19 per cent.
1,046 in Prague.....	37.6 per cent.	33.3 per cent.
889 in Geneva.....	45 per cent.	15.6 per cent.
31,482 Total.....	21.4 per cent.	29.5 per cent.

Commenting on this large group of cases he says: "From this table it appears that in some collections of cases the uterus is the most frequent seat of primary

cancer, while in other collections the stomach takes the first rank. If the sum total of all the cases be taken, the conclusion would be that about one-fifth of primary cancers are seated in the stomach and somewhat less than one-third in the uterus. Even if allowance be made for the apparently too low percentage of cases of gastric cancer in the large Vienna statistics, I should still be inclined to place the uterus first in the list of organs most frequently affected with primary cancer and to estimate the frequency of gastric cancer compared with that of primary cancer elsewhere as not over 25 per cent."

Who that has never been affected by the disease can even begin to estimate the awful sum total of misery suffered by one patient as the disease progresses to its dreadful end.

It would, therefore, seem not unfitting that we should gather from time to time: 1. To discuss our individual results in the treatment of cancer. 2. To criticize each other and to inquire as to the best methods of treatment. 3. To forecast as nearly as may be the best lines of investigation for the immediate future.

In the first place I will lay down the dictum long since accepted but still needing reiteration in our country, that *in every case of cancerous uterus the entire organ must be removed.*

All well know that an epithelioma of the cervix tends in its upward progress to respect in a remarkable way the line of demarcation between the cervix and the body of the uterus, and that an adenocarcinoma of the body in like manner shows a remarkable tendency to limitation at the internal os uteri. There is, therefore, a temptation, particularly in the early stages of these diseases, to do a lesser operation, amputating the cervix, or removing the body.

Let me emphatically declare again that all such partial operations are wholly unjustifiable, as, speaking on the basis of 176 cases of my own, studied most minutely, I find that the exceptions are so numerous that they must for practical purposes be reckoned as the rule. In one instance, many years ago, I left in the vaginal end of the cervix, in a case of carcinoma of the body, and several years later the poor woman returned with the cervix thoroughly diseased and an extensive involvement of the rectum as well. In other cases of cancer of the cervix I have found the disease repeatedly in the body and in one it missed the body but was in the tubes!

The great opprobrium of all our operations lies in the fact that we often leave some of the disease behind. It is essential, therefore, to an intelligent discussion as to the best methods of attacking the disease, that we shall agree as to the methods by which it extends into the neighboring tissues. We have just seen that the entire uterus must be regarded as suspected and therefore removed. With the uterus *we must remove the uterine tubes in all cases of cancer of the body.*

The next great danger area is the vaginal vault. Cer-

* Read before the New York County Medical Association, April 16, 1900.

vical cancer in many instances extends down the vagina in an invisible form under the mucosa, without at first causing any perceptible infiltration or blush of color to excite suspicion. Every operator has seen, at one time or another, a distressingly early recurrence in the scar at the vaginal vault, due to the rapid growth of foci which ought to have been exterminated at the radical operation. It is therefore a necessary precaution to give the disease a wide berth on the vaginal side, cutting at least 2 or 2.5 cm. away from it.

Anteriorly the disease often involves the base of the bladder before it has extended far in any other direction; here good surgery will readily sacrifice and repair the entire affected vesical area, leaving it sticking to the cervix uteri.

The posterior extension of the cancer, in the earlier operable stages of the disease, is fortunately rare, as it is peculiarly difficult to meet this complication with anything like a real radical operation.

Almost all cases of involvement of the bowel are also associated with an extensive lateral involvement.

The lateral extensions of cancer of the cervix to the right and to the left, out through the bases of the broad ligaments, surrounding the ureters, reaching to the pelvic walls, involving the pelvic and the iliac glands, are by far the most important because the most frequent and the most difficult to meet therapeutically.

I think we have all agreed so far, and my dicta will have aroused no opposition, but here we meet our first crux, here opinions are widely divergent. What is the mode of this lateral extension? Is it *per continuitatem*, or is it *per saltum*? Is there a direct steady progression of the disease from the cervix out into the neighboring and from there into the contiguous tissues? Or should we expect to find beyond the manifest disease, a zone of sound tissue, and then isolated foci of disease in the tissues or in the glands? It is at once manifest that according as we hold one or the other of these opposing views, our surgical procedures will vary widely. For the sake of comparison let me cite the operations for cancer of the breast. Under the old idea that the disease was localized in the breast the surgical measures were limited to its amputation. Now the knowledge that the disease jumps from the breast into the axilla and from the axilla into the neck has completely transformed the surgery of this region.

Attracted by an apparent analogy between cancer of the breast and cancer of the uterus, and believing that the frequent recurrences were due in large measure to glandular metastases, there was worked out in my clinic several years ago, by Dr. S. G. Clark, a most ingenious operation, in which the uterine artery was tied back at its origin and the tissues between this and the cervix, together with the glands, were all removed, in addition to dissecting out and removing pelvic and iliac glands. This operation was radical to an extent that no operation had ever been before, and for a time we hoped for great things from the change in our methods, but the close sifting of my material, which immediately followed this change, together with the careful microscopic study of all the glands removed, showed that there was but one case—an adenocarcinoma of the cervix—in which there was an early glandular involvement, while in numerous others, in which I had removed enlarged glands and in which I felt sure from the gross appearance that I was removing cancerous foci, the microscopic study showed nothing but an infiltration with mononuclear and polymorphonuclear leucocytes. Winter has found but two

cases of glandular involvement in 44 operable cases examined.

Allow me therefore to state, further, these two dicta: *Cancer of the cervix usually extends by direct involvement of the contiguous tissue. Extension by glandular metastases per saltum is unusual in the earlier operable stages of the disease.*

If these statistics are borne out by further investigations, then practical deductions of enormous import flow directly as corollaries from these dicta. The operator must concentrate his whole efforts in giving the diseased cervix the widest possible berth, and if he enucleates well out in sound tissues he need not concern himself about the tissues beyond.

One more consideration of the utmost importance, which is bound to have great weight in determining the best mode of operating: What is the danger of implanting cancerous germs and starting fresh foci in the sound tissues in the course of an operation in which the uterus with all the diseased tissues has been enucleated? Experiments from the time of von Langenbeck have shown that it is possible to inoculate cancer either by injecting bits of cancerous tissue into the circulation, when the particles form cancerous emboli which may continue to grow, or by implanting them under the skin, or in the peritoneal cavity. These implantations are much more apt to flourish if they are taken from an animal of the same species and if the transfer is carried out aseptically.

The clinical evidence of the implantation of carcinoma in women is abundant in all cases of peritoneal cancer where the rapid dissemination of the growth is manifestly due to the lodgment of small particles here and there and their continued growth in the new region.

In one of my cases of (Gyn. 3323) extensive ovarian papillomata, seen in February, 1895, there was an extension of the papillary disease from the peritoneal surface out through the abdominal wall to within 2 mm. of the skin surface, through the track of an old trocar puncture. The papillary growth in this unusual situation preserved its ordinary characteristics and many of the little cavities containing the dendroid masses were also filled with desquamated epithelium and polymorphonuclear leucocytes.

A case which I believe was without doubt one of auto-implantation from adenocarcinoma of the body of the uterus into the vagina was that of a patient seen in November, 1895, and illustrated (Nos. 174 and 175) in the first volume of my book (pp. 256, 257). The vaginal affection retained all the characteristics of the uterine growth, which, however, was not suspected to exist at the time the isolated patches of the vaginal disease were removed.

Positive evidence that the cancerous particles can be sown into the abraded epithelial surfaces or into the cellular tissues in the course of an operation for cancer is not abundant, but such evidence as there is is significant; for example: in 1891 Schoff reported a case in which, owing to the narrowness of the vagina, he was obliged to make incisions on each side in order to get at the diseased uterus. Three months later cancerous nodules were found in the scars in both sides of the vagina, without any evidence of a return of the growth in the pelvis above.

Hofmeier had a similar case in 1895, and in less than a year an ulcerated nodule was found below in the left vaginal scar, with no return of the vault. Both the original disease and the implantation were adenocarcinoma. Leopold noted the implantation of a squamous-

celled carcinoma on an abrasion produced by the leg holder, observed at the operation. The nodule appeared within a year and was as large as a walnut.

It is a little difficult to estimate the practical value of such observations and to decide how far they are entitled to influence our technique. The implantations in the vagina below the field of operation are, everyone will acknowledge, rare accidents. The question may be fairly raised whether there is even a small liability of a successful inoculation of the disease in the loose parametric cellular tissue when drainage is used and the wound heals slowly by granulation.

Having in this way cleared the field for the discussion, I will give in the briefest possible manner the practical results of my own work, and a résumé and a critique of various methods of operating.

First and foremost is it not worth while to operate at all on a cancerous uterus? Do not all patients thus affected sooner or later die of a return of the disease? There is a widespread conviction through the entire medical profession, a conviction which, if I mistake not, has found utterance even here in New York through prominent specialists, that the radical operation is really of no lasting benefit, and is one of those things specialists do because they are specialists, but which they would really better leave undone.

The periods of time in which these patients have remained well are as follows:

ADENOCARCINOMA OF THE BODY.		
Gyn. No.	Gyn. Path. No.	Time since operation. Years. Months.
2436	100	6 0
2417	321	5 6
2832	345	5 6
2934	392	5 4
Sanitarium.	944	4 0
422	1133 and 1137	3 8
Dr. Eccles.	1154 and 1192	3 8
Sanitarium.	1349	3 7
Sanitarium.	1350	3 5
4745	1353	3 0
4746	1359	3 2
Sanitarium.	1412 and 1414	2 9
4922	1473	1 11
3876	2161 and 2183	1 10
5958	2233	1 9
6008	2279 and 2283	1 8
6535	2291 and 2750	1 1
6584	2797	0 11
6659	2897	0 11

If we take it for granted that the two patients whose subsequent history could not be obtained, are dead, we still have 19 out of the 30, or 63 per cent., showing no evidence of a return of the growth at the present time.

Of the patients with adenocarcinoma of the cervix who are well at the present time, one was operated on

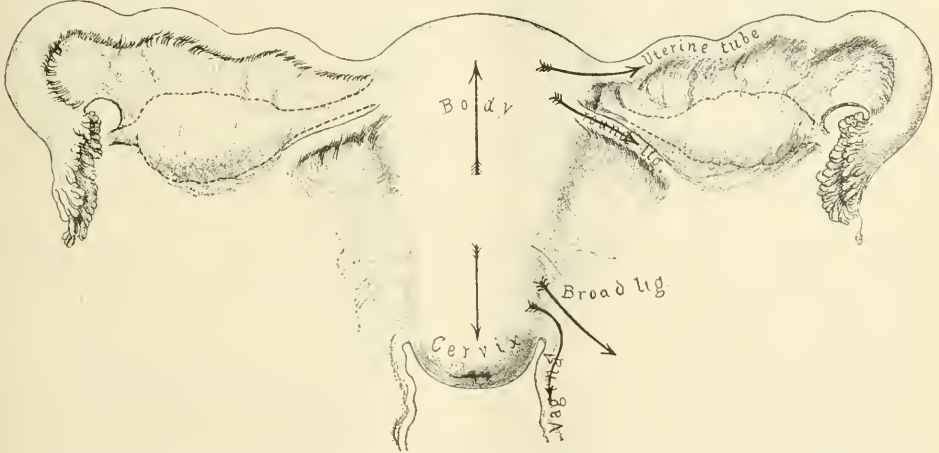

Fig. 1.—Cervical section of the uterus showing the directions in which a cancerous form in the cervix may spread down the vagina, up into the uterine body and out into the broad ligament, following the direction of the arrows. A cancer of the body in its advanced stage often follows the direction of the upper arrows out into the tube or down the broad ligament as well as down toward the cervix.

In citing my statistics in answer to this query let me say that I have included only those cases in which the uterus has been subjected to a rigid microscopic examination at the hands of Dr. T. S. Cullen, my associate professor of gynecology. I know of others still older and in perfect health where there was no doubt as to the diagnosis, but I have not included them, as the entire group of cases operated on at that time has not been rigidly criticised microscopically.

Of this special group of my cases so examined there are 103 operated on and divided as follows: well, without relapse, Jan. 1, 1900—squamous-celled carcinoma of the cervix, 61 cases, 13 in all living or 21 per cent.; adenocarcinoma of the cervix, 12 cases, 2 in all living or 16 per cent.; adenocarcinoma of the body, 30 cases, 19 in all living or 63 per cent.

five years and seven months, the other five years and three months ago.

SQUAMOUS CARCINOMA OF THE CERVIX.

Gyn. No.	Gyn. Path. No.	Time since operation. Years. Months.
2294	78	6 2
2452	109	6 0
4489	1244	3 6
4306	1384 and 1396	3 6
5286	1764	3 1
5577	1936	2 6
5853	2142 and 2152	2 3
5959	2263	1 10
6368	2611	1 9

Sanitarium.	2771	1 0
6590	2782 and 2794	1 11
6656	2890	1 0

I advance no other argument than the bare presentation of these facts: 17 out of 84 patients are well without any sign of a recurrence, at periods extending from three to six years, and 8 over five years since operation—an eloquent tribute to the success of the radical operation, which would still be justifiable if only a far smaller

Fig. 2.—Shows the lines of possible progress of the disease in a sagittal section of the uterus forward into the bladder, down into the vagina, up into the body, and back into the rectum.

percentage of the number could be saved from a life of such dreadful suffering with its inevitable outcome.

Granted then that an operation is justifiable, what

Distasteful as my pertinacity on the next head may be to many who care nothing for cystoscopic work or its methods, I must insist on the supreme importance of catheterizing the ureters, as I have done in all these cases, in order to mark them out during the operation and to enable the operator to work boldly instead of timidly in the parametric tissue.

It is true that it is possible to distinguish the ureters without the bougies, during an abdominal operation, but it can not be done with the same facility, or indeed with any facility whatever; the operation is delayed and the ureter can not be pushed aside as it can when it is splinted by the bougie. In a vaginal operation the difficulties of recognizing the ureter are sometimes almost insurmountable if it is not catheterized. This plan, first put into practice by Pawlik, by slipping a bougie into the ureter through a director and through the water-distended bladder, has for the first time been generally practicable as a routine procedure by my aërocystoscopic method.

Further, the disease must be given a wide berth by ligating far out in the parametrium and, if necessary, dissecting out the ureters, and on the vaginal side by cutting far below the manifestly affected area.

I have now gone as far as I am able to go with assurance; if these principles are borne in mind any operative procedure whatever, which is based upon them, will give results vastly better than those we have secured hitherto. Clark's operation, so thorough in its wide dissection, must receive a most careful consideration.

Fig. 3—Shows the method of extirpating the disease by quadrisection of the uterus. The uterus is first bisected vertically, and segments A and B are removed by cutting out into the broad ligaments, controlling the uterine vessels, the pulling them up in turn and catching the ovarian vessels, removing the entire uterine body in this way. Segment C is next removed, keeping the ureter under touch and giving the cervix a wide berth in tying out into the broad ligament. The real operation begins, however, with the removal of the last segment D. In the side of the infiltration of the broad ligament, and this is done with the sacrifice of all the tissue out to the pelvic wall, including the ureter if necessary.

particular form of operation gives us the best chance of success? Manifestly that procedure which, with the least immediate risk, enables us to give the diseased area the widest possible berth.

Let me then lay down the following dicta, which have been my guiding principles, for your consideration:

The old plan of skinning or shelling out the bare uterus is of all methods the most liable to be followed by a recurrence, and must be abandoned.

A large series of statistics must show us just how often glandular metastases are to be found in operable cases, then by comparing this fact with the increased risk to life from the more prolonged difficult abdominal operation, we will be in a position to decide whether the immediate danger incurred is or is not less than the risks of recurrence of the disease in the glands.

Having in mind the risks of inoculation of the cancer in the cellular tissues, X. O. Werder, of Pittsburg,

Pa., has devised an admirable operation which is at present being extensively tried by Dr. W. W. Russell, my associate professor of gynecology in the Johns Hopkins University. This consists in a combined abdominal and vaginal enucleation, opening the abdomen and ligating and freeing the uterus on all sides, together with the upper part of the vagina. The removal is then affected *via* the vagina, by simply pulling the cervix well down to the vulva and cutting through the vagina at the lower limit of its detachment. In this way there is the least possible contamination. I have tried this operation and am greatly impressed by it.

My most earnest efforts have, however, been turned in another direction, and I will close by briefly describing the operation which I have recently devised and practiced in the cases cited at the end of this paper.

There are two major steps in the procedure:

1. The removal of the tissue down to the side where the infiltration extends deepest.

2. The concentration of all the energies of the operator to the completest possible removal of this last segment.

The steps of the operation are these: Thorough

broad ligament and exposing in this way the uterine artery, which is clamped. The upper half, the body, is now grasped afresh on the cervical side and pulled upward until first the round ligament then the ovarian vessels come into view and are clamped, when this quadrant of the uterus is removed. The opposite quadrant, that is to say the other half of the uterine body, is next removed in the same way. The uterine vessels are now ligated, and the ovaries and tubes are removed after ligating the ovarian vessels near the pelvic brim. The side of the cervix least affected, and there is generally a marked difference, is now removed, carefully tying the vessels as they are exposed and keeping the finger constantly on the ureter.

The steps of the operation thus far described have as a rule been easily and rapidly carried out. Three-quarters of the uterus have been removed and the remaining quadrant, that side of the cervix where the infiltration is most marked, now remains to be extirpated also, completing the operation.

In reality so important is this last step that the operation—*sensu strictiori*—may at this point be looked upon as only having just begun. All the skill and dexterity of the operator must now be concentrated on the effort to

Fig. 4—Shows the four pieces of a cancerous uterus extirpated by quadrisection. On the right side a large section of the ureter has been removed with the cervix.

curettage with a serrated spoon curette, division of the vagina on all sides an inch below the diseased area; separation of the vagina from the bladder up to the vesico-uterine peritoneal fold, which is widely opened; a wide opening of the posterior cul-de-sac. The uterus, now hinged by its broad ligaments, is brought out through the anterior opening as in Martin's operation on the adnexa. This is easily done by pushing back the cervix and climbing up the anterior face of the uterus, step by step until the fundus is reached, with stout-toothed forceps. The peritoneum posteriorly is well protected by an abundant loose gauze pack. The next step is the sagittal bisection of the uterus from the fundus through the cervix and the attached vagina, with scalpel and scissors. As the uterus is cut in halves in this way, each median surface is grasped and held down by a strong-toothed forceps. One half, the most affected, is now allowed to retract into the vagina, while half of the body of the uterus of the other side is removed by bisecting it horizontally at the cervical junction, cutting from the median cut surface out into the

secure the most thorough, wide extirpation of the remaining nodule. In order to meet this supreme indication and to fight the disease in the only stronghold where its invasion has given it a firm hold on the tissues, the extirpation of the three portions of the uterus, that is to say, the entire body and half the cervix, has afforded a maximum space, while the bisection allows the remaining mass to be rotated downward and outward within easier reach.

It is a question with me whether ligature or cautery offers the best chance to go deepest into the tissues in meeting this supreme indication. The ureter will as a rule be bared, and if it is clearly involved in the disease it should be sacrificed without compunction, cut off and reanastomosed into the base of the bladder farther back. The operation may then proceed just as if the ureter did not exist, and the enucleation may be extended all the way out to the pelvic wall. It is my practice, after the completion of the enucleation, to close the wound in the middle and draw down both sides. In simpler cases I close the peritoneum without a drain.

The following cases have been operated on in this way:

All recovered.

I have frankly and without reservation put before you all my own work and my own thoughts on this subject, and I shall be abundantly rewarded if I succeed in inducing some of those present to express their views and throw some light from their large experiences on what is still one of the darkest chapters in surgery.

1414-1418 Eutaw Place.

DISCUSSION.

DR. HENRY C. COE said that he had met with much disappointment when doing the old operation of skinning out the uterus. He believes the radical operation of the future will be an abdominal hysterectomy, as this is the most scientific cutting operation known to-day. The great difficulty is to decide, at the time of operation, between simple inflammatory tissue, and that the seat of malignant degeneration. Dr. Byrne's method of treatment by the application of the electrocautery seemed thoroughly rational, and more than this, is supported by a series of brilliant results achieved by Dr. Byrne himself. Regarding the mode of extension, he does not feel sure that cancer of the uterus always extends by continuity. For example, when the radical removal of a small circumscribed malignant adenoma by abdominal hysterectomy is quickly followed by recurrence in the scar, the explanation, on that basis, is difficult.

DR. EGBERT H. GRANDIN spoke of his personal experience with cancer of the uterus. Although that with the diseases of women has been large, he has seen comparatively few cases of carcinoma uteri—only 48. In 30 of these the bladder, rectum and broad ligaments were involved, and he did not feel justified in resorting to a major operation; he is disposed to believe that, in these advanced cases, the less done the better. Of the 48 cases, 18 were suitable for operation. For carcinoma of the body, total hysterectomy has been the operation of election, and was done in 12. He has been able to trace 7 of these, and has found them free from recurrence. The longest time since operation in these is six years. Vaginal hysterectomy was done on 6 patients in whom the portio vaginalis was implicated, and of the 4 he has been able to follow up, only 1 has remained free from recurrence. Vaginal hysterectomy, whether by clamp or ligature, should be rejected in cases of cancer of the uterus, because more thorough work can be done by the abdominal route. The method of the future will probably be a combination of knife and cautery.

DR. WILLIAM R. PRYOR expressed himself as opposed to the vaginal operation for these cases, nor does he look favorably on Dr. Kelly's method of doing morcellment by the vaginal route in cases of cancer of the cervix. Vaginal hysterectomy is little better than a palliative operation, yet it is attended by a mortality of from 5 to 10 per cent. His preference is for abdominal hysterectomy, and hemostasis by the ligation of the internal iliac arteries.

DR. P. H. INGALLS, of Hartford, Conn., said that most of the cases coming to him were far advanced. A partial operation, as with the cautery, seems to him to rather aggravate than alleviate the condition. Operations for cancer of the body have done better in his hands than those for cancer of the cervix.

(To be continued.)

CLEFT PALATE.

A NEW URANO-STAPHYLORRHAPHY.

BY ALEXANDER HUGH FERGUSON, M.D.

Professor of Surgery, Chicago Post-Graduate Medical School;
Surgeon-in-Chief, Chicago Hospital.
CHICAGO.

STAPHYLORRHAPHY.

In 1764 a French dentist, named Le Monier, proposed for the first time to close the cleft in the soft palate by paring the edges and stitching them together, which was successfully carried out by the elder Roux of Paris in 1819. In 1820, Warren of Boston, and independently of Roux, brought before the profession a similar but somewhat better operation, which he had successfully performed. So closely do the two resemble each other in principle and technique that it might well be called the Roux-Warren staphylorrhaphy. This operation was followed by the best surgeons of that time, for about a quarter of a century by such men as Stevens of New York, Mettauer of Virginia, Wells of South Carolina,

Fig. 1.—Mouth Gag.

Gibson of Philadelphia, Hossack, the younger Warren, Mütter, and Pancoast in this country. Among the surgeons abroad who performed this operation may be mentioned Graefe, Dieffenbach, Sédillot, Liston, Fergusson and Polloch. Fifty-six years ago Sir William Fergusson of London made the first marked improvement on the simple vivification and suture operation. He recognized that the tension on the ligatures was a great cause of failure, and decided that this tension was due to the contraction of the levator palati, palatopharyngei and palatoglossi muscles. To relieve this tension he divided these on either side. He devised a hoe-shaped knife, with which he severed the levator palati muscles by passing it behind the soft palate and cutting from behind forward. In this connection Fergusson was the first to make careful dissections of cleft palates on cadavers. The excellent results obtained by him were also secured by other surgeons who had followed him. His operation super-

seded the Roux-Warren one for several years. The next improvement recorded was in 1860, by Dr. Agnew, of Philadelphia, who pointed out that the tension of the soft palate is in a measure dependent on the contraction of the tensor palati muscles, and these he cut by making an anterior incision close to the hamular process of the sphenoid bone, and thereby obtained marked relaxation. About the same time Dr. Polloch of London carried out a similar procedure. From the case with which the anterior incision could be made and the fact that it cut the lowermost fibers of the levator palati muscles as well, it soon became a favorite. With the exception of a flap-splitting of the soft palate, carried out by many surgeons, nothing new appeared on this subject until Dr. T. W. Brophy, of Chicago, introduced the application of lead plates to the soft palate, which bear the strain of the sutures, thus preventing muscular contractility and tension. He finds it unnecessary to cut the muscles on either side, and maintains that it is harmful to sever them.

URANOPLASTY.

Staphylorrhaphy was an established procedure in surgery before the closure of the cleft in the hard palate was attempted. Before fifty-seven years ago obturators were freely used. Dr. J. Mason Warren, of Boston, in 1843,

Fig. 2.—Crowding procedure for a wide cleft. A, A, gauze crowding the muco periosteal flaps toward the center.

published his method, which consisted in paring away the mucous membrane of each side, raising the flaps of mucous membrane from the bones and suturing them together. Langenbeck effected an improvement by raising the periosteum with the flaps and by making two lateral incisions, one along each alveolar process. In 1873 Sir William Fergusson came on the scene again with his ingenious osteotomy of the hard palate in its entirety, paring the edges of the segments of both hard and soft palate, and brought them together at one sitting, thus completing his urano-staphylorrhaphy. Mason, in 1874, suggested some slight improvements in Fergusson's operation. Garretson of Philadelphia applied to the jaws a horseshoe-shaped clamp, and with it forced the jaws together by means of a screw similar to that of Hainsby. Billroth frequently crushed the hamular processes together, and Wolff utilizes the alveolar processes to close the cleft. Lannelongue constructed a flap, in unilateral cases, from the mucous membrane of the contiguous surface of the nasal septum.

The Davies-Colley method I have performed a good

many times, and like it very much. The cleft is bridged across by means of two flaps. One flap is raised laterally, its outer border being free, while it is left attached at the margin of the cleft. It is then turned upward into the cleft, its mucous surface looking toward the nasal cavity. The flap on the other side is raised like a tongue, its anterior end being free, and is brought across to the opposite side underneath the first flap, raw surface to raw surface, and there fastened with a few sutures. It is an excellent plastic operation.

Brophy's Method (Park's Surgery).—This consists in forcing the two superior maxillæ together with stout silver wire fastened to a lead plate, one placed on the outside of each alveolar process. The approximation is effected by twisting the wire over one of the lead plates. The usual vivification of the segments is made, and sutures applied in the ordinary manner. In infants this operation is feasible. Its author claims but little shock, and excellent results. C. B. Porter, when patients have teeth, uses a vulcanite plate in the mouth to protect the soft palate (Warren-Gould's Surgery, Vol. ii,

Fig. 3.—Os incisivum. A, premaxilla; b, incision to the bone; c, ethmo-vomerine septum.

p. 26). Fillebrown makes an incision along the alveolar processes, raises two muco-periosteal flaps, turns them toward the center of the cleft, and there fastens them together with mattress sutures of silver wire, the edges being vivified and sutured with fine silk.

Instruments.—The only new instrument I wish to present is a mouth-gag (Fig. 1), which I devised and find suitable for all cases. It is small, strong, opens widely, is easily inserted into the mouth, quickly closes, does not strike against the shoulder and lies close to the cheek.

Preparation of Patient.—Adenoids, enlarged tonsils, nasal catarrh, bronchitis, malnutrition, etc., should be treated first. The child should be in the best attainable condition locally and constitutionally before an operation is advised. The day before the operation a dose of castor-oil and a few doses of strychnia should be administered. Irritating the mouth with antiseptic lotions for several days previously is contraindicated.

Age.—In my opinion, all operative procedures on harelip and cleft palate should be completed before the

child begins to talk. The earlier the congenital deformity of the palate is rectified, the less defective will be the speech. In infants a few weeks old the mouth is small, the tissues are friable, and there is a tendency for the flaps to slough. Should the cleft be wider than half an inch, the complete closure of it is not undertaken at the first sitting, but one or more crowding operations can be done to lessen it. (Fig. II.) In this case Langenbeck incisions are made, and iodoform gauze firmly packed into the wounds and beneath the muco-periosteal flaps in such a manner as to crowd them toward the center until they touch. When this is properly done the gauze will remain in place for a week or more. It is not removed until it begins to loosen, after which a second packing may be inserted, but usually this is not necessary, for the new granulation tissue is sufficient to hold the soft structures in their altered positions. Three or four weeks should now elapse before operating again. The palate bones are allowed to become covered over with firm fibrous tissue segments. The crowding operation is most suitable in a class of cases otherwise very difficult to treat, that is, when the segments are horizon-

Fig. 4.—Supra-maxillary osteotomy. A. osteotome; b. cleft on one side.

tal, and the roof is like a Norman rather than a Gothic arch. The flaps in this class of cases are shorter, and by the older methods great traction is employed to bring the pared edges in apposition, hence the frequent cause of failure. When the bony edge of each segment is not well covered by mucous membrane, even though the cleft is narrow, a crowding operation is done as preparatory to the final closure of the cleft in order to obtain flaps sufficiently thick and well nourished to insure success. The more vertical the slope of the palatal segments, the more favorable the case is for operation by old methods.

Os Incisivum and Harelip.—The os incisivum, also called the premaxilla and intermaxilla, protrudes in the center in double harelip, and in single it often protrudes to one side, where it is attached, thus raising the nostril on that side far above the level of its fellow. This deformity has been dealt with in various ways. When met with in infants it is my practice to deal with it before operating on the cleft palate, but in older cases nothing is gained thereby, and then I repair the palate first. When possible, the intermaxillary bone is preserved. A V-

shaped section is removed from the vomer subperiosteally (Fig. III), through a longitudinal incision, the bone nicely fitted in between the superior maxilla, and held there by means of a strong silver wire, taking care to pare off the edges on each side so as to obtain bony union if possible. If, however, the harelip operation is

Fig. 5.—Position of surgeon and patient.

done early, it may not be necessary to perform any operation on the vomer, for in some cases it will be found that the os incisivum has receded to nearly its normal position. When the deformity is one-sided, it is easier to lower one nostril than to raise the other. This is done

Fig. 6.—First step.—A, A flaps hinged by the mucus membrane on the nasal aspect.

by making a supramaxillary osteotomy, as represented in Fig. IV. Here, too, when the harelip is closed in the infant, the deformity is greatly improved and the osteotomy may be obviated. In the development of the child the union of these bones naturally takes place from before backward, so that by repairing the harelip and wait-

ing a few months the alveolar cleft is very much lessened.

Ethmoverine Septum.—The ethmoverine septum is frequently very deficient or entirely absent. When present it materially facilitates the execution of plastic work in the roof of the mouth, by utilizing its mucous membrane.

Fig. 7.—Second step.—A, A, flaps coapted by three sutures and fourth one being inserted.

A NEW URANO-STAPHYLORRHAPHY.

The operation which I now wish to describe has been carefully studied and practically developed. It was done on fifty-three patients, extending over a period of eleven years. In 1889 I successfully performed it on three sisters. In one the defect extended through the soft palate alone, and in the other two the hard palate was involved, but not the alveolar process. Since then I have managed to prepare my patients so that finally in nearly all of them I could perform my operation, resorting to the crowding operation to this end.

Fig. 8.—Third step.—a, a, flaps inserted into nostril; B, last stitch of first row; C, C, C, second row of sutures being inserted.

Wrap the child in a sterile sheet with its arms extended along its sides; fasten a towel wrung out of a bichlorid solution around the head, or put on a rubber cap; place it on a table with a headpiece that can be raised or lowered; administer chloroform drop by drop; mop its face, mouth and throat with equal parts of alcohol and water; with a 4 per cent. cocain solution on cotton, touch the palate and pharynx; if secretion is profuse, give a hypodermic of atropia, the dose to suit

the age of the patient; insert the mouth-gag; sit at the end of the operating-table, with the patient's head well thrown back (Fig. V), and you are ready for work.

The anesthetizer has a difficult task to keep the patient well under the influence of the chloroform, and also allow the surgeon sufficient time to work. It necessitates a wide range of the degree of narcosis, thus coming to and going under alternately, but this fluctuation in the administration of the chloroform is much safer than keeping the patient constantly in a state of surgical anesthesia by spraying the chloroform through a nostril.

OPERATION.

1. *Making the Flaps.*—With a slender, slightly curved, narrow-bladed knife, cut through the mucous membrane of the mouth about one-sixteenth inch from the edge of each segment, and divide all the soft structures to the mucous membrane on the nasal aspect of the palate, but not through it. (Fig. VI.)

2. *First Row of Sutures.*—With a small, round, fully curved needle, not larger than one-half inch between the eye and the point, held in a suitable needle-holder, and threaded with fine silk, closely insert inter-

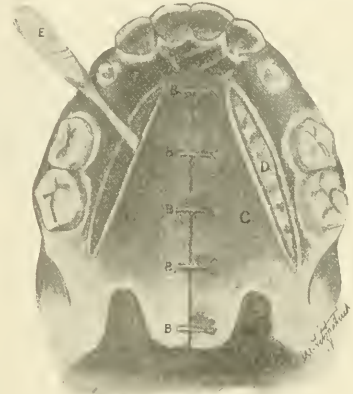

Fig. 9.—Fourth step.—B, B, B, B, etc., second row of sutures tied; C, C, muco-periosteal flaps; D, gauze packing; E, periosteal elevator; (a), the flaps and first row of sutures are no longer to be seen.

rupted sutures by passing the needle through the free borders of the flaps from the mucous surface to the raw, and from the raw to the mucous surface, and tie them as you proceed from before backward, all the knots being situated on the nasal side. (Fig. VII.)

3. *Second Row of Sutures.*—Take the same needle and needle-holder and complete a row of interrupted stitches of horsehair on the buccal surface of the palate from the tip of the uvula forward, and tie them where apposition is possible without tension. The soft structures of the hard palate can not usually be brought together until the next step of the operation is taken. (Fig. VIII.)

4. *Muco-Periosteal Flaps.*—Place the forefinger of the left hand on the hamular process; take a short, strong, slightly curved, narrow-bladed knife, and make a curvilinear incision on one side, beginning just behind the hamular process, cutting down to the bone and extending forward along the alveolar process, as far as desired; prevent hemorrhage by pressure with the finger and gauze; rapidly raise the muco-periosteal flap, with a strong periosteal elevator, from the segments of the hard palate, and immediately pack the wound firmly

with iodoform gauze. Repeat this performance on the opposite side, and tie the horsehair stitches not already secured. The soft structures of the hard and soft palate are beautifully held in apposition without tension on the stitches. (Fig. IX.)

In packing the iodoform gauze in the wounds, fixation points are obtained by forcing some of it into the bone, also between the teeth and under the mucous membrane. If this is properly carried out, the gauze will remain in place for a week, and sometimes longer. It is removed when it becomes loosened, by which time it has generally fulfilled its usefulness. A second and occasionally a third packing may have to be inserted.

It will be observed that this is not a flap-splitting but a flap-formation operation, the flaps carrying with them two narrow strips of the firm, strong, buccal mucous membrane of the palate, which holds sutures securely, and when they are turned upward and held in coaptation by means of the first row of sutures they form an ideal protecting roof to the raw surfaces beneath them, and afford twice the width of denuded tissues for apposition, and the nasal mucopurulent discharge is shed off to either side. (Fig. X.)

Fig. 10.—Supposed transverse section when operation is finished. A, A, flaps made and turned into nostril; B, first row of sutures; C, second row of sutures; D, muco-periosteal flaps coapted by C; E, E, gauze; F, F, Garth; G, G, Segments of bone (palate); H, H, nasal cavities; I, mouth.

After-Treatment.—Every two or three hours the mouth is to be cleansed with a feeble antiseptic solution, such as boric acid, etc. The child readily takes to whisky and water, which is given after taking nourishment, to wash the liquid food off the area operated on. Nutrient enemata are to be administered if deemed necessary, and the stitches removed not earlier than the twelfth day. If the patient cries much, we should keep it quiet with an opiate. A special nurse, experienced in caring for cases of this nature, should be employed.

Cases Suitable for the Operation.—1. The cleft in the hard palate must not be wider than half an inch, but if it is, a preparatory crowding operation is done first. 2. The mucous membrane covering the inner edge of each bony segment should be thick and well nourished; if not, the crowding operation is resorted to primarily. 3. It is suitable for all clefts in the soft palate.

Commendable Features.—1. The results are vastly better than I have been able to obtain by any other method. I have had only one primary failure. 2. No tissue is removed. 3. Very broad raw surfaces are coapted. 4. The danger from sepsis is minimized by turning the flaps upward, as described.

Disadvantage.—It is more difficult to perform.

ONE OF the features of the Paris daily, the *Figaro*, is a column each week devoted to a summary of the leading articles in the principal medical journals. It is written over a pseudonym by M. de Fleury, a well-known physician and contributor to medical literature, and presents, in popular style, the latest medical achievements.

A CASE OF HYSTERICAL HIP-JOINT.

BY JOHN LINCOLN PORTER, M.D.

Instructor of Orthopedic Surgery, College of Physicians and Surgeons. CHICAGO.

Miss E. H., a schoolgirl, 11 years old, came under observation Jan. 24, 1898, with the following history: She had had measles, chicken-pox and whooping-cough in childhood, and scarlet fever three years before I saw her. After this she had severe headaches, pain in the upper dorsal region and "trouble with her stomach." The gastric disturbance consisted of attacks or crises, occurring at quite regular intervals of about a month, with headache, eructations, sometimes vomiting, and pain of an intermittent character in the abdomen; and

FIGURE 1.

with this was extreme nervousness amounting at times to nervous storms. These attacks lasted for two or three days, and rapidly passed off, leaving the patient in good health. She had never menstruated. In September, 1897, she began to complain of pain in the right hip, and these pains recurred, with intervals of perfect comfort, for six months; then a slight limp developed, which had been gradually getting worse, though she had been up and about as usual all the time.

Family History.—There was no history of tuberculosis, syphilis or insanity in either branch of the family as far back as, and including, the grandparents. Both parents were living, also five other children, all of whom were in apparent good health. The mother and her four sisters were all of very nervous temperament and subject to severe headaches.

Condition on Examination.—The patient was a red-haired, blond girl of fairly good development for a girl of 11 years, and apparently anemic. She had large, full eyes, with a restless expression, was alert and quick-motivated, looked at every one and all approaches with suspicion, and clung to her mother in a timid manner. She would not talk, but answered direct questions with a shake or nod of her head. Her standing position and gait at once attracted attention (Figs. 1 and 2), for she stood with the right thigh flexed and rotated outward, and only the toes touching the floor. In walking the same position was maintained, the weight being carried on the toes, but the flexion increased each time the weight was borne by the right leg. On inspection, the affected hip and leg seemed perfectly normal, there be-

ing no swelling. The length of the two legs was the same, but the circumference of the right thigh was one-half inch greater than that of the left one. The latter was easily flexed, rotated and put through the normal motions, but as soon as any motion was attempted in the affected leg a resistance was felt. This resistance was vibratory in character and corresponded exactly to the amount of force exerted by the examiner; for if the leg was forcibly flexed and suddenly released it assumed extension without any evidence of pain. Fig. 3 shows the amount of flexion secured after repeated examinations, through coaxing the patient to help and using a little force. If the forcible flexion was continued until all resistance was overcome, the thigh went up into normal flexion on the trunk and could be rotated freely. Though she covered her face with her arms and cried a little, she did not shed tears or give indications of pain.

Dr. Ridlon and myself have forcibly flexed the thigh on the pelvis several times, and if flexion was maintained until she found that resistance was useless, it ceased. No acute symptoms whatever followed the forcible manipulations. Fig. 4 shows the affected leg completely extended in Thomas' position. The foregoing examinations, together with the absence of any objective indication of intra- or para-articular disease, such as swelling, thickening of the tissues or local elevation of temperature, gave the findings on which a diagnosis of hysterical hip-joint was made.

In discussing the differentiation and the later developments that proved the diagnosis, I shall consider only tubercular hip disease and hysterical hip. The chronic nature of the case, persisting for more than a year, with no history of injury, or of any acute inflammatory symptoms, will exclude traumatism or acute infectious arthritis. The measurements, the symmetry of the two hips and the gait exclude coxa vara. In making a differential diagnosis we must consider chiefly the etiology, symptomatology and, in certain cases, the result of treatment. The symptoms have been brought out in the foregoing examination, and as to etiology, the absence of any tubercular predisposition, inherited or acquired, such as is found in a large percentage of tubercular joint cases, and also the lack of any traumatism, must be noted. But on the other hand, she is a young girl of marked neurotic temperament, as evinced by her every action: and where there is added to this a family history which is decidedly of this type, we have a combination that more than suggests a strong neuropathic

FIGURE 2.

element. I have been unable to make any satisfactory examination for anesthetic areas in her, she would not keep her eyes closed a moment, and when blindfolded, the nervous tension and lack of control was so great that she was twisting and writhing about continually, and no definite information could be obtained, but her whole behavior was such that this element was clearly shown. In a tubercular joint where the disease has not progressed far enough to produce any fullness, thickening, or other objective signs about the joint, some passive motion is usually possible and often quite free in some direction, and the resistance which is encountered is a muscular rigidity, that is peculiar and is felt suddenly when the limit of painless motion is reached, but here there is no true rigidity, only a resistance of a vibratory character, to all passive motions, that corresponds in power exactly to the force exerted by the examiner. In true hip disease the limp often appears before any pain is felt, while here the pain, of an intermittent type, was noticed six months before the limp. Then, too, the limp in early hip disease is due to incomplete extension of the thigh on the pelvis as the body is carried forward, and the patient walks on the sole of the foot; while in this case, the patient stands with the leg flexed and abducted with only the toes on the floor, and limps because the leg is shortened by the flexion. Furthermore, I believe no hip disease ever progresses to a flexion deformity of 40 degrees without some abnormality being evident about the joint. When asked if she had any pain, she nodded and put her hand on the anterior outer surface of the thigh and calf, the very places where muscular fatigue would be felt from constantly maintaining the flexed position and constrained gait. In 90 per cent. of cases of early hip disease the pain is either in the joint or referred to the inner surface of the knee. Firm pressure over the trochanter, driving the head of the femur into the acetabulum, produced no pain in this case, as it usually does in hip disease.

Atrophy of the thigh and calf muscles, which is always an early accompaniment of hip disease, was not only lacking, but, as noticed above, the circumference of the affected thigh was one-half inch greater than that of the other. This was confirmed by measurements made by others at different times.

The above differences would be sufficient to exclude hip disease, but out of curiosity I tried the following trick maneuvers: with the patient standing, I asked her to flex the affected thigh so as to lift the toes off the floor; she made a few feeble attempts, lifted the knee an inch or so, and stopped. Then I asked her to sit on the table, and she did so with the thighs flexed to a right angle without any apparent discomfort, and perfectly unconscious of the significance of the change of position. Again, with her lying supine on the table, and maintaining the constant slight flexion of the thigh, I made an effort to slowly increase the flexion, asking her to help by bringing the leg up, but she resisted and whimpered and said she could not. I at once asked her to sit up, and she did so easily, with her legs straight and before her, thus producing a voluntary flexion of nearly 100 degrees. Then I put my pencil just beyond her heel and asked her to pick it up, and she did so quickly and easily, thus bringing the thigh into complete flexion against the chest.

Another incident shows the inconsistency of these cases. Convinced that the attitude was not due to true joint disease, I tried in every way to get the patient to put the entire sole of the foot on the floor when walking,

thinking that the additional comfort thus obtained would gradually result in abolishing the flexion at the thigh, but although motion at the ankle-joint was perfectly free when she was sitting or lying down, she could not be induced to flex the ankle enough to bring the heel down on the floor when standing. Out of curiosity, I put a plaster cast on the leg from ankle to groin, at the

me again, the foot and leg were still held in the same position. As the cast was somewhat broken, I removed it, and the original flexion at the hip and knee immediately reappeared, and, just as quickly, the rigidity and inversion at the ankle disappeared.

As a final test in my examination of the patient, I took occasion to see her when she was asleep. In a

FIGURE 3.

same time correcting the flexion at the knee, knowing that with the latter extended she would either have to extend the thigh normally or flex the foot, as she could not walk on the tips of her toes with the thigh flexed. The cast was applied while she was lying on the table, and she took an active interest in the proceeding, not knowing why it was done. When she was allowed to get

diseased joint, the muscular rigidity and spasm persist during sleep and are only abolished by deep anesthesia, but when I reached her bedside she was lying on her side, soundly asleep, with both knees drawn up to perhaps 80 or 90 degrees. While I was estimating the amount of flexion, she turned on her face, and straightened both legs out into complete extension. Her mother

FIGURE 4.

off the table she stood momentarily on the entire sole of her foot, and her surprise, when she could not bend the knee, was almost ludicrous. She said she could not walk, but when told that she would have to wear the cast home, finally left the room, pushing the stiffened leg before her with the toes kept persistently on the floor and the ankle rigid. I realized that she would probably discover that by tilting the pelvis and straightening the thigh she could walk on her toes; and when she came back a week later that was the attitude, except that the flexion at the thigh was not entirely abolished, and the foot was inverted, making her walk on the outside of the foot and toes. She would not voluntarily correct the position of the foot, and attempts to do so passively elicited the same kind of resistance that had been found at the hip. Later she was noticed standing on the sole of the foot, her attention being diverted to something else. During the next week she passed through one of her gastrointestinal attacks, and, when she returned to

then turned her on her back, and I began making passive motion with the affected leg, finding rotation free. Here she woke up and, seeing me standing by the bed, hid her face in the pillow and went through all sorts of restless movements, drawing her knees nearly up to her chin, and then extending the legs out to their fullest extent, manifesting no difference whatever between the two extremities. I did not see her again for several months; and when I did, December, 1898, some flexion and limp still persisted, but in April, 1899, her mother brought her to me to show how perfectly she had recovered; then gait and position were normal, and about the leg or hip there was no indication of any previous trouble whatever. Her mother remarked that she had taken nothing but the medicine I had first prescribed, which was a bitter tonic—I think tinctura nux vomice and tinctura cinchona comp.—that I had given the first time I saw her, with the positive assurance that she would get well.

EUSTACHIAN CATHETERIZATION.*

BY STEPHEN OLIN RICHEY, M.D.

WASHINGTON, D.C.

To quote Politzer, "Most emphatically, it frequently happens that catheterism of the tube, as a diagnostic and therapeutic agent; can not be replaced by any other method." Gruber calls it "an indispensable aid to both the diagnosis and treatment of many aural affections." In agreement with these veteran otologists, I think, of the many methods of reaching and influencing diseases of the middle ear, which form the vast majority of those for which the aurist^t is consulted, that no one is so important as, or has the precision and efficiency of, the catheter. This is so true, though not generally accepted, that I venture to suggest that no man should claim to do the best character of aural work unless he possesses skill and dexterity in its use; the skill to enter the Eustachian orifice with reasonable promptness, fully appreciating the effect he is producing with and through it on the middle ear and the contiguous tissues; the dexterity to do this without harm and with comparative freedom from pain, as the performance appears formidable to the patient, and lacks no element of an operation save the destruction of tissue.

In proportion as it is the more difficult to the surgeon than the Politzer and Valsalvan methods of *inflation*, is it the more precise, conservative and effective. The Politzer and Valsalvan methods, like the use of Eustachian bougies, have always seemed to me a kind of veterinary surgery; unscientific, and worthy only of indolence and incompetency. They are replete with possibilities of unavoidable mischief, though Politzerizing in modified form is justifiable with some children, in some conditions; but its explosive effects are alarming even to adults. The Valsalvan method can fortunately rarely be practiced by children, and should never be a resort, except in the presence of the surgeon, and while he is removing secretion from the middle ear through a perforated drum membrane.

In neither method can the effect be addressed to one ear alone; each method selects the ear least affected, and air with unmeasured force passes in the direction of least resistance. The effect of each is chiefly mechanical, exerting no therapeutic influence beyond temporarily overcoming a tubal stenosis, and proportionately temporarily relieving local venous stasis, *if the air does pass through the tube*.

That the force of Politzerization is often unknown is illustrated by the experience of an aurist, related by him to me some years ago. In his attempt, by this means, to free a stenosed tube, the drum membrane of the unaffected ear was ruptured.

The frequent repetition of either method in chronic non-suppurative inflammation of the middle ear often results in a flapping drum membrane, with vertigo when air enters the cavity during the act of blowing the nose, and sometimes with that of swallowing.

In cases of acute middle-ear inflammation these means may clear the tube of secretions trying to find their way into the pharynx, but only by driving them in the direction from which they have come; fortunate if they stop in the cavity, though the risk is great that, loaded with germs, they may be propelled into the antrum to cause disturbance there which might have been avoided. Neither method contributes anything to antisepsis of such secretion, thus started on its way to

the mastoid spaces, into which other applications of the same kind may drive them, and thus excite a mastoiditis. It would seem that this must happen more frequently than formerly, judged by the increasing number of mastoid trephinations deemed necessary, and for which it is not pleasant to think the aurist may in any degree be responsible.

In reading the reports of cases of mastoid involvement as a sequel to otitis media acuta, I have received the impression that often the extension of the malady would not have occurred except for the mediation of this form of inflation. Mastoid complication from acute middle inflammation, even when symptoms of invasion of the antrum existed, has occurred but once in my work; and I have not had a mastoid trouble from chronic suppuration of the middle ear, unless it existed when the case came under my care. My fortune in this respect has been so great that it is not easy to find a reason for such experience unless in the methods of treatment adopted. It varies so much from that of most writers, that I do not find occasion to perform the excisions and trephinations so common now.

I *always* use the catheter in affections of the middle ear, acute or chronic, and have never seen anything but good result from it, and think the danger of introducing germs from the pharynx into the middle ear by means of the catheter, properly used, to be purely visionary. This claim has been made, but I have never seen an instance of it, and do not fear it. It might be done, but with proper precaution it is avoided. The catheter must be sterilized before introduction, and an astringent and antiseptic solution must be blown gently through it into the tube, not necessarily into the cavity the first time; indeed, generally better not. The solution dilutes the secretion it reaches, favoring its more ready escape; it more or less destroys the germs; its astringency increases the caliber of the tube, acting antiphlogistically. At the next sitting the solution may be carried farther up the tube, or into the cavity. If the drum membrane is perforated the solution may be permitted to reach the cavity at the first interview, and it will act in an equally benevolent way there. The dilution and antisepsis of the secretions, *gently done*, is the important feature.

Another purpose served by the catheter, and a wise one, is the *withdrawal* of the secretion from the tube by suction. I have, at times, removed the catheter half-full, with less once or twice more; relieving tension and pain, thus making space and more safety for the solution to follow, and sometimes aborting acute trouble, and avoiding paracentesis.

However, it is the extension of the malady beyond the middle ear which is most important, and my experience coincides with that of Dr. Burnett, of Philadelphia, who says that he "has never seen a case of acute mastoiditis following acute otitis media in which he has had charge of the treatment from the beginning." Such cases may be due either to neglect, or overtreatment; in my judgment chiefly to the practice of the Politzer method.

A number of times I have heard comments by foreign otologists upon the seeming independence of the Eustachian catheter in this country, especially in chronic suppuration.

In stenosis of the Eustachian tube, not due to adhesion, patency of the tube has been secured by means of the catheter, in my experience, without exception, and naturally a resort to bougies seems bungling. Think of a bougie retained in this region for half an hour! Yet this has been advised.

*Read before the Medical Society of the District of Columbia, March 14, 1890.

The catheters I use are made of malleable silver, to facilitate ready adjustment of the curve of the tip to the variation in size of different nares and pharyngeal spaces. A different adjustment is often necessary for the two sides of the same person. The best sizes of the catheters are given in the text-books.

The substitution of a local anesthesia soft rubber bulb for the unwieldy Politzer bag, by requiring but one hand for its manipulation, is an advantage. By the resistance of the bulb to the hand some appreciation of the force being used and of the character of the obstruction may be gained, and the volume of air carried in may be approximated, as is not possible with a large bag.

Clamp and headband are worse than useless, like much other awkward trumpery that has been devised for use in this region. The "modified" catheter is either an attempt to compensate for the possession of thumbs for fingers, or, like the modified pessary, it is designed to record a claim to cheap glory.

ABDOMINAL SURGERY.

FIVE INTERESTING CASES: PANCREATIC CYST; HEPATIC CALCULI; FECAL FISTULAE; COMBINED APPENDECTOMY AND NEPHRORHAPHY.

BY FLOYD WILLCOX MCRAE, M.D.

ATLANTA, GA.

CASE 1.—W. R. Britt, Columbus, Ga., white, male, aged 60 years, farmer, married, was admitted July 17, 1899. His father died, he believes, of some growth in the abdomen. His mother, brothers and sisters are healthy. Sixteen years before, while in Florida, he had chills and fever for a year. About thirty years before, he was taken with sudden, excruciating pain in left lumbar and iliac regions, which persisted three or four hours, i. e., till after the application of mustard plaster. He passed bloody urine at that time. He had similar attacks four to five times a year for the next twenty years, diagnosed renal calculi.

When having an attack he has a constant desire to urinate, but voids only very small amounts. The left side always remained tender. Fifteen or twenty years ago, stepping on the hub of a wagon wheel, he struck his left side on the rim of the wheel, causing severe pain for about an hour. For the last twenty years, on considerable exertion and getting warm, as in ploughing, he has become completely exhausted, weak and nervous. During the past few years he has had a burning sensation in the upper part of the abdomen, and could not eat as much as formerly because of a sensation of fulness; no vomiting, but occasional pyrosis. No abnormal appetite nor dislike for food was present, but he has always had a tendency to constipation, and for the past year or two this has been worse, the bowels seldom moving without a cathartic. There has been no diarrhea since 1860.

When in the hospital, two years ago, he became aware that something was wrong in his abdomen, by the sensation of a moving and contraction of the bowels. Two months before admission, he noticed a mass about the size of his hand, just below the right ribs, and about the median line, above the umbilicus. He had no pain, but an uneasy feeling in the abdomen, and lost seven to eight pounds in the last four or five weeks.

After some medication, six weeks before, he had a good appetite, but food seemed to do him little good. There was a large, hard mass in the left middle abdominal region, firmly fixed, of a slight cystic feel. Diagnosis was in doubt, but malignant disease suspected, and an unfavorable prognosis given.

An exploratory incision was decided on and done the day after admission, July 18, at 9 a.m. A large cyst of the pancreas was revealed on going into the abdomen, the trocar introduced and about three pints of oily, straw-colored fluid obtained. The cyst was firmly adherent to the concavity of the spleen, which latter was slightly enlarged and displaced downward, and formed the left boundary of the tumor, thus greatly enhancing the difficulty of diagnosis. The upper and lower ends of the incision were closed with through-and-through silkworm gut sutures, and peritoneum sutured to the skin for the middle $2\frac{1}{2}$ inches of incision, with fine silk. The cyst was then opened, the edges of the opening sutured to the abdominal wound with fine silk, and a large drainage-tube—rubber—introduced, containing gauze wick; this was held in place by silkworm gut sutures. Absorbent dressing was then applied and the patient put to bed.

Strychnia, gr. 1/30 every three hours, was given, and no trouble was had with nourishment, which was gradually increased from that time on, giving chicken broth, albumin, panopepton and buttermilk, one or the other, every three hours. On the second day his temperature reached 101 F., and on the three succeeding days it ranged from normal to 99.6, and 100 once or twice daily; thereafter it was normal. He was given a light diet on the sixth day. The dressings were changed as necessitated by the amount of discharge, at first twice daily, later daily, and so on.

His recovery was rapid and uneventful, and he was discharged "improved," on August 14.

CASE 2.—Mrs. C., aged 34, gave a negative family history. She had been healthy, except dyspeptic for several years, and subject to attacks of colic, or what she supposed to be acute indigestion. About six weeks prior to operation, she had a severe attack of colic, followed by "bilious fever" (?) for two weeks.

I saw her first in consultation with Dr. G. G. Roy, August 8. Examination revealed a tumor about the size of a fist, occupying the region of the gall-bladder, and extending about two inches below the ribs. There was slight jaundice. The lungs, heart and kidneys were normal. A diagnosis of gall-stone cholecystitis, was made and early operation advised.

Operation, August 9, was under ether. Coming down on the tumor I found what seemed to be an enlarged gall-bladder, but which, on examination, proved to be an enlargement of the liver itself. The growth was very hard and nodular, presenting many of the characteristics of malignancy. Dr. Nicolson, who helped me, and I were in doubt as to just what its character was. Introduction of an aspirating-needle showed that it contained a dark serous fluid, but nothing definite was determined as to its character. I immediately stitched the parietal peritoneum to the surface of the liver, leaving a space as large as a 50-cent piece, uncovered. I then packed the wound with iodoform gauze, closing the two extremities with silkworm gut sutures. The packing was left in three days, when it was removed, leaving the surface of the liver uncovered. I immediately made an opening down to a hard body in the substance of the liver, and, with a curette, removed thirty gall-stones of almost uniform size and shape. A drainage-tube was inserted, and gauze packed around it. August 4th three more stones were removed; the 16th, ten; the 20th, one; the 24th, three; the 26th, two; the 30th, two, and eight have come away since. There is still a discharging sinus, but practically no pain.

The patient has gained flesh rapidly, and weighs fifteen or twenty pounds more than she ever did, and enjoys the very best of health.

CASE 3.—D. S. P., white, male, aged 37, a stair-builder, was admitted August 9, 1898. He had been operated on for appendicitis the preceding March and a suppurating sinus remained and afterward developed into a fecal fistula, which discharged very freely, especially when the bowels were loose. This gave him some pain at times. He had indigestion all summer, but had been able to work. The bowels had been moving about twice daily.

Operation, August 12, at 1:50 p. m. The sinus was packed lightly with iodoform gauze, and an elliptical incision then made outside this tract, through the abdominal wall. The surrounding tissues were carefully dissected and separated from the sinus, which was found to enter the cecum at the base of the appendix. The latter was very large and indurated, and surrounded by a mass of inflammatory deposit. This I dissected out down to the base—"near" cecum—removed it, cauterized with carbolic acid and buried the stump in a fold of the gut with sutures of No. 7 silk, four or five tiers of these being put in. The operation was tedious, occupying two hours and fifteen minutes of uninterrupted work. Iodoform gauze wick, surrounded by a fenestrated rubber-tissue drain, was left in and the wound closed with silkworm gut. The drainage was removed and left out next day, the wound being clean. The temperature went up to 102 F. on the 14th, but came promptly down on administration of quinin bisulphate, gr. v, every four hours to seven doses, and remained normal thereafter. Recovery was uneventful, after removal of the sutures on the 19th, and the patient was discharged cured, Oct. 11, 1898.

CASE 4.—J. B. S., white, male, aged 37, a dairyman, was admitted May 16, 1899. His health was good until four years prior to admission, when, on catching a falling milk vessel, he had severe pain in the right inguinal region. This grew worse and he had to go to bed. The right leg seemed affected, always feeling better when flexed on the thigh. He was in bed three months at this time, and noticed a "lump" in his right side. About Jan. 23, 1899, the iliac region of his right side began to pain him slightly, but he had no general abdominal tenderness, nor vomiting, though the bowels could not be moved for a week. When gas accumulated in the bowels, the mass inside seemed to get larger. The right leg was still more comfortable when flexed. He was admitted with a mass in the right iliac region to the inner side of the crest extending downward—slight tenderness. The temperature was 102.8 F., the pulse 88, the tongue rough and coated. There was no appetite and some diarrhea.

Operation was performed May 18, at 2 p. m. (Dr. Nicolson). The point of tumor in the right iliac region, which would be tympanitic at times, dull at others, was tympanitic while on the table, before operation. Incision over McBurney's point reached an extensive cavity three inches long by two inches deep, which contained an ounce of creamy pus and a concretion about the size and shape of a partridge egg. The inner wall of the cavity was formed by the outer surface of the cecum, in which was a fibrinated opening admitting the index finger. The appendix was not found. The cavity was sponged clean and the wound closed with silkworm gut sutures, an iodoform gauze drain being left at its middle.

The fecal fistula was dressed daily, and oftener when necessary—sometimes four or five times daily;

irrigations at times, then none; packing at times, then none—from the first operation until September 11, when the second was done. The opening in the gut could be easily felt and plainly seen with the light at a proper angle, but it closed very little under all the forms of treatment tried.

A moist gauze (saline) dressing, daily, seemed to exert the best influence over the discharge, amount, odor, absorption, and so on. A cavity holding from two ounces at first down to one-half ounce just before the operation, persisted, the contents of the bowel dropping into it from the opening in the gut and, when the cavity was filled, the dressings becoming saturated. When this cavity was well packed it seemed that the discharge was lessened, probably by pressure on the opening in the bowel.

On September 11, the second operation was performed under chloroform anesthesia by Dr. McKee, Dr. Nicolson assisting. The opening of the old fecal fistula was enlarged—mucous membrane of gut very unhealthy for an area the size of a silver dollar, about the opening in the cecum. Adhesions of the cecum to the abdominal wall were broken up, and the remainder of the appendix—about 1½ inches—also separated from a bed of adhesions. A small portion of cecum at the site of opening and the appendix were resected, and the edges of the gut brought together with a Czerny suture, and four or five layers of Lembert sutures of No. 7 black silk put in, one layer above the other. Cicatricial edges of the wound were then trimmed off and sutured with silkworm gut. Gauze drainage was put in and moist saline dressing applied. This was changed on the third day (13th), when the wound was clean, no odor; moist saline dressing reapplied.

A thin yellowish fluid oozed from the drainage wound for twelve days, necessitating a daily change of dressings. The cavity held from 1 to 1½ drams of fluid when filled. This closed slowly but steadily, and the patient was discharged, cured, on October 7, twenty-six days after the operation.

CASE 5.—Miss L., aged 29, was admitted Oct. 12, 1899. Father died of heart disease, mother of consumption, one brother of rheumatism. The patient was always delicate; subject to cold. She had had very painful menstruation. Tubo-ovarian disease existed for three years and she was in bed five months, prior to removal of the ovaries and tubes, in July, 1895. Floating kidney was found, but nothing done for its relief except directions given as to abdominal support. There was no relief from removal of the tubes and ovaries.

On July 6, 1896, I did a right nephrorrhaphy, with complete relief for fourteen months, when she had a fall down a flight of steps, and partially broke the anchorage loose. This fall was followed by subacute appendicitis, and she was in bed for seven weeks. She rested up and after a few months felt as well as before injury, and resumed nursing one year after her fall, without inconvenience until March, 1898, when she had an attack of appendicitis, with high fever, and was confined to bed for two weeks. She never felt well afterward, but was about till September, 1898, when she had a mild recurring appendicitis, more or less pain all the while.

On admission, the heart and lungs were negative, but the urine showed a few hyaline and granular casts. This cleared up under treatment, till at time of operation, October 17, only two casts were found.

Operation was done under ether, the usual incision along border of rectus for removal of an appendix. Ap-

pendectomy was completed in the usual way, except closure of the abdominal incision: I separated the parietal peritoneum down to the right kidney, which was very readily accomplished. With a full curved Hagedorn needle, three sutures were put in, after incising the perirenal fat. The sutures took a "good bite" of the kidney and were then carried deeply into the muscles and brought out again. They were tied without much difficulty, and held the kidney well in place. Kangaroo tendon was used. Considerable difficulty was experienced in putting in the sutures, but this was finally accomplished in a very satisfactory manner. The abdominal wound was closed in layers and the patient put to bed in excellent condition. In some way the superficial structures were affected—evidently streptococcus infection—and the subsequent fever and prolonged convalescence were due to this cause.

She suffered much pain after operation, morphia being necessary twelve hours after it. Temperature was 101.6 six hours after operation, and the quantity of urine was very small. An enema of normal salt solution was giving on taking her off the table, and the following day alum enemata, followed in two to five hours by saline, were started and kept up daily. Strychnia, gr. 1/30, was given every three hours, and morphia was occasionally necessary. On October 20, diuretin, in 7½-gr. doses, t. i. d., was begun, and 1 gr. of calomel given at bed-time. Lithia water *ad libitum* was started next day, and she was persuaded to drink as much as possible. The quantity of urine steadily increased from day to day, from ten to sixteen ounces after operation to thirty-five to sixty October 28 to 30. No morphia was used after the 23d.

The temperature ran high after operation, going steadily up from day to day until, on the 23d, it reached 103.4. Chloroform was administered and an incision made through a hard mass in the right side over the kidney area, and about three drams of pus and some bloody serum evacuated. This was dressed daily, and temperature declined some, but never reached normal till after an exacerbation on November 8, when it went to 103.6; the high fever here remained only two days, and normal range was reached and held to from November 11.

Case 1 presents several features of especial interest. The history of repeated attacks of renal colic, and the location of the tumor, pointed to hydronephrosis: the general appearance, rapid emaciation, obstipation, age and general characteristics of growth to malignancy. I should have made a positive diagnosis of malignant disease but for the fact that the tumor seemed cystic toward the median line. Dr. Cooper, who saw the patient, made a rather tentative diagnosis of cancer of the stomach. Dr. J. H. McDuffie, the family physician, suspected hydronephrosis. Exploration of the cyst revealed no cause for its development, and the utter impracticability of its complete removal. I have kept up with the case, and while there is still a considerable discharge of pancreatic fluid, the quantity is constantly diminishing. The general condition of the patient is good.

Case 3 puzzled me exceedingly. Quite a number of the stones removed are about the size of large buckshot, highly polished, almost black, and irregularly quadrilateral. They were evidently formed in the gall-bladder, ulcerating through its roof into the liver. The adhesions were such as to make a careful examination of the under surface of the liver impossible.

Cases 3 and 4 illustrated one of the untoward consequences of incomplete operations for appendicitis.

No operation for this condition, that consists in simply opening and draining an abscess without complete removal of the appendix, can be considered curative. A large proportion of such patients will require a subsequent operation to effect cure. The method of closure adopted in these two cases is worthy of further trial. In both there were extensive adhesions, great induration and thickening of the cecum. I do not believe any other method, except a complete resection of the cecum, would have proven curative. I shall in future employ the method with much confidence, in this very troublesome class of cases.

Case 5 represents an entirely new procedure, i. e., that of appendectomy and nephrorrhaphy through the same incision. I did not do the operation as I had originally planned to do it. It was my purpose to remove the appendix, separate the peritoneum, incise the perirenal fat, put my sutures in the kidney with a long, straight needle on each end of each suture, then have my assistant make a lumbar incision through the skin and superficial fascia. I next intended forcing the needles through the lumbar muscles, and tying the sutures, closing the skin and fascia over these, thus burying them. After getting down to the kidney, however, I felt sure that I could accomplish the same result without making another incision, and finally succeeded in doing so. The infection of the wound that followed was a most unfortunate circumstance. I feel sure this was due to an unguarded act of one of my good friends who is a surgical enthusiast. He came in just as I had finished putting in the renal sutures, and after explaining to him what I was doing, he thoughtlessly put his dirty hands on the operating-field. Whether the infection was due to this or some other cause I do not know. I do know, however, that it was only superficial, but very virulent, and showed a tendency to burrow. The operation of appendectomy and nephrorrhaphy is a practicable one.

I am indebted to Dr. Hal Moncrief for the histories of Cases 1, 3, 4 and 5.

ANTITOXIN AND INTUBATION WITH A REPORT OF 100 OPERATIONS.

BY BURT RUSSELL SHURLY, B.S., M.D.

Laryngologist to the Woman's Hospital and Foundlings Home;
Junior Attending Physician, Harper Hospital; Lecturer
on Physiology, Detroit College of Medicine.

DETROIT, MICH.

The results of progress in scientific therapeutics can be most thoroughly demonstrated in the treatment of laryngeal diphtheria. The uncertain pathology of this disease has assumed a clear and definite position under the light of modern bacteriologic research. Arguments on the nature of the causative microbe are past, and the claims of the Klebs-Loeffler bacillus are established. The question has been decided, and the presence of the Klebs-Loeffler bacillus is demonstrated in primary pseudomembranous laryngitis almost without exception.

A careful investigation of the management of diphtheria patients, and a study of the development of new cases from day to day leads to the conclusion that the great mortality can be reduced one-half by early treatment. The great importance of more care in recognizing the causes and enforcing the means of preventing diphtheria are obvious. The causes of the rise and fall in the number of cases in our city require careful scientific study. Local atmospheric conditions, prevailing winds, seasons of the year, personal hygiene, sunlight, overcrowding houses and schools, conditions of cellars, sewers, unpaved streets, drainage of vaults and ventila-

tion are among the factors. A disease which shows in this city 1009 new cases reported in 1896 with 260 deaths, a mortality of 25.76 per cent, demands the use of every prophylactic measure known to science. Municipal attention in the care and control of smallpox is immediate in the outbreak of any epidemic, but diphtheria with a mortality of 25 to 35 per cent., 90 per cent. of whom are under 9 years of age, receives but passing mention.

The general adoption of a prophylactic dose of antitoxin to every child of croup age, viz.: under 10 years, exposed to diphtheria, is the chief remedy advocated to diminish the mortality. The presence of adenoids and enlarged tonsils would especially indicate the use of this preventive measure.

Intubation and antitoxin are now recognized throughout the world as the best methods of treatment in laryngeal diphtheria. Notwithstanding the efforts of some prominent members of our profession to impair the usefulness of these two life-savers, antitoxin and intubation are here to stay. They no longer need argument in their support. It is only necessary to use them intelligently and the results will speak for themselves. We have no more exact demonstration of the interdependence of medicine and surgery than that shown by statistics of intubation without antitoxin, 70 per cent. mortality; with antitoxin, 30 per cent. mortality.

The marvelous curative influence which antitoxin has in laryngeal diphtheria is now a well-accepted fact. As a specific in primary pseudomembranous invasion of the larynx its claim is well supported. The early use of a full dose is of the greatest importance, and a more general recognition of this fact by the profession and the laity will result in a great diminution in the number of cases of secondary laryngeal invasion, at present 16 per cent., and therefore operative interference will become limited. No case of laryngeal diphtheria should receive less than 1500 units, and children over 2 years should have 2000 units, and an additional dose of 1000 units may be repeated every twelve hours according to symptoms. The more concentrated the serum, the more satisfactory for our use. It would seem that many of the unpleasant effects, such as rash, occurring in 5 to 40 per cent., pain and swelling, were increased with the additional quantity of serum injected.

The reported dangerous effects of antitoxin which made such an impression on the laity have proved to be without foundation. Fatal results are due to the disease, not the antitoxin. The fault lies usually in late administration. Serum showing evidence of general turbidity should not be used. The date of issue from the laboratory is stamped on each package and should be noted, as after six months the antitoxic value diminishes.

Additional medicinal treatment is of great value. The continuous inhalation of alkaline steam acts efficiently in softening laryngeal pseudomembrane, and intubated patients expel secretion more easily when moist and liquefied. The more adherent membranes are not so easily affected. Medicinal vapors from combined solutions of eucalyptus, oil of turpentin and carbolic acid are then more beneficial. Fluids should be given in large quantity, with the same object in view. In younger children who do not expectorate properly, a daily dose of calomel is of great importance. Calomel vaporizations are useful in septic cases, and the bichlorid given every hour in doses of 1/60 grain has many enthusiastic supporters. Iron is useless in the acute stage of the purely laryngeal form. Strychnin and alcohol are

given in all cases where a respiratory or cardiac stimulant is needed. Nasal or nasopharyngeal exudates should receive appropriate local treatment.

After the differential diagnosis is made the indications for operation are dependent on many factors which experience only can fully impress upon us. One fatal mistake in judgment in an effort to avoid too early operation will bring one to a full realization of his responsibility. The points for consideration are: 1. Stage of disease. 2. Age of child. 3. Intelligence of parents. 4. Surroundings. 5. Trained nurse. 6. Amount of antitoxin and time when administered. 7. Distance of patient from operator. 8. Amount and character of dyspnea. 9. Complications. Operation in laryngeal diphtheria should not be refused because it is too late. Many can be saved at the last hour, but the mortality rate is necessarily high. Judgment, discrimination and experience show that early surgical interference does the patient no injury. A small frequent pulse, cyanosis, aphonia, marked retraction of chest wall and epigastrium are urgent indications. Mechanical relief is so sure and painless that it seems little short of criminal to allow a child to suffer and struggle for want of it. Where the two methods of surgical interference are possible intubation should always be the primary operation.

The technique of intubation is most minutely described in our various text-books. Particular attention should be paid to the position of the child and the selection of the tube. Ill-fitting tubes injure the larynx. The operation should not be attempted without previous practice on the cadaver. If not skilfully performed the child's life is endangered, or the larynx and surrounding tissue wounded, and the operation brought into serious disrepute. It is remarkable how intubated patients recover with little or no care. Many of these little ones, among the pauper and ignorant classes where this disease thrives, will be found playing around the room on the second day, the tube still in place. Careful directions as to rest, feeding and medication were entirely unheeded.

The Casselberry method of feeding is especially useful for children under 4 years of age, and the catheter method, body horizontal, face down, is more successful with older children. In none of my cases has it been necessary to resort to lavage or nasal feeding. The former argument of difficulty in feeding can be relegated to pre-antitoxin days. Instruction by the attending physician, and the selection of a proper method for each patient is all that is necessary. In many cases practically no medication except antitoxin was given and any tendency to membrane extension was met by an additional dose of serum.

The extraction of the tube is the most difficult part of the operation, and should be performed whenever an intubated child suffers from returning dyspnea. Food or membrane may have obstructed the tube, or the tube may have been swallowed.

The prolonged use of a tube may be required. In four cases reintubation was necessary after extracting the tube at the termination of four days. An additional forty-eight hours was sufficient to permanently relieve two of these patients. The remaining two proved very interesting and illustrate some of the difficulties the operator encounters.

CASE 1.—A girl, aged 1 year and 9 months, a patient of Dr. G. H. Sherman, gave the usual history of a descending type of laryngeal diphtheria with the primary exudate on the tonsils. Dyspnea and cyanosis were

severe and intubation was performed with immediate relief. One thousand units of antitoxin were administered. The tube was removed on the fourth day, dyspnea returning in a few hours, and reinserted six hours after extraction. It was again removed two days later and dyspnea did not return until four days after the second extraction, when intubation was again urgent, a piece of membrane being loosened as the tube was inserted. One thousand five hundred units of antitoxin were given and, although the tube was coughed out twice during the next four days, on extraction the breathing was good and the patient recovered. The conclusions from this case, confirmed by later experience, show that if the tube can not be removed at the end of four days an additional 1500 units of antitoxin should be given. The retained tube was evidently necessary on account of persisting membrane, showing the original dose of 1000 units insufficient for this case. The tube was worn ten days.

CASE 2.—A girl, aged 2 years and 9 months, was seen with Dr. Rodd, Feb. 2, 1897. A glance at the child was sufficient to show that the marked cyanosis and comatose condition promised a speedily fatal termination. A three-year tube was quickly prepared and, with only a nervous woman as assistant, and no one to hold the head, an attempt was made to pass the tube, but the faulty position and large size of the tube made two efforts unsuccessful, and it was at once apparent that one more failure was certain to prove fatal. I exchanged the three-year tube for the one-year size, and at this juncture Dr. Rodd arrived. Our next effort was successful and no more inspiring or delightful sight can greet the eyes of the surgeon than this picture of returning life to the asphyxiated child. An hour later the one-year tube was coughed out, and a two-year replaced it. The case progressed favorably but reintubation was necessary on the fourth, sixth, eighth and tenth days. A loose piece of membrane was removed at one of these operations and 1000 units more given. The tube was finally removed on the seventeenth day, twelve intubations having been performed.

A case which illustrates the possibility of saving life when the patients are moribund was seen with Dr. Geo. Bassett, May 25, 1897. A boy, aged 3 years and 5 months, had been ill with diphtheria involving the tonsils, pillars and larynx for some days and no physician in attendance. On entering the room it seemed that death was a question of only a few minutes. There was no radial pulse and the child was completely comatose. It luckily happened that a three-year tube prepared for another patient was ready for use, and as the tissues were completely relaxed it was quickly passed without disturbing the position of the child on the bed, and artificial respiration resorted to. The tube gave perfect relief and the patient was sent to the hospital for treatment, 1500 units of antitoxin having been given. On the fourth day the tube was extracted, but dyspnea returning next day a second operation was performed and 1000 units administered. He coughed out the tube 2½ days later, and was discharged from the hospital fully recovered fifteen days after admission.

From a study of these cases and general observations in the treatment of diphtheria, we can formulate a series of definite conclusions and rules of procedure which apply to all cases of laryngeal diphtheria.

1. Administer antitoxin early without waiting for a bacteriologic diagnosis.
2. Tonsillar exudate attended by a croupy cough or

partial aphonia is an indication for a full dose of 1500-2000 units of antitoxin.

3. Antitoxin administered twelve hours or more prior to operative interference will reduce the mortality of intubated cases at least 50 per cent.

4. Immunize all exposed children of croup age.

5. Continuous steam inhalations are of great value in all cases.

6. Early operation is most strongly advocated.

SUMMARY OF ONE HUNDRED CASES.

Number of operations, 190; recoveries, 69; deaths, 31; mortality under 3 years, 49 per cent.; mortality over 3 years, 19 per cent.; complicating measles, 3 cases, 5 deaths.

Age of patients operated on: 1 to 2 years, 16, of whom 9 recovered, 56.25 per cent.; 2 to 3 years, 23, with 11 recoveries, 47 per cent.; 3 to 4 years, 20, of whom 16 recovered, 80 per cent.; 4 to 5 years, 15, of whom 12 recovered, 80 per cent.; 5 to 6 years, 11 cases, with 10 recoveries, 90.9 per cent.; 6 to 8 years, 10, of whom 7 recovered, 70 per cent.; 8 to 12 years, 5, of whom 4 recovered, 80 per cent.; number of doses of antitoxin, 160.

Eighty-five per cent. of the cases occurred on streets that were not paved.

USE OF OPIUM IN INFANCY, SEEN IN ADULT LIFE.*

BY T. D. CROTHERS, M.D.

SUPERINTENDENT WALNUT LODGE HOSPITAL.

HARTFORD, CONN.

The danger of opium as a remedy in infancy has only recently been recognized. Many physicians give the drug or its alkaloids without the slightest recognition of its possible injurious effects on the organism in the future. In a recent text-book, a statement is made that the action of opium is transient in infancy, and without danger except in large doses. The prominence of certain proprietary drugs, as soothing syrups for children, and the characteristic effects of opium, with the great injuries noted later, have brought out facts of the damage from these sources.

In current literature little notice is taken of this danger, and yet a great variety of facts are constantly appearing, pointing out the disease and degeneration clearly traceable to this cause. In all probability the largest use of opium in infancy comes from its domestic application. The various tinctures and infusions are household remedies and, in many sections, the gum from the poppy is gathered and put away regularly as a household necessity. It is the most convenient and practical of all remedies in the obscure disturbances of childhood. No doubt, some physicians find it very useful and often give it thoughtlessly. The drug store files show how commonly it is used in infantile therapeutics, and often it is given in a routine way for a long time, particularly for neurotic and intestinal disorders.

My purpose is to call renewed attention to this danger, and show some new facts from the clinical side, that are not uncommon and, no doubt, can be confirmed in the practice of many physicians.

In adult life, opium and its alkaloids, in a general way, are marked excitants or depressants. Either one or the other is most prominent, and both always are in the same person. This is not dependent on the doses, although that is marked in many cases. One will have a long, early stage of stimulation and wakefulness, and

*Presented to the Section on Physiology and Dietetics, at the Fifteenth Annual Meeting of the American Medical Association, held at Columbus, Ohio, June 8-9, 1899.

then depression and sleep. The other will have only slight exhilaration, and rapid marked sedation. In one case recovery from its narcotic action is followed by malaise and much physical discomfort; in the other, rest and a degree of satisfaction resembling that which follows natural sleep. The psychic effects vary: In one, most pleasing mental quietness and satisfaction follow; in the other, unusual buoyancy followed by total oblivion and discomfort and recovery. In the former, the mind falsely reasons that some new, exalted mental condition has been attained, most desirable for the future. In the latter, the discomfort from reaction calls for relief in the removal of the drug. Both classes soon have a reactionary period of discomfort and nerve disturbance. These are general states to which there are almost infinite exceptions and variations. While the sedation from opium falls most markedly on the sensory centers, and nerves of sensation, its localized action on the psychic and organic functions varies widely. In one case profound alterations of the functions appear, and rapidly extend to the mental operations. The organism, after a period of sharp irritation, apparent in nausea and deranged digestion, seems to take on a certain immunity and toleration, or the organism appropriates opium as it does food, and a demand for its continuous use becomes more and more imperative. This is the state of the habitués, and is the result of a long use of it, or appears in some cases at the beginning of its use. It is evident that some unknown states of the organism are more susceptible to its physiologic action than others. It is a common observation that coarse, low organic natures, or imperfectly developed minds and bodies are less susceptible to the sedative effects of opium than high-grade, finely developed, nervous persons. In practice, opium as a medicine varies in its effects very largely from these conditions—the finer the organism, the more pronounced the effects and the smaller the dose required; the coarser the organism, other things being equal, the larger the dose to get its physiologic action. These general facts, with others, are the same in infancy as in adults, only less observed. The child who is given laudanum for some condition, and appears better, has had the pain distress-signals covered up, and at what sacrifice, or organic changes which follow, no one can tell. At all events, the same exhilaration and depression occur as seen in the adult. The former may not be noticed and the latter only seen, but the same conditions follow. In the infant the small power of resistance and the extreme susceptibility to physiologic influence from narcotics is not overcome by dosage. The physiologic action of $\frac{1}{2}$ gr. of opium on an adult, and in $1/40$ gr. on an infant is the same in degree, only in one case there is little or no resisting power. The infant has an unknown and undeveloped organism. The adult is, in some degree, known, and certain physiologic effects may be confidently expected. It is not a single dose or several doses given for certain disorders, although this is often marked in many ways, but it is the long-continued use that is followed by certain degenerations.

Opium given in convulsions, with other drugs, and in intestinal troubles, and for insomnia, nervous irritation and unknown conditions, with apparent good results in temporary relief, is dangerous if continued any length of time.

Opium and its alkaloids seem to have two distinct effects on the nerve-centers and organism of infancy. Its sedative action is of the nature of palsy. Cell functions and growths are slowed up, retarded and finally changed. The changes following long-continued doses

become permanent. The symptoms of dulness and stupor continue in lessened vigor and degrees of imbecility and mental perversion in later life. The freedom from pain and forced sleep with apparent steadiness of nerve force react in increased irritation and instability, with greater sensitiveness to all surroundings.

Nearly all persons who have been injured in infancy and early childhood from these drugs manifest these two characteristics. Increased dulness and stupor, or nervous irritation and instability, often both, may be combined in one. Beyond these are disorders of the nervous system and digestion, with low power of control and subject to morbid impulses that are largely uncontrollable. These various manifestations are better studied in the history of cases, the following of which are illustrations.

In a family of four children, whose parents were strong, healthy persons, living on a farm, one, a boy, was dull, passionate and of a low grade of intellect. He would overeat and drink to excess, water, tea, coffee, or anything he fancied. He was stupid and obstinate, and at times, excessively sensitive and irritable. No one in the family resembled him in any way, but all were healthy and vigorous in mind and body. When 1 year old he had a convulsion and was given opium daily for over a year. Then at long intervals, finally, it was abandoned, and it has not been used since. The parents noticed it was affecting him at the time, changing his mind and habits, and would not permit its use again. This was clearly an example of retarded brain growth with perversion of the functions, and later it will, no doubt, develop into some drug addiction or low form of dementia, disease and death. The history pointed to its use as the most prominent cause of this condition.

In a similarly healthy family, one son became an impulsive inebriate at 18 years of age. The others in the same surroundings and conditions of living are very temperate and well. During the infancy of this boy he was given morphia for intestinal disturbances. At one time it was taken for nearly a year, by advice of the physician. He was stupid and dull much of the time this was taken, and its use was continued as a medicine for years, at long intervals, and in one or two doses a day. He began to use spirits to excess soon after puberty, and is now a periodic inebriate. The clinical study indicated a degree of mental and physical perversion and degeneration, dating from the use of morphia in infancy. A case which came under my observation was that of two children of a distinguished missionary, one, a young woman, who at 24 years of age suddenly began to use opium and spirits to excess and showed much mental disturbance. During infancy she was nursed by a Hindoo woman, and was noted for her stupor and tendency to sleep. In early and later childhood she was extremely nervous and suffered from many hysterical affections. She was an accomplished teacher and a woman of great pride of character and ambition. Her brother, born two years later, was nursed by the same woman, and was noted for his somnolence and general stupor during this time. Later it was found that the nurse was an opium-taker, and that both children had been under the influence of opium from nursing. The boy grew up extremely nervous and irritable. At one time he drank beer to excess, then was a gambler. He was changeable and notional, became a clergyman; then a physician, and finally a speculator. He is now an opium-taker and neurasthenic, and invalid, although not 30 years of age. Two other children of this family, one born before this Hindoo woman became a nurse, and the other after she was discharged, are strong and healthy

and free from any peculiarities of mind or body. The elimination of all other cases leaves the poison of opium the specific central factor in these cases. In my studies of the heredity of all alcoholic and opium inebriety, about 10 per cent. give some history of drugging in infancy. Paregoric and laudanum are the most common. Narcotism from opium by accident has been followed by defects which finally culminated in drug or spirit-taking. A boy, 2 years old, ate a large number of opium and candy lozenges and was narcotized for two days, and with difficulty prevented from dying. He grew up an erratic, unstable, and feeble child. Digestion was impaired and sleep broken, and finally, at 21, he became a spirit-taker and inebriate. Two brothers were healthy and strong. This was probably the result of narcotism. In cases of defective parentage, where nervous degeneration and unsoundness exist, the use of opium in infancy will intensify these states, and make them more pronounced. In children from drug-poisoned families, such as inebriates or those who, from nutritional disorders are suffering from autointoxication, opium may prove a most seductive drug for a time, but in the end be followed by more serious evils. Children of brain-exhausted, worn-out parents are often found to enjoy the effects of opium, and receive great apparent benefits from its use. Later they easily become drug-takers, and are the most incurable. Neurotic infants and children are, no doubt, very susceptible to these drugs, and the physiologic impression is so pronounced as to suggest organic changes.

A few instances are on record of hydrocephalus following the use of opium in children, suggesting serum in the ventricles, ending usually in exhaustion, coma and death. Many parents manifest an unreasoning therapeutic credulity in drugs in infancy, which physicians cultivate and sometimes heartily believe in. In such a case a very strong medical man continued an opium prescription for over a year, and the child grew up feeble-minded and is now an invalid. The next child in the same family is a hearty, vigorous man. He was not treated for any length of time during childhood by drugs. The use of laudanum in infancy was traceable in ten cases of epilepsy associated with spirit drinking and petty criminality. As these patients came from the lower classes and had a defective heredity, the influence of opium could not be separated as a specific cause. Undoubtedly, it was a large contributing one. I have gathered many histories which seem to confirm the impression that opium-taking in infancy and childhood is often an exciting cause of a latent hereditary predisposition to the drink mania. At all events, a large proportion of such persons seek relief from alcohol in the physical strain and stress of life, then take opium when the effects of alcohol become prominent.

Opium and its alkaloids, given to healthy children occasionally for some special purpose, are in all probability without injurious effects. In unhealthy, neurotic children, with defective ancestors, and evident imperfect development, the increased degeneration which follows the use of opium is clearly from this source. Where this drug is combined with other remedies, and given a long time, the effects are the same. They can not be lessened by the action of other drugs. No form of opium should be given to infants or children for more than a day at a time. While the effects of continuous sedation may be overcome by correct living, the cell injury and perversion of function is never repaired. The growth and development of other organs may do much to overcome in part, and cover up the injury, but the defects will appear from

the presence of the slightest exciting cause. The following case has recently come to my notice.

Five children of healthy parents became inebriates, both alcoholic and opium, when about 20 years of age. There was no heredity nor any special exciting causes. The home life and example were good, and both parents were total abstainers. Each one seemed to be nervous and feeble, and lacking in vigor, then without any reason began to use alcohol and opium freely, and finally were addicted to its constant use. It was found that from early infancy and through childhood they had been given laudanum and other forms of opium, for all sorts of ills. The mother had treated them without the aid of a doctor, and opium was used continuously for several months at a time. They all suffered from nutritional and digestive disorders, and were all nervous insomniacs and irritable and dull at times. This domestic treatment was, no doubt, the cause of the degeneration and neurosis in manhood. Three of these persons are decidedly feeble-minded. One is a talented musician, the other an actor of some ability. Two use spirits alone; two use alcohol and opium; one uses opium alone. They are of the imbecile grade of inebriates.

Another case reported to me was that of a very highly cultivated woman who, at 34, began to use morphia without any apparent cause in pain or sickness. She was a philanthropist and on the visiting board of a hospital where such cases were treated, and was acquainted with the dangers of the use of the drug. All the possible causes were eliminated in the study and the remarkable fact appeared that opium was used very freely in the first two years of her life. It was with difficulty removed and she was feeble and very nervous until after puberty, when she became strong. Her own statement was that she found such peace and comfort from its effects that she could not abstain from it.

Several persons using alcohol have given, as a reason for this addiction, the fear of becoming opium-inebriates. They have found opium so seductive and pleasing as to be irresistible; with alcohol they felt safe. Opium-taking in infancy is the common history of many cases, and is generally the domestic use of laudanum at first, for disorders of mind and body.

The presence of nervous dyspepsia, which begins soon after puberty and by early or middle manhood becomes a most distressing disease, is often traceable to the free use of opium in infancy and early life. Early and profound exhaustion from slight overwork or excitement, seen in young persons, indicating low vitality and feeble nervous organism, is the result of opium-taking early in life. Early precocity or failure to sustain the expectations created have been noted in the cases of early addiction. The many constitutional defects and degeneracies which appear after puberty and in early manhood should always create an inquiry concerning the early therapeutics and drugs given in childhood. Where soothing syrups and prescriptions for seductive effects have been used a long time, the suspicion is strong that an opium diathesis has been created. I wish to emphasize that the use of opium and its alkaloids in infancy will, in a large proportion of cases, create a diathesis or predisposition to its use in later life. This predisposition is manifest in irritation and exhaustion, with intense, uncontrollable impulses for relief.

Alcohol, chloroform, chloral and many of the most common narcotics are welcomed and largely used to supply this demand. This opium degeneration may take on sexual and nutrient manias and leave the brain in an infantile condition of vigor and stability. A "Christian

Scientist" who has made some reputation by his delirious theories, was, according to a Boston physician, brought up on opium. His mother was a narcotic, and to protect herself, gave her son opium freely in early life. He grew up undersized, and with a highly sensitive brain, full of delusive dreams and fantasies. This was another form of opium diathesis.

The second fact that I would note is that opium in infancy acting on the most unstable organism, the brain cells and centers, not only retards but prevents healthy physiologic growth. In defective heredity this is permanent, although it may be concealed until later in life. This physiologic action of exaltation and depression, the latter being the principal stage, is manifestly toxic and injurious from the functional derangement which follows. Where no disturbance is recognized, the real danger is concealed. The cell growth and functions suffer, mechanically, nutritionally and psychically, by checking activity, diminishing nutrition and changing direction and purpose of action. This is true of opium in all cases. Sometimes one effect is more prominent than others. In DeQuincy the psychic action was prominent. In some cases the anemia shows in the disturbance of nutrition, and in others the depression and suppression of organic activity is apparent.

The third fact to be remembered is the concealed danger from opium-drugging in infancy. If only neurosis is present, if defects of growth and function exist, opium will of necessity increase this condition. Anemia, exhaustion and perversion of organic activity follow. If some temporary state is present, opium, by covering up the pain-signal is not curative, but may be destructive in many ways not easily recognized until later in life. No one can tell whether this danger begins with the first dose or only after a succession of doses.

Lastly, the magnitude of this danger is not recognized as it will be in the future. Neurotic disturbances, obscure and open, and toxic diseases of many forms, have an early history of opium drugging. The ignorant mother who uses soothing syrups freely, to suppress the irritation of the infant, is not the only offender. The routine, and often thoughtless, physician who uses opium freely in infantile prescriptions is responsible in many ways for the wrecks of later life. The toxic cases under my care are striking illustrations of this evil. Inquiry in others brings out this cause with great frequency. While it is difficult to narrow down the etiology to this one factor, it is clear that the danger from this source has been and is a potent and wide-spread cause. We need more clinical researches and clinical studies in this direction.

THE BUBONIC PLAGUE IN SAN FRANCISCO.*

BY W. H. KELLOGG, M.D.
CITY BACTERIOLOGIST.
SAN FRANCISCO, CAL.

We have always regarded the plague as something very distant and impossible, and have read of its ravages in India and China with much the same feeling of composure and security that we read about an uprising of the natives in Madagascar. Or perhaps we have considered it as a matter of historic interest on account of the fearful epidemics which in pre-sanitary days used to sweep over Europe, devastating countries and hardly leaving enough people behind to keep up the archives and records of the state. Even now that it is among us, and in America for the first time, there seems to be a

tendency to underrate its importance and dismiss it without a thought, as a scare designed for base political motives.

While I do not believe in becoming unduly excited about it, or in publishing far and wide that there is plague in San Francisco, I do not think that we should try to deny among ourselves the very existence of it, but should accept the situation as it is and do our best to stamp it out while it is still within our power. It would be folly to ignore its presence and allow it to increase to such an extent that the national government would be compelled to step in and take from our hands the work of fighting it and perhaps quarantine the whole city with U. S. troops, thus advertising to the world that San Francisco was not only financially negligent in the face of an epidemic of a disease which is guarded against by the U. S. Marine-Hospital Service with more watchfulness and dread than any other.

San Francisco should look at the history of Oporto, and profit by her experience. The bacteriologist who announced the first case, in January, 1899, narrowly escaped being mobbed. The health authorities were hampered by the merchants and the press, who harped on the injury to trade caused by the announcement of the existence of plague which the laymen, in their infinite wisdom, declared did not exist. The health authorities were refused assistance until finally so many cases appeared that the government stepped in, surrounded the city with a cordon of soldiers, absolutely stopping all travel and business, and it was only after the lapse of one year, and after the experience of a partial famine, that the city was released and declared no longer infected. In the meantime its citizens had parted with the small sum of \$7,000,000, a good deal of money, but the probability is that by that time, even the omnipotent and scientifically wise press had arrived at the conclusion that their lives were more valuable than their business.

Just how the disease was introduced into this country is a mystery, as the first case discovered was in a Chinaman who had been in Chinatown sixteen years. The probability is that he was not the first, and this theory is strengthened by the fact that there had been an increased mortality in that district during the months of January and February. During those months there were 97 deaths reported from the Mongolian quarter, and of these 20 were ascribed to lobar pneumonia, 5 to bronchopneumonia, 4 to typhoid fever, and 7 to acute miliary tuberculosis. Now all of these diseases, in the beginning of an epidemic of plague, should be regarded with suspicion, and examined bacteriologically, for they are simulated very closely by the pest.

The assistant city physician, whose duty it is to inspect all dead Chinese who have died without attendance by a regular physician, is at a great disadvantage in arriving at the cause of death. He simply sees the body after death, and by questioning the relatives or undertaker, who are ignorant and use very broken English, he makes a guess at the cause of death, taking into account the appearance of the body. According to the Caucasian statistics of San Francisco, the number of deaths from pneumonia, typhoid, and miliary tuberculosis, to every 97 deaths, would be 12.3, whereas the assistant city physician, with the means at his command, has been forced to consider that there were 36 of these cases out of a total of 97 deaths for the two months. Since the plague can readily be mistaken for these diseases, we are justified in the suspicion that some of these cases were plague. Nor is the fact that we have not now a wide-

*Read before the San Francisco County Medical Society.

spread epidemic proof to the contrary, for it has been the history in other parts of the world that the plague gets a foothold very slowly and insidiously. There is a first case, and then it may be a couple of weeks before the second, and they may appear occasionally and at intervals of several days or weeks, until the houses and the quarter become infected, and then the real epidemic breaks out, and hundreds of cases occur. I will commence the account of the recent occurrences by history of the first case as supplied by the Chinese Consul. We have found that the only way we can get histories of these cases is by turning them over to the police department, and by means known to the detectives they find out a few items.

CASE 1.—Wing Chuc Ging, aged 41, in Chinatown sixteen years, died March 6, 1900, in the basement of 1001 Dupont Street. He worked in a woodyard on Pacific Street, and stated to Wing Ging, his brother, that he had been sick for six months. On February 7 he called at the office of Dr. Chung Bu Bing, 309 Dupont Street, complaining of headache, tired feeling, pain in the head, back and chest and fever. The symptoms and pain in urinating had been present in the bladder for two or three days. A diagnosis of inflammation of the bladder was made and medicine given for this. On February 14, the patient consulted Dr. Wong Wo, 766 Clay Street, and told him he had contracted gonorrhoea. He had no fever and no pain except in the genitals, complained of a lump in the right groin and was somewhat lame on that side. He also stated that he had a urethral discharge, but would not allow a special examination. He was given some medicine to relieve the difficult and painful urination, and a plaster to apply to the lump. No surgery was instituted and no further medical treatment. He was in bed two weeks, but would not tell his brother of his trouble. A few days before he took some Chinese medicine which he obtained from Dr. Wong Wo. This caused vomiting, profuse diarrhoea, and collapse, followed by death.

From the history this was evidently an ambulant case, in which an exacerbation occurred, marked by the vomiting, diarrhoea, and collapse ending in death. I saw this patient with Dr. Wilson, in the basement of the Globe Hotel, on March 6. I observed that there was a swelling of the inguinal lymphatic glands on the right side. There was no suppuration and the skin was unbroken. The glands about the saphenous opening were enlarged, and in this situation there was an open sore, which was dried and partially healed over. As a mere matter of routine I removed some of the glandular tissue, not expecting to find anything in it. No autopsy was performed. Smear preparations from the interior of the gland showed large numbers of a small short bacillus resembling the bacillus of bubonic plague. Isolation of the organism was commenced by culture methods. The next day a rat, guinea-pig and monkey were inoculated with an emulsion made from the gland removed from the Chinaman. The following is the account of the results obtained:

(The municipal laboratory being short of animals, and short of funds, and as it was deemed unsafe to conduct experiments with plague inside the city limits, the invitation of Dr. Kinyoun to use his laboratory was accepted and the inoculation experiments detailed below were performed in the Government Laboratory at Angel Island, by Dr. Kinyoun of the U. S. Marine-Hospital Service, assisted by Dr. Agnes Walker and myself.)

March 7, 1900, 2 guinea-pigs—each 700 grams—1 half-grown white rat, and 1 monkey, were inoculated with an emulsion made from a piece of glandular tissue removed from the body of Wing Chuc Ging on March 6, 1900. The animals were

placed in appropriate cages, protected in the usual manner. Cover-slip preparations were made from the glandular tissue, in which were found a number of micro-organisms, suspiciously like the bacillus of plague both as to their morphology and staining. Cultures were made from a portion of the tissue. March 8, the animals were in good health. March 9 and 10, there was no change and the animals ate well. March 11, one guinea-pig was found dead at 8:30 A.M., the other quite sick, the white rat dying, the monkey dull, listless, and would not eat; at 11 a.m., both the rat and sick guinea-pig were dead.

Post-mortem examination of guinea-pig No. 1.—On section there was an extensive edematous area on the left side extending from the axilla to the groin, the center of which contained a large quantity of exudate. The tissues about the site of inoculation were necrosed. The inguinal glands were considerably enlarged and reddened. Cover-slip preparations made from the exudate, at the point of inoculation, showed almost a pure culture of a short bacillus with a tendency to bipolar staining. The groupings of these organisms was quite characteristic. The peritoneal cavity contained a small quantity of bloody serum. The spleen was enormously enlarged, fully three times its normal size; the surface was very much reddened and covered with small yellowish dots; the spleen was also very friable. Cover-slip preparations made from the spleen showed an enormous number of a short diplobacillus, quite rounded, with a marked tendency to bipolar staining. The liver was enlarged and contained several yellow spots similar to those observed on the spleen. The mesenteric glands were not appreciably enlarged. The pericardium contained a considerable quantity of pale, straw-colored serum. The heart's blood was fluid and contained large numbers of the same organism as that found in the spleen, and at the point of inoculation. The lungs showed no evidence of change. The pleura contained about 3 c.c. of bloody serum. Cultivations on agar and in bouillon tubes were made from the spleen and heart's blood.

Post-mortem examination of guinea-pig No. 2.—The body was well nourished. On section the whole left side of the abdominal wall was in a state of coagulation necrosis, more intense at the point of inoculation, and extending from the axilla to the groin. The axillary and inguinal glands were much enlarged and reddened. A small hemorrhage was noticed in the inguinal region. The peritoneal cavity contained a small quantity of bloody serum. The spleen was very much enlarged, fully as much as that observed in guinea-pig No. 1; it, however, did not contain the yellow spots. The liver was engorged and contained several yellow spots on its anterior surface. Cover-slip preparations made from the spleen showed the same short bacillus, with rounded ends, presenting the same poles as those found in the first pig. The pericardium contained a considerable quantity of bloody serum. The heart's blood was fluid, and contained great numbers of the same short bacillus, which took the characteristic stain. The lungs were to all appearances normal. The pleural cavity contained a small quantity of bloody serum. A cultivation on sugar and in bouillon was made from the spleen and heart's blood.

Post-mortem examination of white rat.—Dead about two hours. At the point of inoculation there was a small area of coagulation necrosis, surrounded by a considerable area of edema. The peritoneal cavity was dry. The spleen was enlarged to about four times its natural size, very dark in color, and friable. Cover-slip preparations made of splenic pulp and stained with aniline colors, particularly thionin, demonstrated enormous numbers of a short bacillus with rounded ends, staining more deeply at the poles. The heart's blood contained the same organism in large numbers.

Post-mortem examination of monkey (March 13).—It had been dead about six or eight hours, having been inoculated on March 7, with an emulsion made from a piece of glandular tissue removed from the groin of the dead Chinaman, and having died on the morning of the 13th, after showing signs of illness for two days. At the point of inoculation, which was in the left breast, there was considerable coagulation necrosis. Subcutaneous edema was well marked, especially on the left side over the abdomen. The axillary lymphatic glands on the left

side were enormously enlarged, forming a mass as large as a walnut. There was no enlargement on the opposite side. On section the gland showed congestion and hemorrhages into the gland substance. Cover-slip preparations were made from the interior of the gland and stained with thionin. They showed the presence, in large numbers, of a short coccobacillus, with rounded ends, staining more deeply at the poles. The spleen was greatly enlarged, dark and friable and contained the same organism in enormous numbers. The pericardium contained a considerable amount of turbid fluid. The heart's blood was fluid and contained great numbers of the organism described above. The lungs showed the presence of a well marked pneumonia.

The organism which was present in pure culture in the lymphatic gland of the Chinaman and which was the cause of death of these animals I have obtained in pure culture from all these sources, first from the gland of the Chinaman, and from the heart's blood and spleen of the inoculated animals. I found that it had the following characteristics and have compared it with a culture from Bombay isolated by Pozzi.

Bacillus Pestis, San Francisco.—A small, short, thick bacillus, with rounded ends, frequently occurring in pairs, and in agar and bouillon cultures in short chains. They are non-motile and no spore formation was observed. Colonies on agar plates, in seventy-two hours at 35 C., were .5 to 1 mm. in diameter, round, semitranslucent, with a bluish or opalescent tinge. The surface is rounded, smooth and moist looking, and the consistency in older cultures tough and stringy. The bacillus was a facultative anaerobe and did not liquify gelatin, and was pathogenic to white rats. It stains readily with the aniline dyes, frequently taking the stain more deeply at the ends, the so-called pole staining. This peculiarity was more marked with the carbol fuchsin, but thionin seemed to give the most satisfactory results. In old cultures there were many swollen and rounded forms, which showed the bipolar staining in an exaggerated manner, causing them to almost have the appearance of little circles and crescents. It deodorized by Gram's method. Bouillon was not clouded, and a film formed on the surface, and settled downward in a fine cloud when the tube was jarred. Bouillon cultures answered to Widal's test with Yersin's serum in a most typical and satisfactory manner.

In addition to the above-described case, I have assisted Dr. Wilson in the post-mortem examination of three other Chinese, two of whom I feel positive were plague cases, but I have been unable to prove this for the following reasons:

The cases were in such an advanced state of decomposition when I saw them that there were many organisms present in the blood and organs in addition to one which resembled the bacillus pestis. The animals which were inoculated from the tissues of these cases all died, but of a mixed infection. I succeeded in obtaining a tube of nearly a pure culture of what was morphologically the bacillus pestis from Case 3, and a rat was given the entire tube at one dose, with the result that it died in thirty-six hours. The post-mortem did not show sufficient bacilli in the organs to clinch the diagnosis of plague. My theory is that there were enough toxins present in the culture to kill the rat before the organism had time to multiply in its body. A guinea-pig was inoculated from this rat, but it died of pneumococcus infection, the plague organism having totally disappeared in the passage through the bodies of the two animals. As I have no more material nor cultures from this case I will never be able to prove it was plague, by inoculation experiments, although the post-mortem appearances and the presence of the organism in the blood would ordinarily be considered sufficient evidence. The results obtained in the other two cases were practically the same as in the one just described.

I am of the opinion that the thorough disinfection and cleaning up of the Mongolian quarter, which the San Francisco Board of Health has been carrying out with considerable vigor, has been of invaluable service in checking the spread of the disease before it had fairly gained a foothold. Vigilance should not yet be relaxed in the least, for it would not be surprising if other cases were discovered in the near future. In such event the measures taken will have to be most radical, for the re-appearance of the pest will be evidence that a focus of infection has been established which nothing short of fire will obliterate.

VESICORECTAL ANASTOMOSIS.

WITH SPECIAL REFERENCE TO THE TREATMENT OF EX-STROPHY OF THE BLADDER.

BY JACOB FRANK, M.D.

Surgeon to the German Hospital; Consulting Surgeon to the St. Elizabeth Hospital; Jewish Orphan Home and Home for Aged Jews, Chicago; Corresponding Member of the Sociedad Médica "Pedro Escobedo"; Member of the Pan-American Congress, International Medical Congress, AMERICAN MEDICAL ASSOCIATION, etc. CHICAGO.

(Concluded from page 1178).

EXPERIMENT 4.—A male pug cur, weight 22 pounds, was operated on May 6, 1899, and killed May 21. At the post-mortem the abdominal incision was found firmly united. The omentum was partly adherent around the site of the anastomosis. The bladder was empty and greatly contracted. On opening the bladder no appreciable changes were noticed, and the opening between the bladder and rectum admitted the tip of a finger. The rectal mucosa below and a slight distance above the fistulous opening was reddened, probably by the urine. Both kidneys looked bluish, not enlarged, nor thickened; the capsule stripped easily and was not thickened. On cut section the pelvis was found undilated, perfectly smooth and to all appearances normal. The proportion of cortex to medulla was normal. All other organs were found to be perfectly healthy.

Bacteriologic Examination.—A blood-serum and a glycerin-agar tube were inoculated from the pelvis of each kidney. Of these four culture-media, three remained permanently sterile. One blood-serum tube on the third day showed a moist, shiny, whitish growth which liquefied the culture-soil. The growth consisted of very small bacilli, the character of which was not studied any further. They were not colon bacilli, and their appearance was probably due to contamination. At the site where the anastomosis was made the tissue appeared perfectly smooth and normal. No redness nor swelling was noticeable to the naked eye. Microscopic sections made from this part included both the bladder and rectum.

Microscopic Examination. (Figs. 5 and 6.)—In the rectum the following conditions were noted: The intestinal and bladder walls were completely united, and blended in such a manner that the two tissues formed an acute angle of about 80 degrees, which projected into the bladder. The intestinal surface was lined by mucous membrane, the bladder surface by stratified epithelium. Both these tissues presented a normal appearance. They did not come completely together. On one side the intestinal mucous membrane was thinned out; on the other, layers of epithelial cells lining the bladder were gradually reduced to a single layer. It appeared as if from here the epithelial cells were in the act of growing over to reach the rectal mucous membrane, although a small strip of tissue had not yet been covered by epithelial cells. Here connective tissue laid free to the surface. This tissue consisted of cells of an embryonal type and of fibroblasts. The union between the bladder and rectal walls was complete throughout its entire thickness. One could not distinguish—at the line of the union—what was originally bladder and what was intestinal tissue. The mucous membrane of the rectum, and the epithelial lining of the bladder entirely disappeared at the line of

union. Still, one could see the lymphoid tissue of the rectum at the site of the union, although the lymph follicles varied from the normal in that they showed a diffuse infiltration of polymorphonuclear leucocytes. So numerous were the latter that they predominated over the cells of a lymphoid character.

Fig. 5.—From dog No. 4, operated on May 6, 1899; killed May 21, 1899. Section of anastomosis (high magnification). The line of union is to the right, it is not seen in the photomicrograph. The latter shows the vesical epithelium; in it a cell with a karyokinetic figure, indicating a regeneration of the epithelium.

Gram's stain showed, in the tissues of the anastomosis around the line of union, short bacilli with rounded ends, which had kept the stain poorly. These micro-organisms were probably colon bacilli. The examination of the kidney tissue—cortex, medulla and pelvis—showed normal conditions, with no evidence of inflammation or degeneration.

EXPERIMENT 5.—A male dog, weight 30 pounds, was operated on May 11, 1899, killed May 12, and the bladder and rectum removed *en masse*, both ends of the latter tied, as well as the urethra, and water injected into the rectum by means of a syringe. The parts were distended to their maximum without any leakage. The bladder showed a slight redness, although the rectum did not.

EXPERIMENT 6.—A small bitch fox-terrier, weight 15 pounds, operated on May 11, 1899, was killed May 12. The same conditions prevailed as in Experiment 5.

EXPERIMENT 7.—A male black and tan cur, weight 14 pounds, operated on May 16, 1899, died May 20. The post-mortem did not reveal the exact cause of death. The external wound was in good condition, with no peritonitis, and no fluid in the peritoneal cavity. The bladder was empty and contracted and, on opening, showed signs of inflammation. The coupler was still in place and softened. Both kidneys were of the same size and not enlarged, but slightly congested. All other organs were normal except the liver, which was very much congested.

EXPERIMENT 8.—A large Dane bitch, weight 65 pounds, operated on May 18, 1899, died May 21. The autopsy showed the abdominal cavity to be full of a serohemorrhagic effusion which escaped in large quantities. The omentum was engorged with dark blood, and adherent to the abdominal wall at the site of the operative incision as well as to the place of the anastomosis. Peritonitis was absent and all the internal organs, including the bladder, kidney and ureters, were normal.

The macroscopic condition of these does not point to a cause of death in consequence of the operation. The dog had an enlarged thyroid gland, with more or less detached masses growing into the mediastinum, which proved to be a struma colloidea, on microscopic examination. No further microscopic or bacteriologic examinations were made.

EXPERIMENT 9.—A male spaniel, weight 25 pounds, operated on May 21, 1899, died June 9. Several days after the operation a paraphimosis and gangrene of the penis developed. On opening the abdominal cavity, it was found to be empty, with no signs of peritonitis, which was also true of the pelvic cavity. The bladder was contracted and the internal surface somewhat dark red in color. The anastomosis was firm and admitted the tip of the index finger. The bladder surface and rectal mucous membrane about the anastomosis appeared normal. The kidneys were slightly swollen and pale, and the capsules stripped easily. The relation of the cortex to the medulla was normal, and the cortical markings distinct. The pelvis were normal, not enlarged and the mucous membrane smooth. They contained no fluid. The ureters were normal and not dilated. All the internal organs were normal excepting the spleen, which was soft and of a dark color.

Microscopic Examination.—Pieces were taken, for microscopic examination, from the cortex and medulla of both kidneys. The latter pieces included the mucous membrane of the pelvis. The tissue of both kidneys was found to be normal and free from inflammatory and degenerative changes except as to one point. In the medullary portion of the right kidney, near the pelvis, two small foci of round-cell infiltration were found. The infiltrating cells consisted of lymphocytes and polymorphonuclear leucocytes. Bacteria could not be demonstrated in these two small inflammatory areas. The possibility that these foci were due to micro-organisms having migrated from the rectum through the ureters into the kidney can probably be excluded. The round-cell infiltration probably owed its origin to hematogenous influences, possibly from some toxins circulating in the blood.

From the results of the post-mortem and the microscopic examinations, it appears that the death of the dog was not due directly or indirectly to the operation, nor was anything found that pointed to an infection of the kidneys from the intestines.

EXPERIMENT 10.—A male fox-terrier pup, operated on May 27, 1899, died May 29. The autopsy revealed the fact that the dog died of a general peritonitis. The abdomen was full of a sanguinous fluid and the omentum engorged with blood. The

Fig. 6.—Dog No. 4, operated on May 6, 1899; killed May 21, 1899. Section of anastomosis (low magnification). The line of anastomosis is shown in the middle of the field, running from above downward. To the left is the vesical, to the right the intestinal tissue.

bladder was contracted and empty, and the mucous membrane, on cut section, showed signs of inflammation. The site of anastomosis was firm and showed no leakage. The coupler was still in place and retained its shape. The right kidney was slightly congested, but not enlarged. The capsule stripped easily and the cortical markings were not well defined. The pelvis contained no fluid and the ureters were not enlarged. A similar condition was found on the left side. There was no microscopic nor bacteriologic examination made.

EXPERIMENT 11.—A large black, male Gordon cur, weight 85 pounds, was operated on May 30, 1899, and killed June 5. The post-mortem showed the external wound suppurating and the abdomen empty. The bladder was contracted and thickened and the mucous membrane of both bladder and rectum appeared reddened on cut section. The site of anastomosis was firmly united and, on distending the bladder and rectum with water, no leakage occurred. Both the kidneys and ureters appeared normal, with the exception that the vessels of the capsule were slightly congested. No further examination was made.

Fig. 7.—Dog No. 13, operated on June 1, 1899; killed June 28, 1899. Section of anastomosis (high magnification). On the left of the field the vesical tissue, on the right side the intestinal mucosa. The columnar epithelium of the intestinal mucosa has grown toward the vesical side and lines to some extent the vesical surface.

EXPERIMENT 12.—A male dog, weight 30 pounds, operated on June 1, 1899, was found dead June 3. A post-mortem revealed the abdomen empty, with an absence of peritonitis and the omentum adherent to the line of operative incision. The bladder was thickened, well-contracted and showed signs of inflammation, but it did not extend below the sphincter vesicæ. The mucous membrane was swollen and reddish-brown in color. Under hydraulic pressure there was no leakage at the site of anastomosis. The coupler was still hard and in place. The kidneys were of normal size, but bluish in color, and on stripping off the capsule the surface vessels were found enlarged. On cut section the cortex, as well as the medulla, was of a dark reddish-brown color with the cortical markings ill-defined and the pelvis smooth and containing no fluid. The ureters were to all appearances normal. All the other organs were normal excepting the liver, which was greatly congested. A further examination was not conducted.

EXPERIMENT 13.—A bitch, weight 40 pounds, operated on June 1, 1899, was killed June 28. The animal was well nourished, in perfect health, very playful and lively, and killed by chloroform narcosis. Externally the abdomen presented, in the median line, beginning about an inch above the symphysis pubis and extending upward for a distance of about $2\frac{1}{2}$ inches, a healed, smooth, linear cicatrix. On opening the abdomen by a long median incision, the large omentum was found very slightly adherent to the internal surface of the abdominal parieties at the site of the cicatrix. The extent of these adhesions was very small. The omentum showed no signs of inflammation. The abdominal and pelvic cavities did not contain any fluid. The peritoneum was smooth and shining, and showed no redness nor evidence of inflammation. The bladder was well contracted, firmly united to the rectum, and the place of union everywhere covered by an uninterrupted coat of smooth peritoneum. An inspection of the intestines showed them to be normal.

The kidneys were of normal size and appearance, but, like all the internal organs, were congested in consequence of the death by chloroform. The cortex and medulla showed

normal relation and appearance. The pelvis did not contain any appreciable amount of fluid. The mucous membrane of the pelvis was smooth and pale, and presented no signs of inflammation. The ureters were not enlarged. The internal surface of the bladder, which contained some fecal matter, was thrown into rugæ. In color, this organ was pale pink, and showed no inflammatory changes microscopically. The anastomosis was firm, and admitted the tip of the index finger. The anterior aspect of the ring was lined by bladder tissue, the posterior by rectal mucous membrane, which appeared perfectly normal. Where the tissues from the bladder and the rectum met there was a slight depression which ran along the whole opening. The rectal mucous membrane in the neighborhood of the anastomosis appeared normal. All internal organs, such as the spleen, liver, lungs, heart, etc., were normal.

Anastomosis (Figs. 7 and 8).—The union between the wall of the rectum and that of the bladder was perfect. There was no doubling up of either intestinal or vesical tissue, and the line of union contained very little newly-formed connective—cicatricial—tissue. No evidence of inflammation was found in the line of union. The rectum presented a normal histologic appearance. The internal surface of the bladder, however, showed some marked changes. The lining epithelium at and near the point of union was missing, and the tissue forming the surface had the character of granulation tissue. It consisted of a vascular tissue formed of round cells imbedded in a matrix of fusiform cells and connective-tissue fibers. It appeared, therefore, that the presence of the fecal matter with its numerous bacteria had set up an inflammatory reaction on the internal surface of the bladder. Bacteria, however, were not found in the granulation tissue, nor in the tissue forming the line of union between the bladder and rectum. The following very interesting observation was made at the line of union: In some places the columnar epithelium of the rectal mucous membrane had grown from the rectal tissue over the bladder surface. This covering of the bladder surface by intestinal epithelium was not yet very extensive, but there undoubtedly existed a marked tendency of the intestinal epithelium to grow by extension over the bladder surface and cover it, as in consequence of irritation it had lost its own epithelium. In neither kidney did the pelvis, medulla nor cortex pre-

Fig. 8.—Dog No. 13, operated on June 1, 1899; killed June 28, 1899. Section of anastomosis (low magnification). The left side of the field shows the vesical, the right side the intestinal tissue.

sent appreciable histologic changes, and there were no signs of inflammation or degeneration. There were found, however, a few micro-organisms in both organs, as follows: In the right kidney, in tissue near the surface of the pelvis, were bacilli, a few diplococci and some deeply staining round bodies, which looked like either torula saccharomyces or protozoic bodies; in the cortex, a few bacilli in the convoluted tubules and in Bowman's capsules. In the left kidney, in tissue near the surface

of the pelvis were a few bacilli; in the cortex, likewise a few bacilli. These micro-organisms were nowhere found in large numbers, but only seen sparingly here and there.

Bacteriologic Examination.—Two glycerin-agar tubes were inoculated from the pelvis of each kidney. Of each of the two groups one developed a growth, consisting in each instance of a mixture of bacilli—colon as it appeared—and diplococci.

It must be conceded that both kidneys in this case had become infected, but it appeared, moreover, that the infection must have only recently occurred. The number of micro-organisms found in the kidney was not large, and there were not yet present any appreciable histologic changes. The mucous membrane of the bladder, it seems, in consequence of the irritation from the fecal matter, had lost its epithelium, in part at least, and had developed signs of a reactionary inflammation. It is not unreasonable to suppose that the infection which had occurred might have been prevented by regularly washing out the bladder, which, in the case of a dog, can not be well done, but which could be done with a human patient.

EXPERIMENT 14 (Fig. 11).—A black bitch, weight 23 pounds, operated on June 5, 1899, was killed November 22, before the Chicago Medical Society. On opening the abdominal cavity, the peritoneum, including the omentum and all the abdominal structures, appeared normal and free from any inflammatory changes of reaction. The anastomosis between the bladder and rectum was firm and covered by normal peritoneum. Before cepting as to an infection *in situ*, the kidneys were freed and disturbing the relation of the anastomosis any further, ex-lifted out of their normal position, and inoculations made from the pelvis of each, into glycerin-agar tubes, in the usual way. The kidneys and ureters were normal in color and size, and the substance of the kidneys was also found to be normal on cut section. The bladder was firmly contracted and the mucous membrane of both bladder and rectum looked perfectly normal. The fistulous opening between the bladder and rectum was small, and the tissues forming it corrugated and healthy. The other organs were found normal.

Fig. 9.—From dog No. 15, operated on June 10, 1899; killed September 11, 1899. Section of anastomosis. Spencer prof. $\frac{1}{4}$ in.; Leitz. oc. No. 3. The upper part of the field shows the intestinal, the lower part of the field the vesical mucularia.

Bacteriologic Examination.—The four test-tubes inoculated from the pelvis of the kidneys were kept in the incubator, at blood temperature for six days, and remained absolutely sterile, no growth of any kind developing.

Histologic Examination.—The tissues of the cortex and medulla of both kidneys were normal. The pelvis of the kid-

ney on either side was lined by normal epithelium and the subepithelial tissue of the pelvis showed a moderate amount of round-cell infiltration. The cells forming this infiltration

Fig. 10.—Experiment No. 3.—A. Opening between bladder and rectum. B. Bladder. C. Prostate. D. Kidneys. E. Ureters.

were of the type of young connective-tissue cells and lymphocytes. Polynuclear leucocytes were not seen anywhere in the subepithelial tissue. No bacteria of any kind could be demonstrated, either in the pelvis, the medulla or the cortex of either kidney.

From the above results it is safe to say that the kidneys in this dog were free from any infection and, to all appearances, the canine was in perfect health.

EXPERIMENT 15.—A large male, Gordon cur, weight 50 pounds, operated on June 10, 1899, was killed September 11. This dog suffered from the red mange, but otherwise was apparently healthy. The post-mortem showed the external operative wound completely healed, with the exception of a small stitch-hole abscess. There were slight adhesions of the omentum at the site of the abdominal incision, and it was also slightly adherent to the left side of the anastomosis, at which place a loop of intestine was likewise fastened by small bands of fibrous tissue. There were no other evidences of peritonitis. The anastomosis was firm and covered by smooth peritoneum with the bladder well contracted. The right kidney and ureter appeared normal in color and size, but the left kidney showed injected vessels and was of a darker color than the right. The left ureter was increased to double the size of the right. All other organs looked normal. Inoculations were made from the pelvis of both kidneys and the colon bacillus developed from both groups.

Histologic Examination (Fig. 9).—The subepithelial tissue of the pelvis of both kidneys showed granulation tissue densely

infiltrated with round cells. In this were also demonstrable short plump bacilli with rounded ends (colon bacilli) and staphylococci. The kidney substance proper, of the right kidney, did not show any marked changes, but in the interstitial connective tissue there were found a very few bacilli of the

Fig. 11.—Experiment No. 14.—A. Opening between rectum and bladder. B. Rectum. C. Ureters. D. Kidneys.

type described above. The left kidney showed interstitial foci of small round-cell infiltration, and these areas also contained many colon bacilli and a few staphylococci. Numerous bacilli were likewise found in the glomeruli.

The line of union at the site of the anastomosis demonstrated a very intimate blending. There was practically no connective-tissue scar, the muscularis of the rectum and that of the bladder being in the closest apposition. The rectum was covered by normal mucosa with a normal epithelial lining. The internal surface of the bladder was void of epithelium, but there was present granulation tissue containing many young embryonal connective-tissue cells and lymphocytes as well as colon bacilli and a few staphylococci.

The results of this examination unquestionably showed that an infection had occurred of both the bladder wall and kidneys, although the changes in the right kidney were comparatively slight.

CONCLUSIONS.

From the careful histologic and bacteriologic examination which was conducted in a number of the cases operated on, it appears beyond a doubt that vesicorectal anastomosis may be performed on a dog without leading to an infection of the kidneys. In two instances both the histologic and bacteriologic examinations showed a

total absence of infection, and one of these cases was that of a dog killed six months after the operation. If the results on dogs, which naturally can not be kept under the best hygienic conditions and where no after-treatment could be instituted, furnished results like the above, it is not unreasonable to expect far better terminations in the human patient where after-treatment such as washing out the bladder could be commanded.

The advantages of vesicorectal anastomosis may be summarized as follows: 1. Simplicity and shortness of time required for the operation. 2. No danger of ureteral constriction by the bowel scar, nor sloughing of an implanted trigone, as in Maydl's operation. 3. Comparatively little danger of infection. 4. It is not only applicable in extrophy of the bladder, but also in other pathologic conditions of that organ rendering life a burden.

In concluding this paper I desire to extend my thanks to Dr. Sylvan Kunz, Dr. Mortimer Frank and Mr. Richard Espig, for their valuable assistance.

ARGUMENT AGAINST SENATE BILL 34, FIFTY-SIXTH CONGRESS, FIRST SESSION, GENERALLY KNOWN AS THE "ANTIVIVISECTION BILL."

BY WILLIAM H. WELCH, M.D.

PROFESSOR OF PATHOLOGY, JOHNS HOPKINS UNIVERSITY, BALTIMORE, MD.

On February 21, 1900, the Senate Committee on the District of Columbia, with Senator Gallinger in the chair, gave to advocates and opponents of the "antivivisection bill" a public hearing, at which I presented in its main features the following argument. After this hearing, on March 9, 1900, an amended or substitute bill, still designated S. Bill 34, was printed for the committee. The principal changes from the original bill, in brief, are as follows: 1. The title now reads: "A bill for the regulation of vivisection in the District of Columbia." 2. The restrictions apply for the most part only to experiments on warm-blooded animals instead of to those on all vertebrates. 3. Experiments to acquire "surgical experience" are now allowed. 4. The class of officers of the United States Government who may experiment without a license from the District Commissioners is defined. 5. The use of other anesthetics besides ether and chloroform is allowed. 6. "Tests of foods" and "experiments relating to the communicability of disease" are added to the small list of experiments in which the animal need not be anesthetized nor killed afterward. 7. The permission to illustrate lectures in hospitals by animal experiments is withdrawn. 8. The requirements for special certificates by act from licensees—to experiment on a dog, or cat, on a horse, ass, or mule, are omitted. 9. The acquirement of physiologic knowledge is omitted as a permissible purpose of demonstrative experiments in lectures to medical students. 10. Licenses may be granted to any qualified person over 21 years of age. 11. All places where experiments are performed must be approved and registered. 12. The reports on the methods, the number and species of animals used, and the results of experiments must be made on January 1 and July 1, to the Commissioners, a delay not exceeding six months for unapproved or unfinished experiments being granted. These reports must be published.

The only concessions of importance made by these changes relate to the exclusion of cold-blooded animals, the omission of two classes of special certificates, and a wider choice in the selection of diseases. In several particulars the restrictions are made more severe, and in general the worst features of the bill remain unchanged.

In the following argument I have taken into consideration the changes made by the substitute bill, so that in some respects it differs from that presented at the public hearing on February 21.

It is most significant that, notwithstanding the chairman's suggestion at the outset of this hearing, that time might be saved by the omission of a detailed presentation of the benefits of vivisection, inasmuch as this bill, it was said, is not intended to hinder useful experimentation on animals, so large a part of the remarks of the previous speakers on both sides has been devoted to a discussion of this very subject. In truth, it could not be otherwise, for the principal line of division between the advocates and the opponents of this bill is marked by their opinions on the utility of animal experimentation. However much the advocates of the bill may assert that its enactment will not interfere with the proper uses of such experimentation and is designed only to check abuses, it is to be noted that the main part of their argument is an attack on the practically unanimous opinion of well-informed scientific and medical men that experimentation on animals is essential to the advancement of physiology and medicine and has conferred inestimable benefits on mankind. Nor is it surprising that antivivisectionists should cling tenaciously to this position, indefensible as it has become, for it is apparent that those who are convinced of the great value of experiments on animals, to science and humanity, will hesitate long before approving any legislation likely to check the progress of scientific and practical medicine.

Men who hold this conviction are not likely to give any favorable consideration to legislative proposals intended to restrict the use of an important method of scientific research until it has been demonstrated that its possible abuses are in fact common and great and uncontrollable by existing legislation and by public opinion, including that of the medical profession. They will inquire carefully whether the proposed legislation will actually reach the abuses, if these should be shown to exist, and, even if it should do so, whether it may not do more harm than good by obstacles put in the way of proper and useful experimentation. They may even pause to consider whether there may not be some inequality in singling out for penal legislation the infliction of pain on the lower animals for the purposes of biologic and medical science, while leaving untouched an immeasurably greater amount of suffering inflicted on animals by man for his food, his adornment, his amusement and other objects which it would be difficult to show are higher and more worthy than those of the physiologist and the physician.

I have sometimes wondered at the attitude of mind of professed humanitarians who are so eager to collect all testimony, even the most obscure, trivial and discredited, which may make the public believe that some new remedy or improved method of treatment, such as antitoxin or antiseptic surgery, demonstrated to the satisfaction of most physicians to be a price-

less boon in saving human lives and relieving suffering, is of no value whatever. Still, it must be admitted that for the sake of their cause the antivivisectionists do well to ransack, as they do, medical journals and books for statements which may minimize the effects on the public of the constantly increasing evidences of the benefits to mankind, and indeed to animals also, derived from the results of animal experimentation. Of course, they can find statements in contradiction of almost any generally accepted truth in medicine, as they could in any science, but in view of the proverbial disagreements of doctors, and of the little interest which most of those who apply scientific discoveries have in informing themselves of the sources of their knowledge, it is on the whole surprising that the familiar list of medical quotations, which has so long done duty in antivivisectionist publications in opposition to the great value of experimentation on animals, should be so meagre, in contrast with the enormous preponderance of testimony on the other side, and should be representative of so few names of eminence, I believe scarcely one which would be generally recognized by physicians as of a writer especially competent to speak on this subject, however distinguished in other lines. So rapid have been the advances of medicine and surgery in recent years, attributable to knowledge gained from experiments on animals, that it may be urged that an adverse opinion expressed even a decade ago would be reversed to-day, but I am not sure that the exceptional physician who was blind to this source of light at any time since the days of Harvey would see it to-day, notwithstanding its greatly increased brilliancy.

It has seemed to me appropriate to say this much in explanation of the emphasis laid by previous speakers on the subject of the utility of vivisection, but it is not my purpose to set forth the actual benefits secured by this method of investigation. This has already been done by Dr. W. W. Keen, Dr. H. A. Hare and other speakers, although none of these gentlemen would claim that he had been able to present a tithe of the debt which physiology and the healing art owe to the results of animal experimentation. Those of the public who wish fuller knowledge on this subject, and who care to read a larger part of the evidence which has led the vast majority of the most humane of professions to approve of vivisection I would refer to the recent book by Stephen Paget, F.R.C.S. Eng.—"Experiments on Animals. With an introduction by Lord Lister." (London, 1900.)

One other point before I pass to the examination of the bill before us: I shall be so bold as to remind the distinguished lawyers on the other side, who have to-day so recklessly charged those with cruelty who experiment on animals, that the legal definition of cruelty given by the "Century Dictionary" is: "An act inflicting severe pain and done with wilfulness and malice." Judge Hoar, in a Massachusetts case, says: "Pain inflicted for a lawful purpose and with a justifiable intent, though severe, does not come within the statute meaning of cruelty." (James M. Beck, of the Philadelphia Bar: *The Legal Aspects of Vivisection*, *Medical News*, 1890, lvi, p. 280.) While I do not deny that cruel experiments, in the sense of heedless causing of pain, have been made, I am convinced that they are very exceptional. The accusation of cruelty, when made, as it often is by our opponents, and has been made to-day, against experimenters on animals, as a class, is false and slanderous. In no other group of cases in which animals are made to suffer for the benefit of man is equal care exercised to avoid the infliction of needless pain. The difference is simply immeasurable between the solicitude in this regard and the quantity of actual suffering inflicted in scientific experiments on the one hand and, on the other, the heedlessness and the vast unnecessary amount of pain inflicted in the slaughtering, the sexual mutilation, the transportation, the poisoning, and the hunting, trapping and shooting of animals. On the one side hundreds, on the other millions of animals are concerned annually; on the one side a serious purpose to advance scientific knowledge and directly promote the healing art, on the other the satisfaction of appetite, often in a luxurious way, the exercise of some convenience or economy, the gratification of the desire for sport or of some whim; on the one side insensibility to pain secured by anesthetics, as a rule, whenever practicable, and this is so in the great majority of cases, on the other very little regard to the avoidance or reduction of unnecessary suffering.

In speaking on a former occasion of the self-sacrifice and benevolence of the members of the medical profession, your chairman justly said that no legislation should be enacted that would unnecessarily hamper them in their pursuit of useful knowledge, and he has to-day very properly asked that it shall be pointed out in what way the proposed legisla-

tion would interfere with useful experiments, with such experiments, for example, as those cited by Dr. Keen, Dr. Hare, and other speakers. It is asserted with much insistence by its advocates, that this bill is "moderate," "reasonable and wise," "restrictive and not prohibitive," "not an antivivisection measure," "does not impede in any way the proper use of animal experimentation," "goes to the farthest extreme of concession in the anxiety of its framers to yield to the wishes of scientific men so far as may be consistent with the principle of legal supervision," "concedes everything of utility." It is my especial purpose to examine these contentions in the light of the specific provisions of the bill, and I hope to be able to demonstrate to the satisfaction of the members of this Committee that this bill is unnecessary, is vague and contradictory in some of its provisions, places the entire control of a scientific method of investigation in the hands of laymen not qualified to exercise such arbitrary powers, absolutely prohibits important and useful experiments and can be administered so as to prohibit all experiments, surrounds the practice of animal experimentation with absurd and vexatious restrictions, and, if enacted into law, would inflict serious injury on the progress of science and medicine.

I have already traversed much of this ground in my letter to a former member of this Committee, the Hon. Arthur P. Gorman, printed as Senate Document No. 104, 55th Congress, Second Session, (also in THE JOURNAL, Feb. 15, 1898, p. 285), which I beg leave to offer for your consideration. I would also call your attention to other documents of similar purport, especially the letter of the Secretary of Agriculture, the Hon. James Wilson, printed as Senate Document No. 112, 55th Congress, First Session, that of Dr. Dabney, President of the University of Tennessee and former Acting Secretary of Agriculture, to the Chairman of the Committee on the District of Columbia, the Hon. James McMillan, and the recent letter of Dr. Woodward (THE JOURNAL, February 10, p. 381), the Health Officer of the District of Columbia, to the Commissioners of the District.

As Dr. Salmon has pointed out at this hearing, and as Dr. Woodward has shown in his letter, just referred to, there is no need for additional legislation restricting the practice of animal experimentation in the District of Columbia. The existing law permits only "properly conducted scientific experiments or investigations, which experiments shall be performed only under the authority of the faculty of some regularly incorporated medical college, university or scientific society." The bill before us attempts to define with considerable detail, what constitutes a properly conducted experiment, and with what success I propose presently to show. A commission of scientific experts would find it difficult, if not impossible, to prescribe with similar detail the proper conduct of all scientific experiments on animals, and most assuredly such experts have had no hand in the drafting of this bill. If it be asked, Who shall be the judge of the proper conduct of the experiments? I reply: In the first instance the scientific men who act "under the authority of the faculty of some regularly incorporated medical college, university or scientific society," then the governing bodies of these incorporated institutions, and in the final decision the courts, as provided by the existing law, and most certainly not, as proposed in this bill, the Commissioners of the District of Columbia, who have no special qualifications to judge of such a matter.

There is not a particle of evidence that abuse of animal experimentation has ever existed or is likely to arise in the District of Columbia or, if it should occur, of the inability of the present law to cope with it. I know that one can conjure up in his imagination horrible possibilities, to meet which no law would seem too severe, and that charges of atrocious cruelty are spread before the public by antivivisectionists with reckless disregard of the facts, but we court the fullest investigation, by any impartial body of men, of the actual conditions of animal experimentation in this District and in this country, and we are confident that such an investigation would show the groundlessness of these imaginings and the wantonness of these accusations. Before any such legislation as that embodied in this bill is recommended, in the face of the unanimous protests of the scientific and medical societies and of the great body of physicians of this country, it surely seems incumbent upon your honorable body to make such an official investigation as we have often asked for.

Although we are here to discuss this particular bill, and not the general subject of legislative restriction of experimentation on animals, I am free to confess that, I consider the public opinion of the medical profession, which is as sensitive to actual cruelty as that of any "humane society," an efficient safeguard in this matter, and amply sufficient when combined, as it is here, with an adequate law. As has been said: "Probably

the members of antivivisectionist societies do not believe that there is any such professional public opinion; but there is, and it is an effectual, though quiet, check on the few who need it. But if any influence from the outside could injure it, it would be the constant ignoring and denying of its existence. It is not generally found an incentive to honesty to tell a man: "you would be a thief if you could, and therefore I shall keep all my goods under lock and key when you are about, and have my eye on you when you don't expect it." Weak honesty grows strong when leaned upon; but even strong humanity, insulted and disbelieved in, may hear itself called callousness until it ceases to care for the charge. (Physiological Cruelty: or, Fact v. Fancy. An inquiry into the Vivisection Question. By Philanthropos. P. 100. London. 1883. This is the best book with which I am acquainted on the general subject of vivisection.)

If all that could be said against the legislation proposed in this bill were its needlessness, it might be allowed to cumber the statute books, with no charge against it more serious than meddlesomeness, albeit, to my thinking, that is not a slight charge. But this legislation is very far from being harmless. While it must be difficult for those unfamiliar with the methods and results of scientific inquiry and practical work in the directions touched by this bill to realize fully all of the ways in which the provisions of this complicated measure would hamper investigations of importance to mankind, enough can be made clear to any reasonable man to show that neither this bill nor anything like it should ever be enacted into law.

Of the many faults of this bill there is none more serious in principle or likely to be more hurtful in the actual working of the proposed legislation than that this bill puts in the hands of men, who need not be and are not likely to be physicians or men of science, arbitrary powers, requiring skilled knowledge in their use, concerning matters of the highest importance to medicine and biologic science and to the welfare of mankind. To the Commissioners of the District of Columbia, of whom two make a majority, is given uncontrolled power to determine by whom and where experiments shall be made, to disallow or suspend at any time permission once granted, to demand at stated times reports in any desired form or detail concerning the methods and results of experiments, which reports shall be published, and to be, in the last resort, the supreme judges as to whether a certain experiment will advance physiologic knowledge or knowledge "useful for saving or prolonging life or alleviating suffering," or will aid in the acquirement of "surgical experience." No provision is made for an appeal or a hearing on the part of any applicant or experimenter who may consider himself aggrieved. Of the partial exemption of officers of the Government and of division of authority with the President of the United States I shall speak later.

Nobody can foretell in what manner the commissioners will exercise these extraordinary powers if conferred on them. It lies entirely in their discretion to grant all licenses and certificates or to refuse all and thereby prohibit all animal experimentation in the District, except that conducted under severe restriction by officers of the Government. It can be confidently predicted that the antivivisectionists will use every political and other influence in their power to secure the appointment of commissioners committed to a policy hostile to animal experimentation. Physicians have other matters to attend to and rarely engage in political agitation. I know of no reason why either of the two eminent lawyers who have spoken to-day for our opponents should not be considered qualified for the office of Commissioner of the District of Columbia, but, entertaining the opinions on vivisection which they have expressed, how could they conscientiously grant a single license to experiment on animals? In whatever way the commissioners might exercise their uncontrolled discretion, whether they made the law mean much or little, one thing is certain: In matters requiring expert knowledge and of high importance to mankind, those who do not know would be put in supreme authority over those who know. This is a monstrously false and dangerous principle to embody in law. It needs knowledge, often a great deal of it, to do good, but none to hinder it.

It has been said that there is no more reason to object to the requirement of a license to experiment on animals than to that of a license to practice medicine. There are differences between the two cases, which I shall not pause to discuss, for this bill is not a simple licensing measure. To make the conditions of the two cases analogous, in accordance with the provisions of this bill, the law to license practitioners of medicine should provide that a body of laymen should determine the qualifications of applicants and grant the license to practice, that the practice of each licensee must be limited to certain specified localities, that the permitted manner of treatment

should be prescribed with some detail, that certain therapeutic procedures should be prohibited, that each practitioner must report at stated times his methods and results, and the number of patients treated to the licensing body, which shall publish the reports, and that a body of inspectors with no statement as to their qualifications should keep the licensed practitioners under surveillance and should report from time to time the results of their observations. Manifestly absurd as such requirements as these would be if applied to the regulation of medical practice, they are scarcely less absurd when applied, as proposed in this bill, to the legal regulation of animal experimentation.

If I were to enter into a criticism of the smaller details of this complicated bill. I should inquire, among other things, why only certain professors in a medical school are accorded the privilege of signing an application for a license, why, for example, the professors of pathology and of physiologic chemistry are excluded, but it seems to me more important for my present argument to take up the larger defects of the measure.

The bill "for the further prevention of cruelty to animals in the District of Columbia," originally introduced in the Fifty-fourth Congress, placed the officers of the United States Government completely under the control of the Commissioners of the District in respect to animal experimentation, although the experimental work of the United States Bureau of Animal Industry concerns itself with the agricultural and stock-raising interests of the entire country. The subjection of Government officers to the authority of the District Commissioners in a matter of this kind is so manifestly improper that the bill, after several modifications, now exempts from the necessity of securing a license from the commissioners any "medical or scientific officer of the United States Government duly authorized by the head of a department." But the bill still provides that those officers of the Government who engage in animal experimentation must report to the District Commissioners twice a year on "the methods employed, the number and species of animals used, and the results of their experiments, in such form and with such further details as the said commissioners may require," and all these reports must be published. It is not the head of a department who is to make these reports, but such of his subordinates as may be engaged in experimental work. All of the other restrictions of the bill, some of which will require interpretation by the administrators of the law, also apply to the experimental work of the officers of the general Government, which work is therefore still placed to a considerable degree under the control of officials of the District of Columbia.

The present bill, in its recently amended form, requires "that every place for the performance of experiments on living animals shall first be approved by the Commissioners of the District and shall be registered in such manner as the said Commissioners may direct." In the previous bill the provision as regards registration of places was mandatory only for places of medical instruction. It will be noted that this provision applies to experiments on any living animal, invertebrate as well as vertebrate. This bill is the first which has ever taken under its protection mollusks, worms, insects and other invertebrates. This is really so absurd that it may be presumed to be the result of inadvertence, but, if so, it illustrates the lack of care in the construction of the bill.

The requirement that no experiment shall under any circumstances be made except in a place previously approved and registered is a very injurious one. A number of instances might be cited of the ways in which this requirement may interfere with useful experimentations and even involve some danger to human beings and animals. An emergency may readily arise in which some inoculation test for diagnostic or other purposes can most advantageously be performed where the material obtained directly at autopsy or from a patient or sick animal is directly at hand. In some instances absolutely fresh material, possibly inoculation directly from one animal to another, or from a human being to an animal, is essential for the success of an experiment. There may be considerable danger involved in the transportation of some highly virulent material, perhaps for a considerable distance, to a registered place, and there may be good reason for not taking infectious material away from a locality already infected and introducing it into an uninfected registered place. To confine the work of an experimenter absolutely and under all circumstances to the particular place for which he has secured a ticket of registration is a hard and unnecessary restriction, and in introducing this provision the new bill has gone beyond its predecessors and beyond the British law.

Undoubtedly the provision of this bill, as of all antivivisection bills, which is dearest to the heart of the antivivisectionist, is that for the official inspection of experiments on

animals. The bill provides (Section 6): "That the President of the United States shall cause all places where experiments on living warm-blooded animals are carried on in the District of Columbia to be, from time to time, visited and inspected without previous notice for the purpose of securing compliance with the provisions of this Act; and to that end shall appoint four inspectors, who shall serve without compensation and who shall have authority to visit and inspect the places aforesaid, and who shall report to the President of the United States from time to time the results of their observations therein, which shall be made public by him."

It will be observed that this section introduces a second authority in the administration of this law. The Commissioners of the District grant the licenses of persons and places, while the President of the United States appoints the inspectors and receives their official reports. This division of authority would not seem conducive to the smooth working of the law and might readily lead to serious conflicts in its two-headed administration, especially if one head be friendly and the other hostile to experimental investigations.

But the monstrous evil of the provision regarding inspectors is that not a word is said as to the need of any special qualifications on the part of those who are to scrutinize and report on the experimental work of physicians and scientific men. The duties of these inspectors, according to the law, will require them to base their reports on such matters as whether animals are completely anesthetized, whether movements of an animal are manifestations of conscious pain or only of reflex action whether experiments are conducted by competent persons and in a proper manner, and whether they are useful for the particular purposes specified in this bill, and fall under the categories of permitted experiments. Surely some knowledge of physiology and some appreciation of the needs of medicine and surgery are required for the performance of the remarkable and responsible functions of these inspectors.

The bill originally introduced provided that this inspection should be by an agent of the Washington Humane Society, a notoriously antivivisectionist society, which claims the responsibility for this bill. It can not be doubted that this Society and antivivisectionists in general will claim and in all probability will secure representation among the inspectors. It would be quite within the power of even one energetic and officious inspector, without physiologic knowledge and opposed, as most antivivisectionists are, to all investigations requiring experimentation on animals, to make the conditions of experimental work simply intolerable. Anybody who has serious and legitimate business to attend to has a right to object to constant intrusion and disturbance, and work requiring delicate manipulations and undivided attention can not go on under such interruptions. When to this nuisance is to be added the publication of official statements concerning difficult matters of which the observer is not qualified to judge, I submit that before you impose on experimenters this system of inspection you should be convinced that very great abuses are to be corrected and can be corrected by no procedure of a less drastic nature.

It is utterly misleading to draw any analogy between this sort of inspection and the inspection of banks and insurance companies, and it is a libel on common sense to assert, as is done by advocates of this measure, that fear of the exposure of wanton cruelties moves experimenters to object to any such system of inspection as that proposed in this bill. It is not true that secrecy surrounds the practice of animal experimentation. Reports of experiments are published in detail. Any qualified person has free access to the laboratories where such experiments are made, but to throw them wide open to the public is open to the same kind of objections as would be similar publicity for surgical operations. The antivivisectionists are fond of quoting from an address by Dr. Parvin, delivered in 1891, but I have never known them to cite in their writings, except in garbled form, the following sentences from this address: "Should the law restrict the performance of vivisection? I think it ought, chiefly as an expression of public sentiment and for the moral effect, for violations of its provisions could usually only be discovered by a system of espionage, by the employment of detectives, of spies and informers, utterly alien to our system of government, and who are as a rule abominable." This quotation in antivivisectionist publications always, I believe, stops short with the first third of the last sentence.

(To be continued.)

FIVE MEDICAL professors at the Moscow University have served their quota of 25 years and now retire.

Therapeutics.

Quinin in Malaria.

The following clinical note is from Dr. Ballard, health officer of Natchez, Miss:

In the simple intermittent fever quinin is undoubtedly a specific; but when cured, and no change is made in the environments—as with the cotton planter of the lowlands on both sides of the river—re-infection is certain to take place, and in these cases quinin, in usual doses, is extremely dangerous. All cases of hematuria of malarial origin occurring under my observation (in whites) have been due to re-infection and followed the protracted use of quinin. One or two grains dissolved in half a dram of dilute phosphoric acid is a benefit in preventing a second invasion, and is a tonic of superb power. I use something like the following:

- R. Quinæ sulph. ʒiii
- Tinct. ferri chloridi ʒi
- Acidi phosphorici ʒiv
- Spts. frumenti, q. s., ad ʒviii
- M. Sig. Teaspoonful in one-third glass of water at meals.

Now as to the treatment of hematuria, when found. I use ergot in half-dram doses every three or four hours, and strychnin hypodermically in full doses. I flush the bowels with the hyposulphite of sodium, and I have found an emulsion of turpentin of service in some cases. If the patient is restless and fretful, an enema of sixty grains of potassium bromid is of unquestioned utility.

The so-called typhomalarial fever is a malarial fever in which quinin is entirely useless, save in small doses as a tonic. I have never seen a case of intermittent fever that would not yield to an acid solution of quinin, if a cathartic is used to begin treatment. For this I use:

- R. Hydrarg. chloridi mitis gr. x
- Podophyllin
- Ipecac, āā gr. i
- Ext. nucis vomicæ gr. ʒss
- Ext. hyoscyami gr. iv
- Sodii bicarb. gr. xi

M. The solution is left for some minutes in contact with the ear. The treatment induces desquamation of the tympanum and of the meatus, which calls for frequent cleansings. This action of picric acid contraindicates its use in cholesteatoma.

Experimentia docet. We do not use quinin in the hemorrhagic forms of malarial fever, and are now successful, whereas we were failures with quinin. —*Therap. Gazette.*

Suppuration of the Ear.

Lanoix, in *Rev. Medicale*, states that picric acid, being not only analgesic and antiseptic, but also keratoplastic, he was led to employ it in suppuration of the ear, when it is sought especially to cauterize the secreting membrane of the tympanum. He has attained unhoped-for benefits from its use. He uses the following solution:

- R. Acidi picrici gr. ii
- Alcoholis—90 per cent. m. xlʒ
- Aquæ destil. ʒʒv

M. The solution is left for some minutes in contact with the ear. The treatment induces desquamation of the tympanum and of the meatus, which calls for frequent cleansings. This action of picric acid contraindicates its use in cholesteatoma. —*N. Y. Med. Jour.*

Treatment of Migraine.

Lyon (*Revue de Therapie*, February 1; *British Medical Journal*, March 24, "Epitome") treats the attack of migraine with antipyrin—unless there is some coexisting renal disease—given in Vichy water or in cachets with an equal quantity of sodium bicarbonate or in the granular effervescent form. If there is gastric intolerance the drug may be given in solution as an enema. Sometimes a combination of acetanilid, phenacetin and quinin valerianate is more efficacious. Sodium salicylate, methylene-blue and caffeine, either alone or combined with sodium benzoate may be recommended. If caffeine be rejected by the stomach it may be given hypodermically. Aconitin may be tried in minute doses. The prophylactic treatment is both dietetic and hygienic. The patient should eat moderately and abstain from all alcoholic drinks, in fact, should take water only. He should avoid all indigestible articles of diet and live principally on milk and vegetables. Tobacco should be interdicted and a sedentary life avoided. Errors of refraction should be corrected and massage with suitable baths tried. Alkaline

baths are of especial value for the rheumatic and the gouty. For the neurasthenic the use of phosphates alternating with arsenic, either with or without iron, is a promising plan of treatment.

Syphilitic Alopecia.

Gaucher, in *Riforma Medica*, recommends the following: The hair should be kept short, and frequent applications of the following lotion made to the head:

- R. Hydrarg. chloridi corrosivi gr. iiii
- Chloralis gr. lx
- Resorcin gr. xxx
- Olei ricini gr. xv
- Alcohol (at 90 degrees) ʒl

M. At the same time friction should be made with the following ointment:

- R. Calomel gr. xlv
- Vaselini ʒxv
- Acidi salicylici gr. iv

Or, the following:

- R. Precipitated sulphur gr. xlv
- Vaselini ʒxv

This latter ointment is to be prepared when the alopecia is accompanied by seborrhea and pityriasis of the hairy scalp.

—*N. Y. Med. Jour.*

Treatment of Burns.

According to the *Jour. de Méd. de Paris* of Nov. 19, 1899, the following treatment may be instituted in cases of burns:

Compresses saturated with a solution of potassium nitrate may be applied, the solution being of the strength of 5 per cent. This preparation relieves the pain, and prevents a rise of temperature. The patients may be placed in a warm bath containing this material. If the well-known carron-oil or linimentum calcis is employed, it is suggested that carbolic acid in the strength of 1 per cent. should be added to it, or that thymol in the strength of 5 per cent. should be applied; or vaselin containing 10 per cent. of boric acid may be used. The following formula is said to be employed by Réclus.

- R. Vaselini ʒiii
- Acidi borici ʒi
- Antipyrin ʒi
- Iodoformi gr. xiii

Another one is:

- R. Vaselini ʒiii
- Essence of thyme
- Essence of granium
- Essence of origanum, āā gr. iv
- Sodium naphtholate gr. xv to xlv

Other formulæ are as follows:

- R. Mentholi
- Iodoformi, āā gr. xv
- Glycerini ʒiii
- R. Cocaini gr. iv
- Salol ʒi
- Vaselini ʒi
- R. Europhen gr. xxx
- Lanolini
- Vaselini, āā ʒii
- R. Orthoform gr. xlv
- Vaselini ʒi

All these ointments are intended to prevent suppuration and to relieve pain and burning.

Another method of treatment is to apply bismuth subnitrate and other drying materials in powdered form, particularly where the burn is wet and bleeding.

Still another application which is excellent where it is desired to favor cicatrization in burns which have existed for some little time is the following prescription:

- R. Ichthyol gr. xv—xxx
- Magnesii carbonatis ʒiii
- Zinci oxid. ʒvi
- Thiol
- Talc.
- Bismuthi subnitratis, āā ʒi

M.

So far as general treatment is concerned, the patient should receive opium to relieve the pain, and if necessary subcutaneous injections of morphin in small doses, and during the period

of suppuration, if it occurs, the system should be supported by means of tonics, such as quinin, kola, and iron.

—*Therap. Gazette.*

Treatment of Hemorrhoids.

The following prescriptions are given in *La Presse Médicale*:

- R. Chrysarobin gr. i
- Iodoformi gr. ss
- Extract belladonnæ gr. 1/8
- Cacao butter gr. xxx

M. ft. One suppository.

Two or three of these suppositories are to be inserted into the bowel each day, or, instead of these suppositories, the following ointment may be used:

- R. Chrysarobin gr. xii
- Iodoformi gr. v
- Ext. belladonnæ gr. x
- Vaselini ʒss

M. Sig. Apply locally several times a day.

If small indurated projections of skin and mucous membrane are present, with a good deal of induration around the part, the following may be employed:

- R. Potassii iodidi gr. xv
- Iodini gr. ii
- Glycerini ʒi

M.

This is to act as a local alterative. Later, if irritation is absent, a stronger solution may be employed, composed of:

- R. Potassii iodidi gr. lxxx
- Iodini gr. xv
- Glycerini ʒiss

M.

Small doses of distilled extract of hamamelis may also be given internally with each, and continued for several months.

Sciatica.

Siegrist, of Zurich, has found the application of hot moist compresses to afford striking relief in this affection, says the *New York Med. Jour.* A piece of flannel is placed in very hot water, then wrung out so that it does not drip. This can be done conveniently by wringing it inside a towel in such a way as to protect the hands. The flannel is then laid along the thigh of the patient—if the skin is very sensitive a layer of flannel is placed under the compress—and the whole covered with several thick layers of dry flannel. The compress is changed in about ten minutes, and the process kept up for an hour or two at a time, and repeated several times a day. The value of these fomentations in many painful affections is well known to students of hydrotherapy, but is not sufficiently recognized by physicians in general. The treatment demands considerable time, and must be skilfully executed in order to gain the desired results.

Alterative.

- R. Arsenici chloridi m. i
 - Ammon. chloridi ʒi
 - Tinct. ferri chloridi ʒiv
 - Hydrarg. chloridi corrosivi gr. iss
 - Syrupi ʒiiss
 - Aque, q. s. ft. ʒvi
- M. Sig. One teaspoonful three times a day.

Syphilis.

- R. Hydrarg. protoiod gr. v to x
 - Strych. sulph. gr. ss
 - Ferri sulph. gr. xx
 - Pepsin pulv. gr. xl
- M. ft. in cap. No. xx. Sig. One capsule after each meal.
- Dr. J. D. Thomas: Intern Med. Mag.*

Sporadic Dysentery.

- R. Pulv. ipecac et opii gr. xxx 2|
 - Bismuthi subnitratiss ʒiv 16|
 - Salol gr. xxx 2|
- M. et ft. Chart No. xii. Sig. One every hour or two.

—*J. M. Anders.*

Ointment for Gonorrhœal Rheumatism.

- R. Salol ʒ parts
 - Menthol ʒ parts
 - Ether ʒ parts
 - Lanolin 60 parts
- M.

Nephritis in Children.

- R. Liq. ammon. acetatis ʒi
 - Tinct. digitalis
 - Spiritus chloroformi, aa ʒi et m. xx
 - Aque dest., q. s., ad ʒviii
- M. Sig. Tablespoonful three times a day to children from 6 to 10 years old.
- Ashby: Med. Record.*

Gastralgia.

Dr. Saundby, of Mason College, Birmingham, recommends the following method: The patient is put to bed, receives for sole nourishment 1 fluid ounce of a mixture, in equal parts, of milk and lime water every hour, the quantity to be gradually increased to 4 fluid ounces every hour as the symptoms disappear. At the same time, two tablespoonfuls of the following mixture are given three times a day:

- R. Magnesii sulphatis ʒvi
- Ferri sulphatis gr. xv
- Acidi sulphurici diluti ʒiiss
- Aque menthae pip. ʒviii

The rapid improvement under this régime soon permits the use of a small quantity of bread and scraped meat, then solid foods, and finally recovery ensues.

Medicolegal.

Dying Declarations Touching Accidents.—The Supreme Court of Louisiana points out, in the case of Marler vs. the Texas Pacific Railway Company, that the circumstances under which dying declarations are made, with a view to testimony in criminal cases, differ greatly from those where they are made with reference to future civil proceedings for damages occasioned by the injury causing death. In the one case the party making the declaration has no personal interest in making a false statement, and would be actuated in doing so only by hatred or malice, while in the other relief for the family he is leaving behind him might furnish a strong motive for giving a wrong version of the facts of the occurrence. Hence the court holds that such declarations are not admissible in evidence in a civil action brought to recover damages, though made under a sense of impending death or even if made to the physician called in to minister to the party particularly when not elicited to aid him in treating the case.

Statements of Experts are Advisory Only.—This is the view taken by the Supreme Court of Missouri. For example, in the malpractice case of Hoyberg vs. Henske, the jury was told, in effect, that in determining the question as to whether or not the defendant exercised such skill and care of the plaintiff's broken arm as, under the law, he should have exercised, it was not bound by the opinion of expert witnesses, but had the right to disregard all or any part of such opinions as appeared to it to be unreasonable. In this instruction the supreme court says that it fails to recognize the vice which counsel sought to point out. It is the established law, as declared by this court, it goes on to state, that, where experts are called to testify, their statements are not to be considered as evidence of facts, but are of an advisory nature, and they are permitted to express opinions because of the peculiar knowledge they possess. But, the court continues, juries are in no wise bound to blindly accept their ideas, but, after receiving the advice of experts, are permitted to use their own judgment in passing on the things concerning which the opinions are given, and they are necessarily permitted to disregard the testimony of such experts as may appear to them unreasonable. Were it not so, the court thinks that, because of the widely diversified notions and wholly different results arrived at by separate individuals, even when forming conclusions on the same facts and circumstances, juries would be wholly at sea, and to refuse to permit them to be their own judges of what is reasonable and what is unreasonable would operate as a failure of the purposes for which they are called in this class of cases. Nor does the court appreciate the force of the criticism that the instruction under discussion was defective in that it failed to tell the jury that, in order to disregard the opinions of the experts presented to them, they must do so solely on some other

facts and circumstances in the case drawn out by the testimony. It maintains that the right of a jury to reject the mere opinion of an expert or experts is not more restricted than the right to reject the testimony of a nonexpert upon a question of fact. Juries are required, in cases of this character, to apply their own experience, knowledge, and judgment, and the issue is to be determined, not merely by the opinion of experts, but, further, by the exercise of their own judgment of the facts on which the opinions are given. Finally, a verdict of \$5500, the court holds not excessive for malpractice, where a child 4 years of age broke one of the bones of the left arm, just above the elbow, by a fall from a lounge, and the treatment was such that the arm festered and parts of the flesh came out and then left the arm without strength from the elbow down.

Communication About Medical Examiner.—Omitting here the names, a medical director of a life insurance association wrote this letter to an agent at a certain place, with reference to the medical examiner there: "I have before me the application of ——. This application shows on the face of it to be a forgery of his signature, and it is written by Dr. — instead of the applicant. He has fallen down in his undertaking to imitate the handwriting of the applicant, by his misspelling the name. We have returned the application to the doctor, and given him to understand that it must be corrected at once; and you are hereby notified that in the future no more examinations will be accepted, when made by Dr. —. We will appoint another physician at that place, and will notify you of the appointment of same. We have no longer any confidence in Dr. —, and, as above stated, we can not accept any more examinations made by him." The doctor referred to in some way learned of the letter, and sued the medical director and association for libel. On the trial the action was dismissed as to the medical director, and the doctor obtained a verdict and judgment for \$2300 against the association. But the judgment of the district court is reversed by the Supreme Court of Iowa. The jury was instructed that the letter of communication, made and published in the manner and under the circumstances under which the same was made and published, was not a privileged communication, and the circumstances under which the same was made and published did not justify the association in so making and publishing the same. More than that, it was instructed that the letter was libelous in and of itself, and that the only matter to be considered was the amount of damages. Not so, however, thinks the supreme court. It holds that the addressee, as soliciting agent, was entitled to know who was the accredited medical examiner of the association at the town where he was making applications. The company also had the right to inform its soliciting agent of the discharge of its medical examiner in the locality where the soliciting agent was operating. The occasion, it therefore holds, *Nichols vs. Eaton*, was undoubtedly privileged, and it was the duty of the court to so instruct the jury. That being established—that the occasion was privileged, and that the publication was about a matter in which both parties had an interest, excess of statement the supreme court pronounces material only as bearing on the question of malice—a **question of fact** for the consideration of the jury.

Who May Testify as to Insanity.—The Court of Appeals of Kentucky says, in the case of *Abbott vs. Commonwealth*, that it is well settled in that state that persons who are not experts, but by association and observation have had an opportunity to form an opinion as to the sanity of a person, may testify to that opinion; giving, also, the facts on which the opinion is based, so that the jury may judge for themselves what weight the opinion is entitled to. The reason it gives is that insanity if often shown by a flash of the eye, an expression of the face, a movement of the muscles, or a number of slight circumstances which, while they may produce a conviction in the mind of the observer, can not, in many cases, be reproduced before the jury as they were exhibited to the eye of the witness, so that, if testimony of this sort were not allowed, great injustice would in many cases be done. The judgment of a person's intimate friends and acquaintances as to his soundness of mind it holds is therefore always competent in

cases where the insanity is pleaded as a defense to crime. Moreover, the courts says that it is not necessary that a medical witness should claim to be an expert on the subject of insanity to entitle him to give an opinion as an expert on a hypothetical case. Any practicing physician, doing a general practice, who has studied the subject of diseases of the mind, with other forms of disease, it holds, may testify on the hypothetical case, on the ground that, as insanity is a disease, one who is skilled in detecting and treating diseases is competent to give an opinion, the extent of his learning and experience going alone to his credibility. Yet it manifestly does not consider every physician competent to give an opinion as an expert on the question of insanity, as it holds, right in this connection, that the testimony of a certain doctor was properly rejected, as it did not appear that he had given the subject of insanity a sufficient study to entitle him to speak as an expert on the hypothetical case put to him, though it does not explain any further just what his qualification or disqualification was.

Both May Testify in Abortion Case.—A husband sued a physician for damages for producing an abortion on his, the plaintiff's, wife. This was in Missouri, where the statute modifying the general rule of the common law prohibiting a married woman in testifying in behalf of her husband could not be said to include a case of this character. There, too, a physician or surgeon is prohibited from testifying concerning any information which he may have acquired from any patient while attending him or her in a professional character, and which information is necessary to enable him to prescribe for such patient as a physician, or to do anything for such patient as a surgeon. Naturally, therefore, there was objection made to the wife being allowed to testify in behalf of her husband. Likewise, objection was made, on the other side, to the physician testifying, in his own behalf, concerning information which he acquired from the wife of the plaintiff while attending her in a professional character, by an examination of her body, and from conversation with her, which was necessary, according to his testimony, in order to enable him to treat her; as well, also, as to the conversations had between himself and her with respect to her condition, and the treatment necessary in her condition—what he said to her, etc. Taking up this last objection first, the Supreme Court of Missouri, Division No. 2, points out, *Cramer vs. Hurt*, that the facts with respect to the condition of the wife, the doctor's treatment of her, and the facts obtained from her with respect to her condition, were within the exclusive knowledge of her and himself. No other person knew, of his own personal knowledge, anything about them. Hence, while it must be understood that such evidence can not be admitted, merely because other evidence of the facts can not be obtained, in a suit against a physician by the husband for damages, the court holds that, where it is clear that no other person besides the physician and the wife knows anything personally about the facts, and the proof of such facts is necessary in sustenance of his defense, it is no error to permit him to testify to such facts in order to prevent injustice being done. But it must, the court continues, for the same reason, follow that the wife is a competent witness for her husband, notwithstanding at common law, as a general rule, a married woman is incompetent to testify in behalf of her husband, and the state statutes may not have removed the disability as to such a case as this. Moreover, the court thinks that the wife is a competent witness in such a case on general grounds of public policy, for, it says, if it be known that a married woman is a competent witness for her husband in a suit for damages by him against a physician who produces an abortion on her without the consent of her husband, in consequence of which her health is injured, and he is deprived of her services, to which he is entitled by law, and expenses are entailed on him in her nursing and for medical treatment, it might, to some extent, put a stop to such revolting and unnatural practices. However, the court does not consider that the privilege, which belonged to the wife personally, was waived by her being offered as a witness by her husband, nor by his bringing an action of this kind.

6. **Present Status of Rectal Surgery.**—Mathews calls attention to the neglect of the subject of proctology in certain surgical text-books and to some of the misstatements they contain. He notices the progress of the specialty of rectal surgery, but condemns the rushing into specialism of those who are not fully prepared by previous general practice. The society is not to be composed of men who devote themselves exclusively to this subject, but those who desire to become better posted in this class of cases. He suggests that it be annexed as a section to the AMERICAN MEDICAL ASSOCIATION, and that the rules be rigid in the admission of members.

9. **Defense of the Organism.**—Meltzer maintains that the prevailing opinion of bacteriologists, who regard the defense of the body against hostile germs as due exclusively to a single element, whether it be alexins or leucocytes, is neither correct nor advantageous. He believes that it is not by a single tissue or a single function, but by concentrated action of independent factors that this defense is maintained, and illustrates this by the conjunctiva, which is usually sterile, notwithstanding its constant exposure. The causes of this are the reflex closure and blinking of the eyes and the bactericidal effect of the tears; similarly the respiratory organs, which are constantly invaded, are protected by the tortuous part of the upper portion of the tract, the action of the epithelial cilia, and the thinness of the epithelial layer, admitting the bacteria quickly to the lymph-glands, which take good care of them. Other defenses are the sphincter muscles at the entrances of some cavities of the body, and such secretions as tears, saliva, mucus, etc. Two new factors, however, which he thinks assist in the work of destruction of bacteria in the body, are proposed. One of these is plasmolysis. He attributes to different osmotic pressures of the fluids, the important part in this function. The second new factor is the heart's impulse. A certain maximum of vibration is indispensable to all forms of life, and can not be overstepped by any one. Every species has its certain individual minimum in this respect. He thinks that the vibrations emanating from an impulse of the heart probably form the optimum of the vibration for the living cells of each individual animal. Recent experiments have shown that the vibrations communicated through the body by the heart are deleterious to extra-vascular dead blood and the suggestion which he wishes to make is that those emanating from the heart-beat of the animal are more than a maximum for all the bacteria invading the interior of the animal body, especially in the injured state in which they are placed by the other influences of the body, for instance, by the plasmolysis. Thus, while we constantly live in a state of latent infection, as Adams calls it, it is not a force to normal health or life, but is rather a confederate in their defense.

13.—See abstract in our society reports of this week.

14. **United States Pharmacopeia.**—Wood's address reviews the history of the Pharmacopeia and notices the fact that it is especially a book for the pharmacist rather than the medical profession. He congratulates the recent convention for revision on its success and the high standard it has maintained, and makes the proposition that the committee on revision should be divided into two parts, one to prepare and the other to publish the Pharmacopeia.

17.—See ¶ 1, above.

18. **The Tropical Army Ration.**—Munson's article answers the question whether the present army ration is suitable for the tropical service, in the negative, and this involves the consideration of the physiology of hot climates, which is taken up. He finds that the body temperature in the tropics is elevated in new arrivals; the vital forces must frequently neutralize heat reception under external conditions to keep

the bodily temperature down toward the normal. This produces an alteration in the metabolism, and there is additional work for the kidneys and liver, for an excess of nutritive material which in temperate climates would be oxidized here requires to be excreted. The loss of weight occurs in hot countries as in summer in temperate climates. Loss of weight, provided the decrease is limited to the adipose tissue, however, may be considered as strictly beneficial. Tropical heat lowers the pulse-rate, and increases the respiratory capacity by making an alteration in the relative proportion of blood and air in the lungs. Respiration is diminished, perspiration increased and urinary excretion diminished. Through the loss of fluid resulting from increased perspiration, there is a diminished secretion of saliva, mucus, bile, gastric and pancreatic juices, and as a consequence there is dryness of the throat, weakness of appetite and improper digestion, gastric fulness after eating, and habitual constipation.

19 Stricture of the Urethra.—Of all the causes of stricture of the urethra, gonorrhoea stands first, other disorders being various diseased conditions, non-gonorrhoeal inflammations and traumatism; this last stands second as a cause to gonorrhoea, in fact, is relatively more frequent, but the number of cases of gonorrhoea being so much greater than the number of cases of traumatism, those of gonorrhoeal stricture of the urethra are proportionately increased. In many cases, however, the etiologic factor is not discovered. It is possible that an abnormal state of the urine may produce the condition and that it may thus be accounted for in gouty or rheumatic cases. The constitutional disorder mentioned by Cunnison is scrofula, though he does not credit it as a factor or believe in masturbation as a cause; calculi may be a cause, and may account for many rheumatic cases. The pathology of the condition and its symptoms are described at length and also the consequent bladder changes.

20. Nitrous Oxid; Ether; Chloroform.—Goldan insists on the necessity of not being too wedded to the use of any one anesthetic, as is too often the case. In many cases chloroform is preferable, as in acute pulmonary diseases, and in disorders of the circulatory system, since it lowers the blood-pressure and the chance of artery rupture is lessened. Where compensation has occurred, ether is to be advised. Alcoholic and drug habitues are better with chloroform, and it is preferable in obstetrics, though it is contraindicated if surgical narcosis is necessary, and particularly if hemorrhage is present. Chloroform should not be used at night as decomposition takes place when the vapor is brought into contact with an open flame, and the irritating vapors produced are dangerous. Ether can be used at night with safety if the light is above the patient and care is taken as to the inhaler and the container. In emergency cases, chloroform should not be used with the very young or the very old, and ether is practicable, if properly given in old or even young, where it has been claimed to be contraindicated. The after-treatment of the patient is important; he should be put in a bed that has been warmed, should be well covered, and have fresh air admitted to the room. Washing out the mouth with water in which there is a little lemon juice or peppermint will remove any unpleasant taste or odor from the ether. Vomiting should be encouraged, as it relieves the stomach of mucus and saliva. Of the various emergencies arising during anesthesia, the following are mentioned: a falling back of the tongue, which should be looked for; posture, which sometimes interferes; a valve-like action of the lips in very old persons, that sometimes interferes with respiration; spasm of the glottis, chest muscles or lower jaw muscles; vomiting, when loose teeth or particles of food are especially dangerous; insufflation of blood into the larynx, causing asphyxia. He speaks of performing tracheotomy before prolonged operations, and packing the pharynx with sponges as a safeguard against such accidents. In operations on children, for adenoids, etc., chloroform should not be used, as there is a danger of insufflation. In those cases where asphyxia occurs, artificial respiration should be practiced, the patient on the side and inverted, with the head extended. The dangers from the improper administration of the anesthetic are chiefly of the asphyxial nature

when ether is used; direct paralysis of the respiratory function is rare, as is also the depression of the circulation. With chloroform, there may occur depression and paralysis of the vasomotor centers, great fall in blood-pressure, and more rarely, paralysis of the heart. The respiratory centers are only secondarily involved. Collapse from ether rarely occurs without the warning of a shallow gasping respiration, and small rapid, irregular pulse. With chloroform the most frequent symptom of danger is an ashy gray pallor, with a rapid failure of the pulse. The possibility of collapse occurring without warning is mentioned, though he thinks this rare. Artificial respiration, except in operations on children, for adenoids, etc., already mentioned, is best done by Sylvester's method, as inversion permits the blood to gravitate to the vital centers in the medulla. Rhythmic traction of the tongue, according to Laborde's method, is also described, as are also other methods for exciting reflex respiration. Of the drugs that may be used, alcohol is condemned and ammonia recommended; harm may be done to the respiratory apparatus if too much is given. Strychnin is given as probably the best circulatory and respiratory stimulant, but if improvement does not result after a fair-sized dose, no further dependence should be placed on it. Other drugs mentioned are atropin and digitalis though they are not especially recommended, and amyl nitrite, which is found to do more harm than good, when chloroform is administered, though it may be useful with nitrous oxid. Saline infusion is of the greatest value in the treatment of shock where much blood has been lost. The introduction of hot fluid into the colon, though not practiced to a very great extent, is one of the best methods of treating shock and urinary suppression and relieving thirst. Goldan is doubtful as to anesthesia ever being in itself the cause of pneumonia, it is due rather to faulty management. However, he does believe that nephritis or suppression of the urine may result from supersaturating with anesthetics. Paralysis following anesthesia may be due to faulty posture or apparatus, or to rupture of a blood-vessel from improper management.

21. Modern Medical Conceptions.—Coulter calls attention to the progress of medicine, as influenced by improved methods of instruction and the use of the microscope, etc., in building up scientific conceptions. He thinks the fact that so many specialties have progressed so far is evidence that other departments can also be put in the same advanced position.

22. Tuberculosis.—Russell's paper is a plea for dispensary treatment of the consumptive poor who are not able to go to sanatoria, but can be cured or helped by proper treatment. He thinks that in the early stages of consumption, by patient and long-continued treatment, many can be cured, all can be benefited, all so taught as to be capable of directing and teaching others. He believes that the proper establishment of these methods would break down the idea that consumption is in all stages incurable, and would lead to measures for relief in the early stages.

23. Management of the Hair During and After Fevers.—According to Jackson, during the illness we can do little or nothing, except keep the scalp in a good condition. If the patient is a man, that will be a comparatively easy task, but if a woman, it will be more difficult. As a rule, the hair does not begin to fall out until some six weeks or more from the beginning of the disease, then if the patient has recovered with her hair in a snarl and is under 15 years of age, the easiest course to pursue is to cut it off as short as necessary, but if she is elder, or even in a child under certain conditions, the careful attention of the nurse will unravel the snarls. Then the hair should be combed and brushed daily, for only diseased hair can be brushed out, and the sooner that is removed the better. Once or twice a week a little pomade, containing a dram of precipitated sulphur to an ounce of good cold cream, should be gently worked into the scalp, or a 3 per cent. lotion of resorcin in oil and alcohol can be used. Once in every two or three weeks the hair and scalp should be washed, and the best kind of soap is a liquid one, such as the tincture of green soap. This should all be washed out and the best way to do it is to place the head under a full stream

of water as from a faucet. After washing the hair, it should be carefully dried and a little pomade rubbed into the scalp to take the place of the oil which has been removed. With this method the patient will regain all the hair she has lost and sometimes more, and be saved the discomfort of wearing a wig.

25. Ether Anesthesia.—Burrows would give four drams of sulphate of magnesium four hours before the anesthetic, and an injection of a quart of warm water an hour previous; he would restrict all food during the interval, with the exception of perhaps milk, and discontinue that at least four hours previous to the operation. He gives plenty of water, but empties the bladder before the operation, and removes false teeth from the mouth. He says there is no use of giving atropin prior to the anesthetic, which should be commenced gently, with irritation to the respiratory mucous membrane avoided by the gradual admixture of air. Stoppage of breathing in the early stages should not be considered alarming, but the inhaler should be raised and fresh air allowed to strike the nostrils, using a little ether on the chest to help start breathing at once. Plenty of ether is to be used in the early stage, but mixed freely with air, and we should watch the pupils, and if they are dilated widely and irresponsive to light, look out. Always keep the patient thoroughly anesthetized, watch the tongue, and if necessary use tongue forceps. Withdraw the ether occasionally and allow a few breaths of air. Be sure and keep the patient warm. If shock has been considerable, give a hypnotic of 1/30 to 1/15 grain of strychnin and do not leave the patient until reaction begins.

27. Ophthalmic Memoranda.—DeBeck's paper considers the medicolegal cases in eye surgery, which are not common, but do sometimes occur and are of importance. He mentions several interesting suits for malpractice, some of which are due to fraud, and also suits for services rendered. In one case of ophthalmoplegia an agreement was arranged by which he made an examination under the joint auspices of both parties and submitted a report to each. The result was a mutually satisfactory compromise, and he thinks this an ideal way of obtaining expert testimony.

28. Mould in Stomach.—Einhorn reports four cases in which he found spores and mycelia of fungi abundant in the washings of the stomach. These organisms do not find favorable soil for their development in the normal stomach, and any considerable growth would not be possible unless a colony had become so firmly adherent that it had not been carried along with the onward passage of the chyme. It is improbable that any considerable surface of the stomach can be thus occupied and yet be unattended by disturbances of the functions, though it is not easy to say exactly how this may occur. In his cases Einhorn found the mould formations in two groups of gastric affections: 1, in cases of excessive hyperchlorhydria occasionally attended with hypersecretion and vomiting; 2, in gastralgia with normal or reduced gastric secretion. In some of these cases lavage, followed by spraying with a weak solution of nitrate of silver, caused a disappearance of the mould flakes and a subjective improvement in the condition of the patient. He thinks, therefore, that it is probable that mould fungi are connected to some extent with the above-mentioned conditions, and from a therapeutic standpoint, it is therefore desirable to free the stomach from these moulds, and this is best done by irrigation in the fasting state, followed by a spray of an antiseptic solution of silver nitrate, 1-2 per 1000. Otherwise the treatment of these cases must be directed in accordance with the special disease present.

29.—See abstract in THE JOURNAL of Dec. 2, 1899, p. 1424.

31. Tricuspid Regurgitation.—Huntington finds his experience at variance with text-books for, in his examinations, he discovered a large number of tricuspid regurgitations accompanied by conditions more or less abnormal. It is usually described as rare, and yet a certain amount of regurgitation at that valve is said to be normal. He discusses the subject at length and objects to the conclusion that there is a normal regurgitation, on anatomic grounds. He thinks that the

structure of the columnæ carneæ shows that the valve has an automatic safety action and does not depend on a defect for its salvation.

33. Eye Strain.—Satterwhite's paper is a plea for the relief of various conditions, epilepsy, insanity, insomnia, etc., by operation for eye strain. He reports one or two cases that indicate the value of this method.

34. Nephritis in Childhood.—After a historical introduction, Moncorvo reports a number of cases of nephritis complicating malaria that he has found in his experience, which he thinks goes to prove that in cold or temperate climates, malaria plays the same part in the production of nephritis in the young, as does scarlet fever. The disease is of short duration and generally favorable in its outcome. Edema is sometimes extensive and the secretion of urine more than usually diminished, while albuminuria is almost constant and hyaline cysts are also present. As regards its pathogenesis, he suggests the theory of an antitoxin from malaria parasites.

35. Care of Feeble Infants.—Ransom makes the statement that allowing 15 per cent. of the children in the United States born to be either premature or feeble, we have 420,000 of them annually, and he details caring for these infants by incubators, etc., that can be improvised in the poorer homes.

36. Tuberculosis.—According to Gardiner, the reasons why tuberculosis spreads more rapidly among cattle than the human race, are: 1. A normal temperature nearer to that which is most favorable to the growth of the germ. 2. Generations of in-breeding of milk cattle. 3. Local stable conditions favorable to ready contamination.

38. Etiology of Beri-beri.—Ashmead discusses and disputes some of the theories in regard to the origin of beri-beri, which he attributes not to a germ, but to carbonic acid poisoning. He thinks it is a peripheral "neuritis and myelitis of the extremities and of the heart, dropsy following by osmosis through the paralyzed coats of vessels. Dangerous symptoms are respiratory and heart complications, gasping for breath, cyanosis, vomiting, etc. Evidently the pneumogastric nerve is implicated. The best treatment is transplantation to an altitude, fresh air, oxygen by tank, and diaphoretics, and diuretics. Hemoglobin being deficient in every case of beri-beri, and the red corpuscles being always normal, prove that the disease is not caused by insufficient alimentation."

45.—See abstract in THE JOURNAL of Dec. 2, 1899, p. 1421.

47. Pneumothorax.—From an analysis of fifty-one cases examined in the Boston City Hospital during a period of eighteen years, Morse concludes that pneumothorax is an uncommon condition, and that at least 70, and probably 85, per cent. of the cases are tubercular. In non-tubercular cases the prognosis is good when it is due to trauma, and fair when secondary to pulmonary abscess. The results of rib-excision in these cases are very encouraging. Tubercular pneumothorax is most common in males, is most frequent in the third decade of life and occurs about twice as often on the left as on the right side. The onset is acute in less than one-half the cases, and sudden pain with dyspnea is the most common initial symptom. Pneumothorax may be the first sign of tuberculosis. Displacement of the heart always occurs, being most marked in left-sided cases. Pneumothorax is usually complicated by the presence of fluid. Air is rarely present alone in patients living more than a week, and the fluid is more often purulent than serous. About 15 per cent. may recover, but they are practically all serous, and usually die later from pulmonary phthisis. Pneumothorax is a direct cause of death in 60 per cent.; and 80 per cent. die in less than a year, while only 10 per cent. live over five years. The prognosis is worse when the pneumothorax is right-sided or when it is purulent rather than serous, and when found in women. Surgical intervention is at least worthy of consideration in purulent cases. People with these disorders are sometimes able to be up and about, and often able to work.

48. Acute Pneumonic Form of Tuberculosis.—Elting details cases with pathologic findings. There were fibrous exudates filling up a large part of both lungs, and necrotic foci in the older portions. The latter were found also in the liver,

though neither tubercle bacilli nor any other bacteria were found in connection with them. They are, he believes, the result of the direct action of the toxin. The main clinical features of the disease are onset very often without chill, though it may occur; fever, often of an elevated character, but very frequently irregular or remittent and practically always the latter in advanced stages; an absence generally of marked dyspnea and cyanosis; physical signs; consolidation of greater or less proportion of the lung; pain in the side, with cough and sputum, which is at first typically pneumonic, but at the end of a week or ten days may assume a greenish tinge, and containing tubercle bacilli. In the cases reported they were found seven days after the onset.

49. Senile Bronchitis.—Wilcox describes and discusses the degenerative condition of old age and the pathology of senile bronchitis. Bronchorrhea with senile cough is common and passes often so rapidly and imperceptibly into active bronchitis that the patient is taken by surprise. Chilly sensations, general malaise, increase of cough, local pain, may all be wanting, but the increasing purulency of the sputa and the high rectal temperature and duskiness of the face show that bronchitis is present. The auscultation and percussion signs may also be insignificant. The diagnosis from pneumonia is made largely by the physical signs and the general prostration, but it is not always easy to distinguish it from tuberculosis. Sometimes only the post-mortem will establish the diagnosis. The tendency is for the condition to become chronic, as it can not be cured unless we can say that we can cure old age. The drugs in which he puts most confidence are ammonium carbonate and strychnia. The tissue conditions should be looked after and massage is often useful. The points as summarized are: 1. Careful diagnosis. 2. Use of strychnia and ammonium carbonate. 3. Prohibition of opium. 4. Systematic massage, especial attention being given to the chest. 5. Improvement of the general health.

50. Neurofibromata of Nerves.—Keen and Spiller report a case of multiple neurofibromata of the ulnar nerves, illustrated by elaborate drawings of the pathologic conditions. Spiller reviews the literature of the subject and refers especially to the possibility of degenerative malignant change in the tumors.

51. Ectopic Gestation.—Three cases of ectopic pregnancy are reported by Davis, and the diagnosis briefly discussed. He believes that shock referred to the abdomen, occurring in a woman capable of pregnancy, should always occasion a suspicion of this condition, though no tumor be found and the signs and symptoms be obscure; if the shock be pronounced, the abdomen should be opened and the condition present be diagnosed and treated. In one of the cases here reported the absence of shock was the only thing which made him doubt the diagnosis.

52.—See abstract in THE JOURNAL of March 17, ¶ 688.

53. Plague.—Clemow concludes his article on the clinical aspects of plague, by giving the manifestations of the disease. He calls attention to the varying character of different epidemics, as for example, the recent serious recrudescence of the disease in Poona during the monsoon, something entirely contrary to its behavior in previous years, there or in any other part of India. The disease, however, is unquestionably connected with, if not solely caused by, the entrance of specific bacilli into the body, and the subsequent production of specific toxins which, circulating through the tissues, produce the varied general and local symptoms. The toxins appear to have a special and early action on the brain and nerve structures. They are primarily nerve poisons, and the affections of other organs are, to a very great extent, perhaps more than is generally thought, due to the profound disturbance of the nervous mechanism that controls their action and nutrition.

61. Puerperal Sepsis.—The points of Polak's paper as summarized by him are: 1. Puerperal sepsis usually begins in one of two forms of endometritis, i. e., putrid or septic, except when the infection has been direct through the inoculation of lacerations and abrasions by the streptococcus or by the tetanus or diphtheria bacillus. 2. While the curette is in-

dispensable to the successful management of putrid endometritis, it is harmful in an empty uterus, such as is commonly found in the septic form. 3. All forms of septic infection are benefited by general stimulation and supportive treatment. 4. Of the antitoxins used, unguentum Cr d  has proved its superiority over the antistreptococcic serum. 5. Blood-washing and artificial production of a hyperleucocytosis are valuable adjuncts to the routine treatment. 6. Hysterectomy, post-partum, should be limited to those cases in which the sepsis is localized, as a metritis with pyosalpinx, or tubo-ovarian abscess, after the acute symptoms have somewhat subsided. Finally, the most parametric pus collections can be more safely handled by vaginal section.

62. Carcinoma Uteri.—Boldt reviews the methods employed for the palliative treatment of uterine carcinoma and concludes that curetting and the actual cautery are the best therapeutic methods for the treatment of this condition.

70. Intrauterine Implantation of the Ovary.—Dudley reports a case in which he had performed a double ovariectomy, and in order to preserve the function he took the right ovary, cutting away the portion which rested against the pyosalpinx, and planted it within the uterus, fastening it there with fine silk sutures, then closed the uterus, which he dropped back into the pelvis. The patient made a good recovery, and menstruation continued, but as she is an unmarried prostitute he does not look for pregnancy in her case, but he will in future watch for such cases, hoping to find a case of pregnancy following such a procedure.

71. Heat in Pruritus.—Andrews calls attention to the value of heat as a cure for intolerable pruritus, especially in those forms occurring in connection with chilblains, and in the anus and adjacent organs. As a historical fact of interest, he shows that the first Napoleon used this method to relieve a distressing pruritus of the thigh, and mentions the case of an old farmer who had made the discovery independently in his own case. The later authorities are beginning to recognize the value of this agent, but he thinks it should not be depended on too exclusively, though it is a powerful source of relief.

84. Typhoid Fever.—Wilson's article is a report of an experimental therapeutic study of the treatment recommended by Alude, for typhoid fever, in which he advises the use of nuclein and copper arsenite. The results with this method are not favorable, and he thinks Alude's assertion that typhoid fever can be brought to a favorable termination in from three to five days by this method is absolutely without support.

85. The Alleghenies for the Tuberculous.—Spangler points out the climatic and other advantages of the Allegheny region for the treatment of tuberculosis, and shows a climatic meteorologic table. He pleads for legislative interference to preserve the forests of this region and endowments for public sanatoria there.

86. Pulmonary Tuberculosis.—The measures recommended by Forrester for the prophylaxis and management of phthisis are: The regulation of marriage of consumptives, the legal checking of indiscriminate expectoration, regulation of possible tuberculously contaminated foods, proper clothing, early care of catarrhal troubles of the respiratory tracts, outdoor occupations, fresh air, plain nutritious diet, etc. He appears to indorse Mays' theory of the neurotic origin of the disease and the value of silver nitrate injections.

94. Relation of Uric Acid to Migraine.—Lichty reports the results of his studies of the urine, with especial reference to uric acid and urea in their relation to migraine. For the estimation of urea, Liebig's method was employed, and for uric acid the method of Hopkins, modified by the use of a decinormal solution of sulphuric acid with methyl orange as an indicator, instead of titrating with the unstable potassium permanganate solution. When the headache began, the patient was instructed to save the urine in separate vessels during the entire period of the attack, and that voided at the time of the greatest intensity was examined, as was also that specimen collected as soon as the headache disappeared. Several times examinations of two urinations during the attack were made, and also one or more similar examinations in the interval be-

tween the attacks. From these studies, carried on during the past three years, it was found: 1. That both uric acid and urea were diminished during the height of the headache, but their own relation was not disturbed. 2. That after the headache, the urea increased to about what it was between the attacks; while the uric acid increased much more, thus changing the former ratio. These results do not agree with the uric-acid theory of migraine, but the control experiments made by Lichty seem to confirm them. He found that the uric acid wave associated with migraine does not appear for some hours after the culmination of the attack, and that, therefore, this increase of uric acid is to be taken as the effect rather than the cause. By careful chemical analysis, he finds that there was no excess of uric acid in the blood during the attack of migraine, and that in some cases there was even a slight increase of alkalinity.

96. **Curability of Nervous Diseases.**—Punton finds that practical knowledge and experience prove conclusively, that when the two great classes of nervous diseases are compared, irrespective of their seat, the organic diseases are well-nigh incurable, while the so-called functional disorders are in most part curable if recognized early. While there are some exceptions to this rule, its general validity can not be disputed. He notices the views of different individuals on this question, such as, for example, claims that epilepsy is curable, which he rejects.

97.—See abstract in *THE JOURNAL* of April 21, p. 1005.

102.—See abstract in *THE JOURNAL* of April 14, p. 934.

103. **Diagnosis of Pneumonia.**—Several cases are reported by Behrens, which show the difficulty of making an immediate diagnosis of pneumonia, the symptoms and physical signs being obscure. He emphasizes the following points as important in making the diagnosis in non-typical cases: 1. Be in no hurry to pronounce a case pneumonia of special type unless you have examined the patient thoroughly, both as regards objective and subjective symptoms. 2. Remember that no sharp line exists between the ending of a severe bronchitis and the beginning of capillary or catarrhal pneumonia. 3. Depend always on a physical examination as being of the most importance. 4. Children under 6 years have, as a rule, capillary catarrhal pneumonia; 6 to 16, croupous or catarrhal; adults, lobar pneumonia. 5. Do not lose sight of chest exploration, if peculiarities arise in continued fevers.

111. **Latency or Cure of Pulmonary Tuberculosis.**—Von Ruck points out the possibility of latency of phthisis, and insists on the necessity of treatment and testing of cases by the tuberculin reaction before they are pronounced cured. Patients that have been treated by tuberculin preparations can not properly be tested at the discontinuance of treatment, but six months later would give a sufficient interval to make the test of value.

118. **Diaphoresis in Pneumonia.**—In the *Medical Register* for Aug. 15, 1897, Miller reported the use of wrist heat for producing diaphoresis in the treatment of pneumonia. Since that time he has successfully used the treatment in a number of cases with uniform good results, with one exception. "The method of application of the wrist heat is to heat several bricks (six will usually suffice) in the oven and then thoroughly saturate them with boiling water, after which they are to be wrapped in cloths, preferably flannel, and placed about the patient. Sweating must be kept up from two to forty-eight hours, relief of pain being a most valuable indication for discontinuance. The bricks may be removed from time to time by carefully withdrawing them one at a time, and replacing each as removed by a new one prepared as above. Patient's clothing and bed-clothes should not be changed until thoroughly dry." Several cases are reported.

127. **Babinski's Symptom.**—According to Wood, the toe reflex can not be relied on as a basis for diagnosis. He has studied it in children and adults, and has not been able to corroborate the statement of Collier, as to the correctness of the original claim of Babinski, who held that there are two distinct forms of the plantar-reflex, one of the normal adult, and one of the child; and that in certain cases of disease, a rever-

sion of the former reflex occurs in the adult so that it is possible to make a diagnosis as to the seat or even the nature of the disease by this symptom.

128.—See abstract in *THE JOURNAL* of May 12, ¶ 46, p. 1185.

140. **Yellow Fever.**—Carter has analyzed the cases of yellow fever that have occurred in two Mississippi towns, with the special object of ascertaining the regular interval that must elapse between the development of yellow fever in non-infected places, and the development of that contracted by infection. The points involved are, the time from the development of the infecting case until that of another, plus the time the individual in question was exposed to the environment before he contracted the disease, plus the time from the contracting of the disease until its development. He thinks there is much evidence that is usually in, or not sooner than, the third week that the secondary case develops. There is no definite time limit that may be called the situation of "safe" or "unsafe," but hope of safety increases with the passage of the third week and the lapse of time after this. The first group of cases infected from the initial case occurs generally in from two to three weeks. These form new foci, the original ones remaining active; and in two or three weeks more a fever should be "scattered" in tertiary foci, just beginning. Prior to this it is found only in those who have had a common exposure, seldom in more than from four to eight places.

141. **Heroin.**—Floekinger has used heroin at first in 1/6-grain doses, but with this he noticed gastric disturbances in several cases. Since then he has used it only in 1/12-grain doses, and he has found that the hydrochlorid is admirably adapted for hypodermic injection. The dose is from 1/24 to 1/12 grain, whether given hypodermically or through the mouth. He does not think one is liable to become addicted to the use of heroin, as its narcotic effect is so much inferior to that of morphin. In conclusion he says that we possess in heroin an excellent sedative of the respiratory tract, which is devoid of the narcotic effect of morphin or codein and, therefore, in physiologic doses is entirely uninjurious.

143. **Gall-Stones.**—Cordier considers that cholelithiasis is of frequent occurrence and is usually accompanied by symptoms. Cholesterin as a gall-stone-producing agent must be present in an abnormal quantity, for it is largely a product resulting from the destruction and disintegration of the epithelium of the biliary ducts and gall-bladder. Bilirubin-calcium, an insoluble compound of bilirubin and the lime salts is a nucleus of all stones found in the ducts and the majority of those formed in the gall-bladder. Jaundice, ptomain poisoning and suppurative are late symptoms, while dyspeptic ones, swarthy skin, uneasiness in the region of the gall-bladder, and loss of weight are some of the remote and local ones. The most direct causative factors are inflammatory diseases of the duodenum and bile passage. While some patients get well without medical or surgical assistance, the physician can greatly aid the progress. The surgery is especially difficult and should not be undertaken by the inexperienced. A ball-valve stone continuously gives rise to symptoms until surgically removed, and when septic ones occur from gall-stones surgery is required.

144. **Fracture of the Ankle and Elbow.**—Ochsner calls attention to the fact that in a very large proportion of cases there is painful ankle-joint following Pott's fracture, due to the foot being in the equinus position, and resulting from the position in which the foot was fixed when the fracture was first treated. This is nearly always in an obtuse angle to the leg, and the gastrocnemius muscle is in a condition of tension. He would remedy this by putting the leg in a flexed position with relaxation of *this muscle*. To obtain a good result we should always place the foot at a little less than a right angle. In the treatment of fracture of the elbow-joint one of the most common difficulties is a partial ankylosis, especially in children, and the best result he has had in the treatment of this condition is obtained from encouraging the use of a wheelbarrow, something a child will enjoy, and that will cause a spontaneous straightening of the arm.

Acoustic Principles Affecting Conduction of Sound by Bones of Head. ALBERT A. GRAY.—The object of the author's investigations was to find out the acoustic principles on which the tuning-fork tests depend. The fact that the same results can be produced by apparently opposite means in these tests gave rise to certain questions which he sought to solve. His experiments were made on an individual who was unacquainted with the principles involved, and by means of a probe introduced through the meatus against the drum membrane, and by gently pushing it forward against the handle of the malleus and other portions of the drum membrane the sound of the tuning-fork was modified. It was found that inward pressure of the outer parts of the membrane and of the manubrium produced opposite results, and the author accounts for it by the anatomic arrangement of the muscular fibers. The normal position of the drum membrane is slightly depressed in the center, like a funnel, with its apex pointing inward and its convex sides outward. When pressure is applied to these convex sides the radiating fibers will be relaxed and the circular ones become tense. When this occurs the former fibers become worse conductors of sound and the latter better ones, because the increased tension of fibrous substance produces increase in its sound-conducting power, and vice versa. So when pressure is brought to bear on the convex surface of the membrane, the radiating fibers are relaxed and the intensity of the sound conducted by the hammer is diminished. When, however, the probe is applied to the handle of the hammer, the results are different. The apex of the funnel is pressed inward and the tension of both sets of fibers, circular and radiating, makes little or no difference because the paths for the conduction of sound are the radiating ones. The latter are tenser than when the membrane is in a normal condition and the sound is conducted with less loss to the ossicles and thence to the labyrinth. The manner in which the atmospheric pressure causes alteration in the tension, however, is peculiar. Were the membrane equally strong in all parts and not attached to the ossicles, when the atmospheric pressure was increased or diminished the movement of the membrane would be greatest at the middle. Now after very slight increase of pressure of air this is true; the tip of the handle of the hammer and center of the membrane move more than the outer parts, which causes an increase in the tension of the radiating fibers and hence increase in the subjective intensity of the sound conducted by the bones of the head. This explains the fact that if the finger is inserted in the meatus the duration of sound is increased by better conduction. If, however, the finger is pushed forcibly into the meatus, the movement of the center of the membrane and the handle of the hammer soon stops, partly because the ligaments of the ossicles come into play, also because the eeg at the head of the handle catches on the incus and further movement inward is prevented or greatly diminished. The cause of the changes in the bone production when the air is condensed in the meatus seems, therefore, to be this: At first, under very slight increase of pressure, the center of the membrane with the handle of the hammer is drawn slightly inward, while the remaining parts of the membrane increase their convex form; this increases the tension of the radiating fibers, and hence their sound-conducting power; so with very slight increase of pressure of the air, increased intensity of the sound conducted by the bones is produced. If, however, the pressure is increased to more than a slight extent, the center of the membrane remains stationary while the convex surfaces of the membrane become flattened; hence relaxation of the radiating fibers occurs, and diminution in the intensity of bone-conducted sound takes place. The practical applications of the investigation to the test of hearing by better conduction in the deaf, and the experiments which have been made with the view of ascertaining the part played by the tympanic membrane in the generation of different tones will be published later.

The Lancet, April 28.

Case of Pernicious Anemia Treated by Antistreptococcal Serum. WILLIAM ELDER.—The writer reports a case of this affection in a man, 35 years of age, who had suffered

much from defective teeth. He presented all the symptoms characteristic of pernicious anemia. The blood test, two days after admission into the hospital, gave 797,500 red corpuscles, hemoglobin 24 per cent., leucocytes 4520. The treatment was a thorough disinfecting of the mouth, 5 gr. of salol and 15 gr. of bismuth salicylate internally every six hours, and 10 gr. of antistreptococcal serum injected into the subcutaneous tissue, every second day, the total amounting to eighteen injections up to March 19. This, with the exception of an occasional hypnotic and laxative, constituted the whole treatment. Improvement was rapidly progressive. On March 20, forty-five days after the commencement of treatment, the blood was practically normal, red blood-corpuscles 4,800,000, hemoglobin 104 per cent. While it would be a mistake to draw very decided conclusions from this one case, Elder thinks that it is suggestive and believes this form of treatment worth a further careful trial in pernicious anemia.

Cysts of the Breast; Their Relative Frequency, Diagnosis and Treatment. THOMAS BRYANT.—From his experience the author concludes that cysts of the breast are far more common than generally supposed, and that they are chiefly found in women during the same period of life as that in which cancer occurs. They are mostly amenable to local treatment without the sacrifice of the breast glands in which they are situated, and there is no reason to believe that women who have these cysts are more prone to cancer than those who do not have them. He carefully analyzed his notes of cases, and found that they suggest the conclusion that out of every four cases of tumor of the breast more or less simulating cancer, one at least will be cystic or of a simple nature. He thinks these are originally involution cysts in most cases. Their diagnosis may not always be easy, especially when in a middle-aged woman with a hard, slow-growing lump in the breast, and without any history of influence of lactation or any inflammatory breast condition. A careful medical examination should be made and, if the surgeon's sense of touch is keen enough to detect elasticity in the swelling, or even fluctuation, the diagnosis of cyst may be hazarded. If a clear serous fluid can be made to flow from the nipple, by manipulation or pressure on the tumor, the probability of the cyst being a simple one is much enhanced. If the fluid is brown or blood-stained the possibility of intracystic growth of some kind is suggested, and if more like pure blood, the presence of a soft solid growth, sarcomatous or carcinomatous, should be feared.

Strychnin as a Factor in Causing Cerebral Hemorrhage. LACHLAN GRANT.—The author calls attention to the importance of cautioning elderly patients with arterial defects against drugging themselves with tonic syrups and tabloids containing strychnin. On account of the danger of producing arterial rupture in the brain special care should be taken by the physician in administering strychnin to patients who have reached the degenerative age, especially in cases of cirrhotic Bright's disease, chronic gout and syphilis, or where the patient has thickened or tortuous blood-vessels, or even where there has been an hereditary tendency to apoplexy.

Revue de Médecine (Paris), March and April.

Liver in Scarlet Fever. H. ROGER.—This author has found that the alterations noted in the liver in scarlet fever are most extensive in the subacute cases. Fatty degeneration is the lesion most frequently observed. The organ usually appears enlarged, pale, marbled and crowded with leucocytes, while the cells degenerate. These alterations vary in intensity, and in one case of death after a month of scarlet fever nephritis, the liver seemed to be almost normal. The clinical manifestations of these hepatic lesions offer an interesting field of study.

Semaine Médicale (Paris), April 18.

Benedikt's Syndrome. GILLES DE LE TOURETTE AND JEAN CHARCOT.—The syndrome described by Benedikt, paralysis of the third pair with crossed hemiplegia and tremor, is easily diagnosed, the tremor differentiating it from Weber's syndrome, which it most resembles. With an unpublished ob-

ervation found in Charcot's papers and two personal cases, the writers were able to collect only six observations on which to found their study of the affection, including Benedikt's three. It commenced at the ninth month, or fourth, sixteenth or thirty-sixth year: gradually, with a premonitory cephalalgia for a year, or suddenly, with ictus inducing coma for three days. The hemiplegia is the ordinary spasmodic form, and may vary in intensity. The tremor may appear with it or not until a year or two later. The symptoms were doubled in one case, producing a dual syndrome. One case terminated fatally in four months, a child of 4; in another—a young woman—the affection has remained stationary since infancy; in a third—a negro, 39 years old—the syndrome has gradually increased in intensity since its sudden onset sixteen years ago. Benedikt attributes the syndrome to a lesion in the peduncle of the cerebrum near the nucleus of the motor oculi, where this nerve emerges, and he was able to establish its existence in one case by an autopsy. The motor or pyramidal fibers entering the peduncle may be affected "by continuity or contiguity" of the lesion, and to this the tremor must be ascribed, and the variability in its nature, although it has the constant characteristics that it is exaggerated with the voluntary movements and ceases during sleep, but otherwise may suggest the tremor from sclerosis in patches or paralysis agitans, hemichorea or hemiathetosis, with and without abolition of the reflexes. The character of the anatomic lesion seems to be immaterial; the localization in the peduncle at this point is the essential factor of the syndrome.

Grece Medicale (Syra), March.

Aporetic Disturbances of Temperature. TRIANTAPHYLIDES.—A number of tests on 130 subjects in health and aporetic disease, instituted by the writer at Batoum, differed in their results from the dicta of the text-books. He found that the normal temperature varied from one subject to another by more than a degree, but that it was more or less constant in each one. Healthy persons with subnormal temperature (35.8 or 36C.) are not rare at Batoum, and inquiry usually elicits malarial antecedents, unless the hypothermia is due to age or a recent disease. In such cases fever might be masked by the habitual hypothermia and a considerable elevation of temperature fail to be recognized on this account. He reviews the disturbances in the calorification in 101 cases of typhoid fever, 81 of pneumonia, and numbers of other diseases, and concludes that the calorification is one of the organic functions most frequently disturbed by affections which in one way or another touch the entire organism, and that affections in which the calorification is disturbed have a much more serious prognosis than others in which it remains intact. Regulation of the calorification is frequently a sign of a favorable issue.

Berliner Klinische Wochenschrift, April 2 to 23.

Toxicity of Thyroid Alimentation.—In the tests reported, dogs fed with fresh thyroid glands showed besides the usual phenomena a leucosuria amounting to .5 per cent, which persisted several days after discontinuance of the thyroid feeding.

Apparato-Therapy. P. JACOB.—This communication from v. Leyden's clinic extols the remarkable benefits that may be derived in long-seated paralytic affections of the central nervous system by the judicious use of apparatus, either to substitute the function of the paralyzed muscle or group of muscles, to assist and reinforce a partially disabled muscle, or to assist and reinforce the sound muscles to compensate the disability of the others. Two instructive observations are described, one a woman of 33 years of age, who could neither walk nor take hold of anything on account of spontaneous juvenile atrophy of the feet and hands. In the other, myelitis luetica had rendered the patient helpless. This latter case was improved by dural infusion of a solution of iodine, and function practically restored to the members by gymnastic exercises while lying on a hammock in a bath, exercises absolutely impossible in such cases without the support of the water.

Water-Secreting Power of Kidneys. G. KOVESI.—In this study, made at Koranyi's clinic, of the disturbances in the water-secreting power in generally diseased kidneys, Kovesi found that certain important facts might be learned by combining a dilution of the urine, by copious ingestion of water, with the determination of the freezing-point. The lowering of the freezing-point of the urine in renal affections depends on three conditions: 1, on the localization and the degree of the morbid process, which together determine the extreme limits of the variability in the concentration of the urine; 2, on the amount of water ingested, and 3, on the permeability for solid molecules still retained by the kidney. The quantity of water which when ingested produces urine isotonic with the blood, may vary with each case. When the nephritic subject drinks this amount, the kind of renal affection from which he is suffering will have no influence on his urine. If he drinks considerably more than is required to produce this isotonic urine, then, in case of parenchymatous nephritis, the urine will be much more concentrated than in case of contracted kidney. If he drinks less than this special quantity, the freezing-point of the urine falls much lower in case of contracted kidney, while it scarcely varies with parenchymatous nephritis. Tests on twenty subjects with normal or generally diseased kidneys have established several points and thrown light on others. Each drank 1.8 liters of Salvorator water during the noon hour. Study of the urine then showed: 1. That by determining the lowering of the freezing-point and the quantity of urine eliminated during the twenty-four hours, the amount of molecular diuresis can be ascertained and in pronounced cases molecular oliguria be recognized. 2. That by determining the freezing-point of the blood it can be ascertained whether the molecular diuresis is sufficient for elimination of the molecules capable of passing into the urine, formed during metabolism. If the molecular diuresis is insufficient in proportion to the metabolism—corresponding to the diminished permeability of the diseased kidneys for solid substances—then the freezing point of the blood becomes lower. 3. Hypostenuria indicates diminished water-absorbing power on the part of the kidney. 4. The more or less negative result of the "dilution test" indicates a decrease in the water-secreting power. The tests showed that the water-secreting power in the kidney is diminished in parenchymatous nephritis in proportion to the severity of the lesion, while it is retained to a greater or less extent with contracted kidney, as also in renal affections due to heart troubles. Congested kidney, in the tests, behaved like a transition form between chronic parenchymatous nephritis and secondary contracted kidney.

Centralblatt f. Inn. Med. (Leipzig), March 31 and April 21.

Rendering a Toxin Harmless. E. V. CZYHLARZ.—The German title to this article, "Entgiftung," means, literally, "disintoxication." The experiences related were made in the course of studies to determine the power possessed by the various organs, to render a toxin innocuous for the organism. A ligature was placed on the hind leg of a guinea-pig above the knee and a fatal dose of strychnin injected below. The ligature was removed after one to four hours, and none of the twelve animals showed a trace of intoxication at that time or later. Others snuclembed as usual to strychnin intoxication if the ligature was removed in a half hour, but an hour's interval before removing it was sufficient to save the animal from the toxic effects of the drug. Czyhlarz attributes these results to a binding or neutralizing of the strychnin in some manner by the living subcutaneous cellular tissue, muscles and blood and lymph fluids.

Intervals Between Feeding Infants. A. KELLER.—The writer states that five meals in twenty-four hours are sufficient for infants, and no more are allowed at the Breslau children's clinic. At the same time he has established that the absorption and retention of nitrogenized substances and phosphates is not influenced by the length of the interval between feeding. Consequently chemical tests are no criterion by which to regulate an infant's feeding-time.

Deutsche Medicinische Wochenschrift (Leipzig), April 26.

German Malaria Expedition. R. KOCH.—In this third

report Koch describes the results accomplished during January and February in German New Guinea, where he discovered 157 cases of malaria among 734 persons, while he was unable to discover more than 30 cases in five weeks at Batavia. He includes in his list only those in which the presence of the malarial plasmodium could be demonstrated. On a large plantation 12 of the 21 Europeans were affected; 26.3 per cent. of the 240 Chinese laborers; 25.3 per cent. of the Malays; 10.9 per cent. of the Melanese. Among 217 natives examined, he was unable to find a single case of malarial infection in the 154 who were over 10 years of age, and only four between the ages of 5 and 10. But 80 to 100 per cent. of the children under 2 were affected, and over 40 per cent. of those between 2 and 5. "The only means, therefore, of establishing the absence of malaria at a place is investigation as to the children." No cases were found among those at the mission station on an island off the coast, but all were over 2. The form of malarial infection among the children was, in 29 cases: tropical fever in 18, tertian in 5 and quartan in 6. Among the 157 adults it was: tropical in 65, tertian in 20 and quartan in 73. The gradually acquired immunity of the natives after early childhood is apparent from this research, both in Java and in New Guinea. The results of the author's investigations are tabulated and show that elevated regions are certainly more exempt from malaria than low-lying regions, although this is not an invariable rule. There was no malaria to be found, for instance, at Soekaboemi, which is about 1809 feet above the sea, although four different varieties of anopheles were discovered in considerable numbers. On the other hand, at Bandoeng, which is at an elevation of about 3280 feet, over 40 per cent. of the children under 1 year old were affected, and over 14 per cent. above this age.

Pathology of Bronchial Asthma. A. FRAENKEL.—The mucous nature of Curschmann's spirals seems definitely established by the post-mortem findings reported by Fraenkel in two fatal cases of bronchial asthma. The anatomic findings are not always the same, but the morbid process, whatever its nature, seems to be restricted to the more delicate bronchial ramifications. There is, however, one constant bond between all the cases, that is, the abundant desquamation of the epithelium. It is impossible for us to understand the modus operandi of the process which in one case causes the shedding of such abnormal amounts of epithelium in the bronchioles that the lumen is almost completely occluded, while, in another, the mucus-producing capacity is augmented to excess and a peculiarly tenacious mucus is secreted, leading to coagulation and spiral-formation. The only possible assumption is the influence of the nervous system, differing in individual cases, on the vascular and secretory apparatus of the bronchial mucous membrane. The central threads in the spirals are most probably, he thinks, long-drawn-out cell bodies from the ciliated epithelium, around which the mucus accumulates.

Treatment of Obesity. W. EBSTEIN.—Starvation and courses at watering-places to reduce obesity are not the proper methods to pursue, according to Ebstein. He would have the entire life altered to one of self-control: three meals a day, ceasing to eat at the first indication of satiety, food restricted to about 1300 calories for a man weighing 70 kilos; for breakfast, tea without milk or sugar, and 50 gm. of bread with plenty of butter; for dinner, soup, 120 to 180 gm. of roast meat with cabbage and green vegetables, salad, baked fruit without sugar, and fresh fruit, no turnips, parsnips nor potatoes; for supper, one egg, fat ham, smoked fish, 30 gm. of bread with plenty of butter, a little cheese and fresh fruit. This menu is agreeable to most persons and the appetite can be still further appeased by giving a large place in the menu to vegetables free from carbohydrates. Children of parents with a tendency to obesity should be watched over and not allowed to get into habits that would induce it. This rational, life-long treatment of obesity is also applicable to gout, diabetes, etc., and keeps the subject well and energetic. A good test of the amount to be eaten at a meal is whether one returns to work with zest after it. Milk and the products of milk are allowed when much craved, and the effort is made to substitute the albumin of

vegetables for that of meat as far as possible. No naps are allowed after meals.

Mittheilungen a. d. Grenzgebieten (Jena), vi, 1 and 2.

Tumors of Bladder. W. WENDEL.—In four of the sixteen observations described, the patients were workmen in anilin factories, which is a suggestive fact. In all the cases the benign papillary tumor of the bladder evidently originated in a primary proliferation of the epithelium, soon accompanied by proliferation of the vessels and connective tissue. These tumors manifest a decided tendency to malignant degeneration, the first indications of which are the appearance of masses of epithelium in the lymph-spaces of the stroma and in small nests, which have no direct connection with the surface. Epidermoidal formations are due to leucoplasia, and the epidermoidal cancers of the bladder and urinary passages are to be explained as metaplasia. This leucoplasia may develop without a preceding cystitis, and epidermoid cancer without a preceding leucoplasia. The most careful study of the tumors failed to disclose any evidence of a parasitic origin, but it enforced the necessity of extirpating the foundation on which the tumor grows, for quite a distance into the apparently sound tissue, even in case of pedunculated tumors.

Operative Treatment of Abdominal Tuberculosis. A. FRANK.—The remote results of operative treatment in 63 cases of chronic abdominal tuberculosis and allied conditions are tabulated and the following conclusions in regard to the prognosis are deduced: 1. Tuberculous peritonitis with effusion affords the best prognosis, as 40 to 50 per cent. recovered. 2. The prognosis of the dry variety with adhesions is more serious; only 25 per cent. recovered after operation. 3. The three patients with the ulcerative, suppurative variety died. 4. Among the cases with and without effusion the largest number of recoveries occurred in infection proceeding from the female genitalia: 75 per cent. in the former and 50 per cent. in the latter. 5. The attempt to relieve a patient with indications of peritoneal stenosis, by laparotomy and entero-anastomosis, is a justifiable procedure, although the results are far from brilliant. 6. Tuberculous fecal fistule indicate an exceptionally grave prognosis. 7. Tuberculous peritonitis occurring with ovarian cystoma is so rare that the prognosis can not yet be formulated.

Results of Operative Treatment of Basedow's Disease. G. REMBACH.—Four to ten years have passed since Mikulicz operated on his first series of nine cases of Basedow's disease, and the remote results are extremely gratifying. All the objective symptoms were nearly or entirely cured by the operation, and the patients have been completely restored to their working capacity and enjoyment of life. This article reviews the results in 18 operated on. Resection was done in 13 with success; enucleation in 3; bilateral resection in 4 at one time, and in 2 at two separate sittings; unilateral resection in 4. The arteries were ligated in 5 cases. No constant pathologic-anatomic alteration could be discovered specific for the Basedow goiter.

Zeitschrift f. Geb. u. Gyn. (Stuttgart), xiii, 1 and 2.

Conservative Treatment of Pyosalpinx. G. HERBMAN.—Reviewing his experience with thirty-four cases of inflammatory affections of the adnexa, Hermann recommends resolute, antiphlogistic treatment of acute cases as long as possible, in view of possibility of spontaneous recovery. He would operate in chronic cases where the sterility of the pus can be counted on, that is, nine to twelve months after the end of infectious process, obtaining, if possible, certainty of sterility of pus with a test-puncture. His method is laparotomy, conservative in the extreme.

Ultimate Results of Bilateral Operations on Adnexa. F. BARUCH.—The ultimate results in the cases in which the uterus was removed with the adnexa have proved more favorable than in those in which it was left, according to Baruch's experience with sixty-seven patients followed to date. He attributes this fact to the recurring painful inflammation in the ligated stumps and the stump exudation, which occurred scarcely at all after the radical operation. Other factors were the hemorrhages from the retained uterus, and the eliminative

disturbances, which were much less intense in the fourteen from whom the uterus was removed. Abdominal salpingo-oophorectomy proved effectual in every case, and half of the patients were definitely cured. The percentage of cases in which the working capacity has been restored is about the same with and without removal of the uterus—83.3.

Parietal Bone Presentation. H. BOLLENHAGEN.—Only two out of eight cases of this presentation, at the Würzburg clinic during the last three years, required versio-extractio. The rest terminated spontaneously, consequently Bollenhagen advises awaiting as long as possible before resorting to intervention.

Osmosis Between Mother and Fetus. J. VEIT.—The first result of the research reported was the discovery that the freezing-point of the blood of the child at the moment of birth is lower than that of the mother's blood. It was then noted that the freezing-point of the amniotic fluid is higher than that of the blood of either mother or child. It seems evident from these and other facts mentioned, that the dividing wall between mother and child has something of the nature of a dialytic membrane. Veit adds that further study of the subject may lead to a more rational and effective method of treating eclampsia.

Blood-Pressure in Health. S. JELLINEK.—No relation between blood-pressure and pulse could be detected in tests on 532 healthy soldiers in Vienna. The normal blood-pressure varied between wide limits, from 80 to 185 mm. mercury. The average ranged from 100 to 160 mm. The blood-pressure was higher on the right than on the left side in a number of instances. External stimuli and influences: marching, eating, sharp-shooting, baths, did not affect the blood-pressure materially. In some it was increased, in others, lowered, and in quite a number no effect was perceptible.

Pathogenesis of Eclampsia. W. STROGANOFF.—Several series of cases of eclampsia, occurring at the St. Petersburg Midwives' Institute, sustain the theory advanced by Stroganoff that eclampsia is an infectious disease. Analyzing cases reported by others he notes that Olshausen records eleven series of cases of eclampsia, 83 in all, occurring within 250 days, and Zweifel records twenty series. A curve made up from these and his personal observations shows the same striking accumulation of cases the sixth day after the first infection. He affirms that eclampsia is an acute infectious disease, caused by an air-borne contagium, which usually penetrates into the organism through the air-passages. The disease germ is very slightly virulent. Men and children are not susceptible to it, nor women at any period of their life except during the puerperium. It can also find favorable conditions for development in the fetus, and makes no distinction between male and female in this respect. The germ is very resistant and in hospitals retains its virulence about three weeks. The period of incubation is short, from three to twenty-four hours. Primiparae, women bearing twins and women with renal affections are most susceptible. Strict isolation of all cases and disinfection of attendants are imperative. Nocard also admits the infectious nature of the disease from his observation of its occurrence in cattle and dogs when casting their young.

Klinitchesky Journal (Toscow), ii, 1.

Significance of Pains in Female Pelvic and Peritoneal Cavities. V. T. SNEOUTREFF.—The great importance of the characteristics of the pain in gynecologic troubles, for differentiating affections and indicating treatment, has never been appreciated heretofore. Snegoureff reported a year ago nine cases of severe endometritis dolorosa cured by dilation of the cervix and tamponing the uterus with gauze. As described in *THE JOURNAL* at the time (March 11, 1899, p. 552), he ascribes endometritis dolorosa to an inflammatory lesion of the uterine mucosa, and not to neuralgia or general neuropathy, as others are inclined to believe. He has been following his cases to date and eight new ones, and has obtained valuable and unexpected information by locating the painful points—which correspond mostly to the emerging points of nerves—and by determining the nature of the pains. He has established, in the first place, that one variety of endometritis dolorosa is a

threefold affection, involving the three orifices, anus, urethra and internal orifice of the uterus, which all become spasmodically contracted. The pain is similar in its cause and nature to that of fissura ani, and is benefited by the same treatment as the latter; dilation under narcosis and, if necessary, cutting the fibers of the muscular ring. All the pains vanish at once, showing that compression of the nerves and not an organic lesion was the cause. His method of anterior sphincterian hysterotomy is shown in the cut. One stroke of the concealed knife cuts the internal orifice across and the anterior wall of the cervix. No narcosis is necessary. The patients do not feel the slight incision nor know when it is done. There is no danger of hemorrhage, as he has established that the anterior median line of the uterus, the uterine linea alba, is free from vessels. Even if the bladder should be incised, of which there is scarcely the slightest danger, the incision would close and heal at once with a permanent catheter inserted and left for a time. The region of the incision in the cervix is tamponed with gauze for a couple of days. The significance of the renal plexus in the etiology of pains in the pelvic and peritoneal cavities is another result of his research, and the great benefit derived

from hot rectal injections, which far surpasses the effect of vaginal in these cases. He reports cases of pelveoperitonitis, antelexio uteri with perimetritis posterior adhesiva, and retroversio fixata, in which the patients were cured of their pains by hot rectal injections and appropriate general measures, calomel, etc., as indicated. As an illustration of the significance of the pains his first observation of endometritis dolorosa is typical. The patient, a multipara, 40 years old, complained of frequent and extremely painful micturition, and pain during coitus and defecation; menses irregular, constipation, digestive disturbances, and hypogastric pains. The painful points were located at the tuberculum pubis on each side, on the inner surface of the thighs, at the renal plexus on both sides, and at the solar plexus and rectum. Sounding the uterus induced intense pain at the internal orifice and in the fundus. Nothing abnormal was noted in the nervous, respiratory or circulatory systems. The uterus was normal in size and consistency. The external orifice allowed the passage of finger tip. The "threefold affection", as he calls it, was in this case treated with gradual dilation, under narcosis, of the three painful orifices—anus, urethra and internal orifice of the uterus—and the latter organ packed with a strip of iodoform gauze, left for two days. In five days all the pains had vanished except in the solar plexus, where they lasted a couple of days longer. Hot rectal injections were also ordered and general tonic measures. The patient left the clinic in three weeks, cured of all her pains, and feeling well and strong. In another observation the painful points were the same as above, and also a point on the spina anterior superior. The pains were much more intense on the left side, and subsided somewhat during menstruation. The other organs and micturition were apparently normal. Coitus was painful at times. This case was treated with dilation of the internal orifice and anterior sphincterian hysterotomy as in the illustration. No narcosis was used. Tamponing was with iodoform gauze left for three days. By this time all the pains had disappeared except in the fundus, and these also soon vanished and the patient was dismissed completely

cured in ten days after operation. The painful points are to be sought by pressure, and the sympathetic connection between them is evident. He calls the emerging points of the nerves along the anterior rim of the pelvis the most important, five in all, with the renal, solar, spermatic, and superior hypogastric plexuses, the sycondrosis sacroiliaca, McBurney's point, and two spots on each side a trifle inward and downward from McBurney's point, which correspond to the most sensitive ones in the uterus. In examining these points the patient lies in the dorsal decubitus, the lower limbs together and extended. Besides these areas he calls attention to five others noted in the perineal region. One is the emerging point of the ilio-inguinal nerve; another of the superior internal cutaneous, also of the pubic nerve and, lastly, a point near the edge of the levator ani, equidistant from the anus and the opening of the vagina. Each of these thirty-two points is fraught with significance to the gynecologist, and will reward further study.

Allen County Medical Society.—The election of officers for this Society, which met in Lima, Ohio, May 1, resulted as

follows: president, W. H. Parent; vice-president, Frank Steiner; secretary and treasurer, Andrew Rice.

Camden District Medical Society.—At the annual session of this Society, held recently in Camden, N. J., the following officers were elected: president, J. F. Leavitt; vice-president, Wm. F. Powell; secretary, P. M. Meecray; treasurer, E. R. Ramsdell.

Berkshire Medical Society.—The members of this Society met May 3, in Pittsfield, Mass., and elected the following officers: president, W. W. Scofield, Dalton; vice-president, M. L. Woodruff, Pittsfield; secretary, L. C. Swift; treasurer, W. L. Paddock.

Warren County Medical Society.—This Society met in Monmouth, Ill., May 16 and 17. The following new officers were elected: president, Cynthia Skimmer, Monmouth; vice-president, A. R. Graham, Little York; secretary, Della Nichol; treasurer, J. C. Kilgore.

Southeast Missouri Medical Association.—This Society met in Poplar Bluff, Mo., May 1. The new officers elected were: president, M. Rosenthal, Kennett; vice-president, C. F. Greene, Poplar Bluff; secretary, G. S. Cannon, Jackson; treasurer, R. F. Henderson, Jackson.

Fort Dodge District Medical Society.—At the recent meeting of this Society in Fort Dodge, Iowa, the following officers were elected for the ensuing year: president, C. J. Sanders; vice-president, T. F. Grayson; secretary, A. H. McCreight; treasurer Dr. Ristine.

South Carolina Medical Association.—This body met in Charleston, S. C., April 18 and 19, and elected the following officers: president, Geo. R. Dean, Spartanburg; recording secretary, T. P. Whaley, Charleston; corresponding secretary, A. J. Buist, Charleston; treasurer, B. E. Baker, Charleston.

Southern California Medical Society.—This Society closed a three days' session in Riverside, Cal., May 5. The new officers elected were: president, Fred Baker, San Diego; first vice-president, A. S. Parker, Riverside; second vice-president, C. M. Browning, Highland; secretary, F. D. Bullard, Los Angeles.

Union Medical Association of Northeastern Ohio.—At the 115th quarterly meeting of this Association, held in Canton, Ohio, May 2, the following officers were installed: president, T. J. Reed, Massillon; vice-president, J. F. Fox, New Philadelphia; second vice-president, Geo S. Peck, Youngstown; recording secretary, J. H. Seidler, Akron.

New York County Medical Association.—This Association will meet in New York City, May 21. Papers will be presented by Drs. Wm. L. Leszynsky, Wm. S. Gottheil, Wm. H. Bates, Herman M. Biggs, Francis Quinlan and others of New York City; Dr. S. Solis-Cohen and Prof. John B. Shober of Philadelphia.

Nebraska State Medical Society.—At the meeting held in Omaha, Neb., May 8-10, the officers elected for the ensuing year were: president, H. M. McClanahan, Omaha; vice-president, Inez Philbrick, Lincoln; corresponding secretary, H. B. Loury, Lincoln; recording secretary, A. D. Wilkinson, Lincoln; treasurer, J. L. Greene, University Place. Thirty-seven new members were added.

Arizona Medical Association.—This Association met May 3, in Prescott, Ariz. Fourteen new members were enrolled and the following officers elected: president, T. B. Davis, Prescott; first vice-president, John Dennett, Congress; second vice-president, Albert E. Ealy, Kingman; secretary, Chas. H. Jones, Tempe; treasurer, H. W. Hiram, Tucson. Phoenix was selected as the next place of meeting.

Clark County Medical Society.—This Society held its annual meeting in Springfield, Ohio, May 4. Arrangements were made for the semi-centennial celebration to be held there May 31. The following officers were elected: president, B. D. Titlow; vice-president, T. M. Reade; second vice-president, S. R. Hlutchings; secretary and treasurer, C. B. Bliss.

Norfolk District Medical Society.—The fiftieth anniversary of this Society was observed in Boston, May 8. Dr.

Harold Crust delivered an oration upon the work and progress of the society, and short addresses were made by many of the guests. The following officers were elected for the ensuing year: president, F. W. Goss; vice-president, C. F. Withington; secretary and librarian, Jas. C. D. Pigeon; treasurer, E. G. Morse.

Ohio State Medical Society.—The fifty-fifth annual meeting of this Society was held in Columbus, Ohio, May 9-11. Cincinnati was chosen as the next meeting-place, and the following officers were elected to serve the ensuing year: president, F. D. Bain, Kenton; first vice-president, J. S. Beck, Dayton; second vice-president, A. W. Francis, Ripley; third vice-president, L. B. Tuckerman, Cleveland; fourth vice-president, Frank Warner, Columbus; secretary, J. A. Thompson, Cincinnati; treasurer, J. A. Dun, Toledo.

American Surgical Association.

Annual Meeting, Washington, D. C., May 1-3, 1900.

PERFORATING ULCER OF DUODENUM.

DR. ROBERT F. WEIR, New York City, used this as the subject of his presidential address, and considered it under six different heads viz.: sex, causes, frequency, age, size, and symptoms. The last was given considerable attention, and a large number of statistics and references were presented, accompanied by an expression of his opinion concerning the most important. The diagnosis was also considered in detail and the treatment from several standpoints. His experience in the surgical treatment of a duodenal perforation was confined to one case, which he described, including the post-mortem findings. The paper concluded with a list of all patients who have undergone this operation up to April, 1900.

GASTRIC ULCER: NON-PERFORATING: HEMORRHAGE.

DR. WILLIAM L. RODMAN, Philadelphia, read a paper on this, and considered the subject under eight headings, viz.: morbid anatomy, etiology, age, symptoms, hemorrhage, physical signs, prognosis and treatment. Extensive statistics were given under several of the headings, and the treatment of the condition was divided into medical and surgical, the latter in turn being divided into gastrotomy and gastrostomy with curetting, cauterizing, etc.

The mortality of the various methods of treating gastric ulcer by different operators was detailed and twelve different operative measures mentioned in the treatment of gastric hemorrhage. The results of 55 autopsies in non-operative cases were given, in 17 of which occurred ulceration of the splenic artery.

The literature bearing on gastric ulcer was most carefully reviewed, and all operative cases up to date included in the summary. Gastroenterostomy was referred to as being the most generally practiced operation for hemorrhage and as likely to remain so for some time on account of the difficulty in locating the bleeding vessel. Excision is, however, the ideal operation in both hemorrhagic and non-hemorrhagic cases, and should be practiced unless there are prohibitive adhesions.

PERFORATING ULCER OF STOMACH.

DR. J. M. T. FINNEY, Baltimore, Md., considered the history, etiology, frequency of occurrence, pathologic anatomy, symptomatology, diagnosis, treatment, surgical treatment and prognosis of this condition. He said that the nature and extent of the development of a peritonitis in these cases depends on the site of perforations, their number and size, the character and amount of the gastric contents, and the number and varieties of bacteria that escape from the stomach into the peritoneal cavity at the time of perforation. Referring to the first questions needing attention in the treatment of a general septic peritonitis, he mentioned the giving or not of opium; the waiting or not until recovery from shock and the indications existing for an operation. He described the steps of the operation, as he performs it, and called attention to the fact that some of the complications which have been noted were intestinal obstruction from kinking, parotitis, phlebitis, subphrenic abscess, pneumonia and empyema. As to prognosis, he gave seven factors that played important parts:

the condition of the stomach, whether empty or full, when the perforation takes place; the interval between the last meal and the perforation; the time elapsing between the perforation and the operation; the number and size of perforations; the position of the patient at the time of perforation; the perfection of the technique at the operation; the nature of the infectious agent, whether or not streptococcus or pyogenes.

MALIGNANT DISEASE OF STOMACH AND PYLORUS.

DR. WILLIAM J. MAYO, Rochester, Minn., presented this subject and stated that the curability of malignant disease depends on the histologic structure of the growth, its location, extension to neighboring structures, glandular involvement, and the general condition of the patient. He said also that in the beginning, each operation is an exploratory incision, and that this should be a methodical examination, having in view the question of radical operation, palliation, or the inadvisability of attempt at relief. The radical operations to which he referred were complete gastrectomy and pylorotomy and partial gastrectomy; the palliative, gastroenterostomy and jejunostomy, etc.

The preparation of patients for operation on the stomach and the after-care were given considerable attention. He mentioned that malignant disease of the stomach has a peculiarly depressing effect on the patient, and that ascites, even in a limited degree, is a contraindication to operation. Cases of non-malignant disease, too far advanced to extirpate and not requiring palliation, should be closed by the Halsted method. He does not consider that the results of operations limited to the pyloric end of the stomach, taken as a whole, have been satisfactory, although a few cures have taken place in exceptionally favorable cases. He referred to various methods of operating, and mentioned the suture operation of Fenger as an ideal one. The statistics of different operators were given, showing that in 31 gastroenterostomies for benign as well as malignant diseases, in only 2 regurgitant vomiting was marked, both of which were malignant.

BENIGN OBSTRUCTION OF PYLORUS.

DR. FREDERICK KAMMERER, New York City, read a paper on this subject, considering it as congenital and acquired stenosis. He divided the first into two subdivisions: acute, absolute at birth—fetal peritonitis—and congenital hypertrophy of the pylorus. The second or acquired variety, he subdivided into fibrous stenosis; occlusion of the pylorus by benign tumors; syphilitic lesions of the pylorus; gall-stones obstructing the pylorus; spastic contraction of the pylorus—hyperchlorhydria.

He then took up the surgical treatment of benign obstruction, dealing with the dilatation of the stricture and the operative procedures, of which he mentioned three: resection of the pylorus; Loreta's operation; simple division of adhesions about the pylorus. He also discussed relative merits of pyloroplasty and gastroenterostomy, comparing the two procedures and the immediate, as well as remote, results obtained by each, giving many points in their technique.

GASTRIC DILATATION.

DR. B. F. CURTIS, New York City, considered gastroptosis. He said that gastroectasia was almost unknown except in three conditions: malignant disease, benign stenosis and gastroptosis, causing obstruction of the pylorus. This last he treated under three subdivisions: pathology—inclusive of enteroptosis; symptoms and diagnosis; surgical treatment—either gastroplication or gastroenterostomy. He considers that gastroplication is the rival of gastroenterostomy, and that gastroptosis has only recently been brought within the possibilities of surgical treatment. He dwelt on the difficulties of diagnosis of these conditions, and quoted some cases in *extenso* and mentioned some of the details of the operation.

HOOR-GLASS CONTRACTION OF STOMACH.

DR. F. S. WATSON, Boston, presented an article on this subject, considering the condition under three major headings: The different forms of hour-glass stomach and the functional and pathologic changes associated with them. 2. The symptoms and diagnosis. 3. The operative treatment. Under the last he gave the indications and contraindications for the

different operations, together with the reports of some of the cases operated on by gastro-anastomosis.

DIAGNOSIS OF CANCER OF STOMACH.

DR. JOHN C. HEMMETTER, Baltimore, Md., by invitation, read a paper on this subject. The definition of the term "early diagnosis" was given. He then spoke of age, the diagnostic value, the subjective and objective symptoms, the significance of blood and hematemesis, constipation or diarrhea, the emaciation and cachexia, condition of the gastric functions, the secretion of pepsin and chymosin with the method of examining for the same, the lactic acid, and the microscopic examination of the stomach contents, etc.

GASTRIC FUNCTIONS BEFORE AND AFTER GASTROENTEROSTOMY.

DR. CHARLES S. FISCHER, New York City, presented an article on this subject, in which he spoke of several cases that had come under his own observation, and said that examinations of the gastric contents shortly before an operation are valueless.

STRICTURE OF ESOPHAGUS.

DR. FREDERIC S. DENNIS, New York City, read a paper on stricture of the esophagus, following typhoid fever and relieved by gastrostomy. He affirmed that he had had good results.

ADHESIONS OF THE STOMACH.

DR. A. T. CABOT, Boston, made some remarks on this topic, giving the symptoms of the condition and the methods of obtaining relief.

DISLOCATION OF HIP.

DR. OSCAR H. ALLIS, Philadelphia, gave a series of demonstrations on the cadaver, illustrating his mechanism for producing and reducing various dislocations of the hip.

NEPHRECTOMY FOR ANEURYSM OF RENAL ARTERY.

DR. W. W. KEEN, Philadelphia, in a paper on this subject, said he had been able to learn of 12 cases of aneurysm of the renal artery, and of these, only 3 had been operated on; the first, by Albert of Vienna in 1891, the second, by Hahn of Berlin in 1893, and the third, the one in question, which was that of a woman of 45, who, having had at intervals attacks of pain in the region of the gall-bladder for four or five years, together with fever, finally observed that the right side of the abdomen was larger than the left. This tumor had developed in less than five years and without any known cause, and was, apparently, partly cystic, partly solid, painless and fixed. Diagnosis: a partially cystic tumor of the right kidney, probably due to hydronephrosis, but with a possibility of a sarcoma or other neoplasm. The operation was performed Feb. 1, 1900, through an anterior incision 17 cm. long. In less than thirty minutes the tumor was readily separated from its adhesions to the other viscera, after tearing through the outer leaflet, of the mesocolon. The pedicle was so broad that it had to be secured in seven sections, the arteries were numerous and the veins enormously distended. The nature of the tumor was not recognized at the time of operation nor, indeed, until after its removal, when a section of it showed that the kidney was flattened out on the surface of a large mass, measuring 14.5 cm. in diameter and weighing 970 grams, and that nearly all of it was made up of a mass of laminated clots, showing that it was a large aneurysm of the renal artery, a branch of which was traced directly into the aneurysm.

In only one of all the 13 cases collected was a correct diagnosis made. In at least 6 of these the cause was an injury. A recognized tumor was present in only 6, and in the other cases the aneurysm was rather of pathologic than of surgical interest. Pulsation was not present in any of the cases, due to the fact that the artery was small, the sac large and the impulse of the blood not sufficient to distend it and so produce pulsation. Hematuria is only present when the aneurysm either develops in the kidney or bursts into the pelvis. All 3 of the cases operated on by nephrectomy terminated in recovery.

TUMOR OF SUPERIOR PARIETAL CONVOLUTION ACCURATELY LOCALIZED AND REMOVED BY OPERATION.

DR. CHARLES K. MILLS, Philadelphia, presented the medical history of this case—one of unusual interest from the clinical,

physiologic and surgical points of view. The patient was a man 56 years old, who had some neurasthenic and other symptoms since 1884, and began to have paresthetic attacks, affecting his right upper extremity, in 1894. These attacks were of irregular and infrequent occurrence, and were variously described as feelings of crawling, tingling or battery sensations. After the attacks the arm usually felt somewhat heavy, and he frequently complained of a feeling of pressure or discomfort in the head, and especially in the left frontoparietal region. Sometimes this was described as a headache, but he never had the typical headache of a case of brain tumor. Optic neuritis was absent from the first, and vertigo and vomiting were so infrequent as to call for no special consideration, but he was frequently hysterical and despondent.

About five months previous to the operation, he began to show some ataxia in the right arm, and later in the right leg; when investigation of his condition was first made all forms of cutaneous sensibility were impaired, muscular sense was lost. As the case progressed paresis and, eventually, paralysis of the arm and leg supervened and this when complete masked the ataxia. The patient developed a disorder of speech showing itself chiefly as a verbal amnesia and fatigue when he was reading. At one examination he showed a temporary partial right hemianopsia. Reversals of the color fields and contractions of the fields for form, similar to those supposed to be typical of hysteria, were present at several of the examinations. The reflexes of the ataxic and paralyzed side, were somewhat exaggerated, and ankle-clonus was present. The patient was emotional and markedly hysterical.

An operation, which was successfully performed by Dr. W. W. Keen, November 24, exposed a tumor in the exact region which had been assigned as the seat of the growth, viz., the superior parietal convolution.

The patient made a complete surgical recovery, and improved in all his symptoms with comparative rapidity; his speech completely returned, the paralysis of the leg and arm largely disappeared, and cutaneous sensibility was in time restored. He was seen last by Dr. Mills, April 24, when he found that he had regained all the movements of the extremities on the affected side, although he has not full strength in those limbs, and the muscular sense, especially in the lower extremity, is still somewhat impaired, as would be expected from the tissue lost by the encroachment of the growth.

DR. W. W. KEEN, Philadelphia, in giving the surgical history said that as the flap was not to be in the thin, squamous portion of the temple, but in the parietal, it might cause great embarrassment from a very thick skull, not only by the time required to chisel through the bone, but the difficulty of fracturing the base of the osteoplastic flap, so he first made two trephine openings 0.5 cm. in diameter at the two points between which he wished to fracture the flap. The skull was found, as had been feared, unusually thick, being a full centimeter, consequently a Gigli wire saw was passed between the two points, and the bone sawed half through in order to weaken the base of the flap. A large flap, each side of which was 10 cm. long was then made, the anterior border of it being a little in front of the fissure of Rolando; the upper border within 1 cm. of the median line.

As soon as the dura was exposed at the lower portion fluid was suspected beneath it and a dural flap was then cut with the base upward. The tumor suddenly came into view at the anterior superior angle. It measured 5.5 cm. by 4.5 cm., weighed over an ounce, and was made up of small, granular masses like those of an ordinary raspberry, and was of a deep red or purple color. In order to remove the entire tumor, a portion of bone was removed anteriorly. The tumor had begun as a subcortical mass and then burst through the cortex. It was now separated from the brain tissue and removed in connection with a long finger-like cyst which extended, by measurement, 10 cm. into the substance of the brain, and contained from 1½ to 2 ounces of fluid. The patient made a complete and very smooth recovery, the wound being entirely well by the sixth day. On February 23, just three months after

the operation, he walked up the steps of the hospital with a scarcely perceptible limp, and shook hands with ease. His speech was entirely normal and his mental condition excellent, and a week later he started for a pleasure trip on the Mediterranean.

The following officers were elected for the ensuing year: president, Roswell Park, Buffalo, N. Y.; first vice-president, John E. Owens, Chicago; second vice-president, Clayton Parkhill, Denver, Colo.; secretary Herbert L. Burrell, Boston; treasurer, George R. Fowler, New York City; recorder, DeForest Willard, Philadelphia. The next meeting will be held in Baltimore, Md., May 7-9, 1901.

New York Academy of Medicine.

Section on Obstetrics and Gynecology, April 26, 1900.

Wm. H. Thomson, M. D., President.

PREVENTION OF DYSTOCIA.

DR. EDWARD A. AYRES presented a paper entitled "The Prevention of Dystocia Due to Fetal and Pelvic Disproportion." Speaking of the value of the previous history of labors in multipara, the author advised that inquiry be made regarding the length of previous labors, the size of the children, the character of the uterine contractions, and the general appearance of the head of the infant at the time of birth—the latter with a view to forming some conception of the probable amount of head moulding that had been present. He said that it was well to remember that, other things being equal, the pelvis of a stout woman is not so roomy as that of one less fleshy, and that each successive labor usually brings a slightly larger child, up to the age of 35 years, and that after this age the weight and size of each succeeding fetus is less than that of the preceding one. Another element in making the prognosis in a given case of labor is the general size and development of all the bones of the skeleton, and the width of the pubic arch. Special stress was laid on the value of the information obtainable from a method of examination during pregnancy known as tentative engagement of the head. Where there was marked contraction of the pelvic inlet, the head would lie high, and when the obstetrician endeavored with his hand to force the fetal head down into the pelvis there would be a suddenly developed and marked resistance. If, on the other hand, the inlet was fairly spacious, the head could be forced down some distance and would finally come gradually to a rest. Regarding the important subject of the induction of premature labor, the speaker said that this was a procedure which, in effect, transferred the danger from the mother to the child, and the question of the justifiability or advisability of resorting to it hinged chiefly on the extent to which the life of the child was jeopardized by inducing labor two or three weeks ahead of the natural time as compared with allowing labor to come on at full term, the child then being subjected to a difficult and tedious, and possibly an instrumental, delivery. The measures recommended for inducing labor were: 1. The use of a solid, flexible, tapering bougie. 2. The use of a small Barnes' bag to initiate the contractions. 3. The introduction of a tampon.

INDICATIONS FOR PREMATURE DELIVERY.

DR. S. MARK read a paper entitled "Indications for Premature Delivery with Special Reference to Eclampsia—The True Toxemia of Pregnancy," in which he said that puerperal eclampsia, from the standpoint of the clinician, is closely allied to renal insufficiency, and that the quickest way to restore the health is by measures directed to the restoration of the renal function. He dwelt particularly on the fact, so little appreciated by physicians generally, that the mere determination of the presence of albuminuria is of little significance in comparison with the knowledge of the daily quantity of urea excreted, for there may be no albumin in the urine, and yet the careful and thoughtful physician may have good reason for believing that his patient is on the verge of an attack of eclampsia. The daily quantity of urea should be about 500 grains, and the progressive diminution of the quantity of

urea, with or without albuminuria, should be taken as an indication for interference. He advised that all pregnant women be subjected to a pelvimetric examination, but that this instrument be used for purposes of comparison only, and since so much depends on the relative size of the fetal and maternal parts, he cautioned against sweeping deductions from such uncertain premises. When it is found, by pressure from above with the hand, that the head can not be made to engage, it is time to interfere.

TREATMENT OF TUMORS COMPLICATING PREGNANCY.

DR. BROOKS H. WELLS read a paper on this subject in which he said that where a pregnant woman has cancer of the cervix, vaginal hysterectomy should be performed while the uterus is small; that in the early stages it is possible for the cervix to dilate sufficiently to allow labor to proceed, but extensive lacerations are likely to occur; that while a woman with fibroids is not liable to become pregnant, still pregnancy may occur, and under its stimulus the fibroids will grow much more rapidly. The higher up the tumor, and the more nearly of the subperitoneal variety, the less dangerous it is as a complication of labor, but the mortality in labors so complicated has been as high as 50 per cent. in the past. For interstitial tumors, a supravaginal hysterectomy should be performed, and tumors of the cervix should be enucleated when possible. Large ovarian cysts are not likely to block the pelvis, but their pedicles are prone to become twisted and gangrenous. If the case is not seen until labor has begun, and the operation is progressing and the cyst not impacted, the operation should be deferred until after the birth of the child. According to his experience, abdominal operations are well borne during pregnancy.

DIFFICULT OR DELAYED DELIVERY.

DR. MALCOLM McLEAN discussed the question: "When is It Proper to Interfere in Apparently Difficult or Delayed Delivery, Especially in Primipare?" He said that if the presenting part is high up and movable, and the pelvic measurements within the normal limits, one should not interfere, because much unnecessary damage is done to parturient women by attempting surgical interference before the soft parts have had an opportunity to properly relax and dilate.

DR. E. A. TUCKER said that he makes it a practice to advise his patients to do considerable walking during the last few weeks of pregnancy, as a means of facilitating good engagement of the head.

DR. EGERT H. GRANDIN said that if the presenting part will engage under suprapubic pressure, it is highly probable that labor can be completed without assistance, but when such engagement can not be effected with the hand, the physician should at once interfere. He considers the tamponade of sterile gauze the best mode of inducing labor, and the bougie the most tedious and unreliable. He has seen so many and such severe cases of puerperal eclampsia occur in women whose urine has been absolutely free from albumin, that it is his practice, just as soon as there is diminution, both of the total quantity of urine and of the urea, to proceed to empty the uterus, without waiting for cephalalgia, impaired vision and other symptoms of renal insufficiency.

DR. S. MARK said that his own experience has convinced him that it is possible to accomplish considerable for those women who anticipate hard labors because of the large size of the child, by dietetic management, i. e., restricting the starches and sweets, and diminishing the quantity of water taken.

DR. E. A. AYRES indorsed what had been said about the value of walking to the pregnant woman during the last few weeks, but added that while this is an excellent rule for those in good health, its observance in the case of one suffering from renal insufficiency may lead to disastrous consequences.

Chicago Surgical Society.

April Meeting.

CASE OF TENOPLASTY.

DR. L. L. McARTHUR—As Dr. Murphy is down on the program to report a case of tenoplasty, it will add to the interest of the meeting to report a case which I recently oper-

ated on. Briefly, six weeks ago a girl, in going home from school, fell on a slippery sidewalk and sustained a punctured wound between the thenar and hypothernar eminences of the left hand. It was not known whether this wound was produced by glass or ice. It was transverse in direction to the long axis of the arm and about half an inch in length. I saw her four days later, when there was tumefaction, tenderness and pain above the annular ligament of the wrist-joint. There was no fever. The tumefaction and tenderness led me to believe that she had a deep-seated tendovaginitis without superficial redness, and I therefore requested that she be taken to my clinic. On opening the wound I found that there was no infection; that the punctured wound had resulted in the severing of five flexor tendons in the position mentioned between the thenar and hypothernar eminences, and also in a complete severing of the median nerve. It then became necessary to find the retracted ends of the tendons and suture them, and it at the same time became evident that the swelling was not due to inflammation, but to the bunch of retracted tendons presented like a tumor away above the wrist, so that an incision two inches and a half in length was made, and by careful dissection the retracted ends were found, brought down and sutured. The median nerve was also sutured, and primary union obtained. She was requested to return at the end of a week, for redressing, and at that time the stitches were taken out. At the end of two weeks she again returned to the clinic and, to my surprise, had already gained sensation in the first three fingers of the hand, which had been lost at first. This was unusually early for the return of sensation after nerve suturing, the earliest instance with which I am familiar, sensation having returned prior to the fourteenth day. I made suture of the tendons in this case with fine silk worm gut, which is almost comparable to horsehair in size and is of much greater strength, and being unirritating I prefer it to silk or catgut with the possibilities of infection that go with the latter.

The question now arises in my mind as to the period at which it is safe or desirable to break up the adhesions which necessarily form in the tendon sheaths at the site of such suturing. When first sutured, she was unable to move the fingers. She now has excellent use of the flexor sublimis digitorum and can readily approximate the ends of the fingers with the thumb. Much of the flexion is due to the first action of the sublimis, and further action is to be hoped for when we have further interfered with it.

DR. A. J. OCHSNER said that some three years ago he went through the literature of nerve grafting, and he desired to bring out one point in reference to nerve suture and the sequent return of sensation, of which Dr. McArthur spoke, because this point was impressed on him at that time. He had reported seven cases of nerve suture and nerve grafting, and to his surprise he found that within twelve hours sensation returned in those cases in which the nerve had been entirely severed and in which there had been no sensation before.

Another observation which he had made and desired to mention is with reference to tendon suturing at a distance. The longest distance at which he has grafted tendons was about six inches, in a case following a railroad injury, in which the extensor tendons of the hand had been destroyed by infection. The tendon grafting was done by means of fine catgut passed from the remaining tendon above to the remnant below, and then covering it in with available fascia. This operation was done four years ago, and the man is now able to work. He has fair motion and very good extension.

DR. M. L. HARRIS said that one of the most frequent causes of failure to obtain perfect motion after inflammation of the severed tendon is the fact that the cicatrix uniting the tendon blends with the one that unites the skin. Some time ago he published an article which was illustrated by a number of cases of tendon surgery, in which this point was particularly emphasized, and he advised that the surgeon should always interpose a layer of tissue between the cicatrix in the tendon and that in the skin, and that these different layers should all be sutured separately, as he found in several cases

that it makes a remarkable difference in the facility with which motion is regained after these operations.

In reference to the point made by Dr. McArthur, as to the time at which to break up adhesions, Koenig goes into the subject quite thoroughly and as the result of some experimental work which he did on the union of tendons in tendon sheaths, he finds that these tendons unite in a quite similar manner to bone and likens the union to that which formed first between the divided ends of the callus-uniting bone. This callus has a union with the tendon sheath. If the union between the tendon and tendon sheath is broken up too early, the callus is excited to activity and union again occurs. It becomes adherent to the tendon sheath. He advises not to make too active motion in these cases until the callus has time to form and begin its absorption, and the period of time from the formation of this callus to its complete absorption is about six weeks. While active motion should be encouraged to a mild extent previous to this time, too violent, forcible motion should not be instituted previous to the time of absorption of the callus. The material Dr. Harris favors for tendon suture is silk, and it will remain in tendons indefinitely. He has a number of cases in which silk has remained for several years, and the tendons are perfectly movable. Surgeons should select a suture material which will stand considerable tension.

DR. JACOB FRANK said that the swelling referred to is characteristic of tendons that are cut through. He has seen two or three such cases. He mentioned one case in which he cut from high up on the forearm almost down to the knuckles to find the origin of the tendon, and the swelling after the operation quickly disappeared, whereas before it was large. He considers it a true tendonitis. He has learned that in uniting tendons, no matter if the tendon be cut through, not the slightest amount of tension should be used. The hand must be at perfect rest.

DR. L. L. McARTHUR, in closing the discussion, said that in regard to the return of sensation in twelve hours after the suture of the nerve, some authorities are of the opinion that such a return is doubtful as occurring through a sutured nerve, and believe that there may have been a mistake in the diagnosis of sensation, or that it may be a collateral innervation.

In regard to the Harris method of suture, he was ignorant of it and was glad to learn of it.

As to putting in sutures that require tension to approximate the ends of the tendons, in his opinion the proper thing to do is to put these tendons physiologically at rest, to put the parts in that position which will thoroughly relax them, and in his case he took particular pains to close up the fingers, the sublimis profundus digitorum, and the wrist, bandaging so as to relax all tension, and in this way putting the parts physiologically at rest, and therefore having practically no tension on the ends of the tendons.

DOUBLE PYOSALPINX WITH INTESTINAL RESECTION.

DR. JACOB FRANK reported a case of this condition. Although cases similar to the one he desired to report are quite common, he took this opportunity to present one of double pyosalpinx with tubo-ovarian abscess complicated with such firm peritoneal and intestinal adhesions that resection of the bowel was necessary for the removal of the tubes.

The patient, Mrs. B., aged 23, gave the following history: When 17 years of age she was operated on for suppressed menstruation. She was married at 19 and aborted at the second month. From the patient's statements he was led to believe that she had gonorrhoeal arthritis about two years ago, although she insisted it was inflammatory rheumatism. On October 30 of last year she was taken with severe pain in the abdomen, which was very painful on pressure. When sent to the hospital, her temperature and pulse were high. For about five weeks she was treated on the expectant plan, with hot douches, stupes to the abdomen, and occasionally morphia was necessary to allay pain. Everything seemed to progress nicely, when, on the evening of November 22, she presented symptoms of intestinal obstruction, and on the morning of the 23d she was operated on. A median incision was made

and a conglomerate mass of adherent tubes, ovaries, intestines and omentum was encountered. The bowel was flexed by the adhesions and looked edematous, and lying in the midst of the adhesions two small abscesses were found. Owing to the great number and density of the adhesions, which resisted all attempts at careful separation, a rent in the bowel in two different places was accidentally made during removal of the tubes and ovaries. The coil of intestines with the tears was then carefully inspected and the walls were found to be very friable and infiltrated, so it was decided to do an intestinal resection. The anastomosis was effected by means of the Frank decalcified bone-coupler, of which a one-eighth-inch size was used, the measurement having been determined by means of the Frank enterometer. The operation was completed by inserting a Mikulicz and glass drain. The patient left the table in fair condition, but under the usual after-treatment gradually grew worse, until the fourth day, when her life was despaired of, notwithstanding the fact that she had early bowel movements following enemata. At no time, however, was there any escape of fecal matter from the anastomosis. After the fourth day she commenced to improve and left the hospital on Dec. 28, 1899. The piece of rubber tubing was passed on the fifth day following the anastomosis.

Dr. E. W. ANDREWS said that while he believed the Frank coupler is an improvement on any metallic device, yet the one which he used in a case was defective. Perhaps it would not be considered defective if one believes, as Dr. Frank does, that nine hours is sufficient time to get adhesion. Not believing this, however, the speaker was thoroughly alarmed at the rapid manner in which the bone parts of the coupler went to pieces in a case of strangulated hernia in which he used the coupler, although the patient fortunately recovered. In this case he had resected eighteen inches of the intestine. On the following day Dr. Frank demonstrated a new coupler before his (Dr. Andrews') class. The second day after the demonstration Dr. Andrews killed the dog to get the specimen, and he was alarmed to find that the bony parts of the coupler had softened to the consistency of white paste and had flattened out. The bowel was held fairly well by the four stitches which he had put in the form of a quadrant of a circle. Personally, Dr. Andrews does not believe that adhesion strong enough to hold the bowel takes place in six hours, although it may do so in connection with a row of Lembert stitches.

Dr. JACOB FRANK said the couplers can be made to absorb just as readily as catgut if they are formalinized or chromicized, and will come away just as the metal buttons do, but he has not found any need of doing this. The coupler which he used in the demonstration before Dr. Andrews' class was one he brought from Europe, which was made of bone, chemically prepared, and was not as good as the average coupler made in this country.

Kansas Medical Society.

*Thirty-fourth Annual Session, held in Topeka, Kan.,
May 2-4, 1900.*

Dr. Charles Gardiner, Emporia, president.

ADDRESS OF PRESIDENT.

Dr. CHARLES GARDINER, Emporia, in his presidential address, decried patent medicines and physicians who use and endorse them. He paid a glowing tribute to Dr. Benjamin Rush and urged the Society to see that Kansas should contribute her full share to the erection of a monument to his memory.

COMMITTEES AND RESOLUTIONS.

A committee composed of Drs. B. D. Eastman, W. T. Sawhill and W. L. Schenck was appointed to draw up resolutions on proprietary medicines. A resolution was passed, presented by the Douglas County Medical Society, to have a committee appointed to endeavor to secure pure foods and medicines by legislation.

A committee of five was also appointed to draft and present to the next legislature a bill for the protection of regular practitioners from the inroads of quacks and other impostors.

A resolution having in view the appointment of a national board of examiners, certificates from which would entitle

the holder to practice anywhere in the United States, was defeated.

The next meeting is to be held at Pittsburg, Kan., May 2-4, 1901. The following are the officers for the ensuing year: president, J. W. Porter, Pittsburg; first vice-president, J. P. Lewis, Topeka; second vice-president, C. P. Shafer, Topeka; corresponding secretary, J. W. May, Kansas City, Kan.; treasurer, L. H. Munn, Topeka; librarian, S. G. Stewart, Topeka.

There were forty-eight papers read during the session, covering a wide field of professional work.

STATE CONTROL OF TUBERCULOSIS.

Dr. W. E. McVEY, Topeka, in a paper on this subject, said that the laws to regulate and control bovine tuberculosis have not been passed on account of the danger of human tuberculosis resulting, but for financial reasons, as healthy herds are more profitable, while the laity does not realize the danger that really exists from infected herds.

Dr. R. S. MAOEE, Topeka, said that when the city's health board is notified of a tubercular patient dying, or moving from a house, that house is immediately and thoroughly disinfected. This has been the rule in Topeka for some years, and it should always be done.

OCCIPITO-POSTERIOR PRESENTATION IN LABOR.

Dr. J. DILLON, Eureka, read a paper on this subject. He advises, when flexion can not be secured, the use of extreme extension and delivery chin first, a method which is practically unknown.

Dr. G. A. BOYLE, Louisburg, spoke of one case in which he had used that method and in which the eyes of the child protruded extensively, but in about ten days there were no indications on the child of the difficult labor.

SPECIALIZING.

Dr. L. REYNOLDS, Horton, read a paper on "How Much of the Specialties Shall the General Practitioner Do?" He thinks physicians should know more about all the specialties and not send so many patients away, when they should know how to treat them.

Dr. J. W. MAY, Kansas City, Kan., said that he has found that the general practitioner is becoming more of a specialist every year and getting more knowledge on all branches.

VACCINATION.

Dr. T. W. PEERS, Topeka, in his paper, considered modern vaccination, and gave experience in caring for the city patients during the recent epidemic of smallpox. He vaccinated about 1200 and believes in frequent vaccinations. He recommends that legislative enactment provide for the repeated vaccination at stated short intervals, by the city physician, of every man, woman, and child in every city having such an officer. It is much cheaper and more satisfactory to all than to provide and maintain quarantine for a single smallpox patient in each county.

New York County Medical Association.

April 16, 1900.

Frederick Holme Wiggin, M.D., President.

PREVENTION OF INTRACRANIAL AND INTRAVENOUS COMPLICATIONS IN SUPPURATIVE DISEASES OF EARS.

Dr. J. H. WOODWARD read a paper with this title, to be printed in THE JOURNAL.

Dr. FRANCIS J. QUINLAN showed the gravity of otitis media by calling attention to the fact that it was the custom at the present time among the large life insurance companies to decline to accept as a risk any person having a chronic suppurative process of the middle ear above the short process. A mastoid operation should be entirely within the reach of the skill of the average general practitioner. It is most important that it should be done thoroughly, all of the cells being laid open.

WHAT ARE THE ULTIMATE RESULTS IN TREATING CANCER OF THE UTERUS? WHAT IS THE BEST PLAN OF TREATMENT?

Dr. HOWARD A. KELLY, of the Johns Hopkins University, Baltimore, Md., read a paper on this topic. It appears, with the discussion, in this and next week's issues.

THE JOURNAL OF THE
 AMERICAN MEDICAL ASSOCIATION.
 61 MARKET STREET, - CHICAGO.

SATURDAY, MAY 19, 1900.

THE ATLANTIC CITY MEETING OF THE AMERICAN
 MEDICAL ASSOCIATION.

The meeting of the AMERICAN MEDICAL ASSOCIATION at Atlantic City, N. J., next month, promises to be one of the best attended of any yet held. While the West may not be so well represented as it would be were the place of meeting more centrally located, the attendance from the Eastern States will be greater than even at the Philadelphia meeting, judging from reports. The committees at Atlantic City are sparing no pains nor expense to make the meeting a successful and an enjoyable one. The hotel accommodations are ample and no fears need be had on this account.

Railroad rates—one and one-third on the certificate plan—are not satisfactory, as nothing short of half rates ever will be. It would seem that an association whose meetings are as largely attended as are those of the AMERICAN MEDICAL ASSOCIATION ought to be granted half rates on merely asking for them, but the various passenger associations seem to think differently. Every effort to obtain half rates was made by the Committee, but the peculiar location of Atlantic City, as far as railroads are concerned, made these efforts of no avail this year. The time allowed, however, is longer than usual, and this is something for which to be thankful.

The programs of the various Sections, printed in this issue of THE JOURNAL, indicate the character of the scientific work which may be expected. Evidently the officers of some of the Sections have found it impossible to limit the titles of papers to the number recommended by the ASSOCIATION at the Columbus meeting, and if all the papers are read it will mean the utilization of every minute allotted to Section work. The quality, however, is not lowered on account of the quantity in this instance, as the names on the various programs will testify.

At various times in the past attempts have been made, unsuccessfully in each instance, to have the delegates occupy a certain part of the hall in which the meetings were held. This year, instead of repeating this attempt, a distinctive badge will be provided. One will be given to each delegate at the time of registering, on presentation of credentials signed by the secretary of the society which the delegate represents. Members attending as delegates are therefore earnestly urged to have their credentials with them at the meeting. The ASSOCIATION has now become so large that a strict compliance with the constitution and by-laws seems desirable, if not necessary. It is understood that only delegates have the right to vote in the general sessions.

THE GENERAL PRACTITIONER AND THE TECHNIQUE
 OF PATHOLOGIC EXAMINATION.

The so-called laboratory methods in clinical diagnosis are of fundamental importance to the general practitioner, the general surgeon, the specialist, and the hospital physician alike. The necessity of the hour is to make it possible for the individual to make as full personal use of these methods as is consistent with reliable and thorough work. It is seen at once that no one is in greater immediate need of clinical laboratory methods than the general physician, and above all the general physician in the country, more or less remote from large cities. The fact is that the introduction of laboratory methods in clinical diagnosis has greatly increased the already heavy responsibility of the general practitioner. The patients in the country are entitled to the same advantages of these new methods—the earlier, more definite diagnosis and all that that means—as the more fortunately situated dweller in the city; and the community and country at large demand the same prompt protection from communicable diseases, now more surely and earlier recognized, as the more watchful city with its health inspectors, municipal laboratories, and public disinfecting apparatus. The patients in the country can not afford to wait for the report of the laboratory specialist in the city and in many cases they can not be expected to pay the extra expense thus incurred.

The general tendency, in hospital and city practice, is to bring the laboratory and clinic into the closest possible relationship. The true clinician is no longer as fully satisfied as formerly with receiving his laboratory information at second hand. The better hospitals are beginning to establish small, clinical laboratories in connection with the various hospital services or wards as distinguished from the larger, more purely pathologic laboratory. Public and dispensary clinics are making provisions for laboratory facilities of their own because they recognize fully the great advantage of obtaining the information of the microscope and of the test-tube at first hand, of bringing it into immediate correlation with the clinical manifestations and the peculiar chances of error and of delay to which such information is unquestionably subject when it has to be filtered through the mind of another person, working not in the atmosphere of the clinic but of the isolated laboratory, and private practitioners are beginning to realize that clinical laboratory work in their offices is not at all incompatible with other work. This is self-evident. There is no reason why the practitioner should not be trained in the relatively simple details of clinical laboratory work as well as in the technique of physical examination, of the use of the ophthalmoscope, the laryngoscope, and of surgical cleanliness. There is no good ground apparent why a competent practitioner should not rely on his own examination of the sputum or of the blood in the majority of cases requiring such examination just as he relies on his own physical examination in the majority of them. Why always accept

unhesitatingly the verdict, as so commonly done, of the laboratory specialist any oftener than the verdict of the specialist in "diseases of the chest?" Surely things have not come to such a condition that the practitioner must rely wholly on specialists.

If we place so much faith in laboratory methods in clinical diagnosis it is clearly our duty to bring the laboratory facilities as close at hand as circumstances permit, and that is right into our offices and our wards and our clinics. Right here the objection may be raised that thorough laboratory methods are too time-consuming, too complicated for every-day use. But all thorough work is time-consuming. A practitioner who has not the time to do his work thoroughly because of the pressure of a large and extensive practice can well afford to surround himself with young and willing assistants whose work he can supervise and control. In this problem enters also the whole question of organization of the machinery of a practice, and that is a large question which each individual must solve for himself. Laboratory methods may seem complicated to the uninitiated, but to the schooled men they are not too complicated to prevent their daily and constant use. On the other hand, considering the value of the results obtained when rightly used, they must be said to be on the whole quite simple and direct. The first requisite is good training. This the better medical schools and hospitals are now endeavoring to furnish our students, and the larger cities are offering physicians abundant opportunities in the way of post-graduate courses to acquire the knowledge and the skill that their early training and situation may have failed to supply. The next thing is suitable apparatus, the most important single item of which is a reliable microscope, then come a few stains, minor implements, and such special things as blood instruments, etc. The necessary facilities for clinical bacteriology are within comparatively easy reach. It is acknowledged that the question of culture-media may be an awkward one; they may be bought ready-made, however. In the bacteriologic laboratory the "greenest" student generally succeeds fairly well in making the more common ones the first time he tries. It may be that by placing himself in communication with the nearest bacteriologic laboratory the general practitioner, for a small outlay, could receive a fresh supply at regular intervals.

Surely it would not be too much to expect that the general practitioner, as well as the specialist, should be well enough trained to rely wholly on his own chemical and microscopic examination of the urine and to understand fully the importance of examination of the urine of patients in general and of those with certain special symptoms in particular. This, we believe, is even now fairly well recognized by the intelligent and careful physicians.

The methods of examination of the gastric contents are also within the grasp of the man in general practice.

As regards the blood, the estimation of hemoglobin, the counting and staining of the corpuscles, and the study of the fresh specimen are absolutely requisite for the diagnosis or exclusion of a number of diseases, such as chlorosis, pernicious anemia, leukemia, and malaria. It is true that in many cases a diagnosis may be made from the grosser clinical manifestations, but a complete inspection is always desirable, because it furnishes a moral support that makes the professor the master of the situation; and then there are the obscure cases that baffle solution even at the hands of the true expert. All true physicians would be thankful to know that all means within their reasonable powers may be resorted to. The conscientious use of laboratory methods soon brings home a lively sense of the real limitations of one's abilities that discourages dishonest work and the pernicious habit of guessing.

The importance of bacteriologic methods in clinical medicine needs no emphasis. The early recognition of pulmonary tuberculosis by the demonstration of the bacilli in the sputum may save suffering, expense, and even life. In view of the omnipresence of the disease and of its devastation of human life, he must be a callous individual indeed who does not arm himself thoroughly for the struggle against tuberculosis that he feels in duty bound to take up in dead earnest when he assumes the care of the health of his fellow-men. A good microscope, a little carbol-fuchsin, clean slides, and a keen sense of responsibility are essential for successful war against "the white plague," and the outcome of the first encounter rests with the general practitioner.

The definitive diagnosis of diphtheria, in its inception either as a single case or as an endemic, rests largely on the bacteriologic demonstration of the diphtheria bacillus. Should not the general practitioner in the country and the small town where there is as yet no municipal laboratory be competent to settle this question? Will not the settlement of this diagnosis, and similar ones, redound to his great credit?

Among other bacteriologic tests of great value may be mentioned the staining of gonococci in the urethral and other exudates, and the demonstration of tubercle bacilli in feces, in urine, and in pathologic products of various kinds. By following the rule laid down in the extensive article on "The Smegma Bacillus," that has just appeared in *THE JOURNAL*, there should be no danger of confusion of the tubercle and smegma bacilli. The bacteriologic examination of cerebrospinal fluid obtained by lumbar puncture, and of pleural and other inflammatory exudates, may yield information of decisive importance in diagnostic and prognostic problems.

One of the simplest technical methods in clinical diagnosis is Widal's reaction in typhoid fever. It is essential to have a fresh culture of the typhoid bacillus on hand, and in times when typhoid is frequent the

physician would do well to secure the necessary tubes for frequent transplantation. It is essential to know the limitations of Widal's test, and questions of that sort are frequently discussed in our leading journals.

Animal inoculations may be practiced when necessary in order to clear up obscure conditions. Rabbits and guinea-pigs are not difficult to obtain. In case the practitioner does not care to keep a stock on hand a little inquiry will determine a satisfactory source of supply. Suspected local tuberculous processes frequently demand inoculation of guinea-pigs. The operation is simple indeed, the essential requisite being ample precaution against contamination and accidental infection with extraneous microbes.

As regards pathologic tissues, such as tumors and inflammatory productions, one can say that there is no essential reason why a practitioner should not himself fix, imbed, cut and stain the material, and study it microscopically. In case this is not feasible then we certainly have the right to demand that the physician should be familiar with the proper methods of preserving the material preparatory to sending it to the pathologist. The slovenly manner in which pathologic material frequently is treated often renders the result of the microscopic examination everything else than satisfactory.

We plead for a more extensive adoption of laboratory methods in practice. It is feasible. It introduces into routine work a feature that is eminently useful at the same time that it is interesting and enjoyable. It brings the physician a few steps nearer to the secrets of disease. It renders the physician a degree or two less dependent, greatly increases his usefulness, and puts him in touch with his own era. And the young physician, starting out fully equipped to introduce laboratory methods into his practice, at once puts himself at a decided advantage over his competitors who disregard these modern refinements, but who in the eyes of the community, which is quick to see such things, soon reach the unenviable distinction of being regarded as "back numbers."

NEPHRITIS WITHOUT ALBUMINURIA, IN YOUNG CHILDREN.

He will be the most successful diagnostician who early disabuses his mind of the existence of pathognomonic symptoms. The physician, above all men, must train his powers of observation in search of the unusual, the unexpected and the atypical. Apparent paradoxes in medicine are not rare. Thus, febrile disorders are at times unattended with elevation of temperature, epilepsy with the occurrence of convulsions, uremia with the development of coma, nephritis with the presence of albumin and tube-casts in the urine, diabetes with glycosuria. It is true that such occurrences are exceptional, but it is only by an appreciation of their possibility that error is to be avoided. The belief that nephritis may exist without the presence of albumin and tube-casts in

the urine receives support from some observations made by Cassel,¹ who reports a series of nine cases in children in whom, in the absence of disease of the heart, and without a previous history of scarlet fever, widespread anasarca was present, in three also with ascites, while the urine was free from albumin and abnormal morphologic elements.

In two of the three cases that terminated fatally, post-mortem examination disclosed the existence of nephritis. The patients were all young, one being 7 weeks, four 2 months, one 5 months, one 1½ years, and one 2½ years old. In some the anasarca was present when the children came under observation, while in others it developed during this time. The dropsy appeared first in the face, then invaded the dorsum of the hands and the feet, extending to the legs and the thighs, the scrotum or the vulva, and at times to the dependent portions of the back. In two cases the edema had been preceded for two weeks by a vesicular eruption, probably varicellous. In a third case measles developed after the dropsy had been present for two weeks, but the latter was uninfluenced by the complicating disorder. In five cases, however, the hydrops had been preceded by digestive disturbances of acute or subacute character. In one case no etiologic factor whatever could be elicited. Scarlet fever could be excluded with certainty in all. Four cases terminated in recovery in from four to six weeks. In two the results could not be learned and in three death occurred. The urine, obtained by catheterization at different times of the day and night, was pale, of acid reaction and low specific gravity. Tested with acetic acid and potassium ferrocyanid, and by the nitric-acid contact method, it failed in every instance to yield the response for albumin. There was no sediment and none could be obtained on centrifugation. Cassel has succeeded in collecting, from the literature, reports of a number of observers who relate cases of nephritis in which albumin and sometimes also tube-casts could not be found in the urine. In these cases, however, the renal condition was usually a sequel of a preceding disease, such as scarlet fever principally, but other exanthemata also were antecedent in some cases, such as chicken-pox, measles and typhoid fever. It is possible that other infectious diseases also may be attended with the same sequel. The suggestion has been made that the hydrops under the conditions just considered is due not to disease of the kidneys, but to increased permeability of the blood-vessels and the lymphatics of the skin, serous membranes and mucous membranes. A similar explanation may also be applicable when the anasarca attends gastrointestinal disorders, although it has been shown that these may give rise to actual nephritis.

MEDICAL RECIPROCITY.

The necessity of uniformity and reciprocity in medical standards and state qualifications for practice is daily becoming more and more evident. Medical re-

¹ *Berliner Klin. Woch.*, March 5, p. 213.

form is in the air, but it progresses everywhere, largely on distinct lines, and the results are therefore in some regards not all that could be wished. One state does not recognize the qualifications of another, and vice versa, and the outcome is discord and a reflection on the medical standards and the general status of American medicine. If we discredit each other individually, outsiders will discredit us collectively. Aside from this there are still more obvious disadvantages in this lack of reciprocity, not the least of which is the need of re-examination on change of residence, and the manifold inconveniences it involves. Everybody must admit that a uniformly high standard is the ideal and that even the suspicion that we fall short of this reflects discredit on us all. If New York will not recognize Pennsylvania's qualifications, Pennsylvania may retaliate in kind on New York, and both reject those of other parts of the country, and outsiders ignore the whole. It is true that in many states the law authorizes reciprocity in this matter of medical qualifications, but this does not materially improve the case. If the Federal government could assume the control of medical practice, this would be the simplest solution of the problem, but it is one of the disadvantages of our national organization that the Federal jurisdiction is limited in this regard, and it would not be altogether advantageous to our profession in any sense, could construction be placed on certain passages of the Constitution to make them include such jurisdiction—they would include too much.

We have before us the more complicated and difficult task of securing uniform action of the different commonwealths that make up our Union. To do this will require the united action of the medical profession and this, properly exerted, would be invincible. It can only be thus exerted by united action of authorized representatives of all states acting together in a definite, organized body. Anything short of complete uniformity in the medical laws of the various states will be only a partial success, and should not be even the alternative ideal. The difficulties in the way need not be ignored, but they are not insuperable and ought only to stimulate our efforts. There is hardly any subject that more deserves to be seriously considered at the coming meeting of the ASSOCIATION, and we trust it will be thoroughly handled and measures initiated to this end. Two things are certain: One is that this reform must be brought about, the other is that it must be done by the medical profession. As long as each state has its own independent standards and produces physicians only fitted to them, the reputation of American medicine as a whole will continue to be depreciated as in the past.

ALCOHOL IN THE TROPICS.

An army surgeon, in a paper in one of our contemporaries,¹ has expressed the opinion, contrary to that issued from the army headquarters, that the use of in-

toxicating drink is essential to continued health in the tropics, and another, a surgeon of volunteers, in the same issue, though his opinion is modestly given as the result of only one year's experience in active service in the same region, maintains the directly opposite view; he is certain that, as Americans drink it, strong liquor is injurious. The native liquor of the Philippines causes, he says, in its habitués, loss of appetite, fever and diarrhea, and the same results from the irregular American habit of drinking generally. His belief is that "the use of liquor in any form in the tropics is unnecessary, except it be the red wine issued by the Spanish Government to their troops." Judging from the condition and efficiency of the Spanish troops this would not seem to have helped them much. The doctors, however, do not disagree in this matter more than do experienced laymen. In a very limited tropical experience we have heard the most divergent views on this subject from white men there resident, and some who favored alcohol in one form insisted on its deadliness in another. There would seem to be hardly any question of tropical medicine much more important than this, and the burden of proof is certainly on those whose views are opposed to the generally received opinions and statements of authorities.

PRIMARY SARCOMA OF THE INTESTINE.

Based on 29 cases from the literature and three personal ones—32 in all—of primary sarcoma of the small intestines, Westermarck¹ gives the following general statements concerning this form of tumor. As regards frequency, Smoler's statistics show primary sarcoma of the small intestine 11 times in 13,036 autopsies, a percentage of .08. The majority of the recorded cases occurred in persons of the poorer classes. The tumor may be congenital; it has been observed at the age of 70; it is more common before the fortieth year. Of the 32 cases but 8 occurred in women. The growth usually begins in the submucosa, whence the outer coats are involved, the serous remaining intact the longest. At times the growth is nodular, forming subserous masses of varying sizes; or it may appear as a flat, circular infiltration of the intestine, part of which appears to have changed into sarcoma tissue; at other times the growth encroaches on the lumen of the intestine, forming submucous and subserous outgrowths. In a small proportion of the cases the sarcoma has occurred as multiple tumors. Retrogressive changes and hemorrhages are frequent, beginning either on the mucous surface of the tumor or in its interior. Soft tumors may give rise to dangerous intraperitoneal hemorrhages from rupture caused by ordinary palpation. Generally the lumen of the intestine corresponding to the tumor is dilated, the wall losing its elasticity and contractility; in some cases the dilation was very pronounced. In one of Westermarck's cases there was an invagination of the degenerated region into the healthy intestine below. The lower part of the small intestine is more frequently involved than the upper part, and round-celled sarcomas are the more common. The course is rapid, and metastases form early. The most pronounced symptoms are each-

¹ Phila. Med. Jour., April 7.

¹ Phila. Med. Jour., April 7.

exia and loss of strength. In one case of removal by operation the patient remained well for a year, but little is known concerning more remote results. In most of the cases operated on recidivation has occurred in a short time.

STATE ENDOWMENT OF MEDICAL EDUCATION.

A distinguished New York physician and medical educator is quoted as saying: "I hold that the state ought to furnish sufficient funds for the adequate and thorough instruction of all the pupils in every medical institution already legally organized, and for such others as the increase of population may cause to be established under the regulation of the state." It would be injustice to the gentleman to assume that this was other than an undeliberated utterance, since he and every one else in the profession must realize that it would be a very extensive contract for the already burdened public to assume the support of the numerous medical colleges of the country. If there is one thing in which American medical education leads the world, it is in its quantity, but we do not congratulate ourselves on this fact. What we need is improvement in quality, and it would be no loss if three-quarters of the hundred and fifty, more or less, medical colleges of all sorts in this country should go out of business. What the doctor probably meant, but what unfortunately it appears he did not say, was that the state should insure a uniformly thorough scientific medical education in those seeking it, and this necessarily implies a regulation of the standards of education that would be fatal to the success of many of the minor institutions that can command neither the clinical facilities nor the teaching ability that would be required. Whether this can be done uniformly in all the different commonwealths that make up our country is a problem that remains to be solved; that it is desirable no one questions. His remarks also implied that the state should endow and encourage scientific medical research, another thing to be desired, and which it can do to a certain extent though not so universally as he would seem to think. What we do need is endowment of medical instruction, and lifting it above what it is at present to too great an extent in this country—simply a means of nonprohibited medical advertising. Our medical colleges have been too long originated and conducted as business investments, not always for their direct returns, but to supply from their output a consulting clientele for their professors. The stock company medical college, described by a prominent neurologist in the '70s, was a caricature with a broad family likeness to many of the institutions of the time, and there are still in some quarters relics of the same features amongst the medical colleges of to-day.

TUBERCULIN THERAPY.

The use of tuberculin in the human subject, either for therapeutic or diagnostic purposes, has as yet no recognized standing with the profession, and there is a very wide-spread suspicion that it may sometimes revive latent foci and thus arouse at once, what is for the time, at least, a harmless condition into a dangerous state of disease. It has, however, its advocates, and among them we may

include, in a somewhat qualified sense, Dr. Edward R. Baldwin,¹ Saranac Lake, N. Y., who thinks that clinical experience, as well as experiments on animals, shows that it "can favorably influence a pure localized pulmonary tuberculosis and lupus in a well-nourished afebrile patient," but does not, he says, presume to decide whether tuberculins of any sort should be favored for limited therapeutic employment in the light of our present knowledge. This is, indeed, a very qualified endorsement, but it leaves the decision of the question to the individual therapist, who can use it to justify himself in any course he may adopt. It should be added here, however, that he thinks it obvious that this treatment should be limited to institutions, and that the patients should be observed through a series of years. He considers that the action of the tuberculin is in aiding the defective powers of the organism by stimulating the secretion of ferments which attack the tuberculous toxins. It is not established that they are more effective in this way than certain other irritants, such as cinnamic acid or nucleins, but the possibility of producing a toxin immunity makes it more rational to employ a specific irritant. The difficulties and the dangers, however, of thus obtaining any immunity from tuberculins are, he admits, such as leave it practically out of consideration. The question is, therefore, reduced to whether or not we can aid Nature in her contest with the tubercle bacilli by measures that increase hyperemia and absorption. He answers this with, as usual, a qualified affirmative, and quotes, as instances, the effects of laparotomy on tubercular peritonitis, Bier's method of treating tuberculous joints by manipulation, and the action of the X-ray on lupus. The serumtherapy of tuberculosis is mentioned, in conclusion, as still in the experimental stage; and Baldwin is not without hope of results of practical value.

Medical News.

DR. A. GARCELON'S ANNIVERSARY.—We clip the following, concerning the president of the Board of Trustees of the AMERICAN MEDICAL ASSOCIATION, from the *Lewiston (Me.) Journal*:

"Dr. Alonzo Garcelon, of Lewiston, who needs no introduction to the people of the State of Maine, will measure his eighty-seventh milestone on Sunday, May 6. The *Journal* and the citizens of Lewiston and Auburn congratulate the Doctor upon the unusual health and strength which he enjoys to-day. Robust and vigorous, Dr. Garcelon still carries on his practice in these cities and in the surrounding country, and is as light of heart and as jovial company as in the years long gone by. His familiar figure is one that attracts attention upon the streets, being of statesmanlike type of such an earlier period in American history as that of Henry Clay, Calhoun and Webster. Then another characteristic of the Doctor is his great love of good horseflesh. In his stables have always been found some of the finest blooded animals in the two cities, and his old-fashioned chaise has always followed some mighty fast clippers over these country roads. A great lover of travel of any kind, Dr. Garcelon, only this year, made a trip west, covering over 6000 miles. After attending a medical meeting at Chicago, he enjoyed a little side journey for

¹ *Phila. Med. Jour.*, May 5.

pleasure, to Denver and other places in Colorado, where he was entertained richly royally by his many friends. On his way back, Minneapolis, Chicago, New York and Boston were visited, the whole trip being of several weeks' duration. While in Denver, the Doctor had occasion to call upon some friends, but, not having announced his coming, he found them in the midst of a dinner party. The welcome was most cordial. The hostess escorted the Doctor into the dining-hall, and he at once became the most honored guest of the occasion. Introductions were made, and Dr. Garcelon for over an hour entertained the party with delightful reminiscences and stories gleaned from his long and active service in the world. The whole event is said to be one of the happiest in the memory of those present. Again we congratulate the Doctor. Long live one of our most esteemed citizens!"

INTERNATIONAL ANTITUBERCULOSIS CONGRESS.—More than 1200 members assembled at this congress, in Naples, April 25 to 28, a brilliant gathering of the scientists of continental Europe. It was more especially a trilateral than an international assembly, as not a single American or English name appears on the official program of addresses, although all nations were officially represented on the platform. Among these representatives our correspondents mention the names of Drs. Heiser and Willson of this country. In his opening address Baccelli stated that Italy is the most favored land in Europe in respect to tuberculosis, quoting statistics to show that in 1894, when Prussia lost 71,000 inhabitants from tuberculosis and Austria not less than 88,000, the deaths in Italy from this cause were 30,000. He added that old healed tuberculous lesions are found at a third at least of the autopsies in Italy, showing the marked tendency to recovery from the disease in that climate.

De Renzi outlined "The Present Status of the Treatment of Tuberculosis," placing all drugs in the second rank far below prophylaxis and hygienic measures in importance. The two medicines that are considered most effective are creosote and iodine, but the only effect of the creosote is to diminish expectoration, as it would be impossible to administer it to a patient in amounts sufficient to actually destroy the Koch bacillus. It benefits the sympathetic bronchitis but has no influence on the tuberculous processes at practicable doses. Iodine has evidently a favorable effect on local tuberculous processes, but has given conflicting results in experimental research. The Maragliano serum may prove beneficial in light cases. Patients with moderate tuberculosis, under treatment with this serum do not react as usual to injections of tuberculin, which demonstrates that they have acquired a certain resistance to the bacterial toxins. De Renzi's experience with "thiocol Roche" during the last year has been extremely favorable, and he considers its action superior to that of creosote or guaiacol. He concluded by reporting the excellent results he has attained with electric-light baths. Nine patients have been cured and others improved. The beneficial action may be due to the sweating induced. He has established that the sweat of tuberculous subjects is more toxic than in health. Besides the disappearance of all the morbid phenomena, injections of tuberculin failed to produce any reaction after this treatment. He recommends it as a valuable adjuvant to the indispensable hygienic measures, among which he includes pure air, absence of fresh infection, abundant food and gentle exercise. He does not ap-

prove of too much repose, and observes that confined air produces an intoxication of the organism which renders it a peculiarly favorable soil for the development of the Koch bacillus.

Senator exhibited a device for disinfecting the air in industrial establishments, and Ausset proposed that all houses for rent should keep a health record book to serve as a sanitary passport for the habitability of the house. The organization of special tuberculosis dispensaries in cities was advocated by several, and it was observed that sanitarium and dispensary treatment is only a fraction of the task to be accomplished, which should include the support of the patient's family and change of occupation.

Santoliqido, the chief of the sanitary service in Italy, announced that steps are now being taken for the compulsory notification of tuberculosis in poor-houses, dairies, etc., and also in cigar factories. Tuberculous employees are to be excluded from the latter and the state will provide a support for employees thus deprived of a means of earning their livelihood. The Congress voted to establish a permanent trilateral committee for the campaign against tuberculosis, and the Duke von Ratibor was appointed to represent Germany; Lannelongue, France, and Baccelli, Italy. They are empowered to elect an equal number of coadjutors to form the "International League Against Tuberculosis."

The numerous festivities included a trip to Pompeii, where the excavations have been carried on of late with enthusiasm and skill, under the supervision of that eminent member of the profession, Guido Baccelli, who, in his official capacity as minister of public instruction, has had the domestic life of Pompeii resurrected by restoring the famous Vettio mansion, discovered in 1894-95, which has many features of peculiar interest to physicians and sanitarians. The Exposition of Hygiene was inaugurated about the time of the Congress.

NEW YORK.

UNSANITARY PRISON CELLS.

A report on the condition of our state prisons has just been made by a committee consisting of Drs. Austin Flint, J. G. Phelps Stokes, J. Murray Mitchell, J. Seeley Ward, Jr., Eugene Smith, F. P. Bellamy, Henry E. Gregory and William M. F. Round. Referring to the cells at Sing Sing, the report says that the size of the ordinary cell is 3 feet 3 inches by 6 feet 6 inches in height, and 7 feet long, and that there are 1200 of these in a room 60 by 400 feet. In addition to this insufficient breathing-space, the lighting by day is poor, and the prison is overrun with vermin. Auburn prison is not quite so bad, but it is poorly lighted and ventilated, is dangerous in case of fire, and has insufficient sanitary arrangements. Dannemora prison is described as being much cleaner and better in every way, though not what it should be. The discipline was noted to be decidedly lax in Sing Sing, a little better at Dannemora, and excellent at Auburn. This committee, which was appointed under the authority of the supreme court, declares these prisons to be a disgrace to a civilized community.

New York City.

A NEW FIVE-STORY brick and limestone building, costing about \$125,000, is to be erected for Beth Israel Hospital.

A MAN, 65 years of age, recently died here of exhaustion from persistent hiccough, which had lasted about a week, and had resisted all attempts at its control.

THE QUARTERLY report to the president of the Board of Health, for the period ending March 31, shows 221 deaths from la grippe, as against 263 from that disease in the same period of 1899; also 2486 from pneumonia, as against 1654 in 1899.

GIFT TO FLOATING HOSPITAL.

Mrs. AUGUSTUS D. JULLIARD, who has already given the new floating hospital—the *Helen C. Juilliard*—to St. John's Guild, has now donated \$50,000; the interest from which is to be used in defraying the expenses of this hospital. The guild has been still further aided in its work by a gift of \$9046.89 for the erection of a new cottage at the Seaside Hospital, New Dorp, S. L., given by Mrs. Frederick Elliott Lewis in memory of her little son. In the summer of 1899 the guild expended \$60,000 in the care of 82,842 infants, and it proposes to increase its work the coming season.

CONFERENCE ON CHARITIES.

An informal conference on charities has just been held. Dr. George G. Wheelock presented a paper discussing the topic, "Are Public Institutions Adequate to Public Needs?" He said that while there has been some improvement in the department of charities since it was separated from the correction department, still this improvement has been very slow. There has been a decided decrease in the number of inmates in the almshouse, there having been, on Oct. 1, 1899, 743 vacant beds, and there is great need for a convalescent hospital. Fordham Hospital he characterized as "a lamentable instance of an unwise if not culpable expenditure of the city's money." Charities Commissioner Keller, in his address, declared that the most glaring need in his department is a new building to take the place of the miserable and outrageous makeshift now known as the Harlem Hospital.

PENNSYLVANIA.

WORK has been commenced on the new wing of the Lackawanna Hospital at Scranton.

A RESIDENT of Erie was bitten by a cat about five weeks ago, and died May 11 with symptoms of hydrophobia.

TWO CHILDREN living at Allentown swallowed a quantity of butter coloring matter, from the effects of which toxic symptoms developed and one child died.

A MAN, aged 50 years, who had for nearly ten years been isolated at the county house near Media, died on May 9. He came to Pennsylvania in 1887, and, knowing that he had leprosy, jumped from the vessel as it was coming up the Delaware River, and swam ashore to escape the sanitary officers. He stated that he had inherited the disease from his mother.

Philadelphia.

CHARLES LAWRENCE, superintendent of the Philadelphia Hospital, has tendered his resignation.

A LECTURE was delivered by Dr. Simon Flexner at the Museum in Widener Hall, May 10, on "Impressions of the Philippine Islands."

BY THE will of Mary Baker, \$5000 has been left the Philadelphia Hospital for Women, as an endowment of a free bed; \$1000 was left to the Methodist Hospital for the same purpose.

DR. R. N. WILLSON recently delivered an address before the International Convention for the Prevention of Tuberculosis, which was held in Naples.

DRS. H. B. ALLYN and DAVID RIESMAN have been appointed members of the medical staff of the Philadelphia (Blockley) Hospital.

THE COMPETITIVE examination for positions on the staff of the Philadelphia Hospital will occur May 22. The examining board will consist of Drs. James M. Anders, John H. Musser, A. H. Hulsburgher. Sixteen resident physicians will be chosen.

UNIVERSITY HOSPITAL.

Provost Harrison, of the University of Pennsylvania, recently appeared before the Board of Supervisors to advocate an ordinance to strike from the city plan, Pine Street from Thirty-fourth to Thirty-sixth Street, in order that needed enlargement of the University Hospital may be made. Otherwise a gift of \$50,000 can not be accepted on account of the lack of ground on which to build.

MORTALITY STATISTICS.

The number of deaths during the past week was 494, a decrease of 23 from the previous week, and an increase of 90 over the corresponding period of last year. The principal

causes were: nephritis, 26; cancer, 6; tuberculosis, 57; diabetes, 1; heart disease, 32; influenza, 5; appendicitis, 4; pneumonia, 69; peritonitis, 5; septicemia, 4; suicide, 6; tetanus, 1.

PENNSYLVANIA HOSPITAL.

The 149th annual report of this hospital has been made: The total number of cases treated in all the wards, not including the department in West Philadelphia, was 36,126. In the insane department, 619 were treated. The expenses of the Pine Street Hospital were \$116,790.30; the West Philadelphia Hospital for men, \$95,843.32; the Hospital for Women, \$125,490.18. The principal contributions received during the year were: from Frederick F. Ayer, \$25,000; Samuel J. Sharpless, \$10,000; Estate of George Plumer Smith, \$10,000; and \$5000 each from John T. Morris, Elizabeth Baker, estate of Catherine Thorn, Clara Galli and Dr. Joseph Kirkbride. The total contributions amounted to over \$89,500. The sum of \$7968.50 was paid by the Government for the treatment of soldiers during the late war.

MARYLAND.

Baltimore.

DR. THEODORE COOK, JR., has been reappointed physician to the penitentiary.

DR. FREDERICK LAWFOED has been appointed assistant physician to Bayview Hospital.

DRS. WM. B. BURCH, John S. Bishop, and John T. McCarthy have been appointed on the board of police surgeons.

PROF. W. H. WELCH, Johns Hopkins University, has been appointed one of the judges of the Hall of Fame, New York University.

THE WOMAN'S Medical College graduated four women on May 7. Miss Willena A. Peck, of Massachusetts, received the gold medal. The address was delivered by Rev. Dr. J. B. Van Meter, Dean of the Woman's College of Baltimore.

PUBLIC BATHS.

The mayor has approved the city ordinance appointing a commission to take charge of the public baths in Baltimore. Among the seven names on the commission, three are those of physicians: Drs. John S. Fulton, Mary Sherwood and Joseph C. Gichner. Henry Walters has turned over to the city the public baths on High Street, which he has given to Baltimore.

UNIVERSITY HOSPITAL.

The following appointments have been made at the University Hospital: medical superintendent, Dr. S. P. Latane; vice Dr. Spruill, resigned; assistant resident physician, Dr. G. A. Stewart, vice Dr. Fitzhugh, resigned; and Dr. H. Smith, resident surgeons, Drs. Thos. McGreen, A. C. Mathews, and A. C. Hoyt; assistant gynecologists, Drs. C. D. Snyder and C. A. Beck; assistant resident physician and ambulance surgeon, Dr. H. A. Naylor.

VACCIN PHYSICIANS.

The health commissioner made his assignments of the twenty-four vaccin physicians on May 9. Heretofore each of these received \$200 a year for this, and \$100 additional for services at police stations. Under the new law one physician is appointed from each ward to serve as vaccin physician and health warden or sanitary inspector, and medical attendant at the station house. The twenty-four are divided into groups of three, each group to have charge of one of the eight police stations, to look after the health of the prisoners there, and treat minor accident cases. There is some trouble about the salary, owing to insufficient appropriation, as the law allows the health commissioner to pay as much as \$900 a year, and he will not be able to pay the full amount this year.

DISTRICT OF COLUMBIA.

NATIONAL LEGISLATIVE CONFERENCE.

The first meeting of the National Legislative Conference of the AMERICAN MEDICAL ASSOCIATION was held here May 1 and 2, pursuant to the resolution of the ASSOCIATION at its Columbus meeting. The Conference was formally called to order by the Chairman, Dr. H. L. E. Johnson, who stated the object of the meeting. After some general discussion on the

subjects to be considered, the delegates decided, on motion of Dr. Welch of Baltimore, Md., to adjourn to meet the following day, at which meeting the following members were present: Drs. H. L. E. Johnson, representing the ASSOCIATION Committee and the Medical Association of the District of Columbia; Wm. H. Welch of Baltimore, and Wm. E. Rodman of Philadelphia, representing the ASSOCIATION Committee, and the following members representing the states. U. O. B. Wingate, Wisconsin; W. P. Goff, West Virginia; L. B. Tuckerman, Ohio; George Evans Reading, New Jersey; Gustav Eliot, Connecticut; F. J. Tina, Texas; H. M. Bracken, Minnesota; Surgeon-General Wyman; Surgeon-General Sternberg; John B. Roberts, Pennsylvania; George H. Simmons, Nebraska, and Henry Sewall, Colorado. The general matters discussed were "The Department of Public Health," "The Publication of the Index Medicus," "The Antivivisection Bill," "Unification of Medical Practice Acts," Senate bills 4200 and 4274, providing for contract surgeons, and H. R. bill 4483, providing increase in the medical department of the army; H. R. bill 1139 and Senate bill 4171, referring to quarantine, and Senate bill 559, providing for purification of water-supply. The committee of five, consisting of Drs. H. L. E. Johnson, Wm. H. Welch, L. B. Tuckerman, H. M. Bracken, and W. P. Goff, was appointed to wait on the committees of Congress having in charge the bills designated, and urge their prompt passage. The Committee will make a full report to the AMERICAN MEDICAL ASSOCIATION at the June meeting.

ILLINOIS.

SEMI-CENTENNIAL ANNIVERSARY.

Officers of the Illinois State Medical Society were elected May 16, as follows: president, G. N. Kreider, Springfield; first vice-president, Weller Van Hook, Chicago; second vice-president, Denslow Lewis, Chicago; assistant secretary, O. B. Will, Peoria; treasurer, Everett J. Brown, Decatur. The semi-centennial of the society was celebrated in the evening, with a reception and banquet, J. H. Hollister of Chicago officiating. Toasts were responded to as follows: "The Founder of the Illinois State Medical Society," Robert Beal and L. C. Thompson, both of Lacon. "Medical Education for Fifty Years in Illinois," N. S. Davis, Chicago; "Then and Now," James T. Stewart, Podunk; "Reminiscences of Early Day Practice and Hardships of the Pioneer Doctor," W. J. Chenoweth, Decatur; "The Parson to the Doctor," the Rev. D. F. Howe, Springfield; "Reminiscences," C. C. Hunt, Dixon; "Law and Medicine," Judge Charles P. Kine, Springfield; "The Ideal Physician of the Future," F. P. Norbury, Jackson.

Chicago.

A MAN here ruptured a blood-vessel in his head during a severe attack of coughing, death resulting.

PROPERTY ON Forty-ninth Street, near Cottage Grove Avenue, has been transferred to the Chicago Hospital Building Company for a consideration of \$75,000. The building will be renovated and refitted. Dr. Alexander Ferguson is president of the company and chief of the medical staff.

TWO DEATHS have occurred at the Dowie institution the past week. As both were probably preventable, radical measures will be instituted by the State Board of Health.

PERSONALS.

Drs. John A. Robison, Adolph Gehrman, John Hollister, N. S. Davis, J. S. Gill and Daniel R. Brower attended the State Medical Society, just held in Springfield, and presented papers on various subjects. Dr. N. S. Davis is the only living member of the sixteen delegates who were present at the first meeting.

WESLEY HOSPITAL.

The following staff has been appointed for Wesley Hospital: Professors Davis, Edwards and Webster, in medicine; Van Hook, Plumer and Schroeder, in surgery; Dudley and Mergler, in gynecology; Gradle and Allport, in eye and ear; Casselberry, in nose and throat; DeLee in obstetrics; Ridlon, in orthopedics; Danforth, in renal surgery; Hatfield, in children's diseases; Flütterer, pathologist; Zeisler, in skin diseases; Church and Patrick, in nervous and mental diseases.

This institution is devoted entirely to clinical teaching, the services being almost entirely made up of charity cases.

MORTALITY STATISTICS.

There were 527 deaths in the week ending May 12, 39 more than the preceding week and 24 more than in the corresponding period of 1899. The chronic diseases were chiefly responsible for the high mortality. Pneumonia and typhoid fever were also in excess of the preceding week, and there were 15 deaths from measles—the greatest number reported for any week since the weekly mortality records have been kept.

OHIO.

DR. WILLIAM T. GEMMIL, Forest, has been elected president of the State Board of Health.

THE COMMENCEMENT exercises of the Medical College of Ohio were held in Cincinnati, May 7. Prof. Howard Ayers, president of the University of Cincinnati, made the address, and awarded the diplomas to sixty young men. Prof. Jos. Ransohoff made the valedictory address.

REGISTRATION AND EXAMINATION.

Representatives of the different schools of medicine in the state met recently with a committee from the Board of Medical Registration and Examination and discussed the qualifications of those asking for admission to the colleges, and the date of opening. The meeting was the first of its kind, but will hereafter be an annual affair, and will be held at the time of the meeting of the Ohio State Medical Society.

ALUMNI MEETING.

At the annual meeting of the alumni association of the Cleveland College of Physicians and Surgeons the following officers were elected: president, Dr. N. S. Everhard, Wadsworth, Pa.; second vice-president, Dr. G. B. Woods, Washington, Pa.; third vice-president, Dr. H. N. Powers, North Amherst, Ohio; fourth vice-president, Dr. H. C. Crumvine, Cleveland; secretary, Dr. H. B. Ormsby, Cleveland; treasurer, Dr. I. N. Hentzelman, Cleveland.

INDIANA.

A NEW SANITARIUM has been opened in Terre Haute, under the management of Drs. Samuel D. Weir and Louis K. Stock.

THE MAYOR of Logansport issued a proclamation, May 4, ordering citizens to be vaccinated at once; and the State Board of Health has ordered the erection of a pest-house. A case of smallpox in a boarding-house has made these precautions necessary.

KENTUCKY.

COLLEGE CHANGES.

The Board of Curators of the Central University of Kentucky, realizing that it would be more advantageous to have the Louisville College of Dentistry run independent of the Hospital College of Medicine has decided to separate the two. A new building is being erected for the Louisville College of Dentistry. The architect made a personal examination of the different dental colleges of prominence before preparing the plans for this one. It will be four stories high, and devoted solely to dental instruction. Work has begun on the new building and it will be ready for occupancy October 10, when the next session opens. The building and general management of the department will be in the hands of officers selected, because, by experience for many years, both in active practice and intimate connection with dental colleges, they are especially fitted to take charge of the institution.

MICHIGAN.

AT THE meeting of the board of trustees of Butterworth Hospital, held May 7, in Grand Rapids, a new medical staff was appointed.

Detroit.

THE NEW staff at the Harper Hospital is: G. B. Lowrie, house physician; T. F. Heavenrich, S. G. McDonald, R. T. Mason, Dugald Ferguson and W. N. Wilkinson, assistants.

DETROIT COLLEGE OF MEDICINE.

THE thirty-second annual commencement exercises of the Detroit College of Medicine occurred May 10. Dr. W. P. Manton

addressed the class on the subject, "Posthomo Shadows in Medical Science," and Judge J. W. Donovan on "Opportunities." At the alumni meeting, Dr. Don Campbell, of Detroit, was elected president; Dr. E. D. Rice of Flint, vice-president.

LOUISIANA.

DR. J. G. DEMPSEY has been appointed visiting physician to the out-door poor of Truro Infirmary.

THE CITY council of New Orleans has passed an ordinance regulating the management of dairies, with penalties for non-observance. The dairy farms have heretofore been in a very unsanitary condition, and a great improvement is hoped for in the future.

CALIFORNIA.

DR. VINCENT BUCKLEY, of San Francisco, has been appointed to fill the vacancy on the board of health, caused by the resignation of Dr. W. E. Hopkins.

MRS. PHOEBE HEARST has presented to the University of California a complete equipment for the department of medicine, and Dr. Alonzo Taylor is in Germany purchasing the apparatus.

CANADA.

HEALTH PRECAUTIONS.

The Provincial Board of Health of Ontario met May 8 and 9. Among other matters up for discussion and action was that of lumpy-jaw in cattle, and the secretary, Dr. Bryce, was ordered to notify the health officer of Prescott, that any cattle shipped back from Montreal, where the disease had been discovered, as reported to THE JOURNAL a few weeks ago, should be immediately slaughtered. The Board upheld the action of the health officer of Fort William, who prevented a child with tubercular glands in the neck from attending school.

UNSANITARY STREETS.

The unsanitary, dusty streets in Montreal are again causing trouble and caustic comment. The city is so full of scarlet fever as to almost amount to an epidemic; and it is not confined to the poorer classes in the "scums" of the city, for many of the children of the better classes are also victims. The dust of the streets is swirled into the meat shops and provision stores and peppers the foods, so that that which was pure and wholesome becomes polluted and poisonous. It is thought that in this way the large amount of infection arises; but the existing state of affairs continues and the city fathers are being savagely criticised for their negligence in not keeping the streets properly swept and cleaned.

PHYSICIANS' AND SURGEONS' SYNDICATE.

DR. H. W. Shaw, Clinton, Ont., at the last meeting of the Huron Medical Association, in April—an Association which, some fifteen years ago, Professor Osler denominated the best of its kind in Canada—brought forward an idea, which though not perhaps new, will bear close and careful scrutiny at the hands of the profession. It is a plan for cheapening drugs and supplies to physicians and surgeons, and at the same time for profit and perfection in the remedy. It is proposed that a physicians' and surgeons' syndicate be established among doctors, with a capital of \$50,000, in \$10-shares, one physician not to possess more than twenty shares. A supply-house to be opened at some central point, with a competent manager and chemist, from which source all that pertains to the practice of medicine shall be obtained, at a wholesale price to the physician, would necessarily form an important part of the undertaking. The members of the corporation would all have to deal with this house, and share in whatever profits materialized. The accomplishment of some such scheme would do away with travelers wasting the physician's time, a practice which has almost become unbearable; and whatever financial profit there is to these houses would all revert to the doctor. The proposition was well received by the Association, and there is a likelihood of its receiving still further elaboration at an early date.

SMALLPOX AT MONTREAL.

Montreal is fearful of another epidemic of the dreaded dis-

ease. In 1885, when the city was decimated and ravaged to an alarming extent, and something like 3500 people succumbed to the sickness, a lesson was taught the sanitary authorities, which their successors ever afterward do not fail to appreciate. The disease, as previously announced in this correspondence in THE JOURNAL, was brought to the city by a young man coming from Rossland. He occupied a berth in the sleeper directly opposite to one of the victims of the disease at Winnipeg. On arriving at his hotel in Montreal the nature of his trouble was discovered. The whole staff of the hotel was immediately vaccinated, but not before two others of the employees had become infected. Another employee took sick and was sent to the General Hospital, suffering from apparent pneumonia; but the medical superintendent met the case at the hospital doors and diagnosed it smallpox. It was turned over to the Civic Hospital. A doctor has been put in special charge of these cases, another of which has since developed; and the financial committee of the city council has placed at the disposal of the hygienic committee unlimited funds to enable them to ward off all chance of an epidemic. So far all are of a mild character.

Correspondence.

Length of Medical College Curriculum.

HYDE PARK, VT., May 8, 1900.

To the Editor: In view of the coming meeting of the ASSOCIATION and action on the Amendment to Article 2 of the Constitution, proposed by Dr. Reynolds, viz.: "That no state, county or other auxiliary body sending representatives shall receive into its membership any one who may after 1900 receive the degree of Doctor of Medicine on less than four years of graded instruction or an equivalent requirement." I would like to suggest, as a member who will not be able to attend the meeting, that the proposed amendment be changed to read—"who may after 1903 receive the degree of Doctor of Medicine on less than four years of graded instruction, to include at least eight months' attendance at lectures and clinics each year, or an equivalent requirement."

This is offered in view of the fact that all of our leading universities, including such schools as Johns Hopkins, Harvard, Cornell, Columbia, Yale, Jefferson, the universities of Pennsylvania, Michigan, California, Minnesota, Virginia, Missouri, Texas, Chicago and twenty-six other schools, now require attendance on annual sessions of eight and nine months, while there are any number of others keeping the requirements down to six months' annual attendance. On the other hand, every medical school in the country except four or possibly five, which includes the two Georgia schools, has raised the requirements to a four years' required attendance, but, in case of all the southern schools except the university of Texas and one or two others, this requirement only applies to students who matriculate after Jan. 1, 1900, and who receive their degrees after July 1, 1903. To have this amendment apply to all receiving their degree after 1900 would in effect exclude the graduates of nearly every southern school and a number of northern schools who graduate during the years 1901, 1902 and 1903, while to require all graduating after 1903 to have attended four years of eight months each would be giving a fair warning. The extension of the course to eight months could be adopted at the coming session or at the beginning of the session of 1901-02, thereby making the time requirements uniform throughout the country and keeping harmony in the ranks.

It would seem as though the six months' schools extend the time to eight months for their own protection, as the graduates of some of them do not make a very creditable appearance before the numerous examining boards in comparison with those having longer sessions; and how can they, as attendance on annual sessions of eight months means, in four years, eight months' extra work in lectures, recitations, clinics and laboratory? However, in spite of this, some of them will not extend their sessions to eight months until compelled to do so.

Perhaps that would be as far as we ought to go at present, but I would very much like to see, in addition to the above, a requirement that all graduating after 1903, applying for recognition from the ASSOCIATION or its auxiliary bodies, be required to produce evidence that they have had a preliminary education equal to that obtained in a first-grade high school course, as is now required by law in the states of New York, New Hampshire and Ohio (Amendment to Statute passed April 14, 1900).

Johns Hopkins requires a degree in arts, literature, or science for admission. Harvard will require the same from all entering after September of this year. After 1901 the Western Reserve University, Cleveland, Ohio, will require the completion of the junior year in a recognized college, for admission to its medical department, and after 1903 the University of Chicago (see THE JOURNAL, April 21, 1900, p. 1014.) and the University of Minnesota will require the same. While too much can not be said in favor of the adoption of a collegiate education as a standard for admission by our leading universities, still, it would seem that it should be left to the judgment of the individual school, and that the completion of a high school course should be sufficient to require of all schools, but we should insist on that as a condition of admission and that the schools require four annual sessions of eight months each instead of six, and as all of our best schools now require it, let us demand it of all after 1903.

Very truly yours,

WILLIAM T. SLAYTON, M.D.

Deaths and Obituaries.

LONDON CARTER GRAY, M.D., died at his home in New York City, May 8, aged 50 years. He studied in Columbia and Heidelberg universities, and in 1873 took his degree in medicine at Bellevue Hospital Medical College. He began practice in New York City, but afterward moved to Brooklyn, where he was made professor of neurology at the Long Island College Hospital and visiting neurologist to St. Mary's Hospital. He was one of the founders of the New York Polyclinic, and was its professor of nervous and mental diseases. He served as president of the American Neurological Association, the New York Neurological Society, and the Society of Medical Jurisprudence. He was also chairman of the executive committee of the American Congress of Physicians and Surgeons for three successive sessions, and the author of several medical works, among the most important of which is his text-book on nervous and mental diseases.

THOMAS W. GORDON, M.D., Georgetown, Ohio, died April 21, aged 81 years. He was graduated from the Cleveland Medical College in 1846; from 1851 to 1860 he was professor of materia medica and therapeutics in the Cincinnati College of Medicine and Surgery, and during the Civil War was surgeon of the 97th Ohio infantry. He was a member of the AMERICAN MEDICAL ASSOCIATION.

THOMAS DOBINS, M.D., Marysville, Cal., died May 5, of tuberculosis. He was born in Alabama in 1837, but lived in Missouri most of his early life. In 1855, he was graduated from Brunswick College. He was an army surgeon during the Civil War, and at the close went to California, where he has since lived.

CARL BRUMME, M.D., Detroit, Mich., died May 13, aged 83 years. He was born in Göttingen, Germany, and educated there in the public schools and university. In 1852 he came to America and located in Detroit, where he has since resided. He was a member of the Michigan State Medical Society and of the AMERICAN MEDICAL ASSOCIATION.

ROBERT A. ELLIS, M.D., died in Alaska, June 15, 1899. He was about 100 miles from Cape Nome, and news of his death has just reached here. He was graduated from the Kentucky School of Medicine, in Louisville, in the class of 1882, and for fifteen years had practiced in San Francisco. In 1898 he identified himself with a mining company and was looking after its interests when he was stricken with fever.

W. M. BULLARD, M.D., died recently in Fallbrook, Cal.

He was graduated from the Medical College of Indiana in 1876, and then located in Helena, Mont., where he remained until failing health necessitated a change of climate.

DEATHS ABROAD.

DR. RAFAEL LAVISTA, of Mexico, is dead. His name is associated with scientific progress in his country during the last half century; he was the official representative of Mexico at the last three international congresses, and the Pan-American Congress at Washington. The *Revista de Anatomía Pat. y Clínica*, of which he was editor, has suspended publication for the present.

We also note the deaths of Professor Bose, of Giessen, who had recently retired; A. Milne-Edwards and G. Planchow, of Paris.

New Instruments.

An Improved Device for Rapid Hypodermoclysis.

BY EDWIN M. HASBROUCK, M.D.

WASHINGTON, D.C.

IN THE JOURNAL for March 3, page 520, Dr. Evan O'Neill Kane illustrates and describes a simple home-made device for rapid multiple infusion—consisting of a rubber bulb, glass medicine-dropper, rubber tubing and needles. The affair is a most useful one, but for other than absolute emergencies is too unstable in composition, both from the fact that after repeated sterilizations the rubber bulb is bound to deteriorate and eventually become useless—possibly just when most wanted—and that leakage is bound to occur at the points where the tubing is drawn through the bulb, possibly permitting the entrance of air at some stage of the operation.

Acting on the suggestion contained in Dr. Kane's apparatus, I have had made for me a simple little device that, like the eye-dropper, can be carried about in the pocket, or form part of every surgeon's outfit. It can be sterilized at a moment's

notice together with the needles and tubing, and it will last forever. It consists of a single metal tube provided with a bulbous end for holding the receiving tube from the fountain or supply tank. The lower end divides into four tubes, the ends of which are similarly provided for the feed tubes. The accompanying drawing shows the contrivance, exact size. For convenience and speed the four tubes with their needles can be left permanently attached and dried after each usage—the whole apparatus to be kept in a little box in the instrument bag. While the improved apparatus is my own idea, the profession has to thank Dr. Kane for a most useful little contrivance. The instrument here illustrated was made for me by the W. J. McKee Company, of this city.

2422 Fourteenth St., N. W.

The Artificial Defecator and Irrigator.

BY ROBERT N. BARGER, M.D.

HOPEDALE, ILL.

We all recognize the importance of *rest* in the treatment and cure of disease, yet in hemorrhoids and rectal troubles we have never been able to apply this, for the reason that we must defecate daily and have never had a way for avoiding it, or of

Queries and Minor Notes.

doing it artificially. To secure this much needed rest to the diseased parts I have had constructed an instrument which may be called an artificial defecator and irrigator.

I have found that it suits the purpose, i. e., it evacuates the bowels without any expulsive effort, or contraction of the perineal or sphincter ani muscles, thus giving the needed rest. I have used this instrument for six months and find it not only indispensable to patients suffering from hemorrhoids and rectal troubles, but also useful after all serious surgical operations, fractures of the lower limbs, accouchement cases, in all low types of fever, etc.

Not all its therapeutic applications can now be enumerated nor assigned, but they will develop as necessity calls for its use. In the accompanying cuts, Figure 1 represents the instrument closed and ready for introducing into the rectum or

PRACTICE IN OHIO.

BROOKLYN, N. Y., May 12, 1900.

To the Editor: Will you kindly inform me whether one may now register in Ohio under the present law previous to the one recently enacted taking effect July 1, as noted in THE JOURNAL of above date. Please give me particulars how to go about it, to whom apply, etc.

Yours truly, F. S. M.

ANSWER.—There is nothing in the amended Ohio law to prevent registration under the old conditions prior to July 1, 1900. This would give the right to practice, as the amended law reads: "All persons authorized and entitled prior to July 1, 1900, to practice medicine, surgery, or midwifery, in the State of Ohio, under and by virtue of the provisions of an act, entitled, 'An act to regulate the Practice of Medicine in the State of Ohio,' passed Feb. 27, 1896, to which this act is amendatory, may engage in such practice and shall be subject to the law regulating the same; all other persons desiring to engage in such practice in the state shall

FIGURE 1.

FIGURE 2.

FIGURE 3.

vagina. Figure 2 is the instrument open for use after introduction, the arrows showing the different currents of water. "A" is a rubber tube, or syringe for conveying water into the chamber or reservoir which surrounds the sewerage canal, and "B" is a rubber drainage-tube attached to the sewerage canal for conveying the fecal matters off when the patient is in bed. Figure 3 shows the instrument in three parts for cleansing or sterilizing. The two caps show one for defecation with holes and one for irrigation without holes.

The principal points to be noticed in this instrument are: 1. The sewerage canal is unobstructed by any stem or conduit tube; it has lateral currents to clear the opening and has a straight shoot from the rectum to a vessel beneath the bed. 2. The reservoir or chamber, surrounding the sewerage canal and encased by the outer cylinder, so places the water as to throw currents in every direction, thus triturating and liquefying the fecal matter. This placing of the water also makes it a very desirable rectal and vaginal irrigator.

apply to the state board of registration and examination for a certificate, and submit to the examination heretofore provided." There are exceptions in favor of Ohio medical students matriculating before Jan. 1, 1900, and a reciprocity clause. For further particulars address the Secretary of the Board of Medical Registration and Examination, Columbus, Ohio.

THE PATIENT AND PHYSICIAN IN ILLUSTRATION.

MILLVILLE, Mo., May 7, 1900.

To the Editor: Some time ago THE JOURNAL published an account of a series of three pictures, by a foreign artist, representing the patient's attitude toward his physician, during illness, convalescence and health. If you can give me any information regarding these—as to where and how they can be purchased—I would greatly appreciate it.

Very fraternally, J. M. G.

ANSWER.—The pictures referred to appeared in *Janus*, an international journal devoted to the history of medicine and medical geography, published at Amsterdam, by Dr. H. F. A. Peypers (Address Parkweg 212). Several acts were given. The subscription is \$5 a year for twelve numbers of *Janus*. Articles are in German, French or English, as contributed. Surgeon-General Sternberg, Dr. N. S. Davis, of Chicago; Dr. J. E. Pilcher, of Columbus, and Dr. Solis-Cohen, of Philadelphia, are on the list of collaborators.

PATHOLOGY OF CHOREA.

PRINCETON, ILL., April 31, 1900.

To the Editor: Will you kindly tell me whether the pathology of chorea has been satisfactorily determined, and give it to us in as condensed form as possible.

ANSWER.—Its essential lesions are not determined, and none of the several theories that have been advanced can be said to be satisfactorily established. At the present time there seems to be a tendency to attribute the affection to a germ, and it has been claimed that a specific bacterium has been found in cases of chorea, but this has not been confirmed. The other theories, the neurotic and the rheumatic, the latter having many supporters, are also still *sub judice*.

ST. LUKE'S HOSPITAL AGAIN.

LOS ANGELES, CAL., May 4, 1900.

To the Editor: A few days ago I received a letter from the president and treasurer of St. Luke's Hospital of Niles, Mich.

The president of this institution, like many another man of reputation, has several titles—M.D., Ph.D., LL. D.—while the proposition he made me nearly took my breath away, and I began to think that my great merits as a scholar, statesman, writer, orator, microscopist, and struggler-for-a-living were about to be appreciated in Michigan, by appointment on the "medical staff" of a great hospital, and to be given a certificate therefor. Here is a copy of the letter:

By way of introduction, we obtained your name from the list of medical practitioners located abroad from "R. L. Polk & Co.'s Medical and Surgical Register," located in a letter to you, subject to your confirmation. The plan of organization is entirely different to that (here is a Scotticism betraying something) of any other institution of its kind—and trust that we may have the pleasure of adding your name to this list, same as we have this day Dr. N. Banerjee, of Calcutta, India, who sent us \$10.00 for our genuine sheepskin Certificate and Membership ticket.

We will pay you a commission of 25 per cent. of the operation fee of all surgical cases and 10 per cent. of the fee of all medical cases you may send to our hospital (from India and Hawaii!) We charge nothing for nursing patients day or night, as that part of the expense is taken from our "Nursing Fund." We do charge, however, for board and room, ranging from \$1.50 to \$2.00 per week, according to the location selected by the patient.

Should you wish to consult us at any time regarding difficult cases we will freely give you what assistance and advice we can, and will make microscopical analysis of specimens free of charge. It is our intention never to appoint more than one physician in each locality, and should he so desire it, after accepting the appointment and paying the membership fee, and will send us a list of names, not exceeding twelve, including the local newspapers, we will write individual letters recommending him to the copy of which we herewith enclose.

To each of our members we issue a very neat and attractive Certificate setting forth that he is a member in good standing on our medical staff, and entitled to all the advantages and privileges of our hospital. We also issue in addition to our certificate a neat pocket lithographed Pocket Membership Ticket, which we believe, if rightly used, will be the means of securing many patients for our hospital. We charge as a membership fee according to the grade of certificate selected (see Physician's Application Blank), which goes to make up our "Nursing Fund."

Trusting that you will fill out the enclosed application form and return it to us with a remittance covering the amount of the priced certificate selected.

We remain yours fraternally, etc.

In a postscript was added:

Our House-Surgeon, Dr. Geo. A. Steel, is also a graduate of Rush, Class of 1895.

At the head of the letter are the names of some thirty-one physicians comprising the medical staff, from Niles, Berlin, New York, Chicago, Cincinnati, Kansas City, Philadelphia, Louisville, Buffalo, Edinburgh, St. Paul, Brooklyn, Paris, Keokuk, Indianapolis, Dublin, St. Louis, London, and Albany. Three of these names were: J. B. Green, M.D., F.R.C.P.S., president of staff, professor of practice of surgery, Queen's University, L. A. Larsen, A.B., M.D., Rush Medical College of Chicago; A. J. H. Delacey, M.D., University of Edinburgh, Scotland. These names show the cosmopolitan nature of the institution. It annihilates space, and through its wards may fit the attending spirits of Dr. McAdoo of Philadelphia, Dr. Banerjee of Calcutta, Dr. Osborne of Indiana, or Dr. Norwood of London. I call this great!

I received also a membership ticket stating that Dr. _____ is a member of St. Luke's Hospital staff, a blank form of application saying that "the list will be closed shortly" and giving a price of different kinds of certificates; a picture of the president and his hospital, and a printed list of testimonials received from physicians "who are members of our staff." One of them says: "The beautiful certificate of membership has reached me," and another writes: "The certificate is an elegant one, and I shall have it framed and placed in my new sanitarium where all can see it."

The following is a copy of the "individual letter" which would be sent around if the new incumbent so desired:

Dear Sir or Madam: We beg respectfully to call your attention to the fact that we have just recently elected and appointed Dr. _____ of your place, to be a visiting and consulting physician and surgeon on the Medical Staff of our Hospital, on account of his excellent medical qualifications and professional standing. We have no hesitation in recommending him to you, any member of your family, friends or acquaintances, if you should become sick and desire medical treatment. We wish to induce the Doctor and recommend you to patronize him. Should you at any time desire the services of our hospital for yourself, friends or acquaintances, the Doctor will make arrangements with you so that you can come here for treatment.

We have a first-class, up-to-date hospital, with every home comfort, and a Medical Staff of eminent physicians and surgeons, and our charges are less than anywhere else you may go.

In regard to these letters is the following private information: The above we send out upon our regular printed business letter-head (twelve to each certificate holder) recommending or endorsing those members only who have paid for their certificates of membership.

On receipt of this generous offer and before my gratitude could grow cold, as gratitude often does, I sat down and wrote the following note to the president:

Venerated and Distinguished Sir: I do not think that it would be becoming in a man of my humble station to accept of such vast and appalling honors and responsibilities as you suggest in your letter of February 24, just received. My diplomas and certificates have been secured by hard work; to get so much for so little might at my time of life (menopause) upset me completely.

I have often resented the statement that Americans are fond of titles; that they have a love for empty honors, and like to be "humbugged," but, after reading all these testimonials from physicians who have paid \$10 to be placed on the medical staff of the St. Luke's Hospital of Niles, I will be more saving of my indignation. Were the privileges of membership somewhat more difficult to get were the qualifications more shrewdly stated, and, as in the case with so many other easily-secured honors, made to seem special and legitimate, we should not be surprised that many had swallowed the bait. But here any doctor who can pay the fee gets the certificate. A man who has worked hard to get a real diploma from a real college, does not care to see his name on a sheepskin he can buy for \$10; and the older he grows in the experience of the world, the less he seeks the seeming; the more he loves the real.

E. S. GOODRUE, M.D.

Miscellany.

BOOKS AND PAMPHLETS RECEIVED.

Acknowledgment of all books received will be made in this column, and this will be deemed by us a full equivalent to those sending them. A selection from these volumes will be made for review as dictated by their merits, or in the interests of our readers.

BOOKS.

CHEMISTRY AND PHYSICS. A Manual for Students and Practitioners. Series Edited by Bern B. Gallaudet, M.D., Demonstrator of Anatomy, College of Physicians and Surgeons, and William H. Rockwith, Jr., M.D., Assistant Demonstrator of Anatomy, College of Physicians and Surgeons, Columbia University, New York. Series Edited by Bern B. Gallaudet, M.D., Demonstrator of Anatomy and Instructor in Surgery, College of Physicians and Surgeons, Columbia University, New York. Illustrated with 137 Engravings. Cloth. Pp. 374. Price \$1.50. Philadelphia and New York: Lea Brothers & Co.

THE MEDICAL REVIEW. (*Medical and Surgical Review of Reviews*). An Indexed and Illustrated Monthly Summary of all that is important to the Practitioner in the Medical Periodicals of the World. Edited by Nathan E. Body, M.D. Volume II, January-December, 1899. Cloth. Pp. 768. London: Harrison & Sons.

DISEASES OF THE GALL-BLADDER AND BILE-DUCTS, INCLUDING GALL-STONES. By A. W. Mayo Robson, F.R.C.S., Senior Surgeon to General Infirmary at Leeds. Assisted by Farquhar MacKae, M.B., C.M. Cloth. Pp. 313. Price \$3. Second Edition. New York: William Wood & Co., 1900.

TRANSACTIONS OF THE MEDICAL AND CHIRURGICAL FACULTY OF THE STATE OF MARYLAND. One Hundred and Fifth Annual Session (Centennial Anniversary). Held at Baltimore, Md., April, 1899; Semi-annual Session held at Frederick, Md., November, 1899. Paper. Pp. 213. Baltimore: DeWitt, 1900.

A HANDBOOK FOR NURSES. By J. K. Watson, M.D., Late House-Surgeon, Essex and Colchester Hospital, American Edition under the Supervision of A. A. Stevens, A.M., M.D., Professor of Pathology in the Women's Medical College of Pennsylvania. Cloth. Pp. 413. Price \$1.50. Philadelphia: W. B. Saunders, 1900.

ESSENTIALS OF DIAGNOSIS. Arranged in the Form of Questions and Answers. Prepared Especially for Students of Medicine. By Solomon Solis-Cohen, M.D., Professor of Clinical Medicine and Therapeutics in the Philadelphia College of Podiatry, and Augustus A. Eshner, M.D., Professor of Clinical Medicine in the Philadelphia Polyclinic. Illustrated. Second Edition, Revised and Enlarged. Cloth. Pp. 417. Price \$1. Philadelphia: W. B. Saunders, 1900.

PATHOLOGY AND SURGICAL TREATMENT OF TUMORS. By N. Sean, M.D., Ph.D., LL.D., Professor of Surgery in Rush Medical College. Second Edition. Revised. Illustrated by 478 Engravings, and 12 Full-Page Plates. Cloth. Pp. 718. Price \$5. Philadelphia: W. B. Saunders, 1900.

ARMY CHANGES.

Movements of Army Medical Officers under orders from the Adjutant-General's Office, Washington, D. C., May 5 to 10, 1900, inclusive:

Francis J. Bailey, acting asst.-surgeon, from Hillsboro, Ore., to the Department of California.

John M. Banister, major and surgeon, U. S. A., member of a board at West Point, N. Y., to examine military cadets.

Reuben M. Bonar, acting asst.-surgeon, U. S. A., now at San Francisco, Cal., is relieved from further duty in the Philippines, and will report to the Department of California.

George E. Bushnell, major and surgeon, U. S. A., member of a board convened at West Point, N. Y., to examine military cadets.

William J. Endera, acting asst.-surgeon, from Philadelphia, Pa., to the Department of California.

John S. Foxg, acting asst.-surgeon, leave of absence extended.

William M. Hendrickson, acting asst.-surgeon, from Skagway, Alaska, to the Department of California.

Loren B. T. Johnson, acting asst.-surgeon, from Washington, D. C., to the Department of California.

William L. Weller, acting asst.-surgeon, from Chicago, to temporary duty at Fort Logan, Colo.

Thomas B. McCown, acting asst.-surgeon, from Windsor, Mo., to the Department of California.

John L. Phillips, captain and asst.-surgeon, U. S. A., member of a board at West Point, N. Y., to examine military cadets.

John J. Repetti, acting asst.-surgeon, from Washington, D. C., to the Department of California.

NAVY CHANGES.

Changes in the Medical Corps of the U. S. Navy for the week ending May 5, 1900.

(By cable from Asiatic Station.)

Asst.-Surgeon W. E. High, detached from the *Manila* and ordered to the hospital.

Asst.-Surgeon D. G. Beebe, detached from the *Torkosen* and ordered to the *Isla de Luzon*.

Surgeon T. A. Berryhill, detached from the *Monongahela*, on reporting relief, and ordered home to wait orders.

P. A. Surzeon C. M. Wheeler, detached from the *Vermont*, May 3, and ordered to the *Kearsarge*.

P. A. Surzeon G. H. Barber, detached from the *Kearsarge* and ordered to the *Monongahela*.

Asst.-Surgeon D. H. Morgan, ordered to the *Vermont*.

Medical Inspector J. C. Boyd, detached from duty as assistant to bureau of medicine and surgery, Navy Department, and ordered to the *New York*, as fleet surgeon of the North Atlantic Station.

Medical Inspector P. Pizzalomo, detached from the *New York*, as fleet surgeon of the North Atlantic Station, and ordered to proceed home and wait orders.

Surgeon J. D. Gatewood, detached from the bureau of medicine and surgery, Navy Department, May 3, and ordered to duty as assistant to bureau of medicine and surgery, same day.

P. A. Surzeon C. D. Brownell, ordered to the naval training station, Newport, R. I.

MARINE-HOSPITAL CHANGES.

Official list of the changes of station and duties of commissioned and non-commissioned officers of the U. S. Marine-Hospital Service for the seven days ended May 3, 1900.

Surgeon P. H. Ballhache, detailed to represent the Service at the convention for the decennial revision of the United States Pharmacopoeia, at Washington, D. C., May 2.

Surgeon Eugene Waldin, detailed to represent the Service at the meeting of the AMERICAN MEDICAL ASSOCIATION, at Atlantic City, N. J., June 5 to 8.

P. A. Surzeon J. C. Cobb, to report to chairman of board of examiners for examination to determine fitness for promotion to the grade of surgeon.

P. A. Surzeon H. D. Goddings, detailed to represent the Service

at the convention for the decennial revision of the United States Pharmacopoeia, at Washington, D. C., May 2.

P. A. Surzeon M. J. Rosenau, detailed to represent the Service at the meeting of the AMERICAN MEDICAL ASSOCIATION, at Atlantic City, N. J., June 5 to 8.

Asst.-Surgeon D. H. Tabb, upon being relieved from duty at Savannah, Ga., to report in person at the bureau for further orders.

Asst.-Surgeon John McMullen, granted 60 days extension of leave of absence.

Asst.-Surgeon R. H. von Ezdorf, relieved from duty at New Orleans, La., and directed to proceed to Savannah, Ga., and assume command of the Service.

Asst.-Surgeon D. F. Fricks, relieved from duty at Washington, D. C., and directed to proceed to Manila, P. I., and report to the chief quarantine officer for duty.

Asst.-Surgeon G. M. Corput, to proceed to Mullet Key, Fla., and assume command of the detention camp and the steamer *W. D. Bhatton*.

Asst.-Surgeon H. A. Stansfield, relieved from duty at Honolulu, H. I., and directed to proceed to Manila, P. I., and report to the chief quarantine officer for duty.

Hospital Steward E. S. Maguire, relieved from duty at Evansville, Ind., and directed to proceed to New York City (Stapleton), and report to the medical officer in command, for duty and assignment to quarters.

Hospital Steward H. R. Mason, to proceed to New York City and report to the medical purveyor for temporary duty.

Hospital Steward E. M. Holt, to proceed to Portland, Me., and report to the medical officer in command for temporary duty and assignment to quarters.

BOARD CONVENED.

Board convened to meet at Washington, D. C., May 3, 1900, for the examination of P. A. Surzeon J. O. Cobb, to determine his fitness for promotion to the grade of surgeon. Detail for the Board—Surgeon J. H. White, Chairman; Surgeon R. M. Woodward, and Surgeon G. T. Vaughan, Recorder.

HEALTH REPORTS.

The following cases of smallpox, yellow fever, cholera and plague, have been reported to the Surgeon-General, U. S. Marine-Hospital Service, during the week ended May 12, 1900.

ALABAMA.—SMALLPOX—UNITED STATES AND INSULAR. District of Columbia: Washington, April 26 to May 5, 1 case, 1 death.

Florida: Jacksonville, April 26 to May 5, 1 case.

Indiana: Evansville, April 26 to May 5, 5 cases; Indianapolis, April 26 to May 5, 6 cases.

Iowa: Des Moines, April 1 to 30, 16 cases; Ottumwa, April 14 to 21, 2 cases.

Kansas: Wichita, April 26 to May 5, 4 cases.

Kentucky: Covington, April 26 to May 5, 6 cases; Lexington, April 26 to May 5, 1 case.

Louisiana: New Orleans, April 26 to May 5, 50 cases, 18 deaths.

Maryland: Baltimore, April 26 to May 5, 5 cases.

Massachusetts: Chicopees, April 26 to May 5, 1 case.

Michigan: Grand Rapids, April 26 to May 5, 3 cases.

Nebraska: Omaha, April 21 to 28, 2 cases.

New York: New York, April 26 to May 5, 2 cases.

Ohio: Cleveland, April 26 to May 5, 7 cases, 1 death.

Tennessee: Nashville, April 26 to May 5, 2 cases.

Utah: Ogden, April 1 to 30, 2 cases; Salt Lake City, April 26 to May 5, 5 cases.

Philippines: Manila, March 3 to 24, 9 cases, 1 death.

SMALLPOX—FOREIGN.

Austria: Prague, April 7 to 21, 9 cases.

Belgium: Ghent, April 14 to 21, 1 death.

Brazil: Rio de Janeiro, March 23 to 30, 6 cases, 12 deaths.

Canada: New Brunswick—Grand Falls, April 28, present; Ontario, April 18 to May 1, 3 cases; Quebec—Bonaventure County, May 4, 26 cases.

England: Liverpool, April 14 to 21, 18 cases, 3 deaths; London, April 14 to 21, 4 cases; Southampton, April 14 to 21, 2 cases.

France: Lyons, April 1 to 14, 3 deaths.

Gibraltar: Gibraltar, April 15 to 22, 2 cases, 1 death.

Greece: Athens, April 14 to 21, 2 cases, 1 death.

India: Bombay, April 3 to 10, 111 deaths; Calcutta, March 10 to 28, deaths; Surachnee, April 1 to 8, 20 cases, 14 deaths.

Italy: Milan, April 21 to 28, 1 case.

Mexico: Vera Cruz, April 21 to 28, 4 deaths.

Russia: Moscow, April 1 to 7, 7 cases; Odessa, April 7 to 21, 2 cases; 8 deaths; Warsaw, April 1 to 4, 5 deaths.

Scotland: Glasgow, April 14 to 21, 6 cases, 1 death.

Spain: Corunna, April 14 to 21, 1 death.

Straits Settlements: Singapore, March 10 to 17, 3 deaths.

Venezuela: Maracaibo, April 1 to 14, 1 case.

YELLOW FEVER.

Brazil: Rio de Janeiro, March 23 to 30, 7 cases, 23 deaths; Santos, February 18 to April 8, 125 deaths.

Mexico: Vera Cruz, April 21 to 28, 1 death.

CHOLERA.

India: Bombay, April 3 to 10, 15 deaths; Calcutta, March 10 to 17, 77 deaths.

Philippines: Manila, March 3 to 24, 15 cases, 12 deaths.

PLAQUE—INSULAR.

PLAQUE—FOREIGN.

Arabia: Aden, February 21 to April 14, 119 cases, 81 deaths.

Egypt: Port Said, May 4, outbreak reported.

Indo-China: Bombay, April 2 to 10, 608 deaths; Calcutta, March 10 to 17, 744 deaths; Kurrachee, April 1 to 8, 471 cases, 333 deaths.

CHANGE OF ADDRESS.

Dr. M. M. Allueth, from 429 Grand Avenue to 1467 Humboldt Blvd., Chicago, Ill.

Dr. E. F. Brandon, from Detroit, Mich., to Alger, Ohio.

Dr. J. C. Beach, from 3007 Cottage Grove Avenue, Chicago, Ill., to care of Brown & Price, Columbus, Ohio.

Dr. W. C. Bailey, from Hot Springs to Las Vegas, N. M.

Dr. A. C. Browler, from Detroit to Martin, Mich.

Dr. C. M. Brucker, from Denver, Colo., to 805 9th Street, Tell City, Ind.

Dr. E. N. Brady, from 238 Marshfield Avenue to 323 S. Western Avenue, Chicago, Ill.
 Dr. H. J. O'Brien, from 620 Tower Street to Waterman Block, West Superior, Wis.
 Dr. H. A. Brous, from 9th and Pine Streets, Philadelphia, Pa., to Manhattan, Kans.
 Dr. G. A. Bachman, from Detroit to Burnips Corners, Mich.
 Dr. M. R. Beaudoin-Bennett, from Jackson, Mich., to 176 Broadway, New York, N. Y.
 Dr. S. H. Banta, from Detroit to Hubbardston, Mich.
 Dr. I. B. Chadwick, from 1514 Myrtle Street to 4627 E. 10th St., Kansas City, Mo.
 Dr. J. F. Cardwell, from St. Luke's Hospital, Detroit to Durand Michigan.
 Dr. W. H. Curtiss, from 528 S. 9th Street, Lafayette to Frankfort, Ind.
 Chicago Med. Society, from Stewart Bldg. to 203 Michigan Avenue, Chicago, Ill.
 Dr. S. F. Clay, from Washington, D. C., to Lewisburg, W. Va.
 Dr. D. A. Conrad, from Los Angeles to 40 E. Colorado Street, Pasadena, Cal.
 Dr. S. C. Carver, from Winterset to Lorimor, Iowa.
 Dr. T. Chandler, from 1236 to 1318 Noble Avenue, Chicago, Ill.
 Dr. J. W. Duncan, from Atlanta, Ga., to Gay and Vine Streets, Knoxville, Tenn.
 Dr. E. C. Dukes, from St. Louis to Lookout, Mo.
 Dr. L. B. Doeblerman, from 95 Columbia Street East, Detroit, Mich., to Covington, Ind.
 Dr. E. E. Evans, from Detroit to Armada, Mich.
 Dr. A. R. Edwards, from 2818 to 2950 Indiana Avenue, Chicago, Ill.
 Dr. G. S. Edmondson, from Marva to Keamek Opera House, Clinton, Ill.
 Dr. J. P. Freeman, from Glenville to Emmons, Minn.
 Dr. C. H. Frizelle, from Chicago to Sterry Block, Pontiac, Ill.
 Dr. F. E. Gibbons, from 492 Lincoln Street, Chicago, Ill., to Maroa, Wis.
 Dr. R. L. Gallaher, from Wheat, Tenn., to English, Texas.
 Dr. C. O. Gose, from Pleasantville, Iowa, to Hennessy, O. T.
 Dr. S. E. Greenfield, from 682 W. Adams Street, Chicago, Ill., to Drichson, Kans.
 Dr. H. D. Gray, from Newton to Kellogg, Iowa.
 Dr. I. J. K. Golden, from 1045 to 1134 Milwaukee Avenue, Chicago, Ill.
 Dr. F. H. Hansberry, from Milwaukee to Hillsboro, Wis.
 Dr. E. D. Hammond, from Omaha, Neb., to The Sliding, Wyo.
 Dr. Chas. Hines, from 629 Front Street, to 265 Morrison Street, Portland, Ore.
 Dr. O. E. Howell, from Woods to Santa Rosa, Mo.
 Dr. C. P. Horner, from Paxton to Tampico, Ill.
 Dr. S. Hexter R. A. C. Co., from 199 Market St. to 154 State St., Chicago, Ill.
 Dr. F. D. Hollenbeck, from 313 E. Chicago Ave. to 205 North State St., Chicago, Ill.
 Dr. H. J. Hillebrand, from 863 Armitage Ave. to 1059 W. Fullerton Ave., Chicago, Ill.
 Dr. C. W. Heath, from 165 Wood St. to 16 Astor St., Chicago, Ill.
 Dr. J. Hawley, from 3515 Grand Boul. to 3421 S. Park Ave., Chicago, Ill.
 Dr. J. D. Hartley, from 6422 Stony Island Avenue to 7840 Emerald Avenue, Chicago, Ill.
 Dr. R. B. Jackson, from Washington, D. C., to 156 W. 53d Street, New York, N. Y.

 Dr. A. L. Lehman, from Mullan to Wallace, Idaho.
 Dr. E. A. Lawbaugh, from 31 Washington Street, to 237 La Salle Avenue, Chicago, Ill.
 Dr. F. V. Leckley, from 178 Ashley Avenue, Charleston, to Lady and Sumter Streets, Columbia, S. C.
 Dr. R. E. Miller, from 5858 State Street to 5859 Wentworth Avenue, Chicago, Ill.
 Dr. J. F. Minley, from 3457 State Street to 39th and Cottage Grove Avenue, Chicago, Ill.
 Dr. Jno. S. Miller, Philadelphia, Pa., to Louisville, Colo.
 Dr. W. O. Nance, from 6213 Hibbard Avenue to 100 State Street, Chicago, Ill.
 Dr. J. C. Ober, from Malvern Place to 2221 Park Avenue, Cincinnati, Ohio.
 Dr. F. P. Parker, from Centaur to 1423 Euclid Avenue, St. Louis, Mo.
 Dr. H. J. Patten, from 1735 Armitage Avenue to 1093 Tripp Avenue, Chicago, Ill.
 Dr. H. C. Palmer, from 5 Hopper Street to 2 West Street, Utica, N. Y.
 Dr. W. E. Patterson, from 706 Monroe Street, Chicago, Ill., to Greene, Iowa.
 Dr. L. W. Rowell, from 280 S. Leavitt Street to 45 Loomis Street, Chicago, Ill.
 Dr. E. F. Rorbaugh, from 4308 Langley Avenue to 109 42d Place, Chicago, Ill.
 Dr. H. H. Rittenhouse, from 57th and Jefferson Streets to 5729 Rosalle Court, Chicago, Ill.
 Dr. F. C. Rosse, from 1701 H Street N. W., to 1110 F Street N. W., Washington, D. C.
 Dr. B. W. Sippy, from 143 Oakwood Boul. to The Winamac, Chicago, Ill.
 Dr. J. J. Sexton, from 384 S. Marshfield to 835 W. Harrison Street, Chicago, Ill.
 Dr. C. M. Shanely, from Ledgerwood to Forman, N. D.
 Dr. H. B. Stehman, from Pasadena to 217 S. Broadway, Los Angeles, Cal.
 Dr. J. A. Silverman, from 975 Post Street to 822 Geary Street, San Francisco, Cal.

Dr. W. B. Simpson, from New Orleans, La., to Hot Springs, Ark.
 Dr. A. D. Smith, from 295 Marshfield Avenue, Chicago, Ill., to Hicks Bldg., San Antonio, Texas.
 Dr. T. E. Spaulding, from Galveston to Kingston, Texas.
 Dr. L. A. Sholars, from New Orleans to Henry, via Abbeville, Louisiana.
 Dr. J. T. Topinka, from 2534 Wentworth to 2602 Indiana Avenue, Chicago, Ill.
 Dr. C. Vedeler, from Denver to care D. & R. G. Hospital, Salida Colorado.
 Dr. A. S. Walss, from 2691 to 2516 N. Hermitage Avenue, Chicago, Ill.
 Dr. F. E. Wadhams, from 3329 Indiana to 3435 S. Park Avenue, Chicago, Ill.
 Dr. U. R. Webb, from Lenox Flats, 16th and L Streets, to 2021 Hilger Place, Chicago, Ill.
 Dr. T. B. Wingo, from Martin, Tenn., to Dexter, Mo.
 Dr. C. L. Worrall, from Alliance to Magnolia, Ohio.
 Dr. M. N. White, from Augusta, Ga., to 1521 Pitzwater Street, Philadelphia, Pa.
 Dr. O. A. Young, from 626 6th Avenue, Cedar Rapids, Iowa, to 1009 Rusk Avenue, Houston, Texas.
 Dr. A. T. Zeller, from 901 Walnut Street to 603 Locust Street, McKeesport, Pa.

Association News.

Board of Trustees.—There will be a meeting of the Board of Trustees of the AMERICAN MEDICAL ASSOCIATION in Room 237, Hotel Dennis, Atlantic City, N. J., at 10 a. m., Monday, June 4, 1900. Alonzo Garcelon, M.D., President.

Membership Receipts.—Members attending the Atlantic City meeting, and who have paid their dues for 1900, are reminded of the necessity of taking their receipts with them if they wish to avoid annoyance when they register.

The Official Program.—In order to avoid misunderstandings and to protect the interests of advertisers, attention is called to the fact that there is but one official program. This program is copyrighted by the Board of Trustees and contains no advertising matter.

Delegates to the Meeting of the American Medical Association.—Secretaries of societies are requested to forward the names of delegates as soon as possible after these are appointed or elected. George H. Simmons, M.D., Secretary, 61 Market St., Chicago.

General Business Committee.—The first meeting of the General Business Committee of the AMERICAN MEDICAL ASSOCIATION will be held at the Hotel Dennis, Atlantic City, N. J., on Monday afternoon, June 4, at 4:30 o'clock. Subsequent meetings of the Committee will be held at the same place and hour, every afternoon, during the meeting of the ASSOCIATION, unless otherwise directed by the Committee. In order that the business of the ASSOCIATION may be effectively transacted, it is very important that all the members of the Committee should attend all its meetings. L. DUNCAN BULKLEY, Acting Secretary.

Railroad Rates for Atlantic City Meeting.—As previously announced in these columns, the Trunk Lines Association and the Central Passenger Association have granted one and one-third fare rate on the certificate plan for the Atlantic City meeting. Tickets will be on sale in the territory of these Associations from May 30 to June 7, and good to return to June 23. Action has also been taken by the Western Passenger Association, and the same rate announced from all points in its territory, tickets also to be sold on the certificate plan, the dates of sale being May 30 to June 5. The return limit was made June 12 by this Association, but on account of the later limit allowed by the others, it will probably be changed to correspond with that of the Trunk Lines and Central Passenger associations. The certificates will be signed at Atlantic City by Dr. W. Blain Stewart, N. E. Cor. Pacific and North Carolina Avenues, and a special agent will be present on June 6, 7 and 8. The territory covered by the two first-named includes practically everything north of the Ohio River and east of the Mississippi from Cairo to St. Louis, thence east of a line drawn from St. Louis to Chicago, through Jacksonville, Decatur, Gibson, etc. The Western Passenger Association's territory to which the certificate plan usually applies comprises points west of Chicago, Peoria and St. Louis, including Oklahoma, Indian Territory, Kansas, Colorado, Utah, Nebraska, South Dakota, Minnesota, Wis-

consin, Iowa, most of North Dakota and Missouri, and northern Michigan and northern Illinois.

Pathologic Exhibit at the American Medical Association.—The state medical society has constituted the chief avenue through which pathologic material has been solicited for the exhibit, and a number of state organizations have appointed representatives or committees to take in charge the work. Besides, a number of laboratories and hospitals will send on their own account. A partially complete list of the organizations and institutions which will participate, with the committees acting for them, is as follows: Alabama Medical Association, Thos. D. Parke, Birmingham; Colorado State Medical Society, A. M. Holmes, Denver; Florida State Medical Society, Edward N. Liell, Jacksonville; Illinois State Medical Society, Maximilian Herzog, Chicago; Indiana State Medical Society, Frank B. Wynn and H. G. Gaylord, of Indianapolis, L. P. Drayer of Fort Wayne, A. W. Bitting of Lafayette, Edwin Walker of Evansville, George H. Grant of Richmond, Allen Pierson of Spencer and L. J. Willien of Terre Haute; Kentucky State Medical Society, James B. Bullit, Louisville; Louisiana State Medical Society, O. L. Pothier, New Orleans; Missouri State Medical Association, Hugo Summa, St. Louis; New Jersey State Medical Society, F. W. Bailey, Elizabeth; New York State Medical Association, Edward K. Dunham, D. Hunter McAlpin, Leon T. LeWald, and J. W. Draper Maury, New York City; North Carolina State Medical Society, Richard H. Whitehead, Chapel Hill; Ohio State Medical Society, A. P. Ohlmacher, Gallipolis; Tennessee State Medical Society, William Krauss, Memphis; West Virginia State Medical Society, W. P. Goff, Clarksburg; Wisconsin State Medical Society, Gustav A. Kletzsch, Milwaukee; Government Hospital for Insane, A. R. Richardson and I. W. Blackburn, Washington; Iowa State University, Walter L. Bierring, Iowa City; Johns Hopkins Hospital, William H. Welch, Baltimore; Lakeside Hospital, William T. Howard, Jr., and Dr. Perkins, Cleveland; Pepper Laboratory and other institutions of Philadelphia, Alfred Stengel; Pathological Institute of the New York State Commission in Lunacy, Ira Van Gieson, New York City; United States Marine-Hospital Service, Walter Wyman, Washington; United States Bureau of Animal Industry, D. E. Salmon, Washington.

It is urged that representatives in charge of collections, as well as individuals sending specimens, should comply as nearly as possible with the wishes of the committee in the matter of case histories. These should be typewritten, cross-wise on paper $5\frac{1}{2}$ by nine inches in size, leaving a margin of $1\frac{1}{2}$ inches at the top. The first page should be a brief containing the essential facts and striking features of the specimen, to be elaborated in the succeeding pages. For specimens with meager data a large tag will be provided. In the former the case history will be enclosed in a neat cover and placed with the specimen for convenience of reference. Tags and covers may be obtained from the secretary of the committee by specifying the number desired.

Specimens should be packed carefully and labeled "Breakable!" There will be less danger of breakage if the packages do not exceed 250 to 300 pounds in weight. Boxes with rope handles may be checked on the tickets of the representative accompanying the collection. If shipped by freight due allowance should be made for delays. Every possible effort should be made to have the material reach Atlantic City by June 2, and under no circumstances later than June 4, since it will require considerable time and labor to put the collection in order. In every instance the committee should be notified as to the method of transportation, date of shipment and probable time of arrival. All material or communications expected to arrive in Atlantic City after May 21 should be sent in care of the "Pathological Exhibit of The American Medical Association."

The members of the Provisional Committee on the Pathologic Exhibits are: Joseph Stokes, Moorestown, N. J., Chairman; Alfred Stengel, 1811 Spruce St., Philadelphia; W. W. Fox, City Hospital, Atlantic City, N. J.; Frank B. Wynn, 18 E. Ohio St., Indianapolis, Ind., Secretary.

Programs for Atlantic City Meeting.

Following are the lists of papers to be presented before the several Sections at the next meeting of the ASSOCIATION.

SECTION ON PRACTICE OF MEDICINE.

TUESDAY, JUNE 5—AFTERNOON SESSION.

1. Address of Chairman. GEORGE DOCK, Ann Arbor, Mich.
2. A System of Personal Biologic Examinations of the Condition of Adequate Medical and Scientific Conduct of Life. GEORGE M. GOULD, Philadelphia.
3. The Hospital Clinical Laboratory. C. N. B. CAMAC, New York City.
4. Value of Bacteriologic Cultures of Throat to General Practitioner. M. HOWARD FUSSELL, Philadelphia.
5. Dysentery. SIMON FLEXNER, Philadelphia.
6. Notes on Tropical Dysentery. J. H. MUSSER, Philadelphia.
7. Serumtherapy in Croupous Pneumonia. J. C. WILSON, Philadelphia.
8. Influence of Sea Air and Sea Water Baths on Disease. W. BLAIR STEWART, Atlantic City, N. J.

WEDNESDAY, JUNE 6—MORNING SESSION.

9. Pseudo (?), or Modified (?) Smallpox? T. J. HAPPEL, Trenton, Tenn.
10. Yellow Fever: Its Nature and Its Cause. EUGENE WASHIN, Surgeon. U. S. M.-H. S.
11. Prolonged Fevers of Obscure Origin. ROBT. B. PREBLE, Chicago.
12. Some Interesting Cases of Infectious Diseases. DELANCEY ROCHESTER, Buffalo, N. Y.
13. Certain Clinical Features of Influenza Recently Epidemic. H. S. ANDERS, Philadelphia.
14. Influenza With Four Distinct Pneumonic Attacks Accompanied by Otitis Media Purulenta, Cerebral Hyperemia, Colitis, Marasmus. Recovery. JULIUS ULLMAN, Buffa^o, N. Y.
15. Observations on Direct Antiseptic Treatment of Infectious Diseases. C. AM ENDE, New York City.

WEDNESDAY, JUNE 6—AFTERNOON SESSION.

SYMPOSIUM ON MALARIA.

16. Pathology of Malarial Fevers: Structure of the Parasites and Changes in the Tissues. JESSE W. LAZEAR, U. S. A., Havana, Cuba.
17. Etiology of Malaria With Especial Reference to Mosquitoes. W. S. TRAYER, Baltimore, Md.
18. Inoculation of Malarial Fever Through Agency of the Mosquito, with Some Sections and Dissections of the Mosquito. Etiology of Malarial Fever and Some Observations Made in the South Several Years Ago. A. E. WOLDERT, Philadelphia.
19. Entomologic and Practical Aspects of the Mosquito; With Specimens and Drawings. L. O. HOWARD, U. S. Dept. of Agriculture.
20. Some Typical Cases of Estivo-autumnal Fever and Combined Estivo-autumnal and Tertian Malarial Fevers; with a Study of the Parasites Observed in the Blood. CHAS. F. CRAIG, U. S. Army.
21. Experiences with Some of the Pernicious Forms of Malaria. M. GOLDMAN, Memphis, Tenn.
22. Clinical Observations in Malaria. FRANK A. JONES, Memphis, Tenn.
23. Malarial Hemoglobinuria. WM. BRITT BURNS, Deckerville, Ark.

Discussion on Malaria, by WM. OSLER, Baltimore; A. C. ABROTT, Philadelphia; WM. KRAUSS, Memphis, Tenn.; ARTHUR R. EDWARDS, Chicago; JUDSON DALAND, Philadelphia; T. J. HAPPEL, Trenton, Tenn.

THURSDAY, JUNE 7—MORNING SESSION.

SYMPOSIUM ON ARTHRITIS.

24. Pathology of Rheumatism. DAVID RIESMAN, Philadelphia.
25. Rheumatism and Prevention of Heart Complications. JAMES J. WALSH, New York City.

26. Relations of Chorea and Rheumatism.
C. W. BURR, Philadelphia.
27. Heart in Rheumatism.
DELANCEY ROCHESTER, Buffalo, N. Y.
28. Heart in Rheumatism. ARTHUR R. EDWARDS, Chicago.
29. Pathogenesis and Clinical Features of Arthritis Deformans.
A. O. J. KELLY, Philadelphia.
30. Iodid of Iron in Treatment of Certain Forms of Infective Arthritis.
J. C. WILSON, Philadelphia.
Discussion on Arthritic Diseases, by F. A. PACKARD, Philadelphia; J. H. MUSSER, Philadelphia; J. M. ANDERS, Philadelphia; EDWARD F. WELLS, Chicago; CHARLES G. STOCKTON, Buffalo, N. Y.; L. F. BISHOP, New York City; H. B. FAVILL, Chicago.
31. Case of Malignant Endocarditis with Recovery.
N. S. DAVIS, JR., Chicago.
32. Relative Importance of Muscular and Valvular Lesions of Diseases of the Heart.
S. SOLIS-COHEN, Philadelphia.
33. Clinical Study of Myocarditis.
LOUIS FAUGERES BISHOP, New York City.
34. Plea for a More Rational Prognosis in Heart Affections.
JNO. J. MORRISSEY, New York City.
Discussion on Cardiac Disease, by FRANK BILLINGS, Chicago; DELANCEY ROCHESTER, Buffalo, N. Y.; JAMES B. HERRICK, Chicago; O. T. OSBORNE, New Haven, Conn.; D. D. STEWART, Philadelphia; BERTRAM W. SIPPY, Chicago; ROBERT B. PREBLE, Chicago; M. H. FUSSELL, Philadelphia.
- THURSDAY, JUNE 7—AFTERNOON SESSION.
35. In What Relation Does Occupation Stand to Tuberculosis?
W. FREDENTHAL, New York City.
36. Diagnosis and Treatment of Prebacillary Stage of Pulmonary Tuberculosis.
J. M. ANDERS, Philadelphia.
37. Subnormal Temperature in Pulmonary Phthisis; Its Clinical Significance.
J. FRANK MCCONNELL, Las Cruces, New Mexico.
38. Importance of Rest in Pulmonary Tuberculosis.
CARROLL E. EDSON, Denver, Colo.
39. Pulmonary Tuberculosis; Present Condition of Cases Treated During 1898 and Reported Last Year at the Columbus Meeting.
C. P. AMBLER, Asheville, N. C.
40. Tuberculosis of the Lungs.
A. F. LEMKE, Chicago.
41. Rational Treatment of Tuberculosis With Compressed-Air in Saturated Antiseptic Solution for Inhalation and Internal Use.
EUSTATHIUS CHANCELLOR, St. Louis, Mo.
42. Silver Injection Treatment of Pulmonary Consumption.
THOMAS J. MAYS, Philadelphia.
Discussion on Tuberculosis, opened by J. C. WILSON, Philadelphia; DELANCEY ROCHESTER, Buffalo; HENRY B. FAVILL, Chicago; S. SOLIS-COHEN, Philadelphia; JAMES B. HERRICK, Chicago.
43. Hydrophobia and the Pasteur Method.
CHARLES WINSLOW DULLES, Philadelphia.
44. Brain Break and Nerve Strain of the American Soldier; His Mind and Nerve Exhaustion; His Insanity and Neurasthenia.
C. H. HUGHES, St. Louis, Mo.
- FRIDAY, JUNE 8—MORNING SESSION.
45. Diagnosis of Diabetes.
JAMES B. HERRICK, Chicago.
46. Mortality From Diabetes Mellitus in the City of New York During the Decade 1889-1899.
HEINRICH STERN, New York City.
47. Cutaneous Diseases Accompanying Diabetes.
MILTON B. HARTZELL, Philadelphia.
48. Exophthalmic Goiter.
O. T. OSBORNE, New Haven, Conn.
49. Typhoid Bacillus and Its Complete Biologic History From Eberth's Discovery Until To-day.
FELIX VITALE, Coytesville, N. J.
50. Case of Scorbutus in Which Typhoid Fever, Complicated by Acute Leukemia, Occurred.
D. D. STEWART, Philadelphia.
51. Chlorosis: With Especial Reference to Diagnosis, Prognosis and Treatment.
EDWARD F. WELLS, Chicago.
52. Treatment of Typhoid Fever with Bactericidal Agents and Some Consequent Deductions.
JAMES M. PECK, Arlington, Ky.
FRIDAY, JUNE 8—AFTERNOON SESSION.
53. Lesions of Cauda Equina and Conus Medullaris.
BERTRAM W. SIPPY, Chicago.
54. Movable Kidney From the Standpoint of the General Practitioner.
A. MARCY, JR., Riverton, N. J.
55. Antiseptic Treatment of Diphtheria.
D. BENJAMIN, Camden, N. J.
56. Rational Therapeutics of So-Called Uric Acid Lesions With Some Original Investigations.
ALFRED C. CROFTAN, Pasadena, Cal.
57. Some Points on the Nature and Treatment of the Melancholias.
J. JOSEPH KINDRED, New York City.
58. Climatology of Arizona.
WILLIAM DUFFIELD, Phenix, Ariz.
59. Clinical Laws of Immunity of Disease.
LAMBERT OTT, Philadelphia.
- SECTION ON OBSTETRICS AND DISEASES OF WOMEN.
TUESDAY, JUNE 5—AFTERNOON SESSION.
- 2 o'clock.
1. Address of Chairman. W. E. B. DAVIS, Birmingham, Ala.
2. Value of the Angiotribe in Vaginal Celiotomy.
J. H. CARSTENS, Detroit, Mich.
3. Further Experience with Tuffier's Angiotribe.
I. S. STONE, Washington, D. C.
4. Angiotripsy in Abdominal Surgery.
HUGH M. TAYLOR, Richmond, Va.
3:30 o'clock.
- SYMPOSIUM ON FIBROMYOMA.
5. Personal Experience with Uterine Fibroid.
H. D. INGRAHAM, Buffalo, N. Y.
6. Myomectomy Per Vaginam.
J. RIDDLE GOFFE, New York City.
7. Myofibroma Uteri.
H. J. BOLDT, New York City.
8. Arrhythmia Cordis Complicating Fibromata Uteri.
J. WESLEY BOVÉE, Washington, D. C.
9. Antelexion of Uterus; Its Causes and Treatment.
AUGUSTUS P. CLARKE, Cambridge, Mass.
- WEDNESDAY, JUNE 6—MORNING SESSION.
- 9 o'clock.
10. Improved Technique in Major and Minor Surgery of the Female Generative Organs.
HENRY P. NEWMAN, Chicago.
11. The Rubber Glove in Aseptic Surgery.
C. C. FREDERICK, Buffalo, N. Y.
10 o'clock.
- SYMPOSIUM ON OBSTETRICS.
12. Practical Application of Posture During Labor.
EDWARD P. DAVIS, Philadelphia.
13. Plea for Regular and Systematic Examination of the Uterus for Eight or Ten Weeks Following Parturition.
HIRAM N. VINEBERG, New York City.
14. Parturition as a Factor in Gynecic Practice.
JOHN M. DUFF, Pittsburg, Pa.
15. Classical Cesarean Section Versus the Porro-Cesarean.
GEO. M. BOYD, Philadelphia.
16. Forced Re-expansion of Uterus During Labor and Its Relation to Manual Operations for Correction of Malpositions of Child.
D. BENJAMIN, Camden, N. J.
17. Maternity Hospitals and Obstetric Teaching.
GEO. C. MOSHER, Kansas City, Mo.
18. Puerperal Eclampsia.
J. LUE SUTHERLAND, Grand Island, Neb.
- WEDNESDAY, JUNE 6—AFTERNOON SESSION.
- 3 o'clock.
- SYMPOSIUM ON THE RELATION OF PELVIC AND INTRA-ABDOMINAL DISEASES TO NERVOUS DISEASES.
19. Causal Relation Intra-Abdominal Diseases Bear to Nervous Disturbances Recognized by Gynecologists, Ignored by Neurologists.
HENRY O. MARCY, Boston.

20. Traumatism and Malformation of Female Generative Apparatus as Cause of Insanity.
GEO. H. NOBLE, Atlanta, Ga.
21. Neuroses Due to Autointoxication from Faulty Menstruation.
ARTHUR JOHNSTONE, Cincinnati, Ohio.
22. Tubo-Ovarian Adhesions; Their Reflexes.
A. L. BEAHAN, Canandaigua, N. Y.
23. Gall-Stones and Diseases of Gall-Bladder and Nervous Symptoms Resulting Therefrom.
EDWIN RICKETTS, Cincinnati, Ohio.
24. How Shall We Treat Our Cases of Hysteria and Neurasthenia.
JOSEPH TABER JOHNSTON, Washington D. C.
25. Title to be announced.
F. X. DERCUM, Philadelphia.
26. Third Element in Equation Between Pelvic Disease and Disturbance in Nervous System in Women.
H. A. TOMLINSON, St. Peter, Minn.
27. Pelvic Disease as a Factor of Cause in Insanity of Female, and Surgery as a Factor of Cure.
E. C. CARPENTER, Columbus, Ohio.
28. Interrelation of Gynecology and Neurology in Practice.
C. H. HUGHES, St. Louis, Mo.
- THURSDAY, JUNE 8—MORNING SESSION.
29. Abdominal Tumors of Infancy.
DENSLOW LEWIS, Chicago.
30. Aseptic Minor Gynecology with Demonstrations.
AUGUSTIN H. GOELET, New York City.
- SYMPOSIUM ON CANCER OF FEMALE GENERATIVE ORGANS.
10 o'clock.
31. The Prophylaxis and Diagnosis of Cancer of Uterus.
L. S. MCMURTRY, Louisville, Ky.
32. Technique of Vaginal Extirpation for Cancer of Uterus.
R. B. HALL, Cincinnati, Ohio.
33. Combined Abdominal and Vaginal Versus Vaginal Hysterectomy for Carcinoma.
JOHN B. DEEVER, Philadelphia.
34. Operative Treatment of Cancer of Uterus.
E. E. MONTGOMERY, Philadelphia.
35. Operation for Cancer of Rectum in Female.
JOHN B. MURPHY, Chicago.
36. Cancer of Uterus.
W. H. HUMISTON, Cleveland, Ohio.
37. Treatment of Cancer of Uterus.
WM. R. PRYOR, New York City.
- THURSDAY, JUNE 8—AFTERNOON SESSION.
2 o'clock.
38. Nephrorrhaphy: A Study of the Remote Results, With Remarks on the Technique.
CHARLES P. NOBLE, Philadelphia.
39. Resection of Ureter.
HOWARD A. KELLY, Baltimore, Md.
40. Exclusion of Intestinal Areas From Fecal Tract.
JOHN B. MURPHY, Chicago.
- SYMPOSIUM ON INFLAMMATORY DISEASES OF FEMALE GENITALIA.
3 o'clock.
41. Senile Endometritis.
L. H. DUNNING, Indianapolis, Ind.
42. Inflammation of Fallopian Tube, with Special Reference to Specific Origin.
J. R. GUTHRIE, Dubuque, Iowa.
43. Appendicitis Operations in Young Women and Girls.
JOSEPH PRICE, Philadelphia.
44. Tubercular Peritonitis.
A. H. CORBIER, Kansas City, Mo.
45. Source of Infection in Pelvic Suppuration as an Indication for Treatment.
H. D. NILES, Salt Lake City, Utah.
46. Ovarian Dermoid and Large Hematocele, with Twisted Pedicle Which Caused Alarming Conditions Resembling Appendicitis; Patient Ten Years of Age; Operation; Recovery.
MILO B. WARD, Kansas City, Mo.
47. Pathology of Pelvic Suppurations.
F. HENROTIN, Chicago.
48. Plea for More Frequent Avoidance of Exsection of Ovary in Connection with Resections of Diseased Tubes.
PHILANDER A. HARRIS, Paterson, N. J.
49. Residual Symptoms of Gonorrhoea in Female.
EDWARD J. ILL, Newark, N. J.
- FRIDAY, JUNE 8—MORNING SESSION.
9 o'clock.
50. After-Treatment of Laparotomy.
WALTER B. CHASE, Brooklyn, N. Y.
51. Ovulation and Menstruation Not Interdependent Functions.
C. C. THAYER, Clifton Springs, N. Y.
52. Contribution to Study of Dysmenorrhoea.
GEO. TUCKER HARRISON, New York City.
53. The Sins of Omission and Sins of Commission.
G. H. BALLERHAY, Paterson, N. J.
54. Confinement Following a Supposed Double Ovariectomy, Complicated with Intestinal Hernia Through the Old Laparotomy Wound.
HENRI LEONARD, Detroit, Mich.
55. Surgery of Uterus and Other Pelvic Structures, Per Vaginam.
W. H. WATHEN, Louisville, Ky.
56. Treatment of Menorrhagia (Dysmenorrhoea) of Pelvic Origin, by Electricity.
G. BETTON MASSEY, Philadelphia.

SECTION ON SURGERY AND ANATOMY.

1. Suggestions in Plastic Surgery of the Face.
J. B. ROBERTS, Philadelphia.
2. Two Cases of Growths in Frontal Sinus.
W. D. HAMILTON, Columbus, Ohio.
3. Injuries of the Skull and Its Contents.
W. H. EARLES, Milwaukee, Wis.
4. Traumatic Spine: Contribution to Mechanical Treatment of the Same, with Report of Cases.
GEO. R. ELLIOTT, New York City.
5. Laminectomy for Diseases and Injuries of the Cord.
SAMUEL LLOYD, New York City.
- Discussion opened by H. WHARTON, Philadelphia.
6. External Drainage of Superficial Lung Cavities, with Report of Two Successful Cases.
W. L. WILLS, Los Angeles, Cal.
- Discussion opened by J. B. MURPHY, Chicago.
7. A Retrospect of Surgery of the Stomach.
H. O. WALKER, Detroit, Mich.
8. Non-Perforating Gastric Ulcer With and Without Hemorrhage.
W. L. RODMAN, Philadelphia.
9. Anterior Transverse Gastro-Enterostomy with Splitting of the Upper Anterior One-Half of Intestinal Wound.
CHRISTIAN FENGER, Chicago.
- Discussion opened by FENTON B. TURCK, Chicago.
10. Two Successful Operations: a. Cholelithiasis. b. Hepatonephroptosis: Cure by Cholecystorrhaphy.
A. F. JONAS, Omaha, Neb.
11. Diagnosis and Treatment of Cholelithiasis.
W. J. MEANS, Columbus, Ohio.
12. Removal of Mucous Membrane of Gall-Bladder, a Substitute for Cholecystotomy.
W. J. MAYO, Rochester, Minn.
13. Importance of Early Operation for Biliary Calculi.
M. H. RICHARDSON, Boston, Mass.
- Discussion opened by W. W. KEEN, Philadelphia.
14. Colostomy for Permanent Fecal Fistula.
J. A. WYETH, New York City.
15. Exclusion of the Intestinal Area from the Fecal Tract.
J. B. MURPHY, Chicago.
16. Original Investigations on the Anatomy and Histology of Rectum and Colon, Together with Treatment of Obstinate Constipation for Obstruction Based on These Points.
J. R. PENNINGTON, Chicago.
- Discussion opened by G. R. FOWLER, Brooklyn, N. Y.
17. Gunshot Wounds of Abdomen.
W. F. WESTMORELAND, Atlanta, Ga.
18. Gastric and Intestinal Wounds.
D. W. COWLEY, Oakland, Cal.
19. Lesions of Abdominal Viscera Without Injury to the Skin.
GEO. T. VAUGHAN, Washington, D. C.
20. Repair After Resection of Intestine.
W. A. EVANS, Chicago.
- Discussion opened by F. H. WIGGIN, New York City.
21. Appendicitis: Colitis as an Etiologic Factor, and the Operation of Removing the Appendix in All Cases Operated on.
MILES S. PORTER, Ft. Wayne, Ind.
22. Comments on Appendicitis as Commonly Practiced.
JOSEPH PRICE, Philadelphia.

23. Appendiceal Fistula. J. B. DEEVER, Philadelphia.
Discussion opened by ROTT. T. MORRIS, New York City.
24. Treatment of Ventral Hernia in Children
A. J. OCHSNER, Chicago.
25. Treatment of Ventral Hernia.
M. M. JOHNSON, Hartford, Conn.
26. Remarks on Injection Method of Treating Hernia, with
Comments. G. G. COTTON, Rock Rapids, Iowa.
27. Cure of Inguinal Hernia in Men. H. O. MARCY, Boston.
Discussion opened by W. B. DE GARMO, New York City.
28. Diagnosis of Calculus Disease of Kidney, Ureters and
Bladder by Roentgen Method.
C. L. LEONARD, Philadelphia.
29. Movable Kidney. M. L. HARRIS, Chicago.
30. Treatment of Injuries of the Ureter.
B. F. DAVIS, Omaha, Neb.
31. Vesico-rectal Anastomosis for Extrophy of Bladder, with
Report of Case. A. E. HALSTED, Chicago.
32. Extrophy of Bladder, with Exhibition of Case.
AP MORGAN VANCE, Louisville, Ky.
Discussion opened by EDWARD MARTIN, Philadelphia.
33. Tuberculosis of Prostate and Vesicula Seminales.
A. I. BOUFFLEUR, Chicago.
34. Contribution to Surgical Asepsis of Urethra and Bladder.
FERD. C. VALENTINE, New York City.
35. Treatment of Prostatic Hypertrophy.
PARKER SYMS, New York City.
36. Indications of Urethrotomy.
G. FRANK LYDSTON, Chicago.
Discussion opened by C. C. THAYER, Clifton Springs, N.Y.
37. Use of Decalcified Bone Chips in Diseases of the Bones.
J. G. CARPENTER, Stanford, Ky.
38. Bone Tuberculosis. DEFOREST WILLARD, Philadelphia.
39. Treatment of Tubercular Knee-Joint.
WISNER TOWNSEND, New York City.
40. Operative Treatment of Disease of Shafts of Long Bones.
S. L. MCCURDY, Pittsburg, Pa.
Discussion opened by NICHOLAS SENN, Chicago.
41. Fractures of Patella. J. M. BARTON, Philadelphia.
42. Restitution of Continuity of Shaft in Tibia, by Transplan-
tation of Patella Between the Fragments.
N. SENN, Chicago.
43. Operative Treatment for Reduced and Irreducible Dislo-
cations. ARTHUR DEAN BEVAN, Chicago.
44. Ambulatory Treatment of Fracture, with Demonstration of
a New Apparatus for Cases of Fracture Below the Knee.
E. H. LEE, Chicago.
Discussion opened by C. A. POWERS, Denver, Colo.
45. Surgical Errors of Skiagraphy.
CARL BECK, New York City.
46. Report of Five Cases of Tetanus, Treated with Anti-
tetanic Serum. J. D. BLAKE, Baltimore, Md.
47. Old Age Influencing Surgical Operations.
J. P. TUTTLE, New York City.
48. Report of Case of Specific Myositis, Simulating Retro-
peritoneal Sarcoma. ERNEST LAPLACE, Philadelphia.
49. Sarcoma of Colon, with Report of Case.
C. VAN ZWALENBERG, Riverside, Cal.
50. Coccygeal Dermoids.
J. R. EASTMAN, Indianapolis, Ind.

SECTION ON STATE MEDICINE.

1. The Stamping Out of Typhoid Fever.
SAMUEL KNOX CRAWFORD, Chicago.
JAMES MARTIN, Fredricksburg, Ohio.
2. Prevention of Tuberculosis by the State.
BENJAMIN LEE, Philadelphia.
Discussion by J. N. HURTY, Indianapolis, Ind., and HENRY
MITCHELL, Trenton, N. J.
3. Experiences with Recent Epidemic of Rabies in Buffalo.
ERNEST WENDE, Buffalo, N. Y.
4. Municipal Regulation of the Spitting Habit.
E. B. BORLAND, Pittsburg, Pa.
5. Pollution of Streams and Purification of Public Water-
Supplies. GEORGE M. KOBER, Washington, D.C.
6. Present State of Interstate Reciprocity Concerning Licen-
ses to Practice Medicine. E. AMBERG, Detroit, Mich.
7. Venereal Disease as a Social Problem.
W. C. GATES, Rockland, Mich.
8. Pure Food Legislation.
MURRAY G. MOTTER, Washington, D. C.

SECTION ON OPHTHALMOLOGY.
TUESDAY, JUNE 5—AFTERNOON SESSION.

1. Address of Chairman.
H. V. WÜRDEMANN, Milwaukee, Wis.
2. Treatment of Conical Cornea: Optical Therapeutics.
SWAN M. BURNETT, Washington, D. C.
3. Operations.
ROBERT SATTLER, Cincinnati, Ohio.
Discussion opened by HERMAN KNAPP, New York City,
and SAMUEL D. RISLEY, Philadelphia.
4. Keratitis Bullosa, with Report of Case.
E. O. SISSON, Keokuk, Iowa.
Discussion opened by CASEY A. WOOD, Chicago.
5. Observations on Etiology of Scrofulous or Phlyctenular
Keratitis and Its Treatment by Salicylate of Sodium.
H. GRADLE, Chicago.
6. Use of Protargol in Pyogenic Affections of the Cornea.
F. C. HOTZ, Chicago.
Discussion opened by L. WEBSTER FOX, Philadelphia.
WEDNESDAY, JUNE 6—MORNING SESSION.
- EXHIBITION OF SPECIMENS AND NEW INSTRUMENTS.
7. A Double Trial Lens to Balance the Eyes in Presbyopia.
MARK D. STEVENSON, Akron, Ohio.
Discussion opened by JAMES THORINGTON, Philadelphia.
8. Relative Value of Instruments Used for Keratometry,
with Demonstrations of Different Ophthalmometers.
A. D. MCCONACHIE, Baltimore, Md.
9. Astigmatism, Its Detection and Correction.
H. BERT ELLIS, Los Angeles, Cal.
10. Remarks on the Value of Homotropin as a Cycloplegic—
A Clinical Study. E. C. ELLETT, Memphis, Tenn.
11. A Comparison of the Cycloplegic Action of Atropin and
Scopolamin. W. K. ROGERS, Columbus, Ohio.
12. How to Construct Curves Representing Relative Accommo-
dation and Convergence. LUCIEN HOWE, Buffalo, N. Y.
Discussion opened by Edward Jackson, Denver, Colo.
WEDNESDAY JUNE 6—AFTERNOON SESSION.
- RELATION OF OCULAR DISEASES AND VISUAL DEFECTS TO
VOCATIONS.
13. Estimation of Amount of Injury to the Business Capacity
of the Individual from Partial or Complete Loss of
Vision. H. T. HANSELL, Philadelphia.
14. What Amount of Visual Defect Should Disqualify in Rail-
road and Steamship Service? FRANK ALLPORT, Chicago.
Discussion opened by C. H. WILLIAMS, Boston; ROBERT
SATTLER, Cincinnati, Ohio.
15. Amount of Myopia Corrected by Removal of the Crystal-
line Lens. EDWARD JACKSON, Denver, Colo.
Discussion opened by JOHN E. WEEKS, New York City.
16. Lessons Learned from a First Series of 100 Cataract Ex-
tractions. F. T. ROGERS, Providence, R. I.
Discussion opened by E. E. HOLT, Portland, Me.
17. Secondary Operations on Capsular Membranes.
PETER A. CALLAN, New York City.
Discussion opened by H. KNAPP, New York City.
18. Systematic Cleansing of Nasal Cavities Before Operations
Which Involve Opening of the Eyeball.
J. A. LIPPINCOTT, Pittsburg, Pa.
Discussion opened by H. GRADLE, Chicago.
19. Case of Coloboma of Each Lens Without Coloboma of Iris
or Choroid. JAMES MOORES BALL, St. Louis, Mo.
Discussion opened by A. D. MCCONACHIE, Baltimore, Md.
THURSDAY, JUNE 7—MORNING SESSION.
- EXHIBITION OF SPECIMENS AND NEW INSTRUMENTS.
20. An Improved Lantern for Testing Color Perception.
C. H. WILLIAMS, Boston, Mass.
21. A Double Hook for Use in Advancement Operations.
C. F. CLARKE, Columbus, Ohio.

22. Demonstration of a Tubercular Tumor of the Orbit.
H. F. HANSELL Philadelphia.
Discussion opened by JNO. E. WEEKS, New York City.
23. Demonstration of Sections of an Unusual Intraocular Growth.
WILBER P. MARPLE, New York City.
24. The Douche in the Treatment of Purulent Conjunctivitis.
E. E. HOLT, Portland, Me.
25. An Insurance Case in Which Ossification of the Choroid Led to Identification of the Body.
ROBERT L. RANDOLPH, Baltimore, Md.
Discussion opened by A. R. BAKER, Cleveland, Ohio.
THURSDAY, JUNE 7—AFTERNOON SESSION.
- RATIONAL USE AND LIMITATIONS OF THERAPEUTIC MEASURES INTENDED TO PROMOTE ABSORPTION OF EXUDATES WITHIN THE EYEBALL.
26. Medicinal Measures.
RANDOLPH BRUNSON, Hot Springs, Ark.
27. Local Therapeutics.
M. URIBE TRONCOSO, Mexico City, Mex.
28. Present Status and Value of Massage of the Eyeball, with the Consideration What Diseases of the Eye May Be Favorably Influenced by This Therapeutic Measure, and What Are the Best Means of Its Application.
CASEY A. WOOD, Chicago.
29. Use and Abuse of Iodid of Potash in Ophthalmic Practice.
A. R. BAKER, Cleveland, Ohio.
Discussion opened by GEO. M. GOULD, Philadelphia; S. C. RITCHIE, Washington, D. C.; J. SANTOS FERNANDEZ, Havana, Cuba; J. A. PRATT, Aurora, Ill.
30. Use of Heat as a Therapeutic Agent in Chronic Eye Affections.
L. J. LAUTENBACH, Philadelphia.
Discussion opened by LEARTUS CONNOR, Detroit, Mich.
FRIDAY, JUNE 8—MORNING SESSION.
- EXHIBITION OF SPECIMENS AND NEW INSTRUMENTS.
31. A Recording Electric Perimeter.
WM. M. SWEET, Philadelphia.
Discussion opened by H. O. REIK, Baltimore, Md.
32. Treatment of Immature Cataract with Special Reference to Rate of Development and Such Measures as May Check it.
G. E. DE SCHWEINITZ, Philadelphia.
Discussion opened by JOHN E. WEEKS, New York City; ABNER W. CALHOUN, Atlanta, Ga.; and SAMUEL D. RISLEY, Philadelphia.
33. Report of Cases: a. Injury of the Eye, Iridocyclitis, Enucleation, Death from Meningitis. b. Case of Exophthalmus Due to Septic Thrombosis (?) Evisceration of Orbital Contents—Cure.
EDW. J. BERNSTEIN, Baltimore, Md.
34. Paresis of External Recti Associated with Irregular Tabes.
G. ORAM RINO, Philadelphia.
Discussion opened by SAMUEL D. RISLEY, Philadelphia.
35. Glioma of Retina.
G. A. SULZER, Portsmouth, Ohio.
Discussion opened by G. E. DE SCHWEINITZ, Philadelphia.
36. Hemorrhagic Glaucoma.
W. C. POSEY, Philadelphia.
Discussion opened by CHAS. A. OLIVER, Philadelphia.
37. Ocular Complications of Injuries to the Head. With Report of Two Cases.
J. T. CARPENTER, Philadelphia.
Discussion opened by H. T. HANSELL, Philadelphia.
38. Blindness from Drinking Jamaica Ginger: Recovery.
EDWARD STIEREN, Pittsburg Pa.
Discussion opened by R. L. RANDOLPH, Baltimore, Md.
39. Case of Extensive Laceration of External Ocular Muscles with Resultant Diplopia. Spontaneous Recovery.
40. Clinical Lessons of 200 Cases of Hyperphoria.
WENDELL REBER, Philadelphia.
4. Care of Higher Grades of the Feeble-Minded.
A. W. WILMARTH, Chippewa Falls, Wis.
5. A Study of the Circulation in the Feeble-Minded.
J. MADISON TAYLOR and F. SAVARY PEARCE, Philadelphia.
6. Infantile Cerebral Palsies.
A. C. COTTON, Chicago.
Discussion by WM. M. LESZYNSKY, New York City; I. N. LOVE, St. Louis, Mo.; W. S. CHRISTOPHER, Chicago; JOHN S. MUSSER, DE FORREST WILLARD, and F. X. DER-CUM, Philadelphia; H. N. MOYER, Chicago; LOUIS FAUGERES BISHOP, New York City; J. P. CROZER GIFFITH, Philadelphia.
TUESDAY, JUNE 5—AFTERNOON SESSION.
- SESSION DEVOTED TO CONSIDERATION OF DISEASES OF THE BLOOD AND THE CIRCULATION.
7. Antecedents of Valvular Heart Disease in Children.
FREDERICK A. PACKARD, Philadelphia.
8. Purpura Hemorrhagica or Scorbutus: A Clinical Sketch.
HENRY E. TULEY, Louisville, Ky.
SAMUEL E. WOODY, Louisville, Ky.
9. Rheumatism.
J. CLEMENTS, Kansas City, Mo.
10. Chorea.
G. M. BLECH, Chicago.
11. Medicinal and Surgical Treatment of So-Called Scrofula.
G. M. BLECH, Chicago.
12. Essential Points of Difference in Treatment of Adolescent Senile Heart.
JOHN A. ROBISON, Chicago.
13. Abortive Treatment of Pneumonia.
HENRY ILLOWAY, New York City.
Discussion on Pneumonia by EWD. F. WELLS, Chicago.
Discussion opened by ALFRED STENGL, Philadelphia; S. SOLIS-COHEN, Philadelphia; EDWIN E. GRAHAM, and S. S. ADAMS, Washington, D. C.; J. J. MORRISSEY, New York City.
14. Value of Blood Examinations for Diagnostic Purposes.
J. BRANDEIS, New York City.
15. Diabetes Mellitus in Children: Report of Two Cases.
LEOPOLD F. HAAS, New York City.
WEDNESDAY, JUNE 6—MORNING SESSION.
- SESSION DEVOTED TO THE CONSIDERATION OF INFANT FEEDING AND TO DISEASES OF DIGESTIVE TRACT.
16. Milk Supply and Control at the Kaiserin Friedrich Hospital.
ADOLF BAGINSKY and PAUL SOMMERFELD, Berlin.
Read by LOUIS FISCHER, New York City.
17. Infant Feeding.
ALEXANDER McALISTER, Camden, N. J.
Discussion opened by HENRY D. CHAPIN, New York City; VICTOR C. VAUGHAN, Ann Arbor, Mich.; and WILLIAM LELAND STOWELL, New York City.
19. Gastrointestinal Hemorrhage in the New-Born.
EDWARD H. SMALL, Pittsburg, Pa.
18. Infant Feeding; Accidents and Incidents.
WM. F. NORTHRUP, New York City.
20. Causation and Relative Frequency of Typhlitis, Perityphlitis and Appendicitis in Infancy and Childhood.
JOSEPH N. BYRNE, New York City.
21. Differential Diagnosis Between Abdominal Typhoid and Appendicitis, by Means of Iodin Reaction: Report of Case.
S. WEISS, Vienna.
22. Congenital Malformation of Rectum. A Case of Maternal Impression.
THOMAS CHARLES MARTIN, Cleveland, Ohio.
23. Athresia Infantum; Diagnosis and Treatment.
LOUIS FISCHER, New York City.
24. New Home Milk Modifier: Demonstration.
25. Clinical Significance of Stools in Diarrhea of Infants.
WILLIAM E. DARNALL, Atlantic City, N. J.
WEDNESDAY, JUNE 6—AFTERNOON SESSION.
- SESSION DEVOTED TO CONSIDERATION OF CONTAGIOUS DISEASE.
26. Shall Children be Kept from Measles and Exanthemata Usually Incident to Children?
C. F. WAHREER, Fort Madison, Iowa.
27. Rötheln, A Distinct Affection Apart from Measles and Scarlatina, and Its Differentiation from These Exanthemata.
HENRY KOPLIK, New York City.
28. Clinical and Pathologic Study of Rash of Scarlet Fever, with Especial Reference to Origin and Character of Desquamation.
JAY F. SCHAMBERG, Philadelphia.

SECTION ON DISEASES OF CHILDREN.

TUESDAY, JUNE 5—MORNING SESSION.

1. Address of Chairman. EDWIN ROSENTHAL, Philadelphia.
SESSION DEVOTED TO CONSIDERATION OF FEEBLE-MINDED AND TO NERVOUS DISEASES.
2. Etiology of Idiocy and Imbecility.
MARTIN W. BARR, Elwyn, Pa.
3. Physiologic Training of Feeble-Minded.
S. J. FORT, Ellicott City, Md.

29. Differential Diagnosis of Influenza with Eruptions, and Infectious Diseases of Childhood.
A. S. DANIEL, New York City.

30. Fetal and Infantile Typhoid.

JNO. LOVETT MORSE, Boston.
JOSEPH TRUMPP, Munich.

Read by the SECRETARY.

32. Resulting Injuries Due to Extubation.

JANOS BOKAY, Budapest.
Read by ALEXANDER KLEIN, Philadelphia.

33. Treatment of Ear Complications in Measles, Diphtheria and Scarlet Fever. CHARLES W. HOOPES, Philadelphia.
Discussion by WM. M. WELCH, W. C. HOLLOWETER, S. SOLIS-COHEN, Philadelphia; LOUIS FISCHER, WM. P. NORTHRUP and DILLON BROWN, New York City.

THURSDAY, JUNE 7—AFTERNOON SESSION.

SESSION DEVOTED TO CONSIDERATION OF SCHOOL CHILDREN.

34. Symmetrical Development; or, Does Our Present School System Develop the Highest Powers of the Child?
E. STUVER, Fort Collins, Colo.

35. School Break-Downs.

J. HENRY BARTLETT, Philadelphia.

36. Eye Strain. THOMAS H. FENTON, Philadelphia.

37. Care of Ear in School Children.

LOUIS J. LAUTENBACH, Philadelphia.

38. Neglect of Teeth in Children.

A. D. ROSENTHAL, New York City.

39. Physician's Responsibility in Physical Education of School Children. GRACE E. SPIEGLE, Philadelphia.
Discussion by F. X. DERGUM, Philadelphia; C. F. WAHBER, Fort Madison, Iowa.

FRIDAY, JUNE 8—MORNING AND AFTERNOON SESSIONS.
SESSION DEVOTED TO SURGICAL SUBJECTS.

40. Movable Kidney (Floating) in Children.

ISAAC A. ABT, Chicago.

41. Symptomatology of Appendicular Inflammation in Children. THOMAS H. MANLEY, New York City.

42. Normal Salt Transfusion in New-Born for Hemorrhage from Cord. JOHN S. MILLER, Philadelphia.

43. Some Joint Diseases in Children; Their Diagnosis and Treatment. EDWARD A. TRACY, South Boston, Mass.

44. Diseases of Antrum of Highmore in Young Children, with Report of Case. EMIL MAYER, New York City.

45. Surgical Circumcision: Its Technique; Prevention of Infection; Its Legal Control; Should be Performed by None but Physicians.
FERD. C. VALENTINE, New York City.

SECTION ON STOMATOLOGY.

TUESDAY, JUNE 5—AFTERNOON SESSION.

Address of Chairman. EUGENE S. TALBOT.

SYMPOSIUM ON DENTAL EDUCATION.

1. Relations of Dental and Oral Surgery to General Medicine: Professional Status of Properly Educated Practitioners of Dental and Oral Surgery.

N. S. DAVIS, SR., Chicago.

2. Preliminary Qualifications. J. TAFT, Cincinnati, Ohio.

3. Course of Study. W. A. EVANS, Chicago.

4. Methods of Teaching—Didactic or Recitational.

A. H. PECK, Chicago.

WEDNESDAY, JUNE 6—MORNING SESSION.

5. Shall the Dental Student be Educated Independently of General Medicine? G. V. I. BROWN, Milwaukee, Wis.

6. Is Medical Education a Necessary Qualification for Dental Practice? ALICE STEEVES, Chicago.

7. Is Medical Education a Necessary Qualification for Dental Practice? R. R. ANDREWS, Cambridge, Mass.

8. Practical Value of a Medical Education in Dental Practice. W. B. HILL, Milwaukee, Wis.

9. Technical Training versus Theoretic. JOHN S. MARSHALL, Chicago.

WEDNESDAY, JUNE 6—AFTERNOON SESSION.

10. Should the Medical Undergraduate be Instructed in the Principles of Dentistry? M. L. RHEIN, New York City.

11. Post-Graduate Study in Dentistry and Degrees Thereof. W. E. WALKER, Pass Christian, Miss.

12. The Handwriting on the Wall: What does it Portray? A. E. BALDWIN, Chicago.

13. Limitations. EUGENE S. TALBOT, Chicago.

THURSDAY, JUNE 7—MORNING SESSION.

SYMPOSIUM ON INTERSTITIAL GINGIVITIS OR SO-CALLED PYORRHEA ALVEOLARIS.

14. Etiology. G. LENOX CURTIS, New York City.

15. Neurotic Affections. J. G. KIERNAN, Chicago.

16. Indigestion Antointoxication. EUGENE S. TALBOT, Chicago.

17. Chemical Factors in Etiology. W. L. BAUM, Chicago.

18. Constitutional Treatment. J. H. SALISBURY, Chicago.

THURSDAY, JUNE 7—AFTERNOON SESSION.

19. Local Treatment. M. H. FLETCHER, Cincinnati, Ohio.

20. So-Called Glands in the Peridental Membrane. M. H. FLETCHER, Cincinnati, Ohio.

21. Evolution of Decay Continued.

ARCH C. HART, San Francisco, Cal.

22. Co-operation of Public Schools in Teaching. Good Teeth, Good Health. Whatever We Wish to See Introduced Into the Life of a Nation Must First Be Introduced Into Its Schools. RICHARD GRADY, Baltimore, Md.

23. Oral Surgical Operations. G. V. I. BROWN, Milwaukee, Wis.

SECTION ON NEUROLOGY AND MEDICAL JURISPRUDENCE.

The Hotel Brighton will be headquarters of this Section, and the meetings will be held there. There will be no morning sessions unless necessary for completion of the program.

TUESDAY, JUNE 5—AFTERNOON SESSION.

1. Address of Chairman. HUGH T. PATRICK, Chicago.

2. Report of Eight Operations for Brain Tumors and Cysts. HERM. H. HOPPE, Cincinnati, Ohio.

3. Diagnosis of Apoplexy Without Motor Paralysis.

WILLIAM N. BULLARD, Boston.

4. A Case Resembling one of Raynaud's Disease, With Microscopic Examination. WILLIAM G. SPILLER, Philadelphia.

5. Legal Responsibility of Degenerates not Insane.

DAVID INGLIS, Detroit, Mich.

6. Therapeutics of Travel and Change of Scene in Nervous and Mental Diseases. RICHARD DEWEY, Chicago.

7. Post-febrile Insanity and Its Treatment.

FRANK P. NORBURY, Jacksonville, Ill.

8. Cranial Injuries and Insanity, with Report of Case.

EUGENE G. CARPENTER, Columbus, Ohio.

9. Medicolegal Relations of Opium Inebriety.

T. D. CROTHERS, Hartford, Conn.

10. Morphism from the Standpoint of the General Practitioner. T. J. HAPPEL, Trenton, Tenn.

WEDNESDAY, JUNE 6—AFTERNOON SESSION.

11. The Nervous Diseases Caused by Trauma.

CHAS. W. BURB, Philadelphia.

12. Nature and Symptomatology of Traumatic Neuroses.

HAROLD N. MOYER, Chicago.

13. Traumatic Neuroses from the Standpoint of a Railway Surgeon. ARTHUR DEAN BEVAN, Chicago.

14. Medicolegal Relations of Traumatic Nervous Affections.

JAMES HENDRIE LLOYD, Philadelphia.

15. An Analysis of Cases of Traumatic Neuroses with Special Reference to Prognosis.

JAMES JACKSON PUTNAM, Boston.

16. Prognosis and Treatment of Traumatic Neuroses.

WHARTON SINKLER, Philadelphia.

- Discussion opened by DANIEL R. BROWER, HERM. H. HOPPE, and FRANCIS X. DERGUM.

17. Treatment of Neurasthenia.

DANIEL R. BROWER, Chicago.

18. Some Methods of Treating Neuralgia.

W. J. HERDMAN, Ann Arbor, Mich.

19. Modern Treatment of Locomotor Ataxia.

CURRAN POPE, Louisville, Ky.

20. Subject Unannounced.

FRANCIS X. DERGUM, Philadelphia.

THURSDAY, JUNE 7—AFTERNOON SESSION.

2 o'clock.

21. Diagnosis of Hysteria from Organic Disease of the Brain.
CHAS. K. MILLS, Philadelphia.
22. Diagnosis of Hysteria from Organic Disease of the Spinal Cord and Peripheral Nerves.
FREDERICK PETERSON, New York City.
23. General Treatment of Hysteria.
B. SACHS, New York City.
24. Technique of the "Rest Cure," with Indications and Contraindications for its Use.
JOHN K. MITCHELL, Philadelphia.
Discussion to be opened by C. W. BUEB, JOHN PUNTON, WILLIAM G. SPILLER and W. J. HERDMAN.
25. Differentiation of Chorea and Disorders Simulating It.
A. A. ESHNER, Philadelphia.
26. Prophylaxis of Chorea.
J. MADISON TAYLOR, Philadelphia.
27. On a Certain Routine Treatment for Gouty Conditions.
FRANK R. FRY, St. Louis, Mo.
28. Combined Sclerosis of the Lichtheim-Putnam-Dana Type Accompanying Pernicious Anemia.
F. W. LANGDON, M. A. BROWN and D. I. WOLFSTEIN, Cincinnati, Ohio.
29. Aphasia: Report of Case.
GUY MINSDALE, Philadelphia.

FRIDAY, JUNE 8—AFTERNOON SESSION.

2 o'clock.

30. Subject Unannounced.
J. HENDRIE LLOYD, Philadelphia.
31. Migraine, with the Consideration of Heredity.
D. J. MCCARTHY, Philadelphia.
32. Case of Gastric Vertigo Closely Simulating Meière's Disease.
G. W. MCCASKEY, Fort Wayne, Ind.
33. Evolutional and Involutional Types of Nervous Disease.
ED. E. MAYER, Pittsburg, Pa.
34. Effect of Alcohol on the Nervous System.
ALBERT E. STERNE, Indianapolis, Ind.
35. Case of Transient Motor Aphasia. Complete Anomia, Nearly Complete Aphasia and Slight Word-Blindness, Occurring in a Left-Handed Man, and Due to a Probable Lesion of the Third Frontal Convolution of the Right Side.
CHAS. S. POTTS, Philadelphia.
36. Hereditary Color-Blindness.
F. SAVARY PEARCE, Philadelphia.
37. Pathophobia as an Element of Nervous Diseases and its Treatment.
JOHN PUNTON, Kansas City, Mo.
38. Post-Anesthetic Paralysis.
C. C. HERSMAN, Pittsburg, Pa.
39. The Insanities.
WILLIAM FRANCIS DREWRY, Petersburg, Va.
40. The Simplest Explanation of the Functions of the Nervous System.
G. W. DRAKE, Hollins, Va.
41. Drug Habits.
A. J. PRESSEY, Cleveland, Ohio.
42. A Study of Cerebral Syphilis, with Report of Case.
JAS. H. MCBRIDE, Pasadena, Cal.
43. Case of Gastric Vertigo Closely Simulating Meière's Disease.
G. W. MCCASKEY, Fort Wayne, Ind.

SECTION ON CUTANEOUS MEDICINE AND SURGERY.

TUESDAY, JUNE 5—AFTERNOON SESSION.

3 o'clock.

1. Address of Chairman: "Recent Advances in Dermatology Which are of Service to the General Practitioner."
L. DUNCAN BULKLEY, New York City.
2. Treatment of Skin Cancers.
LOUIS A. DUHING, Philadelphia.
3. An Additional Note on Herpes Gangrenosus.
A. W. BRAYTON, Indianapolis, Ind.
4. A Peculiar Progressive Pigmentary Disease of the Skin.
JAY F. SCHAMBERG, Philadelphia.
5. Report of Four Cases of Lupus Vulgaris Treated with X-Rays.
WILLIAM B. EWING, Pittsburg, Pa.

WEDNESDAY, JUNE 6—AFTERNOON SESSION.

6. Leucopathia Ungium; Some Etiologic and Pathologic Considerations.
M. L. HEIDINGSFELD, Cincinnati, Ohio.
7. Syphilis as a Nonvenereal Disease.
L. DUNCAN BULKLEY, New York City.
8. Successful Treatment of Skin Cancers Without Operation.
HENRY W. STELWAGON, Philadelphia.
9. Xeroderma Pigmentosum (With Lantern Slide Illustrations).
A. RAVOGLI, Cincinnati, Ohio.
10. Syphilitic Gumma of Larynx.
EDWARD T. DICKERMAN, Chicago.

THURSDAY, JUNE 7—AFTERNOON SESSION.

11. Acute Suppurative Folliculitis of Scalp.
WILLIAM S. GOTTHEIL, New York City.
12. Diagnosis and Treatment of Pruritus Essentialis.
FRED J. LEVISEUR, New York City.
13. Clinical Study of Pityriasis Versicolor and Pityriasis Rosea.
CHARLES W. ALLEN, New York City.
14. Pemphigus of Mucous Membrane of Mouth.
WILLIAM L. BAUM, Chicago.
15. Some of the Rarer Skin Manifestations of Syphilis.
J. A. FORDYCE, New York City.
16. Treatment of Syphilis: General Discussion.

SECTION ON LARYNGOLOGY AND OTOTOLOGY.

TUESDAY, JUNE 5—AFTERNOON SESSION.

2 o'clock.

1. Address of Chairman.
CHRISTIAN R. HOLMES, Cincinnati, Ohio.
2. Address on Laryngology and Its Relation to General Medicine. (By Invitation.)
J. SOLIS-COHEN, Philadelphia.
3. Import of Bacteria As Found in the Ear, Nose and Throat.
D. BRADEN KYLE, Philadelphia.
4. Comminution of Thyroid Cartilages Due to a Bullet Whose Point of Entrance Was in the Frontal Bone.
EMIL MAYER, New York City.
5. Papilloma of Larynx.
E. T. DICKERMAN, Chicago.
6. Unusual Papillomatous Growth in Larynx.
JAS. S. GIBBS, Philadelphia.
7. Angina Epiglottida Anterior.
C. F. THEISEN, Albany, N. Y.
8. Care and Use of Instruments.
A. DEVILBISS, Toledo, Ohio.
9. Embryonic Defects of Nose, Throat and Ear and Their Causes, with Lantern Exhibition.
GEO. C. STOUT, Philadelphia.

WEDNESDAY, JUNE 6—MORNING SESSION.

9 o'clock.

10. The Atrophic Pharynx.
R. W. SEISS, Philadelphia.
11. Present Status of Antitoxin Treatment.
S. J. ALLEN, Cincinnati, Ohio.
12. Some Experiments on Relation Between Audition and Circulation of Blood.
H. STILLSON, Seattle, Wash.
13. Some Points in Diagnosis of Syphilis of Upper Air-Passages.
GEO. L. RICHARDS, Fall River, Mass.
14. Remarks on Internal and External Operations for Chronic Frontal Sinusitis.
R. C. MYLES, New York City.
15. Hysterical Deafness, with Report of Cases.
A. E. BULSON, JR., Fort Wayne, Ind.
16. Ear Diseases in Childhood and Infancy.
J. HOMER COULTER, Chicago.
17. Value of Enzymol in Treatment of Acute and Chronic Purulent Affections of Mastoid, Tympanic and Accessory Cavities, Based on Bacteriologic Study of Fifty Cases.
TALBOT R. CHAMBERS, Jersey City, N. J.
18. Notes on Two Cases of Voluntary Laryngeal Whistling.
G. HUDSON MARUEN, Philadelphia.

WEDNESDAY, JUNE 6—AFTERNOON SESSION.

2 o'clock.

SYMPOSIUM ON INFLAMMATION OF MASTOID.

19. Tympanomastoiditis in Children. (By Invitation.)
HERMAN KNAPP, New York City.
20. Complications of Mastoid Abscess.
C. W. RICHARDSON, Washington, D. C.

21. Some Observations in Mastoid Operations.
A. W. CALHOUN, Atlanta, Ga.
 22. Primary Tuberculosis of the Mastoid.
M. A. GOLDSTEIN, St. Louis, Mo.
 23. Report of Three Cases of Ligation of Internal Jugular for Septic Thrombosis, Following Purulent Otitis Media: Recovery.
E. B. DENCH, New York City.
 24. Suppurating Mastoiditis, with Report of Cases.
J. H. BRYAN, Washington, D. C.
General discussion on the Symposium, opened by FRED WHITING, New York City.
 25. Limitation of Ossiculectomy and Tympanic Curettement.
FRANK ALLPORT, Chicago.
 26. Bony Defects and Fistulae in the Meatus in the Ear.
H. GRADLE, Chicago.
 27. Accessory Sinus Affections.
E. L. VANSANT, Philadelphia.
 28. Enlarged Lingual Tonsil: Report of Case.
FRANK D. BOYD, Fort Worth, Texas.
THURSDAY, JUNE 7—MORNING SESSION.
9 o'clock.
 29. Sarcoma of Nasal Passages: Report of Cases.
DUNBAR ROY, Atlanta, Ga.
 30. Untoward Sequence of Adenoid Operations.
E. L. SHURLY, Detroit, Mich.
 31. Various Forms of Nasal Hemorrhage.
W. SCHEPPEGREL, New Orleans, La.
 32. General Bodily Resistance as a Factor in History and Cure of Nose and Throat Diseases.
F. L. STILLMAN, Columbus, Ohio.
 33. Limitation of Laryngologist in General Treatment of Nose and Throat Diseases.
H. W. LOEB, St. Louis, Mo.
 34. Treatment of Atrophic Rhinitis by Electrolysis and Some Experiments to Determine Efficiency of Needles of Different Metals.
CAROLUS M. COBB, Lynn, Mass.
 35. Treatment of Deflection of Nasal Septum, Complicated by Traumatic Deformity of External Bony and Cartilaginous Framework of Nose.
E. B. GLEASON, Philadelphia.
 36. Neuroses of Larynx.
J. F. WOODWARD, Norfolk, Va.
 37. Cough Due to Reflex Irritation in Upper Air-Passages.
F. H. S. MILBURY, Brooklyn, N. Y.
 38. Immunizing Treatment of Hay-Fever.
HOLBROOK H. CURTIS, New York City.
THURSDAY, JUNE 7—AFTERNOON SESSION.
2 o'clock.
 39. Ocular Expression of Intranasal Lesions.
ROBERT SATTLER, Cincinnati, Ohio.
 40. Systemic Factors in Catarrhal Deafness.
SARGENT F. SNOW, Syracuse, N. Y.
 41. Diagnosis and Prognosis of Ear Disease.
B. ALEXANDER RANDALL, Philadelphia.
 42. Unusual Ocular Symptoms Following Removal of Septal Spurs.
J. L. GOODALE, Boston.
 43. Lithemia from Otorhinologic Point of View.
CHEVALIER JACKSON, Pittsburg, Pa.
 44. Aural Manifestations of Hysteria.
NOBYAL H. PIERCE, Chicago.
 45. Fistula Auris Congenita. Operation and Important Complications.
JOHN O. McREYNOLDS, Dallas, Texas.
 46. Laryngeal Tuberculosis at Montefiore Home, New York City.
W. FREDENTHAL, New York City.
 47. Operation for Disease of Middle Ear.
W. F. COLE, Waco, Texas.
 48. Modus of Infection of Maxillary Sinus.
M. H. CRYER, Philadelphia.
 49. Nasopharyngeal Growth from Non-Use of Nose.
NOBBURNE B. JENKINS, Chicago.
- SECTION ON MATERIA MEDICA, PHARMACY AND THERAPEUTICS.
- TUESDAY, JUNE 5—AFTERNOON SESSION.
2 o'clock Sharp.
1. Address of Chairman. LEON L. SOLOMON, Louisville, Ky.
 2. Treatment of Acute Alcoholism by Large Doses of Digitalis. A Clinical Study Based on Cases in the Alcoholic Wards of Bellevue Hospital.
HENRY P. LOOMIS, New York City.

7. Properties Which are Possessed by all Foods in Their Relation to Nutrition, and the Relation of Alcohol to Nutrition.
WINFIELD S. HALL, Chicago.

SECTION ON PHYSIOLOGY AND DIETETICS.

ATLANTIC CITY MEETING

BRIGHTON CASINO.

THE special adaptability of Atlantic City for conventions is attributable to several very important facts. First, the weather during the Summer months is cool, and saline breezes from off the ocean are refreshing and delightful, when at other points it is sultry, stifling and altogether objectionable to large gatherings. Second, the spacious auditoriums, at the immediate disposal of large meetings, together with numerous and closely located hotel accommodation, are within so convenient a radius that personal communication may be had, at all hours, without loss of time or inconvenience to those who may desire to visit one or more of the various Section Meetings of the convention assembled.

ATLANTIC CITY'S ADVANTAGES.

As a meeting place for the AMERICAN MEDICAL ASSOCIATION, June 5-8, Atlantic City has, unquestionably, more advantages, socially and otherwise, than any other prominent point at which this worthy body could select to convene. The magnificent Boardwalk, directly upon which are the leading hotels, within a few moment's walk of the great Marine Hall, under the roof of which the main convention will assemble, affords the pleasure of passing to and from the various hostelries along the ocean front at an elevation such that the eye may cover the vast expanse of waters and the beautiful horizon in the distance, with the fresh breezes ever blowing from off the ocean. The Marine Hall, a thousand feet from shore, and directly over the sea waves, is one of the most modern and spacious auditoriums upon the American Continent. The seating capacity of the building is adequate, and the acoustics are of the very best. Visitors can see and hear from every portion of the vast hall, above and below, without the least inconvenience, whatsoever. The design of the great upper circles, provided with the latest and most convenient folding seats, is as perfect as art and mechanism can produce, and the entrances and exits are superb. While the roar of the breakers and surf may be heard for a considerable distance from the strand, there is absolutely not the least sound of the sea reaching the auditorium of the

Marine Hall, and ordinary addresses may be heard at every portion of the building as distinctly as at any inland room.

ARRANGEMENTS.

The Committee of Arrangements, together with the various hotel proprietors, has spared no pains to make this particular meeting an event in the annals of the city. Every conceivable plan to enhance the pleasure and comfort of the guests has been resorted to, and it is expected that not a moment's time will be lost, between business and recreation. It will be understood, however, that, although the Amusement and other Committees are prepared to entertain the visitors and their families in every conceivable manner, there will be no program of festivities during Convention or Section Meeting hours, to disturb the general and important routine of business. Everything is expected to give way to the all-absorbing object of the Association's Convention, which has been scheduled, that business and recreation may be delightfully interwoven during the brief sojourn of the members at the City-by-the-Sea.

HOTELS.

All hotels, halls and places of meeting are connected by phone, and an established ten-cent coach-fare will permit of easy access from point to point, where the Boardwalk is not used for passing from one ocean-front hotel to another.

TRANSPORTATION.

In the matter of transportation the Committee has arranged a one-and-one-third fare for the round-trip, to and from Atlantic City, covering any point of country from which members of the Association may desire to come. The following communication will lucidly explain; the particulars of which it might be well for members wishing to avail themselves of the opportunity to note as to the necessary names and data herein shown.

1. Tickets will be sold on *certificate* plan from May 30 to June 7, inclusive, for one fare and one-third for round trip. A *first-class one-way ticket, together with a properly filled certificate*, must be obtained at the starting-point.

2. The properly filled certificate—not a receipt—must be presented to Dr. W. Blair Stewart and the special agent on either June 6, 7, or 8, to be countersigned. This countersigned certificate will purchase a return ticket for one-third of one full fare, when presented to the proper offices here. Return ticket will be good up to and including June 22.

3. This reduced rate is good only where the fare one way amounts to 75 cents or over.

4. Any one neglecting to obtain the proper certificate at the starting-point or neglecting to have it countersigned on June 6, 7, or 8, will *positively be refused a return ticket except at full fare*.

With an extension of time, from May 30 to June 23, and the Convention proper closing on June 8, members can, if time and inclination warrant, remain at Atlantic City for a stated time, can visit Philadelphia the following week, during the National Republican Convention, or elsewhere before returning to their homes. The

THE INLET.

extension of time will also allow members to visit the alumni meetings and commencement exercises of the Philadelphia and New York Colleges, reached from Atlantic City by short railroad travel over the most modern tracks and in the most luxurious coaches of any railroad in America or on the European Continent.

ACCOMMODATIONS.

In the matter of hotel accommodation too much can not be said for Atlantic City. There is not to-day, at any one American resort, so many hotels, boarding cottages, and boarding-houses, as at Atlantic City. There is not at any other seaside resort a finer class of ocean-front hotels than are to be found at Atlantic City. They are spacious and elaborate, replete with every modern improvement and convenience, and are conducted by men of life-long experience. They are specially designed and built for comfort and sea observation, with broad and lengthy verandas for promenade and seating conveniences, and which, during the winter months are enclosed in glass casings, forming perfect sun parlors, from which the sight of the beauties of a winter storm upon the ocean may be enjoyed, as from the artificially heated apartment of a palatial home. At Atlantic City there is to be found none of the "flunkeyism" and "home-made tape" that abounds, alas, at too many resorts of the upper ten. The guests are charged, at a fixed price, for accommodation, and are provided with the most elaborate indoor amusement. Here the guest arrives at a plain, spacious railway station, where he may select his hotel coach, without hearing the least "barking" from the vehicle stand, quietly enter his carriage and be driven to his hotel, where he finds comfort from the moment he sets foot within the portals of the

establishment. "Polite service" is the motto of Atlantic City's hotels, and from the moment he registers he feels at home, and something like the freedom of the City of London to some distinguished ambassador permeates his whole system, and as he proudly passes from the luxurious dining-halls of his hotel to the Boardwalk, where delightful breezes fan his erstwhile heated brow, he carries with him a happy consciousness that he is as good as any other man—possibly a bit better.

Atlantic City can house and accommodate one million of persons. Outside the immediate Cottage Colony, where a large number of the leading business men and gentry of New York, Philadelphia, and other large cities reside during the summer months, almost every cottage is a boarding one, where at reduced rates the great overflow of humanity, at the busiest seasons, find excellent accommodation for long or short periods. There are absolutely and strictly first-class hostleries where luxury abounds to any extent, and there are hotels of less pretense, still first-class and most admirably conducted. There are still hotels of a lesser degree of accommodation at prices commensurate with the purses of their patrons, all of which are conducted with the utmost degree of civility and cleanliness. The hotel rates vary, of course, according to location and accommodation, and all are operated under the most exacting rules and regulations of municipal government.

HOSTELRIES.

There are more than a hundred really first-class hotels within ten or twelve squares' walk of the great Marine Hall, reached by the Boardwalk and its spacious avenues approaching the ocean. Two great telephone systems, with more than seventy-five miles of call wire, connect with every hotel, and easy-riding coaches transfer passengers from any point of the city to the convention hall for ten cents each. There are also trolley and automobile facilities of the latest and up-to-date convenience, and all at a regulated and low rate of fare. The hotels of Atlantic City are most elaborate and spacious, and are conducted by men of unquestionable experience and the hospitality and entertainment extended their guests are prominent among the features of the resort. Prices range from the very lowest resort charges known to but moderate ones for strictly first-class accommodation.

YACHTING AT INLET.

AMUSEMENT.

In the matter of diversity of amusement and pastime much has been arranged by the Committee for the recreation of the members and families of the A. M. A. between the hours of scientific meetings. The program of entertainment includes musicales at hotels, pier parties, short excursions by trolley, theatrical and musical evenings, and various Boardwalk entertainments that can not fail to impress the visitor with the fact that his trip to Atlantic City will be fraught with business and pleasure combined.

IRON PIER.

SCHEDULE OF RATES.

Appended are some of the most prominent hotels, for which the following rates have been handed the Committee on Entertainment:

NAME.	CAPACITY.	RATES PER DAY.	
		SINGLE.	DOUBLE.
Albemarle	350	\$2.50	\$4.00
Atglen	200	2.00	3.00—\$3.50
Avon Inn	200	2.50—3.50	4.00—6.00
Brexton	300	2.50	4.00
Brighton	300	3.50—6.00	8.00—12.00
Berkley	300	3.00	5.00
Belmont	300	3.00	5.00
Bleak House	300	3.00—5.00	5.00—6.00
Boscobel	150	2.50	4.00
Cornell Inn	200	2.00	6.00
Chalfonte	250	3.00—4.00	6.00—7.00
Canfield	50	2.00	4.00
Colonial	80	2.50	5.00
Dennis	425	3.00—5.00	6.00—10.00
DeVille	300	2.50—3.00	5.00—6.00
Edison	50	2.00	3.50
Garden	300	3.00—5.00	5.00—8.00
Grand Atlantic	600	3.00	6.00
Glaslyn	300	3.00	5.00
Holmhurst	300	3.00	5.00
Haddon Hall	450	3.00—5.00	6.00—10.00
Hotel Esmond	150	2.00—3.50	4.00—6.00
Irrington	200	2.00	4.00
Imperial	300	2.50—3.00	4.00—6.00
Iroquois	250	2.50—3.00	5.00—6.00
Lelande	250	2.50	4.50
Lorraine	200	2.00—3.50	4.00—6.00
Lorraine	250	3.00	5.00
Luray	400	3.00 up	6.00 up

ATLANTIC CITY, N. J.

The event of the meeting of the AMERICAN MEDICAL ASSOCIATION at Atlantic City, on June 5-8, has, upon the part of the Committee of Arrangements, suggested a few facts pertaining to the early history and present advantages of this favorite resort. "Truth is stranger than fiction," and it may well be said that the story of Atlantic City's birth, growth and present greatness reads like a romance.

Within the recollection of the man but scarcely past the meridian of life, Absecon Island, upon which now stands the city, with its palatial hotels and residences, its magnificent municipal government, and its finished modern improvements, existed as a desolate isle, upon whose barren sands and dreary coast washed the billows of the Atlantic Ocean, and over which screeched the seabird, and through whose sage grass and scraggy underbrush ran the proverbial New Jersey jack-rabbit.

Atlantic City was founded in 1854, but lay more or less dormant until after the Civil War. The scant patronage during the late '50s and the early '60s consisted principally of aquatic sportsmen and the few others who cared to make a pilgrimage across barren sands and the wooded tracts of South Jersey.

At this epoch Cape May and Long Branch had been fully established as seaside resorts along this portion of the Atlantic coast, with transportation facilities, which, if not up to those of to-day, were quite in keeping with other railroad branches leading to the sea. In the face of this opposition men of grit and determination set out to plant the banner of success on Absecon Island. No pioneer ever set foot upon a more dreary-looking surrounding than did the original developers of Atlantic City. But they buckled on the armor of pluck, and with the sword of enterprise started boldly forth to meet the foe, and with a rapidity almost unknown in the annals of improvement, a city rose before the world that has astonished beholders, and that now, but a third of a century since actual improvement began, has reached a point of perfection and prominence that places it side by side with the best-known and leading resorts of the Old World, and certainly far ahead of any other seaside resort on the American Continent.

Not only is Atlantic City the most delightful spot for summer recreation, the Eden of our Coast, and the one oasis of the erstwhile New Jersey barren desert, but it is positively a health-giving winter resort. The bare idea two or three decades ago of spending a winter season

A BOARDWALK PAVILION.

at the seashore would have stamped the author of the proposition as a fit candidate for a madhouse, and sent imaginary tremors down the spinal column of humanity. In fact, half a century ago, or less, few persons cared to visit the ocean, excepting for a brief sojourn. It was not a popular resort beyond the extreme heated periods, and even then the few who did make the pilgrimage were more or less frightened to enter the billows without firmly grasping safety ropes and under the closest care of a bathing-master. The sea was not popular with the masses. The bone and sinew of humanity, those people who always make up the successful element of railroad support, preferred the green hills and running rills of nearby country resorts. Hence special inducements had to be resorted to. Social organizations and clubs of various sorts were induced to visit Atlantic City, which brought the advantages of the beautiful climate before the people. With this came faith in the future of the resort, and this faith brought enterprising capitalists, who built modern hotels, and great railroad projectors spanned the barren sands and wild, wooded country with modern facilities of travel, and with this easy access to the sea came to Atlantic City an entirely different class of visitors. Large tracts of ocean frontage were purchased by outside capitalists, and these were platted out, sold, and built upon by other newcomers, and a strong municipal government was established, with absolute protection to man and property that has never diminished nor been allowed to border on demoralization.

The hospitality of Atlantic City is proverbial. The liberal manner in which the authorities and citizens welcome large bodies of individuals in conventions assembled within her gates, the sanitary and roomy hotels, cottages and boarding-houses to be found for the comfort and convenience of guests are perhaps unequalled by the most famous seaside resorts of Europe.

CLIMATIC FEATURES.

Nature, here, is the great physician. The saline atmosphere of Southern California mingles with the balmy breezes of the Adriatic. The chilling blasts of inland winters, with lasting snows, blizzards and almost unbearable temperature are things unknown to Atlantic City. It is in close proximity to the Gulf Stream, which, curiously as it may seem, sheds its glorious influences over but one spot along the American Coast without material change, and that one particular

environ is Atlantic City. The undercurrents of the ocean between the two outer borders of Absecon Island—Egg Harbor and Absecon Inlet—are positively a revelation in sea temperature. Bathing at Atlantic City begins earlier and continues longer than at any other seaside resort along the northern coast of the United States, and in this respect equals, so far as comparison can be made, the famous resorts along the Pacific Slope, with an advantage over any of these in the absolute safety of bathers who are not too over-daring in their amphibious sport.

The month of June, in the early part of which the AMERICAN MEDICAL ASSOCIATION will honor this resort with its Convention, is the most delightful portion of all the year. All traces of the lingering winter have passed, and mid-summer with its mid-day sun-rays has not yet arrived. The days are balmy and the evenings of a medium temperature that no pen can depict. The evening sky, as the sun sinks in the western horizon, is a picture worthy the brush of a master artist, and as twilight approaches, the foamy billows, breaking over velvet sands almost beneath the feet of the Boardwalk pedestrian with their weird and fascinating roar, are among the most pleasant associations of the visitor's sojourn at the City-by-the-Sea.

PROMENADES AND STREETS.

The grand, forty-foot wide, steel Boardwalk, reaching from one end of the city front to the other, and costing, with incidental expenditures, nearly one-fifth of a million dollars, is the admiration of all who see it. It is railed with three-ply substantial metal safety fencing, and will accommodate at one time without in the least interfering with promenade, more than a million persons. The velvet sands stretching from this wonderful esplanade are totally devoid of gravel or petrification of any sort, and the bathing grounds are as near perfection as the world ever knew.

The streets and avenues are thoroughly macadamized and the pavements are broad, and handsomely laid in cement and flagstone. Magnificent lawns and catchy architecture predominate throughout the better resident portions of the city, and improved driveways extend from end to end of the island, a distance of about seven miles.

THE CONVENTION HALL.

The great Marine Hall, in which the Convention proper, upon the occasion of the assembling of the AMERICAN MEDICAL ASSOCIATION at Atlantic City, will meet, is nearly a thousand feet outside the Boardwalk

A BATHING SCENE.

and directly over the ocean, with a broad and elegant promenade extending two thousand eight hundred and eighty feet into the ocean, at the outer end of which is a three-story pagoda, each floor reached by broad and easy approaches, with seating accommodation for upward of a thousand guests, and where the most delightful view of the far ocean with distant vessels and a kaleidoscope of marine beauty can be obtained, rivaled at no other spot along the American Coast. There are four beautiful ocean piers, upon which hourly attractions are provided, consisting of the choice professional talent of the Union, and upon which tens of thousands of delighted visitors are seen at all hours of the day and evening. The most attractive bands of music are programmed for concerts of the highest order of excellence, and a continual series of festivities are kept up day and evening.

The practically ceaseless, indefatigable working of the Committee and the citizens of Atlantic City to welcome the members and friends of the AMERICAN MEDICAL ASSOCIATION promises to eclipse anything ever attempted at a public resort. Every amusement and attraction within the city limits will be prepared for their entertainment and, figuratively speaking, the freedom of the city will be presented to each and every member.

The Committee of Arrangements has most carefully selected from among the leading hotels, including the ocean front and immediate vicinity of the Convention Hall, a list of hosteleries with suitable prices, and with such other arrangements for fishing, sailing, crabbing parties and carriage drives as the extensive facilities of the city afford.

RAILWAY SERVICE.

The luxurious railway service from New York and Philadelphia, with close connection and without change of coach from the great cities and tracks of the East, West, North and South, reflect the highest credit upon both the Pennsylvania and Reading Trunk Railway Systems. The New Yorker can reach Atlantic City in three hours, and the Philadelphian in less than sixty minutes. Pittsburgers can eat a late breakfast at their own homes and sit down to supper, ten or eleven hours

YOUNG'S PIER.

later to the music of the billows at this, the Queen seaside resort of America. Washingtonians can reach her bahny realms in from four to four and a half hours, and the Bostonian in ten pleasant hours' ride. In twenty-nine hours the Chicago lover of sea air and heaven's ozone can reach this paradise of health and resort, and so on with other cities East, West, North and South.

In the matter of transportation to and from Atlantic City, the most important arrangements have been completed with the various railroads of the land. Heretofore excursion rates have been confined to a ten-day limit, in which case far-off visitors have not been allowed time to make the round trip with any degree of satisfaction. But, in this particular case, the Committee announces with much pleasure that a liberal extension of time has been obtained, and which it is believed, will prove to be one of the leading features of the far-off pilgrims' journey to the Mecca of ocean resorts. It must be remembered that at Philadelphia, a short hour's ride from Atlantic City, the National Republican Convention will meet on the 15th of June, at which point and date the returning voyager may remain until a late hour on that date before taking his seat in the railway carriage conveying him to his home.

In closing, a word should be added as to the facility for reaching Atlantic City from Philadelphia, New York and elsewhere. Until within the past two years it has been absolutely necessary for passengers from outside the State of New Jersey to cross the river by ferryboat, necessitating a tiresome transfer through Philadelphia, with the possibility of delay and re-booking—inconveniences that bordered upon horror for certain guests in their journeys from distant points. But this has been entirely obviated by the completion, as a portion of the great Pennsylvania Railroad, of a magnificent bridge, spanning the Delaware, over which trains from New York and Philadelphia convey passengers directly from all points.

OCEAN SPORTS.

The sailing fleet, stationed at the inlet, consists of the finest craft that ever plied in and about the waters of a resort. The guest of Atlantic City may here enjoy an inland sail where a spanking breeze

THE COUNTRY CLUB.

from off old ocean affords all the pleasure of sea sailing without the obnoxious effect of sea sickness. Or, he may pass through the Inlet and ride the billows of the Atlantic Ocean, with an exit and entry that is absolutely safe, and all under the masterly direction of an experienced and licensed helmsman, who knows every inch of the surroundings. The lover of piscatorial sport can, at this resort, enjoy himself to his heart's content. The fishing banks, so-called, are so near to Atlantic City, that one can eat a moderately early breakfast at his hotel, be transported to the fishing grounds, enjoy

several hours of this grand sport, and return in time for dinner with fish galore. Every variety of sea fish common to the Eastern Atlantic coast is here taken in unusually large quantities, and the hook-and-line fishing from off the piers is particularly good at times.

Several lines of steamers ply between Atlantic City and the adjoining seaside resorts, leaving each end of the island hourly, and are in direct connection with the trolley cars at either point. The Western Union Telegraph Company maintains a direct connection with New York and Philadelphia from seventeen of the

leading hotels, together with a complete ticker service in each of these points, as well as on the piers and throughout the city, furnishing a brief of the stock market and the current events of the day. Two excellent telephone lines are in operation, as well as the two national telegraphic corporations doing business, the year round.

There are twenty-two churches, including all denominations and creeds. There are seven elegant school-houses with large and airy rooms and supplied with the latest seating facilities, under the immediate direction of an efficient principal and well-selected teachers. The streets are paved with the best material; the municipal authorities of Atlantic City are composed of the cream of its business citizens; and its police force is known the country over, as among the best and most efficient of any seaside resort on earth. The fire de-

partment is one of the finest to be found in a city of its size in America, and a better stock of horses, or more elaborate apparatus could scarcely be found anywhere.

STEEL PIER FROM BOARDWALK.

partment is one of the finest to be found in a city of its size in America, and a better stock of horses, or more elaborate apparatus could scarcely be found anywhere.

THE GOLF LINKS.

One of the crowning features of Atlantic City's environs is the magnificent home of the Country Club, with its elegant golf grounds. The links have eighteen holes, overlooking Lake's Bay, and are in close proximity, with a five-mile-wide meadow where game is plentiful. In the picturesque distance the ocean and variegated horizon make a glorious silhouette to the east, while the western wildwood and evergreen pine give the surroundings a most delightful appearance. This club has recently been entered as an associate member of the U. S. G. A., and the new honor bestowed upon it

COMING MEETINGS.

As a convention Mecca Atlantic City is making for herself a proud record. Among the many gatherings booked for the present season of 1900, at this writing, are the following:

May 12—Diocesan Convention of the Protestant Episcopal Church of New Jersey.

May 18—General Conference of the Methodist Protestant Church, National.

May 27—Ancient Order of Hibernians, State Convention.

June 1, 2—Congress of State and Provincial Boards of Health of North America.

June 1, 2—Baltimore & Ohio Association of Railway Surgeons.

June 1-4—American Academy of Medicine.

June 4—American Medical Publishers' Association.

June 4—National Confederation of State Medical Examiners and Licensing Boards.

June 4—New Jersey Medical Association.

June 4—The Association of American Medical Colleges.

June 5—AMERICAN MEDICAL ASSOCIATION, National.

June —United States Brewers' Association, National.

July 11—B. P. O. Elks, Grand Lodge.

July —Billposters' Association of the United States and Canada.

August —National Fraternal Congress.

August 2, 3—Reunion Knights of Columbus.

September —State Firemen's Relief Association.

October 16-20—Supreme Grand Commandery, Knights of Malta.

August 23—National United Post Office Clerks' Association.

CHICAGO, ILLINOIS, MAY 26, 1900.

No. 21.

Original Articles.

CARCINOMA IN EARLY LIFE.*

WITH SPECIAL REFERENCE TO EARLIER METHODS IN
INTRA-VITAM DIAGNOSIS.

BY WALTER L. BIERRING, M.D.

Professor of Pathology and Bacteriology, State University of Iowa;
Pathologist to the University Hospital.

IOWA CITY, IOWA.

Carcinoma is usually regarded as the malignant tumor of later life, having its legitimate age limit at 35, though it is most frequently met with after 40 years of age.

With increasing study of the malignant neoplasms, age is gradually losing its hold as a criterion of difference between sarcoma and carcinoma, the former being found at almost any age, while carcinoma is beginning to be noticed more frequently during the earlier decades of life.

Having had the opportunity of examining the material from nine cases of carcinoma between the ages of 23 and 35 years, I have incorporated the same in the subject of my paper, and drawn from them such points as were of pathologic interest.

CASE 1.—Mrs. A. F. R., presented herself in the private practice of Dr. L. W. Littig, who has kindly furnished the clinical data. She was admitted to University Hospital, Dec. 6, 1898, and was 23 years old, married, and had one child 3 years old. The family history as regards tuberculosis and neoplasms was negative. Her health was good to within six months of admission, after which time she had pain in the pelvic region and offensive discharge from the vagina.

Physical examination of the thoracic and abdominal organs, with the exception of the uterus gave negative results; vaginal examination revealed an indurated, warty, slightly ulcerating growth involving the cervix uteri, extending a short distance on to the anterior and posterior vaginal walls; displacement of the uterus did not exist.

A clinical diagnosis of epithelioma of the cervix uteri was proposed and operative removal advised. Following operation, Dec. 8, 1898, of abdominal hysterectomy, no unfavorable post-operative symptoms appeared, except a rather unusual interference in the complete healing of the abdominal incision, by the appearance, a short time after the operation, at the site of suture wound, of a papillomatous, granuloma-like growth which gradually increased in size and within five months presented a warty ulcerating growth the size of a lemon, which had all the macroscopic characteristics of a surface carcinoma or epithelioma. This growth was removed by a second operation on May 11, 1899.

The examination of the uterine growth revealed a complete involvement of the cervix uteri by the tumor

mass, which presented a histology of delicate fibrous stroma separating irregular, narrow bands or rows of pavement epithelial cells, the latter showing numerous karyokinetic figures, and at the edges of the tumor area, indications of extensive infiltration into the muscular structure of the corpus uteri. The diagnosis was carcinoma.

The microscopy of the secondary growth removed from the site of abdominal incision presented a similar arrangement of large, irregular alveoli of pavement epithelial cells, enclosed by a delicate fibrous connective tissue stroma like that in the primary growth.

CASE 2.—This case was in the service of Dr. J. C. Shrader, at Mercy Hospital, in Mrs. M. G., aged 26 years, married, with no children. Her family history as regards cancer was negative. Her general health was good, but during the past five years she had been annoyed by pruritus of the external genitals, accompanied by the slow development of a warty, ulcerating growth at the point of irritation.

Physical examination revealed an ulcerated, painful area on the left labium majus, with papillomatous, indurated edges, being $1\frac{1}{2}$ inches long by $\frac{3}{4}$ inch in width; two enlarged lymph nodes were noted in the left inguinal region.

Operation for removal of primary growth and involved lymph nodes was performed Nov. 15, 1897, and there has been no recurrence to date.

The microscopic examination revealed the typical picture of epithelial proliferation from the surface, and formation of distinct nests or pearls of pavement epithelial cells in the deeper tissues as common to, and indicative of, squamous-cell epithelioma.

CASE 3.—This case occurred in the service of Dr. J. W. Dalbey, in the University Hospital, in O. E. C., a male laborer, aged 28 years, and single. His family history as regards cancer was negative. The right lower eyelid presented an ulcerated area three-quarters by one-half inch, with proliferated edges, which, according to the patient, had been gradually developing during the past five years. This was removed by operation on July 6, 1899, primary union following and no recurrence.

Microscopy revealed irregular columns of pavement epithelial cells extending down from the surface, with well-marked epithelial nests, beneath the surface, giving the characteristic histologic picture of pavement-celled epithelioma.

CASE 4.—The patient was seen in the medical service of Dr. L. W. Littig, in the University Hospital, viz.: R. R. T., aged 30 years, a farmer and single. When presented, Nov. 9, 1897, he gave a history of indefinite symptoms with reference to disturbances in digestion, and distress in the epigastric region; during the two months previous to entrance he had noticed a tumor-like enlargement below the left rib-border. There was no marked localized pain.

Physical examination of the thoracic organs was neg-

*Read before the Des Moines Pathological Society, Nov. 14, 1899.

ative; in the epigastric and left hypochondriac regions a defined area of dulness was noticeable, having a transverse diameter of $3\frac{1}{2}$ inches, palpation revealing a movable, circumscribed growth not influenced by respiratory movement, and separable from the hepatic and splenic areas of dulness.

A diagnosis of tumor abdominalis was proposed, the nature of this by reason of the age of the patient, being left indefinite, and exploratory operation advised. The latter was not granted and the patient passed from observation until death occurred, Feb. 8, 1898.

The post-mortem examination, by request of the relatives, was confined to the abdominal cavity. General emaciation was very marked; panniculus adiposus was greatly diminished. On opening the abdomen a large mass the size of a child's head was found involving the greater curvature of the stomach and the transverse colon; the mass, with adherent organs, was removed; the liver presented a high grade of fatty infiltration but no evidence of metastatic involvement; the spleen was not enlarged, and the kidneys were negative.

Closer examination of the tumor mass showed such an intimate connection with both the large intestine and the stomach as to render it difficult to distinguish from which organ it had its origin. The mucous surface of the stomach was smooth, the wall presenting a diffuse thickening which gradually merged into the tumor mass. In the lumen of the transverse colon extensive ulceration was noted corresponding to the tumor area.

In the microscopic section, representing a section through the mucous membrane of the stomach and into the substance of the tumor mass, the mucous membrane appears atrophic, and the tubular glandular structure is almost obliterated; in the submucosa, irregular tubules are seen, filled with cubical epithelial cells: deeper, elliptical and oval alveoli are noticeable, filled with cells, while narrow columns of cells—sometimes composed of single rows of cells—are seen radiating and infiltrating the fibrous stroma in all directions. Fatty degeneration in the larger cell collections is noted, and numerous karyokinetic figures are seen. The diagnosis was adenocarcinoma, most probably of stomach origin.

CASE 5.—This occurred in a patient of Dr. W. D. Middleton, at the University Hospital, viz.: W. R., aged 32 years, also a farmer and single. When admitted, he presented a large, ulcerating growth of the right side of the face, extending down on to the side of the neck for a distance of two inches, exposing the inferior maxillary bone in several places; the growth was of two years' standing. Microscopic section of particles removed from different portions of the growth gave a typical picture of epithelioma.

Coley's mixture of erysipelas and prodigious toxins was used in the therapy without appreciable benefit and the patient died in the hospital, two months after entrance. An autopsy was not granted.

CASE 6.—This case occurred in the practice of Dr. R. W. Hill, Davenport, Iowa, to whom I am indebted for the following: Mrs. N., aged 34 years, gave a history of several years of constipation, leading to almost complete obstruction when first observed by the attending physician. There was no emaciation, no localized pain, no distinct tumor, but a stenosis due to neoplasm was diagnosed and operation advised.

Laparotomy revealed an obstruction of the descending colon just above the junction with the sigmoid flexure, due to a neoplastic growth encircling the intestine. Resection was performed, removing about five inches of the colon and sigmoid flexure, the end of the descending

colon being fastened to the abdominal wall, to form an artificial anus, while the resected end of the rectum was inverted upon itself. Death occurred five days after operation, from peritonitis.

The gross pathologic appearance of the resected portion of intestine reveals a dense tumor mass enveloping the lumen of the intestine to the extent of two inches, constricting the same so that it admits but the passing of a finger; the entire growth being about the size of a lemon. No ulceration of the mucous surface is present; the cut surface of the tumor presents a dense structure in which numerous areas of mucilaginous softening are noticeable.

Microscopic examination of a section including mucous membrane and a large extent of the growth proper, shows no change in the mucosa, but in the submucous area are noted numerous oval-shaped alveoli more or less completely filled with short columns or cubical epithelial cells. Aside from the alveoli, areas are noted which are quite devoid of cells, and are filled instead with a delicate fibrous material giving the reaction of mucin. The stroma of fibrous connective tissue shows but slight retrograde change. A diagnosis of acinous carcinoma undergoing extensive myxomatous degeneration, was made.

CASE 7.—Miss G. W., aged 34 years, a dressmaker, was admitted Jan. 4, 1899, to the surgical service of Dr. W. D. Middleton, at the University Hospital. Her family history with reference to cancer was negative, and her health good until one year ago, when a small lump was noticed in the right breast, which rapidly enlarged and has been accompanied by sharp lancinating pains.

Physical examination revealed a large, rather circumscribed, slightly movable tumor mass involving the entire area of the right mamma; the surface about the nipple was retracted and over the gland proper, broken by numerous sinuous openings from which milky purulent-like discharge was escaping.

Operation was performed Jan. 5, 1899, comprising extirpation of the tumor and the gland, with three enlarged axillary lymph-nodes.

The cut surface of the tumor presents a growth of semisolid consistency, extending in various directions from the nipple into the substance of the gland, the size of the tumor being about that of a small cocoonut.

Microscopic sections stained in hematoxylin and eosin method, and by Van Gieson's method, reveal elliptical, oval, and irregular alveoli filled with cubical epithelial cells, surrounded by bands of dense fibrous tissue, the fibrous stroma and cell collections being about evenly distributed. The stroma presents occasional small areas of mucoid degeneration. Central areas of cells in the larger alveoli show marked granular and fatty changes. Numerous karyokinetic figures are seen throughout the cell areas. A diagnosis of acinous carcinoma was made.

On March 8, 1899, a secondary recurrent nodule of chestnut size, was removed from the site of the scar of the first operation, and possessed the same structural characters as the primary growth.

CASE 8.—This case occurred in the surgical service of Dr. W. D. Middleton; admitted Feb. 1, 1899. Mr. J. A. G., aged 35 years, married, jeweler, gave no family history of carcinoma, but a history of an attack of acute articular rheumatism of six months' duration, two years preceding admission; during this severe abdominal pain was a prominent symptom. Eight weeks previous to admission he noticed a palpable swelling just below the rib-border in the right mammary line. When first noticed it was of the size of a hen's egg, but gradually enlarged

and was the site of considerable pain which radiated out into the abdomen. Emaciation and anemia were marked.

Physical examination of the thoracic organs gave a negative result. In the right hypochondriac region a palpable, movable tumor, orange-size, was felt. Percussion showed it as not separable from the liver area of dullness, and influenced by respiratory movements. There was no icterus, constipation, nor ascites. Exploratory operation was performed Feb. 21, 1899, by Dr. Middleton, and revealed, on exposure of the abdominal structures, a large tumor mass the size of a child's head, in the region of, and apparently originating in, the hepatic flexure of the colon, and adherent to the under surface of the liver and pyloric extremity of the stomach. The extensive adhesions precluded any possibility of removal, and the abdominal wound was closed after removing from the most prominent and accessible portion of the tumor two small pieces for microscopic examination. A histologic section revealed the picture of adenocarcinoma.

The patient, shortly after operation, returned to his home in northern Iowa, where death occurred within three months. An autopsy was not obtained.

I wish to add to the foregoing an interesting instance of early carcinoma which recently came to my notice in the practice of Dr. G. L. Day, Lone Tree, Iowa. Mrs. W., aged 27, married. Soon after the birth of her child two years ago, a nodular ulcerating growth was noted by the attending physician in the upper part of the rectum. During the last year hemorrhagic ascites prevailed, and in three different tapplings sixteen liters of fluid were removed. Death occurred Nov. 21, 1899. Autopsy revealed a most extensive carcinomatosis of the peritoneal cavity, to which the metastasis was confined; the abdominal structures were all adhered and matted together into one dense mass, the infiltrated omentum having a thickness of two inches. The primary growth in the rectal wall and metastatic manifestations presented the typical macroscopic and microscopic appearance of adenocarcinoma with accompanying myxomatous degeneration.

In the list of examples of early carcinoma noted, the ages 23, 26, 27, 28, 30, 32, 34 and 35 years are represented. Four of the growths had their origin from surface epithelioma and five from glandular epithelial cells.

Of the cases recorded in literature, intestinal carcinomata have been most frequently observed, but involvement of other tissues common to cancer has been reported by trustworthy observers. Since the publication of Mathieu's classic article, in 1884, it has been more generally admitted than before that cancer of the stomach can occur before the age of 35, once regarded as the earliest possible period. Mathieu² himself reported, in 1895, a case of cancer of the stomach in a man 25 years of age. Dock³ has reported two cases of the same affection occurring at 20 and 24 years of age. In a review of carcinoma developing from dermoid cysts of the ovarian region, J. G. Clark⁴ cites three cases at 21, 26 and 29 years respectively. A most remarkable series of precocious cancer is reported by de la Camp,⁵ including 4 cases of a carcinoma ovarii in a girl of 19 years, carcinoma ventriculi in a boy of 14, and 1 of 16 years of age, also a case of carcinoma of the colon in a boy of 16. This author at the same time made a careful search of the literature on the subject, collecting 9963 cases, and of these 19 occurred before 20 years of age. W. Roger Williams¹⁶ collected the record of 11,934 cases.

and found 0.99 per cent occurring before 30 years, and 2.36 per cent. before 35 years of age. Cumston⁶ recently reported 3 cases at 19, 24 and 28 years, occurring in the liver, uterus and ascending colon. A Trayer (*Correspondenz Blatt für Schweizer Aerzte*, Oct. 15, 1899) reported the rare occurrence of carcinoma of the kidney in a man 20 years of age. Many cases are published in so casual a way that enumeration and analysis are out of the question.

Carcinoma in early life often has a slow course, and like that of later years may be latent for a considerable length of time. That cancer in early life is becoming more frequent is very evident; whether it keeps pace with the general increase in carcinoma will be difficult to determine. Certainly a collective study of the statistics reveals the unfortunate fact that the mortality rate of carcinoma is on the increase. Roswell Park⁷ calls attention to the statistics of New York State, showing 2363 deaths in 1887 against 4456 in 1898. In England and Wales, where careful records are kept, the rate of occurrence of cancer has increased from 1 in 5646 population in 1840 to 1 in 1306 in the year 1896, an increase of five times in fifty years. This increase can hardly be ascribed as due to improvements in methods of diagnosis, for rather the reverse is the case, since many cases which were formerly diagnosed as cancer are now properly classified where they belong in other lists.

While the etiology of cancer remains obscure, there is but little hope that the future will offer any abatement in this progressive increase. As careful observation continues to note the occurrence of carcinoma in the earlier decades of life, there is removed from the list of predisposing causes, the influence of age.

It has been an attractive explanation to attribute to the lessened physiologic resistance in connective tissue the rôle of permitting atypical proliferation of epithelium beyond its normal limits. With advancing age the submucous, subcutaneous and interstitial connective tissues undergo atrophic changes, while the covering or lining epithelial elements seem to retain their usual vitality. When glands reach the limit of their functional rôle in the organism, the danger from carcinoma is most marked, while it diminishes again when complete atrophy has taken place. When cancer occurs thus in the developing decades of life, the above influences can hardly be considered.

Bearing on the subject of etiology I must refer again to the peculiar secondary, recurrent growth, noted in Case 1. The removal of the primary growth, with uterus and appendages, was technically as perfect as it could possibly be in any case. There was not the slightest involvement of the peritoneal cavity, and yet, shortly after the operation, there appeared in the abdominal suture wound a secondary tumor, identical in structure with the primary one. The nature of the constituent elements left no doubt as to its metastatic nature, yet if a similar instance were to occur in connection with any of the infections how readily it would be explained. While I do not pretend to advance this as any direct evidence of a parasitic cause or spread of living virus, it does seem to me to mean more than the simple transmission of active epithelial cells from primary to secondary site.

In the entire field of pathology, no subject has proven more alluring to physician and investigator than the etiology of carcinoma. It was no wonder that the development of bacteriologic methods gave a mighty impetus to the search for an etiologic agent, the result of which is well known. Numerous forms of cell inclusions—cancer bodies—have been observed and variously

interpreted. Renewed and repeated attempts have been made to find the curative agent among the protozoa which are to enter the cells and render the same infective. Such workers as Hansemann, Rippert and Schwarz have continued to oppose any such adoption, and it would seem as if that most careful and critical work of Pianese⁸ has about taken the bottom out of the theory. By the use of unique staining methods and very careful technique this painstaking Italian has demonstrated, in proliferating cells, both inflammatory and neoplastic, changes and bodies which appear identical with the various forms of cell-inclusions of other observers, but which are demonstrated to be naught but evidences of different forms of cell degeneration.

An interesting contribution is that of Leyden and Schandinn,⁹ who have found in the ascitic fluid of malignant neoplasms—carcinoma—a new ameba-like body of the family of rhizopoda, which appear as round bodies in the fluid, having clear and yellow granules, with ameboid movement, and pseudopods of unusual length, life and mobility being retained four to five hours after removal on to the slide. The authors do not advance any definite etiologic connection with carcinoma, yet regard their appearance as quite significant.

Italian pathologists, led by Sanfelice¹⁰ and Roncali,¹¹ are still champions of the infectious theory, and their recent publications deal exclusively with certain organisms which they place among the blastomyces, a familiar example of which is the ordinary yeast plant. They regard the organism which they have isolated from tumors in man, and successfully inoculated into animals, as largely identical with the various bodies long observed and variously interpreted as protozoa, cell inclusions, and later as cell degeneration products. Roswell Park finds the work of the Italian pathologists creditable and convincing, and it is to be expected that the New York State Laboratory, in Buffalo, whose special mission is the investigation of tumors, will soon issue some exhaustive work on the subject. If blastomyces occur in cancers in Italy, they can probably also be demonstrated elsewhere.

As yet it is evident that the real cause of carcinoma has not been demonstrated. Perhaps it will be necessary to completely modify our culture methods. Perhaps our optical aids are inadequate in magnifying power, but unless the light comes soon, the nineteenth century will close with the genesis of cancer as much a mystery as when the century began.

Carcinoma continues to be a strictly surgical disease, and in this light I have thought it in place to refer to some of the earlier methods applicable in intra-vitam diagnosis, with special reference to the following: 1, characters of cancerous effusions in serous cavities; 2, necessity of an early microscopic examination of tumor particles, and 3, the proper interpretation of the histologic picture.

The early appearance of ascites and effusions in serous cavities involved by carcinoma, renders the fluid a good object for examination. The first scientific contribution on the subject was offered by Rieder,¹² who called especial attention to the cells found in effusions, to which subject Dock¹³ has also added a most interesting article. I have endeavored to carefully examine all effusions from carcinoma cases it has been my privilege to see, and while my material has been somewhat limited, I have noted the various cell forms described by former observers, and have drawn from these studies the following points:

The specific gravity of cancerous effusions is rarely

above 1015, and in that way is distinguishable from tuberculous exudates in which the specific gravity is usually higher, ranging from 1022 to 1025. Since exceptional instances of a lower specific gravity in tubercular pleurisy have been reported, this differential test must be used with a certain caution in diagnosis. The cells are by far the most characteristic feature about the effusion, the most perfect description of these having been furnished by Rieder. Cells having the appearance of lymphocytes are rare; multinuclear leucocytes are uncommon. Cells containing numerous fatty granules are frequent, the accumulation of granular material being confined principally to certain areas in the cells. Giant cells or aggregations of cells are a special feature, some of the former containing twenty to twenty-four nuclei. The most remarkable feature of the sediment is presented by the great number of karyokinetic figures, which are very numerous, presenting as common forms the equatorial plate and anaphase stages; another very characteristic point noted is the presence of atypical mitosis in the larger cells.

Atypical mitosis is an interesting study and has been demonstrated in all active proliferating pathologic processes, but with especial import in carcinoma.

In ordinary serous effusions, as in serous pleurisy and tubercular peritonitis, the large majority of cells are multinuclear leucocytes; furthermore, there are noted numerous small cells having the characters of lymphocytes, a few large mononuclear cells and some fibroblasts. The large cells with mitosis and atypical mitosis seen in cancerous effusions do not, as a rule, have their counterpart in ordinary exudates, which statement bears a slight modification, owing to the reported finding by Dock,¹³ in the exudate of pleurisy, of large cells showing karyokinesis.

As a diagnostic guide, it is necessary to state that the number of cells showing mitosis and asymmetric mitosis in cancerous effusions is much greater than in those of simple or tuberculous inflammation, and by this quantitative distinction, it would be possible to make a differential diagnosis.

The large cells that have been referred to are principally of the type of endothelial ones, resembling cells seen in scrapings from serous surfaces, with the exception that the latter do not show cell-division-figures.

One can hardly hope to determine the exact histologic character of a growth occurring on a membrane, from isolated cells found in the serous effusions. If it were possible to demonstrate the Leydenia gemicipara, described by Leyden and Schandinn in cancerous ascitic fluids, an additional aid in diagnosis would be furnished.

MICROSCOPI EXAMINATION OF TUMOR ELEMENTS.

The value and import of a knowledge of the nature of a growth, previous to surgical interference, must be apparent to every one, especially since it is becoming manifest that carcinoma may occur at almost any age. Portions of tumors can usually be obtained in a large number of cases. Surface carcinomata, both cutaneous and mucous, are accessible. Uterine scrapings are a great aid. Particles may be observed in stomach washings and in the stools and urine.

While the clinical signs in many instances may be very plain, a microscopic corroboration is always desirable. Frequently the specimens examined in this work represent superficial sections, so that certain caution is necessary in correctly interpreting the histologic picture.

Herzog¹⁴ has called attention to a case in which three pieces were removed from a tumor of the larynx, all of which were called fibroma, while the extirpation of half

the larynx revealed the typical picture of carcinoma. The uneven white elevation seen in the larynx in carcinoma may be merely a deposit and infiltration of fibrin.

In examining uterine scrapings I have noted that while a superficial piece might reveal simply a sort of adenomatous hyperplasia, a deeper section furnished the diagnosis of carcinoma. This would apply whenever adenocarcinoma would be likely to develop, and for the differentiation, histologically, of simple adenoma and adenocarcinoma, I would suggest that the following points be noted: 1, presence of atypical adenomatous glands; 2, absorption of stroma and agglutination of the glands in loops of the same gland; 3, the proliferation of the lining epithelium of glands; 4, filling of gland spaces, rupture of lumen of gland, and proliferation of epithelial cells into the surrounding stroma.

As illustrating a mistake that may be made in connection with ulcerating processes, I would cite a case recently referred to Dr. C. M. Robertson's clinic—a man, 34 years of age, presenting a large ulcer in the region of the soft palate, of six weeks' duration. Naturally the first thought of the clinician was of its being syphilis, but infection being so strongly denied by the patient, and no signs of primary or secondary lesions being detectable, it was set aside for the time being. Examination for tubercle bacilli was negative, tuberculosis of the respiratory tract was not to be detected, and so epithelioma was determined upon, especially as the edges of the ulcer showed a marked proliferation. A small piece, one-eighth of an inch square, was removed from the proliferating edge and subjected to microscopic examination. Section revealed a downgrowth of epithelium from the surface, and two areas of epithelial cells away and separate from the surface, from which it was essential to say that the picture indicated epithelioma.

In the meantime an antisyphilitic treatment had been instituted and the ulcer began to heal rapidly, thus plainly indicating the mistake—one that, in fact, is often made in superficial examination of proliferating epithelial processes, where the direction in which a section is cut may give misleading microscopic pictures resembling epithelial proliferations into the deeper tissues, and emphasizing most strongly the obtaining of deeper sections from representative portions of the growth for diagnostic purposes.

CONTAGION OF HERPES TONSURANS.—Several cases of herpes tonsurans were traced to the barber shop and through one customer to his dog, which had become infected by a monkey in the same house. Berger, who reports the occurrence in the *Derm. Cbl.* for April, arrested the epidemic by prompt destruction of the infected articles in the barber shop. He suggests that stricter hygienic measures be exacted of barbers, who should raise their prices to correspond, and he also warns against the fondling of household pets.

EXPERIMENTS AND OBSERVATIONS IN SCARLET FEVER.*

BY W. K. JACQUES, M.D.

CHICAGO.

Since Chicago has achieved the distinction of being a great city, scarlet fever, in forms more or less severe, has been present. During the summer and autumn of 1897, Dr. I. N. Abt found it prevalent in a light form among the poorer classes of Poles and Bohemians in certain parts of the city. The cases were so light that physicians were seldom called, and no intelligent action was taken to restrict contagion. An epidemic resulted. The health department, while realizing the danger, was crowded by more serious matters, and the afflicted communities enjoyed the blessing of becoming immunized while the disease was in its mildest form. From these localities the fever has gradually spread until it has included the entire city.

In the autumn of 1898, when the reported cases of scarlet fever were greatly increased, Dr. Wynkoop of the city laboratory, while examining a culture from a scarlet fever patient, sent him by Dr. Findley, noticed a coccus which he first took to be a form of the pus coccus. But on growing, it manifested such peculiar characteristics that he began to pursue a careful study of the germ in the laboratory. At a certain stage of its development it became a large coccus, the center of which staid in the shape of a double crescent. While this germ was still under observation by Dr. Wynkoop, Dr. Class described his diplococcus scarlatinae, in a paper before the Chicago Medical Society. While Dr. Wynkoop used the term "crescent" and Dr. Class "diplococcus," I concluded, after a study of many cultures from scarlet fever cases, that both were different forms of the same germ. This attempt to name an organism from some particular stage of its development was responsible for the uncertainty concerning it.

This germ has a wide morphology. Sometimes one stage and then another will become accentuated, according to environment and nutrition. Sometimes conditions are favorable to its growth in chains and the culture will show the streptococcus form. In another case it will grow as a staphylococcus, and in still another as a diplococcus. Again it becomes oblong and almost a bacillus. Early bacteriologists attempted to classify micro-organisms according to shape and arrangement, and they were divided into families of streptococci, staphylococci and bacilli, etc., but in this case we have a germ that may be either or all.

Bacteriology is still too young for us to be bound too strongly by precedent. Professor Koch formulated what he considered the law to which the causative germ of a disease should conform. While this law is applicable to some diseases, many more do not fulfill all the requirements, yet experience is demonstrating that germs are the essential causes of disease in those which do not conform as well as in those which do.

As above stated, the morphology of this germ, which I have been finding in scarlet fever, is one of its most interesting features. The size of the coccus depends on its environment and the medium on which it grows. In the same culture, it will sometimes vary from the smallest point observable under a one-twelfth oil-emersion to a coccus one-third the diameter of a red corpuscle. It appears that these cocci multiply by division, and that the multiplication takes place in various sizes of the germs. When inoculated on a culture-medium, they usually grow to the favorable dividing point and then

*Read before the Society of Internal Medicine, Chicago, Feb. 27, 1900

divide rapidly so that an examination shows a field of nearly uniform size. If the culture is permitted to develop, the older germs attain a large size and show the crescent form on staining. In a culture of the germ inoculated on the Löffler serum, and incubated five to ten hours, there will be an abundant growth of large cocci sometimes arranged as staphylococci. In the same culture there are sometimes found short chains of six to twelve. This is the usual form of growth, but either the staphylococci or streptococci arrangement may predominate. This coccus when stained appears to have a small hole in it. As it enlarges, this hole is seen to be a dividing line of material which does not take the stain. This gives the coccus the appearance of a pair of crescents with their points turned toward each other. This is the last and largest stage of growth. At times the germ much resembles the staphylococcus albus, having a clean, definite cell wall. Frequently there seems to be a glue-like exudate covering the surface of the cocci. When a colony is touched with a platinum needle, this exudate can be drawn out in strings and seems to modify the surrounding medium so that it will take the stain to a greater or less degree. Sometimes the germs of the culture pass into a stage in which the germ wall seems to almost lose its definite structure, and the germ appears a refractive jelly-like mass.

I have examined from six hundred to a thousand cultures from inflamed throats each year for the past six years. During the winter of 1898 this coccus began to appear; at first only in cultures from scarlet fever patients and those who had come in contact with the disease. During the following year its frequency increased, keeping pace with the increase of scarlet fever. The infection has now become so general that fully 80 per cent. of the cultures that come to my laboratory contain this coccus.

As abundant clinical observations have proven that the contagion of scarlet fever lies in the scales, I began a careful examination of these. In twenty cases, from which I collected scales, abundant growths of this germ were obtained. Drs. Gehrman, Wynkoop and myself conducted the following experiment: An emulsion was made from scales taken from a patient recovering from scarlet fever. A twelve weeks' old hog was injected with 10 c.c. of this. An emulsion was also made from scales given to us by Dr. Class and another hog inoculated. The animals showed but little effects from the inoculations. They were larger than we could handle well, but were the best we could secure. It required the combined efforts of two to take the temperature and, after taking it the second day, it was not taken again. The animals were watched daily, but as there was no loss of appetite or other evidence of their being affected, we concluded to try a larger injection. When we examined the animals preparatory to making another injection, twenty-one days after the first, we found they were both scaling profusely. Cultures from the scales revealed the presence of the inoculated germ.

A third animal was obtained and placed with the other two. A rise of temperature followed lasting several days, when this animal also scaled off. A piece of its skin was taken and the germ found in the blood. The children of adjoining apartment houses showed a disposition to use the barn as a play-house and it was not considered safe to continue the experiments. The isolation necessary, the difficulty in obtaining suitable animals on which to experiment, and the limited amount of time we were able to devote to observations made the results less accurate than we could wish, but they are of

some value in indicating lines for future investigation. The chief difficulty in the way of acquiring definite knowledge of the scarlet fever germ is the great care necessary to conduct experiments, as well as the best laboratory facilities and, more important than all, subjects for experiment.

Clinical observation has established the fact that scarlet fever begins with inflamed fauces followed by general constitutional disturbance and characteristic rash; that these symptoms are followed by scaling of the epidermis and that in these scales lies the element of contagion.

Having found the germ present in the initial lesion, and in the scales, it was most important that the connecting link should be found in the blood. I began to examine blood by sterilizing the earlobe with alcohol and then puncturing it. In the first two cases I found the germ present by spreading this blood over the surface of a blood-serum culture-box, such as is used in the health department. Then instead of spreading the blood over the surface, I allowed it to remain as a drop on the surface and incubated the box. Several failures followed, which I attributed to the antitoxic qualities of the blood, or the fact that the germs were not present in the blood when it was taken. In one case, when the rash was just appearing, I collected blood on a sterilized swab, which was dropped into beef bouillon. In two out of three of these cases the germ was found. The taking of blood from the ear not being above criticism, on account of contamination from the skin, I determined to obtain it from venous puncture. This was done in two cases and the germ found in both. But the securing of blood in this manner is painful and not easy in private practice.

In considering the evidence as to whether or not this germ is the essential cause of scarlet fever, we should first study it under laboratory conditions and thus ascertain whether it gives evidence that it is capable of multiplying in the human body. We should then trace the germ through the body and observe its effects on the different tissues.

If the germ has shown itself very sensitive to environment in the laboratory, we should expect this also in the tissues in which it multiplies. If there is a varying degree of susceptibility in the human family, this fact must be taken into account in the study of the disease. If the germ possessed a definite virulence and always affected the human body in the same manner, its study would be a comparatively simple matter; but in scarlet fever we have a germ which is variable in its virulence, and to which there is the widest degree of susceptibility in the human family. Not only are but few individuals susceptible, but even these vary in susceptibility. The various tissues afford a different environment and present different conditions for the multiplication of the germ; also varying degrees in their resisting power, as well as different conditions for the destruction of the germ.

In tracing this infection through the body, we shall begin with the usual site of the invasion, i. e., the mouth. The human mouth, being the entrance to the respiratory passage, is continually fanned by large quantities of air. The mucus which covers the throat is a more or less nutrient medium. The glands and adenoid tissues around the air-passages are of a more or less low grade of vitality. The mucous membrane which lines this cavity is a tissue subject to inflammation. Large numbers of germs inhabit the healthy mouth; many of these become pathogenic when conditions permit. They remain as harmless saprophytes until condi-

tions of susceptibility, such as congestion from cold, deficient renal elimination or other means of lowering the vitality in the surrounding tissues, producing the results which their cycle of activity brings about. In my studies I have found that the angina produced by the scarlet fever coccus in no way differs, except in degree, from the anginas which accompany the disease. The angina produced by scarlet fever infection, however, possesses certain characteristics that do not follow the usual invasion of the pus cocci. There is an intense redness of the tissues; the throat is very sore; and there is a tendency to the involvement of the glands, and it is nearly always accompanied by high fever.

These symptoms do not end in from thirty-six to forty-eight hours, as in ordinary tonsillitis. They do not terminate in the formation of pus; but the inflammation, as before stated, has exactly the same course as that which accompanies scarlet fever. Should the invasion multiply to the extent of producing scarlet fever, there is nothing about the throat but what would be in perfect harmony with the usual angina which accompanies this disease.

When this infection invades the trachea sufficiently to produce stenosis, I have found, in the six cases that have come under my observation, that a prognosis must be given which essentially differs from that of an invasion produced by any other germs causing this condition.

In the invasion of the Klebs-Löffler bacilli, under the magical effects of antitoxin, the tube may be removed in three or four days in the majority of cases. The staphylococcus also has a short period in which the tube must remain. The streptococcus causes a more lasting inflammation, requiring the tube to be worn from six to eight days.

Stenosis of the larynx or trachea from scarlet fever causes the longer wearing of the tube than in any other infection. If the tube is removed in six, eight or ten days, the trachea seems to collapse and stenosis remains, which appears to be more from the relaxed condition of the trachea than from swollen tissues.

In each of the six patients I have intubated this winter, for scarlet fever stenosis, the tube was removed and again replaced from three to twelve times. As I have become more familiar with the nature of this infection, I allow the tube to remain for a longer period of time. Two of these intubations were in patients in whom there were well-marked manifestations of scarlet fever. The other four were in children from whom cultures showed a malignant growth of the scarlet fever coccus, but they did not have the disease; yet the same clinical symptoms followed in the trachea that appeared in the scarlet fever patients.

We have seen that we can have an extensive multiplication of this germ in the mouth, in the mucous membrane of the throat, extending into the glands of the neck and trachea, and yet not have scarlet fever. However, should the germs be enabled to pass into the blood and there find a condition for their multiplication, what symptoms would probably follow? Here it is necessary to study the conditions of environment which this tissue, the blood, presents for the multiplication of the germ. The blood is a highly nutrient medium, always at the same temperature, and may be said to represent the composite product of all the cells of the body. In addition to this, it contains the nutrient material for their support. Were this all it contained, we could readily understand that it would be a fluid which would be a most suitable medium in which pathogenic germs could

multiply. For the defense of the body there are cells which circulate in the blood, one of whose functions is to destroy hostile germs. This, then, in addition to the antitoxic qualities of the blood, constitutes the defense which the body has against the invasion of pathogenic germs. The rapid circulation of the blood brings it into constant communication with every cell in the body, and in this manner they are almost instantly made aware of any addition to it. Should pathogenic germs begin an invasion in or on the surface of any of the tissues, the product of their life is at once taken into the blood current. It notifies all cells throughout the body of the invasion of a hostile enemy, and they are at once stimulated to the production of antigermin, or a defensive antitoxin.

We can thus understand that the blood is most highly antagonistic to germ invasion. At the same time, when germs invade it, their distribution to all parts of the body is but a matter of seconds. Therefore, following the enormous multiplication of the scarlet fever germ in the fauces, numbers of them enter the blood current. If this medium is sufficiently resistant, they are destroyed before any great amount of multiplication takes place. If this is not the case they multiply and are distributed to all parts of the body, and owing to the nature of the exudate which covers them, they would be likely to collect and cling in the capillaries of the tissues. They would carry with them the same irritating effects which we notice in the multiplication in the pharynx, and this would continue as long as they possessed life.

Therefore, the phenomenon which would follow the invasion of this germ in the blood would be entirely in harmony with the rash which characterizes scarlet fever. The condition of the blood in children, where the demand on it is so great for the rapidly growing tissues, and where the mucous membrane of the throat is so tender and easily invaded, indicates why they should be more susceptible than the more stable tissues of the adult.

The resemblance of this germ to the staphylococcus albus when growing under laboratory conditions, suggests the query as to whether or not it is the staphylococcus albus itself which, under a different environment, has adapted itself to the invasion of the blood and thus causes scarlet fever.

Evolution is much more rapid in germ life than in the higher forms, because their cycle of activity is so short. Change of environment may produce change in form and function. This we see illustrated in almost all of the pathogenic germs. The effect of residence in the human tissue may cause it to assume increased virulence and malignancy. For example: puerperal infection containing the ordinary forms of streptococci or staphylococci becomes most dangerous when carried from patient to patient. The study of these germs in the laboratory can give but a meager idea of their possibilities when growing in susceptible human soil. This may also be true of the staphylococcus albus.

The residence of germs in the human body causes them to take on qualities which can not be demonstrated by ordinary laboratory methods. In the laboratory we see, growing on moist filter paper, a fungus which, under these conditions, grows in the branching form of the fungus family and seems to be an innocent mold. Yet this same fungus was and is the bacillus tuberculosis originally taken from a patient suffering from this disease. By change of environment the bacillus was brought back to its original form of a branching fungus.¹

¹ See Haeppel's Principles of Bacteriology.

The great variability in the poisonous qualities of the bacillus anthrax, caused by changing environment, may also be cited as one, and the fact that the cholera bacillus does not become malignant until it multiplies in the presence of decomposing filth is still another illustration of what environment will do.

Therefore, the study of the diplococcus scarlatinae in the laboratory alone can give but a partial idea of its possibilities when introduced into the environment of the human body. Judging from the wide range in the morphology and adaptability of this germ, it does not seem impossible that it was originally the staphylococcus albus and has been modified by its human environment.

In the study of scarlet fever it is most important to appreciate the value of susceptibility in the production of the disease. I think we are justified in calling the blood the essential tissue in which the multiplication of the germ takes place to produce scarlet fever. When we consider that this fluid represents the cell production of the entire body, we can appreciate how it must vary in its resistance to germ invasion, not only from day to day but from hour to hour. Exhaustion, loss of sleep, lack of food, vitiated air or any debilitating cause which modifies the nutrient medium of the blood will affect its resistance.

After the cells throughout the body have been stimulated to the production of a resisting quality, they maintain a continued immunity. Nurses who have had scarlet fever may contract sore throats from virulent cases. Families where all the members have had the disease may also have severe anginas caused by this same germ.

The finding of this scarlet fever coccus in cultures from the throat has a different meaning from that of the Klebs-Löffler bacillus, because it is a different germ, multiplies in a different tissue and is carried in a different manner. In the case of the residence of the germ in healthy mucus, no disturbance of functions follows. When the tissues of the pharynx are invaded, similar phenomena result as in other germ invasions, but this germ in its minute form possesses the power to pass through the barrier of mucous membrane into the blood, where it multiplies, if this medium is in proper condition. The stay of the germ in the blood in patients who recover is very short, because every effort is put forth to destroy the invaders. Leucocytes are poured into the blood current and every cell is stimulated to produce antigermin. Then follows the more gradual process of absorbing the inflamed areas which may still contain the germs. While they are thus rapidly destroyed in all the internal tissues which are accessible to the blood, the skin, which is in a continual state of exfoliation, still contains the germs. During the rash period, the external layers of the skin are filled with germs; their irritative effects cut off nutrition and, as a result, those epidermis scales which are not reached by the blood during the process of recovery are filled with the minute germs. These are carried to other susceptible persons by various means, and the process repeated.

A harmless method of producing immunity by the stimulation of the cells in children exposed to scarlet fever would lessen the fear and the fatal effects of that disease as it has done in diphtheria. As soon as we have sufficient knowledge of the germ and the conditions under which it grows, this will be accomplished. Immunity against scarlet fever is enjoyed by more than 99 per cent. of individuals. Those who have suffered from the disease seldom or never have it again. Thus we see

that immunity is the rule and susceptibility the exception.

In the production of immunity against disease the germ is the most important factor. In the malarial districts of the South, the negroes become immune by continually being in the presence of malaria. In this manner, or by non-fatal attacks, immunity in cholera, typhoid fever and diphtheria is produced. That immunity is conferred by an attack of the disease is already known. From the wide distribution of the germ at present, nearly all susceptible individuals must contract the disease and become immunized. In the production of artificial immunity, the problem is to bring about the cell stimulation in such a manner as not to endanger the life of the patient. In individuals who are slightly susceptible, a residence of the germ as a saprophyte probably accomplishes this, while a sore throat is necessary in those whose tissues of the throat are susceptible; and scarlet fever follows in those who are still more susceptible. In the present epidemic, those who have had an angina in which the scarlet fever germ predominated, have not had scarlet fever.

In the attempt to produce artificial immunity the nature of the germ should be kept in mind. In my laboratory experience, and from clinical observation, I should say that it is an irritating, fever-producing germ and not a toxic or toxin-producing one, the pathologic conditions being caused by the multiplication of the germs themselves and their irritating presence rather than from any toxin which they produce. In this it differs from the Klebs-Löffler bacillus, which is a toxin-producing germ and not a fever or irritating one. In this respect the scarlet fever germ resembles the typhoid bacillus. Bacteriologists say that the difficulty in getting an antitoxin for typhoid fever is because they are unable to obtain a toxin of sufficient strength to stimulate the cells of the animal to produce an antitoxin. This same difficulty will stand in the way of producing an immunizing serum for scarlet fever.

However, another way of causing protection suggests itself to me. In scarlet fever, the site of the invasion usually includes the entire mucous membrane of the pharynx, and from this extensive surface the germs are enabled to enter the blood in overwhelming numbers. Surgeons have often noticed that wounds in other members of a family, where there is a case of scarlet fever, become inflamed and are often slow to heal, but the disease does not follow. On the other hand, the introduction of scarlet fever germs into the vagina of a recently delivered woman is extremely fatal. Therefore, the ease with which the infection enters the blood is a most important factor. In wounds there is a barrier of swollen capillaries gorged with leucocytes which stand between the germs and the blood. In a puerperal case, and also in the throat, there is an open door almost directly into the blood.

Being aware that experiments in inoculation have been disastrous, I had to be careful in this work. My first experience was the inoculating of the puncture after giving diphtheria antitoxin. A little girl was scaling from scarlet fever when her mother contracted diphtheria. The circumstances of the family were such that isolation of the younger brother could no longer be maintained, and I immunized the two children. With the consent of the father I inoculated the site of the puncture in the boy with scales from the sister. A slight rash followed, beginning at the site of the puncture and spreading over the body. The scaling was very much less than in the sister.

The child of a physician became slightly burned. The father had attended scarlet fever patients during the winter. The wound became inflamed and a rash followed with a rise of temperature to 101 F. No throat symptoms were present in either this or the previous patient. I think it rather hazardous to inoculate the germ directly into the blood current, and it seemed to me that the infection in the case of the burn was the mildest.

It is my purpose to experiment with the following method whenever an opportunity presents itself: Raise a small bleb by means of a fly-blistér; with a hypodermic needle inoculate the serum without breaking the blister, if possible. If the patient is susceptible, the germs ought to multiply in this serum, and before passing into the blood, they would have to get through the barrier of inflamed capillaries filled with leucocytes. In this manner their entrance would be slow and the blood could gradually take up the products of germ multiplication in the serum, while the cells would be stimulated to the production of a defensive antigermin.

I have purposely avoided the conflicting literature on scarlet fever. Two things are necessary in a contagious disease, i. e., the germ and a susceptible person. From my standpoint it is impossible to produce the disease under laboratory conditions, as the multiplication of the infection requires not only a living blood environment but this must have, in addition, a peculiar quality which permits the production of the disease. Therefore, the bacteriologist in his laboratory can get at but a small portion of the evidence. A chain is only as strong as its weakest link, and the links of evidence in this chain must not be separated. The microscope must be taken to the living environment and the germ studied under the conditions in which the disease is produced.

No doubt further study and experiment may cause me to change some of these views, but at the present time they are the most reasonable explanations of the clinical phenomena in scarlet fever. If the criticism they provoke prove them false, the discussion may lead to the truth and compensate for the preparation of this paper.

4316 Greenwood Ave.

DISCUSSION.

DR. ADOLPH GEHRMANN said that he does not believe, from the examinations, that he has been able to make out that this coccus, from its microscopic appearance, is sufficiently characteristic to say that it is always the Class coccus. His observations have shown that a bacterium, giving the same appearance, and in a great many cases more cultural characteristics, has been found in other conditions, especially on the skin of individuals who have not been in contact with scarlet fever patients, and in some rather unusual places. For instance, he has found a coccus giving the general characteristics of the Class coccus, in vaccine material a number of times. He has found it in samples of urine and in other specimens in conducting general examinations. Dr. Gehrmann gave his reasons, at considerable length, why he does not think the Class coccus is the only and sole cause of scarlet fever.

DR. WILLIAM J. CLASS called the attention of the Society to the published work he had done with reference to the germ of scarlet fever.

DR. LUDVIG HERTOEN said that it has been held theoretically that scarlet fever is not a toxic disease, but its lesions are those of a toxic one. In the organs of patients dead from scarlet fever, the same necrosis and degenerative changes are found in the lymphatic glands, spleen, bone-marrow, liver, etc., as are found in such diseases as diphtheria, etc., of the toxic nature of which there can be no question. Investigations with reference to the etiology of scarlet fever must go further than a mere investigation of the morphology of a coccus.

DR. L. MAYWIT narrated two cases of scarlatinal sore throat that he saw in a family. Cultures were made and the Class

diplococcus was found. In one case the temperature varied from 103 to 104 F., and in the other from 102 to 103 F., and this elevation of temperature lasted four or five days in each patient. Repeated examinations of the urine were made and albumin was found daily for six or seven days, after which it disappeared. The children had no albuminuria before the onset of the fever, and none after, so he thinks the albumin must have been caused by the scarlet fever germ. The eruption was not marked in either case. Both children recovered.

DR. W. K. JACQUES, in closing the discussion, said that he has found the diplococcus of Class present in great numbers in the throat, the blood, and in the scales of scarlet fever patients. Indeed, he has found this germ as frequently in cases of scarlet fever as is the Klebs-Löffler bacillus found in diphtheria.

DISTILLED WATER AS FOOD.*

BY EPHRAIM CUTLER, M.D., LL.D.
NEW YORK CITY.

Food is any substance received into the human system from without, which normally becomes a biologic part of the system and is needful to life. It includes minerals, as air, water, salt, etc. Aerated distilled is also meant here, and not the ordinary chemical laboratory distilled water, condensed in a closed reservoir. The distillate should have a fall of not less than two inches in open air for aeration, otherwise it may be an abomination of the meanest taste.

HOW TO HAVE IT.

Philadelphia is the great medical center, and yet my patients have been unable to buy anything but laboratory-distilled water. So the best way is to make it. The writer tried to get all the domestic water stills in the market to report on, but was unsuccessful. As he is writing this paper interprofessionally and clinically, he asks to testify simply to what he knows and let the still-makers arrange for their own testimonials. While many stills are in the market, they are too expensive for the average person and too complicated. Between the lines their advertisements read as if they were made for making money, not water. The merchants give an idea that distilling water is an exceptional and difficult thing, obtainable only through their wares, each being the best and all others poor, if not worthless.

A few moments of reflection shows that aerated, distilled water is most abundantly present in the open air, as rain, clouds, dew, fog, mist, invisible vapor; also in solid state, as frost, hail and snow. From all surfaces of water—fresh or salt—or of substances wet in water, water is by nature's evaporation distilled. From the ocean distilled water rises in the air, is held in solution, carried by the winds inland to the mountains and hills, where it is condensed by cold into rain, clouds, etc., and is swallowed up by the earth, or falls in the forests, slowly forming springs, pools, fairy rills, brooks and rivers, whence it runs back to the ocean or inland lakes, to be distilled again. This process has gone on so long that all collections of outletless waters become loaded with the salts and other minerals, as would be expected in the residuum of distilled water, simply because salts and minerals are not volatile like water, which rises as steam even at temperatures below zero (F.). (See works on steam.) Thus the ocean and the Dead Sea have become salt. This natural distillation has existed for ages, on a most tremendous scale, and will continue as long as God wills. It is difficult to see how anybody can monopolize water stills, they are so universal.

The principles of distilled water production, artifi-

*Presented to the Section on Physiology and Dietetics, at the Fiftieth Annual Meeting of the American Medical Association, held at Columbus, Ohio, June 6-9, 1899.

cial, are: Evaporation and condensation in a reservoir. The former is had by heat, the latter by surrounding the reservoir with cold water or cold air.

I remember seeing, when a boy, almost a stream of clean, pure, glistening water fall from the under surface of the cover of my mother's wash boiler, when she removed it to gratify my boyish interest in its seething contents. I think a few drops fell on me, and I found out it was hot water. I wondered where it came from, for I saw there was no contact with the boiling suds, and it was clear water. It was a problem to me then, and I think my boy mind must have solved it at that time, as distilled water condensed by the contact of air which,

Fig. 1.—Vertical section of wash-boiler still, a, b, c, d; e, e, one-inch flange; f, opening; g, tube.

rising as fast as it was heated, was replaced by cooler air, condensing the steam. Every time I saw a wash boiler at work I verified this observation. This principle of making distilled water became a fixed one with me, but it lay dormant and was not utilized for about forty years, when a patient of mine was going to Idaho to teach school and I did not want her to drink the alkali water. I told her to have a common wash boiler soldered all around inside, four inches from the bottom, with a strip of tin one inch wide, at an angle of 45 degrees. At one

Fig. 2.—Vertical tank still; ab, 12 inches; ac, 28 inches; CL, 4 1/2 inches; LL, 1-inch ledge.

end of the boiler this ledge was to be left a little lower for drainage. The tinsmith was to put in a one-half-inch tube running outside for four inches, to drain into a receptacle, at least two inches lower for aeration. The other details were so simple that she had sweet water instead of bitter. The principle of this still is clearly manifest: The steam, condensed by cooler air in the boiler walls, ran down in tiny drops to the ledge and thence into the receptacle. In London, 1889, a like still was made for Sir W. A. Mackinnon, the highest medical official of the British army, who approved of the principle and said he wished he could have had one in

India. I have published illustrations of this still several times.

The still made in London had not surface enough; it got too hot, so it would not condense.

When Fig. 3 was run on the cover over the fire box of our kitchen range it condensed 10 ounces an hour or 2 gallons daily, more than enough for one patient; but placed over the cover next the first named, it distilled just the same amount with the advantage of being out of the cook's way. Increase the height and the product is increased, and perhaps in a greater proportion, as the higher the still the farther away from the fire. This can be done by adding a bottomless still of the same size and placing the cover on top as before. Fig. 3 was made, with a copper bottom, of common tin, for \$4.25, by a plumber.

Suggested forms of this still.—Have a closed, clean tin or galvanized-iron stove or furnace pipe 10 to 25 feet long set upright out of doors, close to the house. Have a small air hole at the top, also an exit tube at the closed bottom next to it for delivery and aeration of the distillate to the receptacle. Connect the steam through an opening four inches from the bottom, from a common tea-kettle or other source. Or run the tea-kettle or other steam into a common wash boiler, through an opening in the cover which has a drip tube.

Fig. 3.—Water still as used by E. C. Air the condenser. Height, 2 ft. 6 in. A, handle to cover; E, side handle; C, C, 1-inch flange; B G, distillate tube; H, receiver.

If steam is easily had, it can be run into a rejected water back-tank—which plumbers are glad to throw away—set vertically outside. These examples are enough to demonstrate the principles of air-condensing water stills which, for their simplicity, cheapness and usefulness should be as free as air, and should be found on ship-board and all places where pure water can not be obtained. The product from sea water, obtained from Fig. 2, is palatable, pure and delicious.

The difficulty with rain water is that there are so many forms, organic and inorganic in the air—morphology—that the taste is impaired. If the rain is filtered, as in mountain springs away from man and beast, the result is delicious and curative as patients testify to the curative effects of pure spring water.

DIETETIC PRINCIPLES OF AERATED DISTILLED WATER.

Negative.—It is not a poison or I would have been dead long ago, as I have for years used all the distilled water I could get. Its osmosis is harmless. A German physician, Dr. Koppe, claims that the turning white of

the epithelia of the alimentary canal by distilled water shows it to be poisonous. There is some truth as to the color, as seen on washer-women's hands turning white in the suds, from long immersion, but I never knew of one being poisoned. I wonder how our German secured his information. For about twenty-five years I have studied the morphology of hydrant, well and ice waters. Rarely, if ever, have I found epithelia absent. Many are so common and well preserved that their presence has become a matter of fact, taken for granted as daylight. Epithelia have a wonderful vitality soaked in water and have no washer-woman's white color. I wish our learned German friends would see if we are right in saying that probably epithelia loaded with diphtheritic or scarlet fever vegetations in hydrant water may communicate these diseases, also as cholera, smallpox, typhoid fever, etc. My patients have freely used distilled water and none were poisoned, in fact have recovered from so-called incurable diseases. Allowing the dictum aforesaid, Nature reproduces epithelia so rapidly as to meet the need, wet or dry, but this is nominal metabolism.

Positive.—Distilled water cleanses the tins that contain or condense it, brightly. This might show that hydric acid = HO = distilled water, is more active than undistilled to dissolve salts and metals—that is to say, having no salts in solution is a great clinical advantage as distilled water will more readily dissolve out granular, crystalline and massive gravels that accumulate: 1, in the blood in rheumatism or gout; 2, in the lungs in asthma, fibroid consumption and chronic bronchitis, colds and coughs; 3, in the kidneys, intestines, liver, vagina, mouth, blood-vessels—arteries; 4, in and on the skin; 5, on the teeth as tartar—in fact all the calculous diseases, no matter what the location.

ROLE OF CALCULI, INCLUDING ALL GRAVELS.

They are formed normally in the body systemic in the performance of its functions. Normally they are saline bodies held in solution, and are dispensed with after use by the skin, urine, feces. This is said advisedly from many years of observation by others and myself. If from any reason calculi are deposited from their solutions in the blood, urine, feces or the skin—whose sweat, tasting of salt, is one proof of these salts—then the respiratory tract vicariously attempts to eliminate these calculi from the system and so irritates the air-passages and causes coughs and colds—as one of Nature's ways to get rid of the calculi as intruders on the peace of the kingdom of the body systemic.

If the lungs and nares do not succeed in the removal, the over-worked kidneys, intestines and skin take a hand and do the best they can, and yet we call these lung, nephritic, intestinal and dermal efforts—diseases—when they are nothing but Nature's efforts to save the health and life of the body systemic. Now the most common sense thing to do in helping Nature to cure these so-called diseases is to wash out the calculi with water, God's great gift to man. It stands to reason that distilled water, having no saline bodies in solution, will dissolve out more gravel than ordinary well or hydrant waters, even if filtered.

A few years ago, Dr. R. H. Sayre, of New York City, returned from Paris saying the French told him this doctrine, and he informed them he had heard it in America.

SOME PRACTICAL EVIDENCE.

A few years ago a veteran captain, War of 1861, had

the signs of fatty degeneration of the kidneys, voiding calculi. The Geneva Spring water was his drink. A large uric acid calculus brought him \$5.00 from the water company and was referred to in advertisements as positive evidence of the marvelous removal of stone by this water. But the man grew worse and went to Dr. J. A. Cutter's hands, who, finding there were some 232 grains of solids to the gallon of the Geneva water, correctly inferred that the water kept the calculi forming in a system which before was saturated with salts. Captain C. was put on distilled water for drink and chopped meat diet. His health was restored and now no calculi are voided. I deem distilled water far better than lithia waters, on the ground of cures and the uselessness of adding more salts when the system is so saturated as to deposit granular, crystalline and massive gravels or calculi inside the viscera and tissues.

CASE TO SHOW THE DIFFERENCE BETWEEN COCHITUATE WATER AND DISTILLED OR SPRING WATER WITH LESS THAN TEN GRAINS TO THE GALLON.

Professor M., of Boston, an old patient of 1876, in the pretubercular state, about 1894 had a severe and harassing cough which, under the circumstances, caused apprehensions of the return of tuberculosis. But the morphology of the blood was not tuberculous nor pretuberculous. The sputum showed gravel—granular, free and encysted—in giant mucous corpuscles distended by the gravel, also crystalline and massive—i. e., like broken glass—and pigment matters. He was, as to drink, treated with spring—as above—and distilled water. Fourteen days later the gravel had mostly disappeared from the sputum and with it the cough.

These opinions are based on a study of the morphology of hydrant and well waters for twenty-five years. My conclusions are that water by itself or inhaled in the air passively and constantly is a food, indispensable to all mankind; that, if so, why feed "calculi" patients on waters which add to the already overloaded collections? that distilled water properly aerated is the best for such rheumatics and asthmatics; that if Germans have been poisoned by distilled water, it is a very remarkable idiosyncrasy in those who have figuratively more vitality, more strength and actually enjoy more rights than Americans; German patent medicines are used by American physicians largely, beneficially, undisturbedly, while cis-Atlantic patent medicines and appliances can not be employed by American physicians; that water is a solvent in biology; that the purer it is, the better will water wash out the viscera, dissolve calculi, ease the flow of blood through the more than 100,000 miles of capillaries in the system, promote osmosis, soften tissues, accelerate secretions and excretions, equalize all circulations, aid cerebration, cardiation, digestion, metabolism; that distilled water is free from bacteria, yeasts, epithelia loaded or not with cryptogamic diseases; that whatever gets in from the morphology of the air of the kitchen can not be so deleterious as some aver, because the culinary queens inhale it all the time, harmlessly.

The writer hopes it will become the fashion to "treat" people with distilled in place of undistilled water and spirituous liquors, as he found it appetizing, satisfying, going to the right spot, clean tasting and beautiful to the eye as well as the palate, wholesome and never intoxicating (toxa=poison) as our experience proves with the Americans and English, though Dr. Koppe asserts it has. I respect him but do not accept what he says, as it does not tally with the facts here given.

CHRONIC CONSTIPATION A SYMPTOM RESULTING FROM A DISORDERED STATE OF THE SYMPATHETIC NERVOUS SYSTEM. ITS CAUSES AND CURE.

BY CHARLES E. STEWART, M.D.

BATTLE CREEK, MICH.

Chronic constipation, although commonly considered a disease *per se*, is in reality only a symptom indicating the presence of some more general disorder. This symptom, if such we may be permitted to term it, is one which accompanies a great many disorders, being most frequently met with in persons having some other digestive disturbance. Whenever encountered, it is an indication of some inhibitory power acting through the motor, vasomotor, secretory, or sensory mechanisms of the alimentary canal. These mechanisms, being involuntary in nature, are under the control of the sympathetic nervous system; consequently the primary cause of the constipation must be sought for in some inhibitory influence acting on any or all of the mechanisms referred to.

A brief survey of the anatomy and physiology of the sympathetic system will make clear the anatomic relationship existing between the cerebrospinal and the sympathetic system, and also their control over the functional activities of the alimentary canal.

The sympathetic system, although not wholly removed from the influence of the cerebrospinal, as will be seen later, has to a certain degree an independent action of its own, by means of which it controls nutrition and visceral rhythm. The sympathetic system consists essentially of: 1, a series of small ganglia located on the posterior roots of the spinal nerves close to their emergence from the cord; 2, a series of ganglia located on either side of the vertebral column, extending from the base of the skull to the coccyx, these being joined together by means of nerve-fibers, at the top by the ganglion of Ribes, and at the bottom by the ganglion impar, thus making a continuous chain of ganglia, commonly known as the gangliated cord, or vertebral ganglia; 3, three large gangliated plexuses located in the thorax, abdomen, and pelvis, known respectively as the aortic, abdominal and pelvic plexuses, or prevertebral ganglia; 4, an innumerable number of smaller ganglia located in relation with the various viscera and blood and lymph vessels, known as the terminal, automatic, or visceral ganglia, and 5, a large number of nerve-fibers. These are of two kinds, communicating and distributory. The former connect the ganglia with each other and with the cerebrospinal nerves; the latter connect the prevertebral ganglia with the automatic ganglia located in the viscera and circulatory system. The spinal nerves are connected with the vertebral ganglia by means of the white rami communicantes, which pass out from the anterior roots of the spinal nerves, some fibers passing to the vertebral, others directly to the prevertebral without communicating with the vertebral ganglia. There are also gray rami, consisting of non-medullated nerve-fibers, passing back from the vertebral ganglia to join the main nerve trunk of the spinal nerve, part of the fibers passing back to the cord as vasomotor fibers to supply the vessels of the cord and its coverings, the remainder passing with the main trunk of the nerve to supply the blood-vessels of the periphery.

The white rami are composed of visceral and vascular fibers, which are medullated. The gray rami contain fibers which are non-medullated, and are vasomotor in their function. The white rami are of special import-

ance in connection with the question under consideration, in that they influence the functional activities of the alimentary canal. Certain of these medullated fibers of the white rami pass from the cord between the second dorsal and the second lumbar nerve, to supply the viscera and blood-vessels, which, according to Gaskell's nomenclature, are called splanchnics. These have been divided into three sets, according to location: 1, thoracic; 2, abdominal; 3, pelvic. The abdominal splanchnics consist of three main nerves, or trunks, designated the greater, lesser, and smaller splanchnics. The first is formed by branches from the sixth to the tenth thoracic ganglia. It pierces the crus of the diaphragm, and joins the solar plexus. The second or lesser splanchnic is formed by branches from the tenth to the eleventh ganglion. It pierces the diaphragm and joins the solar plexus. The third or smallest splanchnic arises from the last ganglion, pierces the diaphragm, and terminates in the solar plexus. These three nerves frequently communicate with one another, and all end in the aggregation of sympathetic nerve substance located posteriorly to the stomach and surrounding the celiac axis.

From this, the greatest of the sympathetic nerve-centers, fibers are distributed to all parts of the abdominal viscera. Its functions are to control the secretory, vasomotor, nutritional, and visceral ganglionic activities. The secretory functions of the intestinal glands are directly under the control of Meissner's plexuses, which are located in the submucous coat of the intestine, and are influenced by the solar plexus.

The vasomotor functions are controlled by means of fibers reaching the blood-vessels through the splanchnics, the greater splanchnic being the largest vasomotor nerve of the body. The nutritional and visceral ganglionic activities of the intestine, while under direct control of the visceral or automatic ganglia, are predominated over by the solar plexus. The independence of action possessed by the visceral ganglia is observed in the rhythmic peristalsis which occurs in the intestine when removed from the body. This is well illustrated in the intestine of the dog.

Auerbach's plexuses, between the longitudinal and circular coats of the intestine, extending from the esophagus to the rectum, are automatic motor centers, and it is through the influence of these that it is possible for peristalsis to take place in the intestine after removal from the body. When these centers are uninfluenced by any stimulus, there is a condition of aperistalsis.

While the automatic motor ganglia are found in both the large and small bowel, there is considerable difference in the rapidity of the peristaltic wave in each. The nerves influencing the small intestine cause rapid peristaltic movements, while those controlling the large bowel and rectum cause slow movements. This difference in activity between the large and the small bowel is undoubtedly due to the difference in innervation; the small bowel is influenced by fibers from the solar plexus, while the inferior mesenteric ganglion of the sympathetic system influences part of the transverse and the descending portion of the colon, the sigmoid flexure, and the rectum. It is a well-known fact that the peristaltic action of the alimentary canal is largely under the influence of the blood-supply, the latter in turn being controlled by the vasomotor nerves.

The relative amounts of oxygen and carbonic acid gas contained in the blood determine to a considerable degree the rapidity with which peristalsis takes place. The greater the amount of oxygen present in the blood, the

less the peristaltic movement; and the greater the quantity of carbonic acid gas present, the greater the peristaltic action. In the absence of other stimuli, and when blood containing a normal amount of blood-gases passes through the intestinal blood-vessels, the usual normal peristaltic movements occur.

The abdominal splanchnics, which contain inhibitory, motor, vasomotor and sensory nerve-fibers, when stimulated, materially alter the peristaltic movements of the small intestine. When the blood-supply of the intestine is normal, stimulation of the splanchnic inhibits peristalsis; when there is an increased amount of blood in the intestinal vessels, stimulation augments peristalsis. The opposite is true when there is an increased amount of arterial blood circulating through the intestinal vessels. The inhibitory fibers are easily exhausted by an increased amount of venous blood. The stimulation of the splanchnics after death always causes peristalsis, which is in all probability due to the fact that there are motor fibers present which remain excitable for a longer time than the inhibitory fibers. The vasomotor function of the splanchnic is observed by the constriction of the blood-vessels which takes place when it is stimulated. When the nerve is severed, there is dilatation of the intestinal vessels. The sensory function of these nerves is observed in the painful conditions arising in certain disorders of the abdominal viscera.

While the functions of the alimentary canal are almost entirely under control of the sympathetic system, the cerebrospinal system has a modifying influence through the action of the vagus on the stomach and the upper portion of the small intestine, and the action of the sacral nerves on the sigmoid flexure and rectum.

KNEADING MACHINE.

In certain diseases of the central nervous system, obstinate constipation results from a disordered state of the reflex mechanism governing the sigmoid flexure and rectum. As a result of this condition, the large bowel is unable to unload itself, while the small intestine keeps forcing its contents onward, thereby overloading the fecal reservoir, and producing obstinate constipation.

Constipation, then, may be considered a symptom characterized by prolonged retention of feces in the alimentary canal, caused primarily by inhibitory influences acting on the motor, vasomotor, secretory, and sensory mechanisms of the alimentary canal. As these mechanisms are chiefly controlled by the sympathetic system, constipation might properly be termed a neurosis of this system.

The etiologic factors in the production of the dis-

orders which give rise to the symptom constipation are many, and, as previously indicated, are those which exercise an inhibitory influence on the motor, vasomotor, secretory, and sensory mechanisms of the canal. The motor mechanism may be disturbed either generally or locally; generally, by anything causing an atonic condition of the muscular or glandular activities of the canal, as cancer, diabetes, chlorosis, anemia, etc.; locally, by strictures, sacculæ, tumors, gravid uterus, enlarged prostate, or anything which locally interferes with peristalsis. Localized pain from hemorrhoids, fissures, tumors, etc., is also an etiologic factor in the production of constipation. This is undoubtedly caused by the individual shrinking from evacuating the bowels because of the accompanying pain. This failure to evacuate soon interferes with the visceral rhythm, which, together with the retained fecal matter distending the canal, soon renders the musculature inactive. Although capable of acting independently, the vasomotor and secretory mechanisms in the main act in unison. This is due to the close relationship existing between the two mechanisms, each being more or less dependent on the other.

Since the amount and character of the secretion depends largely on the amount and character of the blood, a condition of intestinal anemia means an absence of intestinal secretion, which has a tendency to produce intestinal constipation. In these disorders in which there is a diminished amount of secretion, as fevers, and diabetes, constipation is a common symptom. In persons whose occupation keeps the perspiratory glands overactive, constipation is of common occurrence. Failure to respond promptly to the demands of nature in this respect interferes with visceral rhythm and soon results in a constipated condition of the bowels.

Constipation is more common in females than in males, due in part to the more sedentary and indoor occupation of the former, and in part to woman's manner of dress, which limits the action of the intestine, and is also a causative factor in the production of enteroptosis. Chronic constipation is a symptom in active and chronic disorders of the brain and cord, as meningitis and myelitis, and is also observed in tetanus. Diet undoubtedly plays an important rôle in the production as well as the relief of this symptom. It is a well-established fact that dyspepsia, with its long train of varying symptoms, of which constipation is a frequent one, has improper food for its origin in the majority of cases.

Drugs, which are almost universally used for the relief of constipation; but their use usually relieves the symptom by producing another of an opposite character, and one just as disagreeable to the patient. Instead of removing or curing the causative factors, purgatives, by their stimulation of the motor and secretory mechanisms, temporarily increase the sluggish peristalsis, thereby giving temporary relief. After the effect of the drugs has been expended, the original state of sluggishness, but to a greater degree, is usually reached, requiring a more powerful purgative to produce evacuation. This drugging process is frequently kept up until both the patient and the physician nearly exhaust themselves in trying to effect a cure.

Sometimes it is difficult to decide whether or not a person is suffering from constipation, because of the fact that what may be a normal number of evacuations for one person is inadequate for another. However, in a very large percentage of cases, one normal evacuation in twenty-four hours is considered sufficient, while two

evacuations in this period, or one in forty-eight hours, may be considered normal for a smaller percentage. In some one movement per week seems to be sufficient. Besides the retention of fecal matter, there is generally a sense of fulness, lassitude, mental depression, or headache; the tongue is usually coated; the breath may or may not be foul. These conditions are usually relieved as soon as a free evacuation is obtained, but will return again if fecal matter again accumulates. If the bowels remain constipated for a considerable length of time, symptoms of autointoxication are likely to appear. Under such conditions there is likely to be great depression, loss of appetite, sick headache, and even melancholia.

The diagnosis is usually easily made, the patient referring to this particular symptom along with a list of others common to digestive or other disorders. In some cases the diagnosis is not so readily made, and careful physical examination is required before the true condition of affairs can be learned. Diarrhea sometimes accompanies some of the worst cases of fecal impaction, due to the hardened fecal material producing severe irritation, which excites peristalsis, resulting in frequent expulsion of part of the bowel contents.

The prognosis of chronic constipation is favorable unless there is some change in the canal which is not readily remedied. The prognosis is usually favorable, being most so for those patients who can obtain treatment in a thoroughly equipped and scientifically conducted medical institution. While there is perhaps no other symptom so readily relieved by the use of drugs, it is a fact that the fewer drugs used in its treatment the better, for in the vast majority of cases their use is an irrational procedure. It is true that drugs usually promptly relieve the symptom and the patient is satisfied for the time being, but sooner or later the difficulty will return with renewed vigor, and a stronger purgative will then be needed to effect an evacuation. The remedies which once gave such prompt relief have not only failed to effect a cure, but, on the other hand, have been the means of contributing to the causative factors already at work in the production of this symptom.

Constipation, like any other symptom of a general disorder, must of necessity be relieved by directing the remedial agents at hand toward the removal of the cause. The methods of treatment which have been found to be most satisfactory in the cure of chronic constipation are unfortunately such that many of them can not be employed by the general practitioners so as to give the most satisfactory results. Many of these patients require the combined effects of a most carefully regulated diet, hyriatic and electric applications, mechanical and manual Swedish movements, and carefully regulated exercises.

In the treatment of chronic constipation the question of diet is of paramount importance. It is through this channel that the foundation of most digestive disorders is laid. Dyspepsia, so universal in America that it is sometimes termed "the American Disease," is largely caused by dietetic errors, the principal one being undercooked and imperfectly disintegrated starchy foods, giving rise to amyloaceous dyspepsia. Fermentation from this cause results in the production of poisonous substances, these in turn giving rise to autointoxications. These poisonous substances circulating in the blood have a deleterious influence on the delicate structures of the nervous system, which react in various ways, giving expression to the almost innumerable symptoms common to the different forms of digestive disturbance. The use

of condiments and highly seasoned foods has a powerful influence in causing inactivity of the bowels.

The writer is of the opinion that the diet is one of the first factors to be considered in the establishment of a cure for chronic constipation. The patient should be instructed to adopt as nearly as possible an aseptic dietary. This should consist of foods containing the proper amount of carbohydrate, nitrogenous, and fatty food substances required to nourish the body properly. The carbohydrate foods, which make up the largest share of our food, should be taken in the most easily digested and assimilable form obtainable. Foods containing a very large percentage of starch should be thoroughly cooked. Ordinary cooking by means of boiling is not sufficient, for the raw starch by this process is simply changed to amyloextrin, or soluble starch. The soluble starch, however, can be further digested by means of

dry heat. When starch is subjected to a very high degree of dry heat, or moist heat under pressure for a sufficient length of time, it is converted into erythro- and achro-odextrin. The latter, when subjected to the action of the saliva, is converted by the ptyalin into maltose, a product capable of immediate absorption. Food prepared in this manner is so readily digested and absorbed that it relieves the stomach and intestine of the burden of retaining a large amount of starchy material which, under the favorable conditions frequently met with in disorders of digestion, is so prone to undergo putrefactive changes. By the use of such thoroughly cooked starchy foods these fermentative changes are lessened, or entirely checked. The question of nitrogenous and fatty food substances is also an important one. The animal kingdom is relied on to a large extent to furnish these two important elements. The readiness with which animal foods undergo putrefactive changes renders them questionable, especially for those cases in which fermentative changes readily take place. The nitrogenous and fatty material, which can readily be obtained in sufficient quantities and proper proportions from grains, including the legumes, and edible nuts, does not have the tendency to decompose that the same foods from the animal kingdom do. Besides possessing this important qualification, grains are also a very wholesome and economic source of food-supply. When one buys a pound of zwieback or rice, he is not paying for 70 or 80 per cent. of water, as he does when he buys a pound of beefsteak. On the contrary, he is getting more than 80 per cent. of food; he is also obtaining his food direct from nature's garden, and not allowing it to be utilized by some other animal no more capable of storing up energy from it than himself. The use of such pure foods, properly cooked, can not have other than a normal influence on the digestive tract.

Another source of food-supply which might be drawn upon more extensively to good advantage is fruits. In these the quantity of nourishment is not great, but what is present is readily digested and assimilated. Nature does in the fruit, during the ripening process, what art does in the cooking of starch by dry heat, i. e. she converts the starch into sugar. Besides the sugar—and a greater or smaller amount of nitrogenous and fatty food substances—which varies according to the variety, fruit contains succulent juices which promote an abundant flow of the digestive fluids, and furnish the body with a considerable amount of pure water and salts, both of which are essential to proper metabolism. Most fruit juices also have an inhibitory action on germ growth. From the three sources of food mentioned, viz.: fruits, grains, and nuts, an ideal dietary can be selected for both the sick and the well. It was the original diet of man, as outlined in Genesis, and a dietary that will make a sick man well and keep him well. George Cheyene, in his essay on "Health and Long Life," written in 1725, says, "Animal food and strong liquors seem not to have been designed for man in his original make and frame, but rather indulged, to shorten the antediluvian length of life, in order to prevent the excessive growth of wickedness."

In selecting a dietary for a patient troubled with chronic constipation, such dry foods as zwieback, browned rice, etc., are found to be palatable, easy of digestion, and at the same time to present bulk enough to excite gentle peristaltic movements. Nuts, in order to be of service, should go through a special process of preparation. At the present time such specially prepared nut foods as protose, nuttolene, malted nuts, granuts, bromose, and a number of others, can be found on the market. A careful analysis of these nut foods has been made in our laboratory, and they have been found to be sterile and wholesome, and to contain nitrogenous and fatty material in proper proportions to meet the demands of the human economy. A diet consisting of granose, browned rice, protose, steamed figs, prune marmalade, and ripe fresh fruits such as apples, strawberries, oranges, etc., almond butter, and cream, is so palatable, nourishing, and easy of digestion that the most fastidious epicure could find no fault with it.

The patient should be instructed to use no liquid with his meals, other than that which is contained in the food. A glass of cold water half an hour before each meal, and as much hot or cold water as is desired $2\frac{1}{2}$ to three hours after each meal, will prove beneficial. He should also be instructed to eat the dry food at the beginning of the meal. The dryness of the food will necessitate thorough mastication and insalivation, resulting in the thorough digestion of the starch.

After arranging a proper dietary and giving the patient explicit directions concerning it, treatment should be instituted at once to relieve him of the accumulated mass of fecal material. This can usually be done by means of cleansing enemas of warm water, using from one to two quarts at a temperature of 100 to 102 F.; if this fails, two ounces of olive or sweet oil followed by a strong solution of soap-suds, one to four pints, at a temperature of 100 to 102 F. The cleansing enemas should be employed for three successive days, and should be followed by the graduated enema, which is given as follows: The first day after the last cleansing enema use seventy-two ounces of water at a temperature of 102 F.; the second day, 64 ounces at 98 F.; the third day, 56 ounces at 92 F.; the fourth day, 48 ounces at 88 F.; the fifth day,

40 ounces at 84 F.; the sixth day, 32 ounces at 78 F.; the seventh day, 24 ounces at 74 F.; the eighth day, 16 ounces at 70 F.; the ninth day, 8 ounces at 64 F.

The effect of this treatment is to keep the lower bowel from becoming obstructed, and at the same time to give tone to the walls of the bowel by gradually reducing the temperature and the amount of water used. The impressions thus made on the mucous membrane of the bowel reflexly excite the splanchnics, which in turn, through Auerbach's and Meissner's plexuses, excite normal peristalsis. This treatment should be taken at the same time each day to establish a rhythmic movement of the bowel. The cold also stimulates the secretion of the liver, and the portal system, which in turn affects the intestinal circulation. Besides the graduated and cleansing enemas, other hydratic procedures, such as the hot enema, the cold enema, the *umschlag* or moist abdominal bandage, the cold sponge both, cold mitten friction, cold douches, and alternate hot and cold douches to the abdomen, wet sheet pack, and cold sitz bath, are very effective through their influence on the sympathetic centers and splanchnic nerves in exciting the various functional activities of the intestine. The Scotch douche, which consists of rapidly alternating applications of heat and cold, when applied to the abdomen, has a strong tonic influence on the abdominal muscles and also on the involuntary muscles of the intestine. So far as external applications are concerned, the Scotch douche is the one par excellence in exciting to greater activity the motor, vasomotor, and secretory functions of the abdominal viscera.

Abdominal massage, both manual and mechanical, is a very valuable aid in strengthening the abdominal and visceral muscles. Special movements to replace viscera are also valuable. An atonic condition of the abdominal muscles favors enteroptosis, which might properly be termed an etiologic factor in chronic constipation. By properly executed massage movements the abdominal muscles are strengthened and the viscera replaced. In cases of prolapsus of the stomach, after replacement by means of carefully executed manual Swedish movements the organ may be retained in place by the natural abdominal supporter. Great relief is frequently experienced by the use of this support.

The support should be adjusted while the patient is in a reclining position.

The value of abdominal massage in the treatment of chronic constipation has received insufficient attention, undoubtedly from the fact that there are comparatively few scientifically trained masseurs. The bungling work frequently done by many masseurs, instead of giving satisfactory results, has frequently resulted in increasing the patient's discomfort. When given properly massage works wonders in relieving a constipated condition of the bowels: by it the blood-supply is increased, the musculature is toned up, normal secretory functions are established, all of which aid in the re-establishment of a normal peristalsis.

Mechanical devices have been constructed, which, when judiciously employed, give excellent results. Of these the one employed in giving abdominal kneading is of great service in relieving constipation. The apparatus consists of a table with a large aperture near the center of the top. In this opening plays a series of six vertically-placed bars. Each bar is separately connected with an eccentric, to give it an independence of motion. When in motion, these bars have an undulatory movement. The top of the table is so constructed that with

each vertical movement of the bars it moves back and forth, thus bringing the entire abdomen in contact with the kneading bars.

Cannon-ball massage is a valuable adjuvant to other forms of mechanical and manual treatment. This treatment may be employed by the patient himself. It consists in rolling a four-to-six-pound cannon-ball covered with leather over the colon from right to left.

Electricity, although little utilized for the relief of the condition under consideration, in many cases can be used with good results. This is particularly true of the sinusoidal current, which can be used with great advantage where there is an euteroptosis due to relaxed abdominal muscles. When the abdominal muscles are relaxed, the stomach, bowels and other viscera become pendant, and drag on the branches of the prevertebral ganglia of the abdomen, resulting in reflex disturbances which give rise to pain and other symptoms, among which constipation is not an infrequent one. After replacement of the viscera, the application of the slow sinusoidal current to the abdominal muscles, produces results which can not be accomplished by any form of passive exercise.

CANNON-BALL MASSAGE.

By means of a rectal electrode introduced into the rectum, and a pad electrode placed over the abdomen, the musculature of the lower portion of the alimentary canal can be gently exercised by the rapid sinusoidal current. This form of treatment gives most excellent results in those cases in which there is a semiparalyzed condition of the musculature of the rectum due to failure on the part of the patient regularly to evacuate the bowel.

Exercises calculated to develop the body as a whole, and especially to develop the abdominal muscles, are of great importance. If the general musculature of the body is in an atonic condition, that of the alimentary canal is likely to be in a similar condition, and vice versa.

It is indeed surprising to note the readiness with which a functionally disordered sympathetic system will respond to such rational measures as have been outlined, and when these are directed toward assisting the *vis medicatrix naturæ*, the most gratifying results are obtained.

ONE OF the features of the Exposition of Hygiene at Naples is a reproduction of the heating, lighting and water-supply arrangements of a Pompeian house. Naples now boasts of the finest water-supply in the world since the waters of the Serino have been piped into the city, and the transformation of most of the famous Naples slums into handsome boulevards during the last ten years is an interesting feature to be seen in connection with the exposition.

THE PATHOLOGY OF CRIMINAL ABORTION.*

BY MAXIMILIAN HERZOG, M.D.

PROFESSOR OF PATHOLOGY IN THE CHICAGO POLICLINIC.
CHICAGO.

The pathology of criminal abortion has to establish: 1. The causal nexus of premature expulsion of the ovum with the employment of internal medicinal or external mechanical means, adopted for the accomplishment of the desired criminal attempt. 2. To account for the illness or death of the mother during or after abortion.

The latter part of our subject, that referring to death of the mother, is comparatively easy to handle, because in the latter event cases have been frequently thoroughly investigated. The employment of modern histologic and bacteriologic methods to clear up the pathology of such cases is within easy reach. It is different when we approach the other part of our task. It is a notorious fact that only a small minority of the non-fatal cases, more particularly of the cases not complicated with serious, threatening disease of the mother, ever come to the notice of reputable, scientific members of the profession. Consequently our observations are made on a very small fraction of the cases, of which necessary details are, as a rule, lacking. Our data, therefore, lack reliability when we want to draw correct conclusions or establish general principles. Nor is the numerical insufficiency of the material that may be studied, compared with the enormous total figure of cases, the only ground why our conclusions must be unsatisfactory. The main reason lies in the fact that we know so little about the intrinsic cause of causes which normally lead to the beginning of the act of parturition at full term.

By far the largest number of criminal abortions are brought about by internal, medicinal agencies which enjoy the reputation of being "reliable abortifacients."

Lewin, in a recent extensive monograph on "Abortion by Poisons and other Means," considers in general and in special the dynamics of these abortifacients. In the subsequent consideration of the physiologic and pathologic effects of these abortifacients, we follow the views of the distinguished pharmacologist who has gone over the subject in a very thorough manner.

Lewin states that there are certain medicinal and other preparations which have the property to primarily or secondarily exert a pathologic influence over the uterus and the ovum contained in it. We possess certain poisons which can influence the uterus in such a manner that phenomena similar to those in parturition are produced and that the ovum becomes detached from the fruit bearer. But all internal means which, if taken in sufficiently large doses, may bring about this cycle of changes, are substances poisonous to mother and child alike. They have the property to bring about morbid disturbances of physiologic functions. Even a premature irritation of the muscularis uteri itself must be looked on as something pathologic attaining its highest degree in tetanic contraction. Abortifacients can neither theoretically nor practically be looked upon simply as means to produce prematurely a normal labor. In fact the labor and expulsion are generally brought about secondarily. The primary factors are the damaging pathologic influences disturbing the nutrition, or killing the embryo outright. Internal abortifacients generally act first by indirectly disturbing the nutrition of the embryo, by making the mother sick or even moribund, by producing hemorrhages and by detaching the ovum from the uterus. Artificial abortion by internal means is to

*Read before the Physicians' Club of Chicago, March 26, 1900.

be judged in the same light as spontaneous abortion in consequence of disease of the mother such as syphilis, typhoid, etc. The hemorrhages caused by internal abortifacients occur between the fetal membranes, into the amniotic cavity or into the placenta; they lead to a loosening or to a separation of the ovum.

Other pathologic processes noticed in connection with the internal use of abortifacients are hyperemias in distant organs of the mother, inflammatory processes in the gastrointestinal tract, the pelvic organs and in the ovum and its envelopes. Some abortifacients primarily and particularly act on the gastrointestinal tract and extend their influence secondarily only to the pelvic organs.

As a rule, the ovum is expelled when the toxic effects of the internal abortifacient reaches its climax, or shortly after this period.

A few of the more commonly used internal means to induce criminal abortion may be cited to show how these substances act as poisons producing grave pathologic processes, damaging both mother and child. The pathology of some of these drugs and chemicals has been studied in a number of fatal cases and also experimentally on animals.

Phosphorus, used extensively as an abortifacient in some countries, for instance in Sweden, brings about the general symptoms and changes of systemic poisoning and acts as an abortifacient by producing hemorrhages which detach the fetal membranes. This has been shown experimentally on pregnant bitches.

Oleum ruæ produces gastroenteritis, metritis and hemorrhages.

Tansy (*Tanacetum vulgare*) has in fatal cases brought about convulsions, cyanosis, spasmodic respiration, hemorrhages from the lungs and bloody discharges from the uterus and vagina.

Aloe, when used in doses large enough to bring about abortion, produces inflammation of the pelvic organs subsequent to gastroenteritis, nephritis, and hemorrhages between the fetal membranes.

Oleum sabine, one of the most powerful means to bring about tetanic contractions of the uterus on account of its supposed action on the lumbar centers, produces hemorrhagic inflammation in the gastrointestinal tract and in the kidneys. In a fatal case of abortion produced by Savine, a perforation of the stomach was found post-mortem.

Ergot, which has been used for more than a thousand years, in China, and which is first mentioned in Germany as an abortifacient in 1573, causes tetanic uterine contractions, contraction of arteries in general, increase of the blood-pressure, general convulsions.

From the studies which I have made on the normal and abnormal uterine placenta and the placenta in tubal pregnancy, I am inclined to believe that the first step in bringing about spontaneous abortion is very frequently a hemorrhage into the intervillous space and hemorrhages into the spongy layer of the decidua serotina. These hemorrhages come from the utero-placental sinuses, and their effect must be, as a rule, a loosening, eventually a separation of the ovum. It appears to me that a number of internal abortifacients act in the same manner. They first produce poisoning of the mother with circulatory disturbances and changes in the blood-pressure; these then lead to intervillous hemorrhages and hemorrhages into the spongiosa of the decidua serotina and loosening of the ovum. In this manner the pathology of the induction of premature delivery by internal abortifacients would be entirely analogous to the initiatory steps in spontaneous abortion.

Criminal abortion is often brought about by external and mechanical means and manipulations, instrumental separation of the fetal membranes, perforation of the amniotic cavity, introduction of a foreign body into the uterus, etc. As long as these manipulations do not lead to an infection or a serious trauma, with or without an infection, there is little to be said about them from a pathologic point of view.

If, however, as so frequently does, serious trauma and infection occur, then we meet morbid processes and changes which are of much pathologic interest. The question may here be asked: Is the danger of infection after criminal instrumental abortion greater than after the legitimate induction of premature labor? The danger in the former case is *per se* not greater than in the latter case. But criminal instrumental abortions rarely, if ever, are performed by careful, conscientious aseptic physicians, but, as a rule, by unscrupulous uneducated individuals unacquainted with the theory and practice of modern asepsis. For this reason criminal instrumental abortions are so frequently followed by septic complications. Grave traumatism is also one of the complications often met with in successful as well as unsuccessful attempts at criminal abortion.

Marsais collected 68 cases of wounds of the uterus produced in the performance of instrumental criminal abortion. Maschka reported 5 cases of fatal perforation of the uterus during attempts to rupture the membranes. Death occurred from septic peritonitis. Hektoen, Denslow Lewis, Henrotin and a large number of others have published reports of such cases of rupture of the uterus. The instruments used for manipulations to induce premature delivery in making perforating wounds have sometimes slipped away from the operator and have entered the pelvic or general abdominal cavity. The accident of perforating the uterus may, *per se*, not be followed by any dangerous sequelæ or complications, and pregnancy may go on undisturbed or a uterine pregnancy may be changed into an abdominal one, the fetus escaping through the wound of the uterus into the general abdominal cavity. Cases of the latter type have been reported by Leopold and Henrotin. The factor which constitutes the great danger in serious or even minor traumatism produced in attempts at criminal abortion is the same that threatens in every manipulation to induce premature delivery, namely, the occurrence of infection. By far the majority of cases of instrumental criminal abortion, with or without serious traumatism, which end fatally succumb to sepsis, which manifests itself in the form of septic pelvic or septic general peritonitis. The local reaction is characterized by a seropurulent, or fibrinopurulent exudation found on the pelvic or abdominal peritoneum or on both. In cases rapidly fatal, the local changes are often circumscribed and confined to small areas. In subacute cases there may be abscess in the uterine muscularis, the parametrium and perimetrium. Lingering cases of sepsis after abortion often develop distinct metastatic abscesses in joints, and metastatic septic endocarditis. A form of circumscribed septic infection of the pelvic organs following criminal abortion, to which Henrotin has repeatedly called attention, is the ovarian abscess. For such ovarian abscesses following abortion the corpus luteum verum, or a corpus luteum cyst furnishes the fertile soil for the primary seat of the septic process. The latter may remain localized if operation through the vagina is done in proper time, or it may lead to a fatal general septic peritonitis. It has been my privilege within the last three or four years to examine a number of Dr. Hen-

rotin's cases of ovarian abscess following abortion, and I have found in such cases, as the cause of the septic process, staphylococci, streptococci, diplococci, and the colon bacillus.

Tetanus has also been observed following criminal instrumental abortion with severe traumatism. Sudden death in consequence of embolism has been recorded following intrauterine manipulations with instruments and intrauterine air, water, or glycerin injections.

If now we attempt to outline the general principles of the pathology of the criminal abortion, we may perhaps characterize them as follows:

1. Premature expulsion of the ovum, if it occurs as the result of the internal administration of abortifacients, is an integral part of the general toxic symptoms, changes and processes due to those drugs or chemicals, acting in their deleterious influence on both mother and child.

2. Premature expulsion of the ovum if it occurs after detachment of the membranes, perforation of the amniotic cavity, etc., is brought about, because after such manipulations which may or may not bring about the speedy death of the embryo, the ovum acts as a foreign body and stimulates the uterine muscularis to contractions, or because intervillous or interdecidual hemorrhages occur.

3. Septic infection in its broadest sense, following criminal abortion is—*ceteris paribus*—not fundamentally different in its general and special pathology, its sequelæ and complications from other septic infections.

I have almost entirely neglected a pathologic consideration of criminal abortion brought about by copious hot douches, irritating applications to the cervix, etc. I have not been able to find a firm physiologic basis for even a modest attempt at explanation of the causal nexus between these means and the desired or accomplished result. I have to repeat in this respect, in conclusion, what was said above in the beginning: The trouble in trying to clear up the intrinsic pathology of certain types of criminal abortion lies in the fact that we practically know nothing definite about the primary factors which initiate normal labor at full term.

COMPLETE OCCLUSION OF BOWEL.

BY DWIGHT E. CONE, M.D.

BINGHAMTON, N. Y.

Nov. 2, 1899, I saw Mrs. A. B. R., of Greene, N. Y., in consultation with Dr. Williams of that town, who gave the following history: An American, aged 63, her family history was good. She had been married for forty-five years and had one child forty-two years ago. She had been troubled with what she called "bilious" attacks ever since she could remember. About thirty-five years ago she had a very severe illness which was described as inflammation of the bowels and, though "given up" to die, she gradually recovered. Since that time her troubles with her stomach, or "bilious attacks," have been more or less constant.

On September 4, last, she was attacked with vomiting and free purging, and after a week felt some better. In a few days there was another and one week later a third attack lasting about one week, after which there was no more purging, but the stomach sooner or later rejected everything taken, nothing having been retained for more than ten hours.

She was attended by a homeopath for four weeks and, for the week previous to my seeing her, by a clairvoyant. Dr. Williams saw her for the first time about six hours

before my arrival. There had been rapid emaciation, due to inability to retain any nourishment except rectal enemas, while these had not been able to keep up the vital forces. Temperature was 99; pulse 84 and feeble. There was no headache, and but slight soreness over the abdomen, though no point of marked tenderness. The bowels were much distended with gas so that their outline could be easily discerned through the abdominal wall. There was no dullness on percussion, but tympanitis everywhere. The urine was practically normal. Everything given by mouth distressed her, with the exception of 1/10-gr. doses of calomel and a small quantity of peroxid of hydrogen and "alkalol" in water. There had been no movement of bowels for four weeks, except as enemata were given, and the question that confronted us was whether the obstipation was due to some obstruction or paralysis of the muscular coat. The vomitus consisted of whatever might be taken, together with a tasteless and odorless frothy mucus. On November 5 there was no change in conditions, except that the patient was weaker and more easily exhausted. A saturated solution of sulphate of magnesia to the extent of twenty-four teaspoonfuls—a teaspoonful every ten minutes—was given with no result. Gentle massage over the bowels seemed to give relief. A large enema brought some fecal matter and gas. On November 9, when I saw her for the third time, the pulse was very rapid and the vital forces nearly exhausted, the temperature being 97, the pulse 132. There was no fecal vomiting, although the stomach refused to retain even water. There was no pain, except distress produced by distension of the bowels with gas and pressure against the diaphragm. Deeming the case *in extremis*, I advised against any operative measures. The patient died November 10.

Autopsy was held November 11, with Drs. Williams of Greene, Hitchcock of South Oxford and myself present. The body was very much emaciated and the abdomen tympanitic from the distended bowel. An incision extending from the ensiform cartilage to the symphysis disclosed no subperitoneal fat. The cecum and colon, ascending and transverse, were enormously distended with gas, the small intestine but slightly distended. At the junction of the transverse and descending colon there was a constriction five-eighths of an inch in length and three-quarters in diameter, which completely occluded the lumen of the bowel. On the gastric side of the obstruction there were five old cicatrices, probably from ulcers which had existed at some time, but were now only in evidence by their scars.

There was about one quart of liquid feces in the large intestine, and probably much more in the small, but there were no enteroliths larger than a pea and very few of these. On the mesenteric side of the constriction there was a firm band of adhesion, fan-shaped, with its broad extremity attached to the parietal peritoneum. Attempts to loosen this attachment caused the bowel to rupture on the gastric side of the obstruction. The bowels were emptied of gas and feces and the diseased portion excised. The liver was displaced to the left so that the left lobe lay entirely to the left of the stomach, and the right lobe lay directly on the stomach, as did the distended colon. The stomach was empty.

All the organs in the body were healthy and normal with the exception of the point described in the colon. This constricted part consisted of cicatricial tissue only, indicating that it was caused by ulceration and destruction of mucous and muscular coats of the bowel, and subsequent contraction.

The chief points to me are: 1. Why did we not get fecal vomiting? 2. Why did she not have either localized pain, tenderness or headache? 3. Why had this existing condition of incomplete closure not sooner become complete? 4. Should anything have been done for this patient in the line of surgical operation at the time I saw her?

My answer to these questions would be as follows:

1. The fact that the obstruction was so far removed from the stomach and the enormous size of the bowel beyond the ileocecal valve will in a measure account for our not getting fecal vomiting. Also the pressure of the liver and the colon on the stomach prevented the accumulation of any amount in the stomach, forcing it back by mechanical pressure and thus not only preventing the accumulation of food, but also acting as a cut-off for anything regurgitating from the bowels. Another thing is the length of intestinal tract available for absorption.

2. It would be conjectural to say why she did not have either pain, localized tenderness or headaches. My theory is that in the attack in September last, enough irritation was produced at the ulcerated point to cause inflammatory action sufficient to entirely close the lumen of the partially occluded gut, thus producing complete intestinal obstruction, but so low down in the bowel that absorption still took place. Her diet had been very simple and so little of it was retained after complete closure that there was not enough excrementitious matter to produce auto-infection. The real mischief, in my opinion, was done thirty-five years ago, hence there was no acute congestion or pressure on nerve filaments, but simply the discomfort caused by the great balloon in the abdominal cavity.

3. As to why this existing condition of almost complete closure had not sooner become complete, her history was that for the past three years her bowels had been more regular and her health much better, until the attack in September. Still, the same caution in regard to the diet had to be observed. Now why it did not sooner cause a wreck, no one knows.

4. As to whether anything should have been done in a surgical way at the time I saw her, I presume many would say a resection should have been made at once. But we should bear in mind that Dr. Williams had seen her but a few hours before I saw her, also for the first time. We had nothing but her history as given us, and she was then so weak that she would have to rest after every sentence and then the sentence had to be short. Her emaciation was marked and there was no vital energy stored up, the reserve, as the result proved, being nearly exhausted. Again, a median exploratory incision would not have given room to operate on the diseased portion, and the only way would have been to close the central incision and make an oblique incision parallel with the ribs on the left side, directly over the constricted portion of the bowel. This would have been a formidable undertaking under any circumstances, even with a large reserve of vital force to rely on for recovery. Still, I feel now that were I to meet a similar condition again, I would urge an exploratory operation.

THE EDITOR of the *N. Y. Christian Advocate*, Dr. Buckley, recently said that "Christian Science," as a system of therapeutics, would have died ere this if it had not been put forward as a religion; and it would have died as a religion if it had not been put forward as a system of therapeutics.

QUININ AMBLYOPIA.

BY M. COPLAN, M.D.

EX-HOUSE PHYSICIAN, LEBANON HOSPITAL, NEW YORK CITY.
CLEVELAND, OHIO.

Mrs. S., with her boy, 3 years old, called at my office on Dec. 2, 1899, stating that her child had not been feeling well for the last few days, and that his bowels were very loose. The family history was negative, the child's complexion was sallow, with slight anemia, and a coated tongue. He looked dull and depressed and refused to answer any question, not taking any interest in his surroundings. Temperature per rectum was 98.8 F., pulse 106, respiration 38. His mother stated that his bowels moved about eight or ten times during the day, that he had no appetite, and had ceased to play as he once did.

I prescribed small doses of calomel followed by magnesium sulphate and an antidiarrheal and tonic mixture, put him on a liquid diet, told the mother that she must keep him in bed, and if he was not better to let me know.

On Dec. 3, at 9 a.m., I was called and found my little patient vomiting, with a flushed face, injected eyes, the surface of the body hot, and asking for water all the time. Temperature per rectum was 102 F., pulse 126, respiration 44. Thoracic and abdominal examination revealed a yellowish skin, enlargement of the liver and spleen, particularly the latter, and tenderness all over the abdomen.

The mother said that "the child felt very cold about an hour ago, and acted as if he would have had convulsions;" also that he complained of feeling cold before, and sometimes he shivered, but she did not pay much attention to it, thinking that it was due to the weather; she was unable, however, to say when he commenced to complain of feeling cold, and how often.

With the aid of the microscope I diagnosed it a case of malarial fever of the quotidian type. I ordered cool sponging and cold lemonade frequently, and prescribed the following:

R. Quinina sulph. 3
Syrup yerbe sante comp. 60
M. Sig. One teaspoonful t. i. d.

I ordered her, verbally, to give two teaspoonfuls the next morning, about 7:10 o'clock, after the child had taken some food; after that she was to follow the previous directions.

I called on December 4, about 2 p.m., and found my patient asleep, and being informed that he was much better and did not have any attack that morning, I left without making any further inquiry, promising to come earlier the next day. On the following day I saw him about 10 a.m., and was astonished to find him complaining of not being able to see, asking where he was and why they did not light the gas or the lamps.

On questioning the mother, I was told that she gave him two teaspoonfuls four times the previous day, and once on the morning of the same day, so that he had taken about 30 grains in twenty-four hours. On examination I found total blindness of both eyes. The ophthalmoscope showed a pale optic disc, and it was very difficult to make out the condition of the retinal arteries. I at once discontinued the quinin and prescribed strychnin, 1/200 gr. t. i. d. The patient recovered gradually, and on the fifth day, viz., on December 10, could see almost as well as he did before.

A similar case came under my observation during my service at the Lebanon Hospital, which history I will describe in brief:

Mrs. H., aged 30, was admitted to the hospital complaining of headaches and having chills and fever. We soon diagnosed a very obstinate case of malarial fever of the duplicated quotidian type, paroxysms taking place between 7 to 8 a.m. and p.m.; temperature ranging between 104 and 106 F. Quinin sulphate, in doses of 15 grs. three times daily, was administered without any effect. Pilocarpin hypodermically, ergot, liquor potass. arsenitis, methylene blue, piperin, succus lemonis, etc., was tried without preventing a single paroxysm. With the approval of Dr. Zemansky, the visiting physician, we gave her quinin sulphate, 30 gr., three times a day, and 45 grs. two hours before the paroxysm usually occurred; the results were most satisfactory, reducing the temperature in the morning to 100 F. and preventing the afternoon paroxysm entirely, the temperature coming down to 99 F.

On the following day, when I made my usual morning rounds, the patient cried out: "Doctor, I am blind, I can't see, where am I?" She had then received 150 grs. of quinin in twenty-eight hours. On examination we found total blindness of both eyes. Dr. Wm. Cowen, the hospital ophthalmologist, examined the patient and found the optic disc pale, and the retinal blood-vessels very much narrowed. We at once discontinued the quinin, and prescribed strychnin sulphate and digitalis, the patient recovering full sight on the eighth day.

Looking up the literature at my command on this subject, while many cases of quinin amblyopia have been reported in adults, very few have been reported in the very young. Burns¹ reported a case where a child, 3 years old, ingested 30 grs. of quinin in eighteen hours, causing amblyopia. Harlem² reported one where an adult took 100 grs. in a few hours, causing amaurosis. Elis³ reports a case where an adult took 120 grs. in twenty-four hours, causing total blindness. All recovered full acuity, except the last one, which only recovered some of his former vision.

REPORT OF UNIQUE CASE OF APPENDICITIS, WITH SOME REMARKS ON TREATMENT.*

BY JAMES T. JELKS, M.D.

HOT SPRINGS, ARK.

On the night of April 26 I received a note from Dr. A. S. Garnett, asking me to see a patient with him, in consultation, a woman with the following history: On the Friday previous she was feeling very well indeed and climbed Hot Springs Mountain with a party of friends. Saturday night she was taken ill with pains in the abdomen, which demanded relief. Dr. G. A. Hebert was called and found her suffering with the pain and a temperature of 100 F. He gave her a dose of morphin hypodermically, which relieved her. Sunday she had some pain, with a temperature of 101 F., and this lasted through that day and night. Monday found her free from fever, with normal pulse, but slightly irritable stomach, and vomiting whatever she took. Her bowels responded to a cathartic Sunday night and Monday morning. Tuesday they refused to move, nausea increased, temperature and pulse were normal, and the abdomen began to distend. Wednesday the bowels were constipated and there was no escape flatus; the pulse and temperature were normal and there was consider-

able vomiting with the bowels greatly distended, little or no pain.

Wednesday night at 11 o'clock she vomited stercoraceous material, and it was at this time that I was sent for and met Drs. Garnett, Greenway and Hebert in consultation; I found the abdomen distended, and slight pain in the epigastric and appendicular region. The vomited material was unquestionably stercoraceous in character. The temperature was normal, pulse 65, full and regular. The face of the patient bore no mark of suffering nor serious illness, whatever. The gentlemen present had diagnosed intestinal obstruction possibly from bands of adhesions. This diagnosis was encouraged by reason of the fact that six years previously she had one ovary removed by the late J. H. Etheridge of Chicago. Her health did not improve after this operation, and one year ago, while in San Francisco, the other ovary was removed. At this latter operation many bands and adhesions were found, hence it was easy for us to believe in the probability of obstruction produced by bands, in the present illness.

In this light of the case I advised surgical interference in the hope of saving the life of the patient. The situation was explained to her and her husband and they readily consented. Thursday morning she was removed to the Ozark Sanitarium, and with the assistance of Drs. T. J. Crofford, of Memphis, A. S. Garnett, G. A. Hebert and John A. Gaines, of Hot Springs, I operated. An incision was made between the umbilicus and pubic regions two inches in length, through the old scar. I found the omentum adherent, hence I enlarged the incision upward until I got above the line of the omental adhesions. These adhesions were separated by the fingers, and I began to look for intestinal hernia over some band. The intestines were very much distended with gas, and very dark in color; in spots quite black. With the assistance of Dr. Crofford they were rolled out and covered with warm, moist, sterilized towels. We searched for twenty minutes or more expecting to find an intestinal hernia over the band or bands. Failing in this we turned our attention to the appendicular region, where we found the gangrenous and perforated appendix, which was removed in the usual manner and the intestines rolled out of the abdominal cavity. We found the peritoneum ruptured in three places, from overdistention with gas. The appendix having been removed, the abdominal cavity was thoroughly washed out with sterilized salt solution; the intestines also received a thorough washing in the same solution; they were now open in two places and, by the use of rubber gloves, they were easily stripped through my fingers and emptied of gas and feces. These openings in the intestines were closed by Lembert sutures and the intestines replaced in the abdominal cavity. Iodoform gauze was carried to the bottom of the pelvis, and around the stump of the appendix; the cavity again washed out with sterilized salt solution and the abdominal wound closed with through-and-through sutures of silkworm gut, and the patient carried to bed in an exhausted condition. Chloroform was used as anesthetic, with occasional changes to ether. Dr. Gaines, the anesthetizer, was compelled to give her two extra doses of strychnin, 1/20 gr. each, but she died at 8:20 p.m. No post-mortem was held.

This case teaches one lesson which was new to me, that a patient may be dying of general septic peritonitis with a normal pulse and normal temperature. In my experience this is unique. Had I known this patient was suffering from a septic peritonitis as the result of

*Read before the Mississippi Valley Medical Association, Chicago, 1899

a perforated and gangrenous appendix, I would not have operated, because such operations do no good, and bring the work of the abdominal surgeon into bad repute. We may set it down as a rule, to which there are few, if any, exceptions, that general septic peritonitis of thirty hours' duration always results fatally, and that surgery offers these cases no hope.

The question of treatment of appendicitis is a very serious one, and is not yet settled. Much has been written on this subject within the last few years. About twenty-five hundred books and monographs have been printed and the last word has not yet been said. As we see the patients they may be divided into two classes, those seen early before pus has formed or before perforation has taken place, and those seen later.

In forming an opinion as to operative or non-operative treatment, two other factors are also to be taken into consideration, viz.: the mortality when treated medicinally, and the operative skill and technique of the operator. Whether we will or not, these last two elements should have considerable weight in determining the line of procedure. For instance, given twenty cases of appendicitis occurring in the course of five years, in the ordinary village or town, are the majority of patients safer under the medicinal or surgical treatment? I am not discussing the ideal treatment under ideal surroundings and by ideal operators. That is probably settled. We have facts to face, not theories. Then what are these facts? A patient in an ordinary house, attended by the average village physician, is seen for two or three days and finally appendicitis is diagnosed, and if he does not operate the village surgeon is called in. Possibly in the course of his ten or fifteen years of practice he has operated on the abdomen as many times, and the doctors decide to operate. What are the facts here? Simply these: it is now too late for an early ideal operation and too soon for the late one. Still, celiotomy is decided on and carried out to the best of their ability. The patient may recover, most probably will die, and in that community operations for appendicitis are discredited. The next patient, when diagnosed early and offered the operation, remembers the result of the former case and declines until perforation and general septic peritonitis is set up, and then consents. The honest surgeon is willing to do all he can to save the patient and, perhaps anxious for the celiotomy and consequent prominence which it will give him, undertakes what is practically a hopeless task. In this community in the long run, which is the safer line for the majority of patients? We do not hesitate to say we believe the majority, under these circumstances, will do better under proper medicinal treatment than under surgical interference.

Again, given an ideal surgeon, with ideal surroundings, and ideal doctors who make an ideal diagnosis, i.e., in the first few hours of the attack, and insist on immediate operation, we dare say the majority of this class of cases under this set of circumstances are far safer with immediate section and removal of the appendix.

Do we get the cases this way? If we do not and have an aseptic conscience and average ability as surgeons, we say operate immediately. When the case is from four to six days' old, the answer should be different. Here we have a different set of circumstances to meet, and the patient will have a better chance for his life if we wait until the acute symptoms have subsided and operate between the attacks. We say between the attacks for it is probable that others will follow.

What are the statistics of medicinal treatment of appendicitis? The answer to this question depends on

what to the physician attending any case is an unknown quantity, viz.: the character of the infecting agent, and the powers of resistance of the individual. Could we before have known these conditions, the course we should pursue would be plain.

It may be said that when the patient is one with the so-called catarrhal form of the disease—I do not believe in using such an expression—he will get well under the administration of large doses of sulphate of magnesia. Practically all such recover. On the other hand, if they are what is known as the "fulminating kind," 86 per cent. die if not subjected to very early operative interference. We repeat that, given a case within the first twenty-four hours of its occurrence, in the hands of a surgeon who operates frequently, and whose technique is correct, with proper assistants and nurses, that patient will be safer with celiotomy than without; but when the patient is in the country or village, and seen late in the disease, and seen by the surgeon who does not operate on this class of cases often, we believe the majority of patients will do better without operation than with it.

Doctors are frequently captivated by the work of surgeons in large cities, and when the man says he operated in all cases, the surgeon in a small village thinks he must also do so. He forgets that his opportunities to operate come very seldom, while the other man probably operates for appendicitis, as I have seen them do, two or three times in one day.

The statistics of Dr. John B. Deaver, of Philadelphia, with 468 cases in two years, or Dr. J. B. Murphy, of Chicago, or Dr. H. M. Richardson, of Boston, must be far better than those of the surgeon who opens the abdomen but six or eight times a year. This being the case, we believe much harm may be and is being done by the cry that every case of appendicitis should be operated on as soon as seen, no matter what the stage of the disease or the skill of the attending physician or surgeon.

The result of operation in this disease depends again on whether the section is made during an acute attack, or after the attack has passed off. For instance, many operators have a mortality of 15 to 25 per cent. in acute cases, with no deaths in hundreds of cases operated on between attacks.

In a personal communication from Dr. John B. Deaver, he says that in 196 cases of chronic appendicitis subjected to abdominal section in the last two years, he had no deaths. In 264 acute ones, operated on in the same time—two years—the mortality was 17 per cent. Here we have one of the most successful operators in this country, and yet in acute cases his mortality is 17 per cent. Is the mortality in cases treated medicinally any greater than this?

We can not better close this paper than by giving some statistics recently gathered and published by Dr. Chas. J. Whalen, of Chicago:

Fiitz says that 26 per cent. and Stimson that 25 per cent. of all cases of appendicitis prove fatal. According to Fiitz, 60 per cent. of 176 cases of perforated appendicitis died during the first five days, 56 during the first four days, 28 during the first three days, and 8 during the second day, though a large number of cases of simple appendicitis are said to terminate favorably by resolution. Buel, in 1894, placed the mortality at 5 to 6 per cent., although he had collected 450 cases, with only 8 deaths. Deaver collected 200 cases with only 2 deaths.

Armstrong says that in the leading Montreal hospital, from 1853 to 1890, before operations were done—that is, in pre-operative days—the mortality was 23.8 per cent. He reports 517 cases, in which the average mortality was 12.8 per cent. Of

(this number 389 were operated on, and 128 treated without operation. In this latter list the mortality was 3.12; of 319, 81 were interval cases, in which there was but 1 death; of 305 operated on in acute stages, 63 died.

Relapsing Appendicitis.—Dr. Knemmel, of Hamburg, read a paper with this title, which was a review of 100 successful resections of the vermiform appendix. In addition to his own cases, the speaker had collected the statistics of a nearly equal number of cases of relapsing appendicitis in which the operation had been refused. In these cases the mortality after three years was greater than in the operated cases, while the morbidity consequent upon the recurring attacks made the second series of cases incomparably worse.

Dr. Sonneberg, of Berlin, reported 250 operative cases, exclusive of several of tuberculous disease of the appendix. There were 66 cases of simple and 128 of gangrenous appendicitis. In the 250 cases there were 43 deaths. This mortality of 17 per cent. represents the mortality of the disease, not of the attacks.

The 43 deaths were encountered in cases of the perforative form of appendicitis, with complications, as lung and pleural affections, thrombosis, peritonitis, etc.

Knemmel, of Hamburg, in his statistics mentions 51 cases of recurrent form, operated upon during the interval between attacks, with but 1 death. Samuel Lloyd reported 558 cases, of which 226 were operated upon, with 192 recoveries. In direct contrast to this, 265 cases were treated conservatively with only 60 recoveries.

Hawkins reports 264 cases which occurred at St. Thomas' Hospital, with 190 recoveries, making a mortality rate of nearly 27 per cent.; 59 of the cases had one or more previous attacks, of which 6 died, making a mortality rate of 10 per cent. under medical treatment.

Dear (*Med. News*, Dec. 21, 1895) maintains emphatically that early operation is the only justifiable procedure. He has operated upon 200 cases, with only 2 deaths, and these in the first hundred.

Herman Knemmel (*Berlin Klin. Woch.*, April 11, 1898) presents a clinical study of 104 cases of recurrent appendicitis in which operation was performed between attacks. There was not a death in this series.

Examination of the appendices which had been removed showed that in not one case had the organ become normal after the attack.

I have been able to collect 6500 cases, which I classified under the headings: Catarrhal, Suppurative, and Recurrent Appendicitis, of which 1400 were treated medically. Two hundred and fifty-two of these died, a mortality-rate of about 18 per cent. Of the remaining 5100, 987 were operable upon during the catarrhal stage. Fifty died, a mortality of 20 per cent. One thousand four hundred and eighty-three were cases of recurrent appendicitis, with 35 deaths, a mortality of 2.25 per cent. Many report series of 100 or 200 cases without a single death. This low mortality rate in recurrent appendicitis is due to the immunity to infection acquired by repeated irritation. It will be at once apparent to you that out of 5100 subjected to operation, 1483, or 29 per cent., were cases of recurrent form of the disease. As a last word, let us close with the following: Dr. W. W. Keen, of Philadelphia, in discussing appendicitis at the Denver meeting of the AMERICAN MEDICAL ASSOCIATION, concludes his remarks as follows: I protest against the use of opium in rare cases, as it has a tendency to mask the symptoms of the disease, and leads the patient to the grave. I protest against the argument of Dr. Niles, that every case ought to be operated upon, and the appendix is never to be left.

Out of 300 post-mortems on as many bodies, it was found that 100 of the individuals had had appendicitis at some time in their lives, and had all recovered from the disease. I challenge the assertion that through surgical operations all but 2 per cent. of cases can be saved. I challenge any operator in the room to take 100 well persons and operate on them without killing more than 2 per cent. We all fail, gentlemen. I do not know why, but we all fail. I do not believe in operating on all cases of appendicitis.

I would rather have a live man with an appendix, than a dead one without one. (Applause.) I do not believe with the

witty Frenchman that no case is complete without a post-mortem. (Laughter.) If the patient is no worse after forty-eight hours of observation, let him alone: Let him get well.—*Western Medical Review.*

MEDICINE AS A BUSINESS PROPOSITION.*

BY G. FRANK LYDSTON, M.D.

Professor of the Surgery of the Genito-Urinary Organs and Sphylology, in the Medical Department of the State University of Illinois.
CHICAGO.

So live that when thy time has come to join the innumerable caravan which moves to that mysterious bourne peopled by doctors who have died of innutrition, thou go not like the general practitioner called at night, scourged from his office, but, sustained and soothed by the motto "Never trust," approach thy grave like one who wraps his stocks and bonds about him and lies down to pleasant dreams.¹

Some months since I had the honor of addressing a medical club of Chicago, composed of prominent general practitioners. I chose for my theme "The Business Aspect of Medicine." The resulting discussion was so animated, and the participants were so interested in the subject, that I promised to amplify and publish my remarks—a promise that for many and sufficient reasons I have hitherto been unable to keep.

That there are a number of points in this address on which many of my professional brethren will differ with me—possibly with some degree of warmth—I am well aware. Having, however, the material welfare of the profession at heart, and believing that the ventilation of truths—even unpleasant ones—is healthful in the end, I will proceed as though expecting only favorable criticism.

Let the accusation of being Pharisæic be hurled at me, I will take this opportunity of admitting the somewhat obtrusive fact that in some directions I am part of the very machinery the operations of which I am about to criticise. It will hardly be asserted that what I have to say is a wail of distress—any grievances of my own that may be presented are merely illustrative, and being personal, are not hearsay evidence. A spirit of professional altruism, and not a desire to present a bill of little complaints that are out of harmony with self-evident personal results, is my incentive for this lecture. I have in mind the interests of the profession at large, and especially those of the rank and file, who, while they do not sound the cymbal so loudly as some of us college folk, yet constitute the bone and sinew of the profession. Should what is to follow prove somewhat peppery in spots, the mantle of charity should be thrown over what is, at worst, merely the personal equation of the pen.

FINANCIAL REWARDS OF THE PRACTICE OF MEDICINE.

As a general proposition it is safe to assert that the practice of medicine from a business standpoint is a failure. The successful exceptions merely prove the rule. It is also safe to assume that the elements of financial non-success are cumulative in their action—a fact that is easily proved by hospital and dispensary statistics. The average income of the physician is less than that of the high-class artisan, the telegraph operator in an important office; and far less than that of the wide-awake commercial traveler. This, like many other points that will follow it, is threshing over old straw, but such threshing is unavoidable.

The practitioner of medicine, like every man who re-

*Lecture delivered at the public meeting of the St. Joseph County Medical Society, South Bend, Ind., Jan. 30, 1900.

¹ With apologies to the shade of W. C. B.

lies on his own hand and brain for a livelihood, is entitled to a bit of earth that he and his may call their own, at least a modest competence, and a well-earned rest when his sun begins to set and the twilight of his life approaches. How many doctors are in a position to enjoy or even render less awesome their twilight days? As city doctors are all supposed to be rich—at least by the public, that does all it can to prevent their becoming so—it would be interesting to know what proportion of them, even in metropolitan medical centers, own their own homes or have property investments. A far smaller proportion than is just, I fancy.

The assertion has been made that the general poverty of the medical profession is due to a lack of appreciation and a contempt for the rights of the medical man on the part of the public at large. This, however, is a secondary matter which, being self-evident, overshadows the primary cause—the asinine stupidity of the profession itself. As a broad general proposition the reputable profession as a whole has about as much sense as the dodo, and, unless signs fail, will, sooner or later, meet the fate of that remarkable bird. How the profession can expect the respect and appreciation of the public when it has no respect or appreciation for itself is difficult of conjecture. The public can not be expected to keep clean the nest of the medical dodo. Furthermore, the public quite rationally values the stupid thing according to its self-appraisal.

Primarily, the practice of medicine is supposed to be founded on a mawkish, blanket-like sentiment of philanthropy, which is expected to cover both God's and the devil's patients—the pauper and the dead-beat—the honest man and the rascal—the rich and poor alike. The doctor is expected to wallow eye-deep in the milk of human kindness, scattering it broadcast for the benefit of humanity, but he is in nowise expected to even absorb a little of it, much less to swallow a gulp or two occasionally for his own benefit. By way of piling Pelion upon Ossa, the public, having discovered that the doctor sets little value on his own services, proceeds to eye him with suspicion; the tradesman is very careful how he trusts doctors. Of course, the tradesman has his own family physician "hung up" for a goodly sum, but—knowing doctors to be poor business men—the tradesman often cheats them in both the quality and price of goods. It is a great and goodly game that plays from both ends and catches the victim in the middle. The tradesman has one redeeming feature, however; he does his best to teach his doctor patrons a lesson. He either sends his goods C. O. D. or, if the doctor be one of the favored ones, he finds the bill in his mail bright and early on the 1st of the month. I often think my tradesmen must sit up all night in order to get their bills in bright and early on the 1st. If not paid by the 15th, a collector is usually at the doctor's office to see about it. Yet the professional dodo—my apologies to the shade of the "sure enough" dodo—will not learn. He goes on and on, neglecting his accounts, mainly because he is afraid of offending his patrons and driving them off to some other doctor who isn't so particular; and the worst of it is, there are plenty of contemptible fellows who draw their own salaries promptly when due, or present their bills for goods with frantic haste, who consider a doctor's bill a flagrant insult. Will nothing ever inspire the doctor with courage enough to despise and ignore such contemptible trash? Does he prefer the rôle of a lickspittle to that of an independent and self-reliant man?

As illustrations of the value the profession sets on its skill and learning, the amount of gratuitous work done

is striking. Our pauper—or pauperized—patrons are divided into several classes, viz: 1. The free hospital, clinic and dispensary class. This is on the increase. According to Dr. Frederick Holme Wiggin 51 per cent. of all cases of sickness in New York City are now classed medically as paupers, as against 1.5 per cent. twenty years ago! This is appalling. Of these alleged paupers it is safe to say that 75 per cent. are able to pay full or at least fairly good fees. Why should pauperism be shown so prominently in the matter of medical bills, as compared with other necessities of life? And why should the profession carry a burden that belongs to the public? 2. Free patients of the private class: *a*, those who can pay but will not, i. e., dead-beats and swindlers; *b*, persons whose circumstances are such that the doctor feels in duty bound to render no bills; *c*, persons who presume upon social acquaintance with the doctor to "hold him up" for friendly, perhaps informal, consultations.

It requires no great mental effort to see the terrible load the profession is carrying—self-inflicted, and often for fallaciously selfish motives, it is true, but none the less heavy. The college and free hospital may be the professional "old man of the sea," but so much the worse for the medical Sindbad. Whatever the explanation, private practice is on a par with dispensary practice with regard to the impositions practiced on the doctor. It is safe to say that, of the sum-total of surgical and medical patients of all kinds and social conditions under treatment in Chicago at the present time, over one-half are paupers—honest or dishonest. Pay the doctor for the work involved in this wasted and misapplied charity, and the medical profession would plunge into a sea of prosperity that might swamp it. And it is not only the rank and file of the profession that suffers. Ye celebrated professor, reaching out for glory, yea, into infinite space, clutching frantically at everything in sight, no matter how profitless—providing the other fellow doesn't get the case—often defeats his own ends. And the great man dies, and is buried, and we take up a collection for his widow, to meet his funeral expenses, and sell his library—six feet of earth make all men of a size. *Sic transit gloria mundi*.

And when like dog he's had his day,
And his poor soul hath passed away,
Some friendly scribe in tearful mood,
Will tell the world how very good
The dear departed doctor was—
And thus win for himself applause.

FALSE PRETENSES OF PROSPERITY.

One of the most potent causes of professional poverty is the mania of the doctor for a pretense of well-doing. He exhibits this in many ways. One of the most pernicious is an affectation of contempt for money. This it is that often impels him to delay the rendering of his accounts. Oftentimes his patient offers to pay all or part of his bill. With a lordly and opulent wave of his marmosaic hand the doctor says, "Oh, that's all right; any time 'll do." And the triple-plated medical imbecile goes on his way with a dignified strut that ill befits the aching void in his epigastric region, and is decidedly out of harmony with the befringed extremities of his trousers. And then the doctor apologizes to himself on the ground of a philanthropy that is but the rankest and most asinine egotism *en masque*. When will the doctor understand that payment deferred maketh the patient dishonest? When will he consider the necessities of his wife and children as outweighing the feelings of the patient who owes him money? When will he be a

man, and not a time-server and truckler to appearances? He would take the money did he not fear the patient might suspect that his doctor was not prosperous. He wishes the patient to think that the doctor and his family dine with the chameleons, or are fed by ravens. Yet the medical Elijah waiteth in vain for the manna-bearing birds—they know him for what he is, a counterfeit prophet who vainly yearns for the flesh-pots of Egypt—who has a ponderous and all-consuming desire for pabulum, and a microcephalic capacity for finance.

A large proportion of the profession in cities carries its false pretense of prosperity into all the affairs of life. An expensive establishment in a swell locality, a turnout that shall be the envy of all his competitors, the opera, social events galore, expensive dinners, subscriptions to this, that and the other thing in which he has, or should have, no concern—such is the system of blackmail that the doctor often allows to be levied on himself by that hydra-headed, brainless bugaboo termed "society." He submits to the blackmail because he is afraid society will think he is not prosperous unless he makes a splendid appearance, "and," he says to himself, apologetically, "they don't want a fellow who isn't prosperous, you know." A yearly trip to Europe or some swell resort comes in by way of trimming, and before our aspiring friend is done with his tribute to "society," he finds that he has more than he can do to make ends meet. If he only had the spirit of a Vanderbilt, it would do him as good a turn as would quite a bit of that gentleman's money, for he would say "society be d—d," and forthwith stand on his own bottom.

The gilded show of prosperity reacts against the doctor's interests in the same way as his refusal to accept money—the patient, judging by externals, thinks the doctor doesn't need money, hence tardily, if ever, pays his bills.

One of the worst results of a pretense of opulence on the part of the doctor is the inducement it offers to foolish young men to enter the profession. Thinking that doctors make their money easily, and plenty of money at that, young fellows, often illy-adapted to medicine, are frequently induced to join the already over-crowded ranks of the profession.

Speaking further of catering to appearances, how often the struggling young doctor takes unto himself a partner in his poverty, by marrying. Society has an unwritten law that unmarried doctors are not *au fait*. The young doctor feels that way too—and there is usually a sweet girl somewhere who agrees with him—but he doesn't see how he is to support a wife. However, he yields to the pressure of social custom and—two miserable people stand where one stood before. How long will it be before the profession meets the prevalent social opinion on the marriage of doctors with the contempt it deserves? The doctor, of all men, should not marry until he is well over the breakers and into the sea of prosperity. Any other view is mere twaddle, and founded on mawkish sentimentality and a strabismic notion of propriety. The doctor should disregard the opinions of the old women of society—whether the old women be with or without trousers. Why should he be disturbed by the raucous ruminations of these "psychic humpbacks."

LACK OF JUDGMENT OF HUMAN NATURE.

Doctors are supposed to be keen judges of human nature. I often think that this is absolutely without foundation. Defective knowledge in this direction is a very expensive luxury to the medical profession. The confidence-man and sharper can not fool the average

doctor into buying a gold brick, perhaps, but they can come very near it. The oily-tongued and plausible man with a scheme finds the doctor his easiest prey. The doctor has often hard enough work to wring a few dollars out of his field of labor, and it might be supposed that it would be difficult to get those dollars away from him, but no, it's only too easy. He bites at every thing that comes along—he often rises to a bare hook. Mining stocks, irrigation and colonization schemes, expensive books that he doesn't want, will never need and couldn't find time to read if he would, histories of his town or state in which his biography and picture will appear for \$100—proprietary medicine schemes, stock in publications of various kinds; he bites at everything going—he has *embonpoint cérébrale*. Oh, but the doctor is easy! I have very painful memories. The best investment I ever made was when I paid a fellow for painting a sign for the door of my consultation room, reading: "Notice—Persons with schemes will please keep out. I have some of my own to promote."

COLLEGE, HOSPITAL AND DISPENSARY EVILS.

It is rather a delicate matter, perhaps, for a college professor to touch on the evils of medical colleges in their relation to the business aspect of medicine, but I shall nevertheless speak plainly and to the point. While theoretically the better class of medical colleges were founded solely for the advancement of science, it is none the less true that self-aggrandizement has been the pedestal on which most of our disinterested giants in the teaching arena have stood, and are standing. Remove the personal selfish interest of college teachers and most of our schools would be compelled to close for lack of instructors. Let us be honest with ourselves, please. Not that self-interest is reprehensible—I hold the contrary. One may teach for salary, reputation, the love of teaching, or a desire for self-improvement, it matters not, for if he be of the proper timber he is the right man in the right place. Self-interest makes better teachers on the average than philanthropy, providing the primal material is good.

Granting that self-interest is the mainspring of the college professor, is he very "long-headed" from a business standpoint? I submit the following propositions as proving that the average college professor defeats his own ends: 1. He devotes to teaching time and labor over and above the exigencies of ordinary practice which, if devoted to cultivating the good will of the laity, would be much more profitable. 2. While cultivating the acquaintance and friendship of the alumni of his own school—a few each year—he alienates from himself the friendship of every alumnus of every rival school, the instant he begins teaching. 3. He assists in educating and starting in life, young, active competitors to himself. 4. He is compelled to devote a large percentage of his time to the gratuitous relief of medical students and physicians. He may give his time cheerfully, but he yields up his nerve force just the same. 5. Most college professors are less successful in the long run than the more fortunate ones of the rank and file who have never aspired to teaching honors. 6. Greater demands are made on a professor's purse than if he were in the non-teaching ranks of medicine. He, more than all others, is expected to put up a prosperous appearance.

The college clinic—especially of the surgical sort—is far-reaching in its detrimental effects on professional prosperity. Few or no questions are asked, and the millionaire is being operated on daily, side by side with the pauper, free. And the blame does not always lie with the professor who runs the clinic. General practitioners

bring patients to the free clinics every day, with full cognizance of their ability to pay well. Why doctors will persist in thus cheapening surgical art is difficult of conjecture—but they do it just the same.

Of course, the college clinic is supposed to be a theater of instruction. Often, however, it is but a stage on which comedy-dramas are enacted. A brilliant operation that nobody six feet away can see, and an operator bellowing at his audience like the traditional bull of Basham—in medical terms that confuse but do not enlighten, terms that are Greek to most of the listeners—this is the little comedy-drama that is enacted for students who have eyes but see not; who have ears but hear not. Instruction? Bah! Take the theatrical elements, and the plays to the gallery, out of some college clinics and there wouldn't be a corporal's guard in attendance.

Worse than the free clinics are the so-called charitable hospitals. Much has been said of dispensary abuses, but few have had the courage to say anything in adverse criticism of these institutions. While nominally founded to fill "a long-felt want"—and the number of long-felt wants from the hospital standpoint is legion—these hospitals are founded on strictly business principles, save in this respect—the people who found them feed on their innate capacity to get something for nothing. The first thing the founders do is to get a staff of doctors to pull the hospital chestnuts out of the fire. The members of the staff think that the hospital is performing the same duty for them, and everything is serene. And so the surgeon goes on operating on twenty patients—fifteen of whom are able to pay him a fee—in the hope that one among them all is *willing* to pay him a fee. Exaggeration? Well, I can not swear to the accuracy of the foregoing, but an eastern surgeon of world-wide fame once told me that for every patient who paid him a fee he operated on nineteen for nothing; and this man has no public clinic, either. Is it conceivable that the nineteen free patients are all paupers? Many of them go to my friend for operation, from very long distances. Ought the railroads and hospitals to have all the profits? Have we not all had similar experiences in a lesser degree? With the development of charitable hospitals far in excess of any legitimate demand, it has come to pass that surgery is almost a thing unknown in general city practice. Even the minor operations have left the general practitioner—to return no more so long as there are free hospitals and dispensaries. Where is the emergency surgery, of which in former days every practitioner had his share? Railroaded off to the "charity" hospitals to be cared for gratis.

In a recent conversation with a practitioner of thirty years' experience, I said, "Doctor, you used to do a great deal of general surgery throughout this section of the city. Have the hospitals affected your practice in that direction to any extent?" He replied, "Surgery with me is a thing of the past. Even emergency cases are carted off to the nearest hospital. If by chance one does fall into my hands, it is taken away from me as soon as I have done the 'first-aid' work." Personally I see very little use in teaching surgery to the majority of students who intend to practice in our large cities—they will have little use for surgical knowledge.

Here are three cases in illustration of the way our "charitable" hospitals antagonize the business interests of the profession:

1. A very wealthy farmer engaged me to perform an exceedingly important operation. It was understood that \$1000 was to be the honorarium. He was afterwards advised to go to a certain "religious" hospital

where he was operated on by an eminent surgeon who received nothing for his services. The patient paid \$15 a week for hospital accommodation, and \$25 a day to his family physician, who remained with him "for company." What a harmonious understanding between the patient and his family doctor—and what a "soft mark" that surgeon was. I had the pleasure of telling the latter of the gold mine he didn't find, some time later, and the shock to his system amply revenged the body surgical.

2. A patient who was under my care for some weeks and paid me an excellent fee, finally divulged the fact that he had meanwhile been living at a certain hospital as an "out patient," at an expense of \$8 a week. He had become dissatisfied with the hospital attention, he said, and, pretending great improvement, was permitted to get about out-of-doors.

3. A man on whom I operated and who paid me my full fee without argument or question, came to me directly from one of our large hospitals, where he had been sojourning for several months. That medical men in hospitals are imposed on is a trite observation. So long, however, as it appears to be the doctor's advantage to be on a hospital staff, plenty of men will be found who will be glad of the chance. As for the injury which the system inflicts on the profession at large, that is no argument with the individual. Human nature operates here as elsewhere. Knowing that the system is bad, we are all anxious to become victims.

In recommending the payment of salaries to hospital men, a recent editorial² claimed that such a plan will remedy all the evils incident to the professional side of hospital management. I do not agree in the opinion that the payment of salaries to the staffs of institutions for the care of the sick will alone correct the evils of such institutions. The writer of the aforesaid editorial is incorrect, also, when he says that an awakening is at hand. No, not at hand; it is coming though; the handwriting is on the wall. When the revolution does come, this is what will happen: 1. Hospital physicians and surgeons will be paid salaries. 2. Hospitals will take as free patients or patients who pay the hospital alone only such persons as rigid investigation has shown to be indigent. All others will be compelled to pay their medical attendants just as in private practice. 3. Certificates of indigency will be required of every free patient, such certificate being signed by the patient's attending physician—outside of the hospital—and at least two other persons in the community where he or she resides. 4. General and especially country practitioners will cease to deceive hospital doctors as to the circumstances of their patients. One medical man should not impose on another.

Too much trouble, eh? Well, my friends of the hospital and dispensary—for the same charges should apply to the latter—you must either take your medicine or the revolution will go farther and this is what will happen: The profession at large will boycott every man who runs a college clinic, and every hospital and dispensary man. It will fight colleges and hospitals to the bitter end.

The day is perhaps not far distant when doctors outside of colleges and hospitals will run their private practices on the co-operative plan, thus dealing a death-blow to the free clinic and dispensary. Every man of prominence will have his own private clinic and advertise it among his patients. What is fair for twenty or thirty men is fair and ethical for one. Each man can

² Cleveland Jour. Med., Sept. 15, 1898.

have his own hours for the poor; he can eliminate the unworthy ones and, best of all, he can refer all his dead-beat patients to his clinic. Pride may bring fees from patients to whom honesty is a thing unknown. The private hospital will run most of the public hospitals off the earth. There will be no room for anything but municipal hospitals run squarely and fairly for charity, and reputable private hospitals run frankly for pecuniary profit, in which the operation and the attendance fees are the chief factors. Such hospitals will benefit, not hurt, the profession. In passing, I wish to remark that the general practitioner will probably some day cease sending cases to men who make a specialty of diseases of the head, trunk and extremities. The surgeon who to-day grabs an operation case brought to him by the general practitioner, and attends a case of labor in the latter's neighborhood to-morrow, is not just the man to be trusted, yet there are many such—men who persistently decline to "render unto Caesar, those things which are Caesar's."

MEDICAL "TIN-GODS."

One of the most vital flaws in the business sense of the general practitioner is his penchant for hero worship. He hears of the medical tin god from afar, and burns incense on the altar of his greatness. The great man pats the humble doctor on the back, calls him a good boy, and tells him just where to take all his cases. Sometimes he offers to divide fees with him.

The medical tin god is truly a "self-made man in love with his maker." He has "genius stamped upon his brow—writ there by himself." His evolution is interesting. It is history repeating itself: Apsesthus the Libyan wished to become a god. Despairing of doing so, he did the next best thing—he made people believe he was a god. He captured a large number of parrots in the Libyan forests, and confined them in cages. Day after day he taught them to repeat, "Apsesthus the Libyan is a god," over and over again. The parrots' lesson learned, Apsesthus set them free. They flew far away, even into Greece. And people coming to view the strange birds, heard them say, "Apsesthus, the Libyan, is a god; Apsesthus, the Libyan, is a god." And the people cried "Apsesthus, the Libyan, is a god; let us worship Apsesthus, the Libyan." Thus was founded the first post-graduate school.

The medical Apsesthus and the deluded parrots of the medical rank and file are here, and here to stay, until both are starved out. And the modest general practitioner looks up to the medical tin god and wonders "upon what meat does this our Caesar feed that he hath grown so great?" The meat of industry? Perhaps. The meat of prodigious cerebral development? Seldom. The meat of opportunity? Yea, yea, my struggling brother, "and the devil take the hindmost." But, more than all, he hath fed on the meat that the parrots have brought him—Elijah's ravens were not a circumstance to those parrots. "In the kingdom of the blind, the one-eyed man is king." How long will the general practitioner continue to play parrot to the medical tin god of the charitable hospital, the very existence of which is a menace to the best interests of the profession—the profession for which the institution has no charity? In that happy time to be, there will be no tin gods. There will be a more equitable division of work, and every prosperous community will have its up-to-date private hospitals with up-to-date men at the head of them. As for the post-graduate teacher—good or bad—he is already defeating his own ends—he is exciting ambitions in the breasts of his pupils. Here and there among them is

an embryo McDowell, a Sims, or a Battey. The backwoods country produces good rich blood and virile brains. And the Sims, and McDowells, and Batteys of the future will be found in relatively small places, doing good work, and then—good-bye to the tin god and his horn, "for whosoever bloweth not his own horn, the same shall not be blown." And in that day the parrot shall evolve into an eagle, and the hawk had best have an eye to windward. Meanwhile, hurrah for the post-graduate school and its pupils, and more power to the tin gods.

SUPERABUNDANCE OF MEDICAL COLLEGES.

This business handicap is so self-evident that it is hardly necessary to touch on it. We raise the standard of medical education year by year, yet the mushroom colleges do not go—they are here to stay. If one-half the colleges were wiped out of existence, there would still be more than enough to supply the demand for physicians. We have done the best we could to breed competition by manufacturing doctors, and we are doing all we can to make that competition first-class—a queer business proposition in force of the oversupply of doctors. We are unjust, too, to the men we educate, by offering them inducements to enter an already overcrowded profession—but as long as human nature is as it is, I see no way out of the dilemma. This much is to be said of the medical profession, viz., no other profession has had such obstacles thrown in its upward path to a higher education as ours. It is easier for a college of "osteopathy," "vitopathy," "Christian Science" or any other quackpathy to get recognized by state legislatures than it is for regular medicine to get a hearing even on matters pertaining to public health. We are not business-like, and the public is not with us. We do not buy legislation and, I hope, never will; so the lawmakers are not with us.

INCONSISTENCIES AND ABSURDITIES OF ETHICS.

There was once a time when it appeared a goodly thing for the chosen few to get together like the "three tailors of Tooley street," and, after establishing to their own satisfaction the fact that they were indeed "the people," formulate rules for the guidance of the many. These rules were called "ethics." And the profession has been wrestling with its ethics ever since, trying to determine what it was all about, anyhow. The ethical garment of half a century ago no longer fits—it is frayed and fringed, and baggy at the knees; full many a patch has been sewed on it, in individual attempts to make it fit from year to year, until it is now, like the Irishman's hat, respectable by age and sentimental association only. And the public, the ever practical and heartless public, has also wondered what 'twas all about, and exhibits little sympathy for a profession which, while deriving of ethics, has "strained at gnats and swallowed camels." Who does not remember when all the wisecracks with number eighteen collars and number five hats, seriously discussed the relative propriety of "Specialty" vs. "Practice Limited," on professional cards? How times have changed. And then came the discussion by a learned society, of the ethical relations of "Oculist and Aurist" to "Practice Limited to Diseases of the Eye and Ear." And it was decided that men who had the former on their cards were not ethical and could not enter that society. Ye Gods! Is the fool-killer always on a vacation? Must we always see those long ears waving over the top of the ethical fence, built by the fat hogs to keep all the little pigs out of the clover patch? What is the public to think of a profession that winks its other eye at the man who prints on his cards "Diseases of Women Only," but rolls up its eyes like a dying rabbit at the

sight of a card reading "Diseases of Men Only?" What has raised the woman with leucorrhœa to a more exalted plane than that occupied by a man with prostaticorrhea, does not appear. Why so many inconsistencies, and why such hypocrisy! Sir Astley Cooper had his own private "hours for the poor." Our European brethren print their college and hospital positions and all their titles on their cards. Are they less ethical than we? Homeopathy is a dead duck over there, and quackery has a hard row to hoe in Europe—queer, isn't it?

Our system of ethics has not only been hypocritical, but somewhat confusing. The young man on the threshold of medicine doesn't know "where he is at." He is confronted by the unwritten law that only celebrated men and quacks may advertise. Small fry, who haven't the ear of the newspapers nor a chance for a college position, are tacitly ordered to keep their hands off. And the young fellow watches the career of the big man, who hides every other man's light under his own bushel, and marvels much. Especially does he marvel at the accurate photographs, life histories and clinical reports of his more fortunate confrères that appear in the newspapers without their knowledge. Experiences differ. I haven't yet got around to newspaper clinical reports, but it has been my fortune to be "written up" on several occasions. I do not recall that the newspapers drew on their imaginations for my photograph. I wish I might think so, and that their imaginations were distorted—the result was so uncomplimentary. So far as I can learn, nobody protests against being legitimately represented in the newspapers. Why not be honest about it? The hypocrisy of some men is sickening. Paying clandestinely for newspaper write-ups is despicable, yet some of the very men who protest that they "really don't see how that could have gotten into the papers" have paid for the advertising in good "coin of the realm." It is queer that the newspapers should write up the most minute details of the wonderful exploits of some poor fellows, together with their family histories, and publish their photographs, without their knowledge or consent—especially queer when we read in conclusion that "Professor John Doe is the greatest surgeon that ever lived." Why not come out and acknowledge that these are paid for? This would give an equal chance to all, and especially to young fellows who have money enough to pay for similar things. He who has not the price should not find fault with the fellow who has, for, "business is business." Meanwhile my young friends, remember that "big mountains may do what little mountains may not do."

When Koch's tuberculin was yet new, soon after it escaped, half-fledged, from the laboratory, only to be captured and made to perform like a trick monkey for the benefit of the laity, there came a ring at the "phone" of a prominent daily paper: "Hello, is that the *Daily Bazaar*?" "Huh, huh, it are." "Well, I'm Dr. Squirtum Galls. I wish you would send a reporter over here at once. I want to be interviewed on Koch's tuberculin." It is said that \$25 changed hands, but I don't believe it. The gentleman would never advertise—at that rate—"no sir-ree." My informant was once the sporting editor of the *War Cry*, and hence unworthy of credence.

And what wonderful contributions the newspaper-great-men are making to science! The daily paper is the place to study appendicitis and things. It is not long since I learned from a distinguished surgeon friend of mine, via a daily paper, that evidence of a blow having been received on the head is an imperative indication for craniectomy, whether symptoms are present or not.

In preference to the clandestine methods now in

vogue, would it not be better for men of authority to write signed articles for the newspapers and intelligently present medical matter to the public. But that wouldn't be ethical, would it? Such topics as "Advice to Young Men," "Letters to Young Wives," and "How to Keep Healthy," must be left to the quacks. We will confine ourselves to the surreptitious blowing of surgical horns and never mind the false notes. Meanwhile, let us stand back and watch the procession of modest men who never advertise—oh, no! At the head, with haughty mien, comes Professor Keene Carver, preceded by a herald in blood-red garb, blowing a large brass horn. Then comes the "bearded lady," whose blonde and breezy whiskers so delight the hearts of his swell society *clientèle*. He's a homeopath; you can depend on it. And here comes Rip Van Winkle—a middle-of-the-road "eclectic," gathering up his long and weedy beard to keep it from getting tangled up in the scientific barbed wire fence along the route. And here comes another sure-enough "regular," evidently a medicine man—so rare now-a-days. He is riding in a swell turnout and is on his way to his clinic. How do I know that Professor Windy Bowels is a regular? Because the gentleman who is riding beside him to his clinic is a reporter on the Chicago *Daily Jib-boom*.

I presume that the suggestion that I have made of the advisability of taking the public frankly into our confidence and giving it accurate information so far as its comprehension goes by signed articles in preference to clandestine advertising and the promulgation of fallacious ideas of medicine and surgery, will meet with bitter opposition. I nevertheless believe that a better education of the public is the only way to down quackery. The opposition will come chiefly from the surreptitious advertiser, who sees a prospect of other men getting the advertisement that he believes to be his proprietary right. Then there is the tribe of the Microcephali. The howl of protest will be long and loud from the pews occupied by these far-famed champions of medical orthodoxy. "We wouldn't put our discoveries or contributions in the newspapers—not ever." And gazing at their lemur-like front elevations we can well believe that they would have no trouble in establishing a "halibi."

Appropos of "discoveries," it may as well be understood that the public is bound to get the details of them sooner or later, and, when the time is ripe, the matter should be presented to it in a clear and intelligible form—comprehensible to the layman. The time is never ripe until the medical profession has weighed the discovery in the balance and rendered its final verdict on its merits. Taking the public into our confidence prematurely is bad business, and has always proved a boomerang.

(To be continued.)

CARE OF CONSUMPTIVES.—Among the good things said at the last meeting of the Medical Society of the State of New York, one of the best came from Dr. John H. Pryor of Buffalo, who illuminated the economic aspect of state cure of consumptives in these words: "What we ask for is that the consumptive shall be taken care of at the right place and at the right time until he is well, and not at the wrong place and at the wrong time until he is dead." It is merely a question of whether we shall pay early or late. The consumptive is a public charge. We can admit the obligation early and make terms, or we can postpone payment until judgment by default is entered, covering every item of the account.—*Md. Med. Jour.*

ARGUMENT AGAINST SENATE BILL 34, FIFTY-SIXTH
CONGRESS, FIRST SESSION, GENERALLY KNOWN
AS THE "ANTIVIVISECTION BILL."

BY WILLIAM H. WELCH, M.D.
PROFESSOR OF PATHOLOGY, JOHNS HOPKINS UNIVERSITY,
BALTIMORE, MD.

(Continued from page 1244.)

Who are to be subjected to the visits and inspection of these officials? It can be confidently asserted that the inspection will be practically limited to laboratories under the supervision of scientific men of established reputation, who have been selected by universities, medical colleges and heads of government departments for their recognized skill and knowledge. Dr. Bowditch has told you that he knows of no private vivisections by students, and I can say the same. Vivisection by physicians in their homes is very uncommon. The men who, as your chairman said on a previous occasion, do not need legal enactments are precisely the ones who are to be subjected to the annoyances of this system of inspection and in general to the vexatious restrictions of this bill, while, if the class of persons for whom this bill is said to have been framed really exist and now keep effectually concealed without any apparent motive, I do not see how this law is likely to reach them after their detection will lead to the infliction of a severe penalty.

Not only are the inspectors to make reports of the results of their observations which shall be published by the President of the United States, but "the Commissioners of the District shall direct every person performing experiments under this Act to make reports to them on the first day of January and July of each year, of the methods employed, the number and species of animals used, and the results of their experiments, in such form and with such further details as the said Commissioners may require: Provided only, That reports of any series of experiments alleged to be incomplete may be postponed by permission of said Commissioners for a period not exceeding six months. All such reports shall be published." (Sec. 5.)

Inasmuch as the new bill begins, after the enacting clause, with these words: "That hereafter no person shall perform on a living animal any experiment calculated to give pain to such animal, except subject to the restrictions hereinafter prescribed," it would appear that this latter provision regarding reports of experiments and their publication applies to experiments on invertebrates as well as vertebrates, for I know of no reason to suppose that an invertebrate may not suffer pain.

The period of six months allowed for the completion of experimental researches before the necessity of furnishing for publication reports thereon in whatever form and detail the commissioners require is so short that an experimenter will often be subjected to the hardship of either closing an investigation without satisfactorily completing it or of submitting to the outrage of having methods and results of half finished investigations spread before the public. It must be difficult for those unfamiliar with the conditions of scientific inquiry to fully appreciate these hardships. This requirement can not fail to injure the quality of scientific work and there are many useful investigations which would probably not be undertaken at all under such vexatious conditions. It is to be noted that in the previous bill the demand for reports on experiments was left to the discretion of the commissioners, whereas now these reports must be sent in at stated times and not in such form and with such details as the experimenter may wish, but in any form and with any details which the commissioners may require. Here, as with so many other provisions of this bill, the law can be so administered as to harass experimenters almost beyond endurance.

Those unacquainted with the real purposes and the methods of antivivisectionists would probably not anticipate one of the uses to which can be put the official records of licenses and certificates and the reports of experiments, but it is interesting to note that Sir John Simon, the most eminent of English sanitarians, formerly medical officer of Her Majesty's Privy Council, in his testimony in 1875, before the Royal Commission on Vivisection, clearly predicted this use or rather abuse. In replying to questions as to his opinion of a law embodying this system of licenses, inspection and official returns of experiments, he said (Report of the Royal Commission, etc., p. 77, London, 1876): "I think it would not be a security for animals, and I think it would give facilities for the persecution of physiologists. I think that physiologists under law of this sort would in these days run some risk of being treated as Vesalius was three centuries ago. . . . I should be very unwilling, I confess, to see physiologists put in a

position in which those who are now making clamour on these subjects should be able to hold them up individually to popular odium; and under this clause" (i.e., that relating to official returns of experiments) "that could be done." I have here the second edition of a book entitled "The British Vivisectioners' Directory; A Black Book for the United Kingdom," By Benjamin Bryan, with a Preface by Frances Power Cobbe, London, 1890. One sentence from Miss Cobbe's preface will serve to indicate that a main purpose of this book is to blacklist experimenters. In speaking of experimenters on animals she says: "Could the older non-scientific men and the tender-hearted women with whom they associate behold for one moment in some magic mirror, their employment of a few hours before over their torture troughs, they would be shunned and abhorred as unfit to belong to civilized society." The book is accompanied with comments full of misrepresentations and sometimes with gross misstatements of facts.¹ It is for you to consider whether you will place in the hands of antivivisectionists the opportunity to issue such appeals as this to elderly non-scientific men and tender-hearted women to ostracize a list of physiologists, whose names and experiments appear, accompanied by false and misleading statements, in a printed catalogue. It matters not that the list of names is in fact a roll of honor.

I desire to call attention, with especial emphasis, to a question about which more diversity of opinion has been expressed than concerning any other aspect of this bill. Will this bill, if it becomes law, prohibit important and useful experiments? Its advocates are vehement in their assertion that it is simply "restrictive and not prohibitive" and "concedes everything of utility," and they charge its opponents, who claim that the bill prohibits useful experiments, with misrepresentation or with ignorance of its provisions. The bill has been printed repeatedly in medical journals of this country, and has been fully discussed there. The accusation is unwarranted that protests against its enactment, which have been sent in hundreds to senators and representatives in Congress, by medical and scientific men and societies, are based on ignorance of the contents of the bill. There can be no doubt as to which side is the more competent to give a correct response to this question, the great body of medical and scientific men who answer it affirmatively, or those practically unfamiliar with animal experimentation and with physiology and medicine, who represent the negative.

I have already pointed out that this bill leaves it entirely to the discretion of two laymen, who constitute the majority of the District Commissioners, and who can not be shown to possess any special qualifications to judge of the matter, to determine whether any experiments on warm-blooded animals shall be performed in the District of Columbia. I need not recur here to the partial exemption of officers of the Government from the control of the District Commissioners. I have also shown how the numerous restrictions, such as the quadruply endorsed applications, the licenses, the registrations of places, the inspections, the requirement at stated periods of reports of methods, number and species of animals used, and results, the specifications as to purposes and conduct of experiments, place it entirely within the power of the administrators of the law seriously to hamper, and indeed actually to prevent, experimental investigations while nominally permitting them.

But aside from these prohibitive effects dependent on the manner of enforcement of the law, this bill in unmistakable terms expressly prohibits many important and useful experiments. The carelessness of construction and the vagueness, whether accidental or intentional, of certain provisions of the bill leave it uncertain whether some other useful experiments are forbidden or not.

¹An illustration of the way in which antivivisectionists misrepresent facts is furnished by a book entitled "The Nine Circles," which has the name of Miss Cobbe on its title-page, and for which she wrote the preface. At the Church Congress at Folkstone, October, 1892, Mr. Horsely called attention to this book in the following words: "In the book, all the experiments are grouped by Miss Cobbe as English and Foreign, respectively. I have taken the trouble to collect, from this gospel of Bishop Barry and Canon Wilberforce, all the experiments in which cutting operations are described as having been performed by English scientists, and in which I knew anesthetics to have been employed. These experiments are twenty-six in number. In all of them, chloroform, ether, or other anesthetic agent, was employed. But of these twenty-six cases, Miss Cobbe does not mention this fact at all in twenty, and only cites it without qualification in two out of the remaining six. When we inquire into the twenty operations in the twenty-six which we find in the original that again and again Miss Cobbe has, in making her extracts, had directly under her eye the words 'chloroform,' 'ether,' 'etherized,' 'chloroformed' 'anesthetized,' during every experiment the animal has been deeply under an anesthetic, and so forth." (*The Standard*, London, Oct. 7, 1892). Miss Cobbe subsequently explained that the book was "planned and compiled by her direction," but the actual work of compilation was done by another.

The only experiments on warm-blooded animals permitted by this act are those for "the advancement of physiological knowledge or of knowledge which will be useful for saving or prolonging life or alleviating suffering" or for "the acquirement of surgical experience likely to be of use in operations upon human beings" (Section 2, a), in which experiments "the animal must, during the whole of the experiment, be completely under the influence of ether or chloroform (or any other recognized anesthetic)" (Section 2, c). There are six, and only six, exceptions to these requirements, to-wit: 1, "Experiments may be performed under the foregoing provisions as to the use of anesthetics by a person giving illustrations of lectures in medical schools or colleges, on a certificate being given, such as is required for a license as herein-after provided in section seven, to the effect that the proposed experiments are absolutely necessary for the due instruction of the persons to whom such lectures are given, with a view to their acquiring knowledge or experience which will be useful to them for saving or prolonging life or alleviating suffering;" 2, "in so-called inoculation experiments or 3, tests of drugs or medicines, or 4, foods, or 5, in experiments relating to the communicability of disease, the animal need not be anesthetized nor killed afterwards, nor 6, in tests of surgical procedure need animals be kept completely anesthetized during the process of recovery from the surgical operation." (Section 2, c.)

I can not claim familiarity with all of the antivivisection bills which have been introduced into legislative bodies. I know that many are very curious productions, but I should be surprised to learn that there are any, stopping short of total prohibition, which have been more prohibitive in their provisions than this so-called "moderate and reasonable" bill before us. Who was it that, in copying the phrases of this bill from the British act, struck out bodily the three provisions in the latter, absolutely essential for the continuance of experimental work in its legitimate scope, granting permission, when the necessities of the investigations demanded: 1, for the performance of experiments without anesthetics; 2, for the survival of the animal after the operative part of the experiment, and 3, for the performance of experiments "for the purpose of testing a particular former discovery alleged to have been made?" Was it some one who tells us that this bill "goes to the farthest extreme of concession in the anxiety of its framers to yield to the wishes of scientific men so far as may be consistent with the principle of legal supervision?" Does anybody suppose that the exceptions concerning inoculation experiments, tests of drugs, medicines, or foods, experiments relating to the communicability of disease, and tests of surgical procedure can begin to take the place of all the experiments forbidden by the omission of the provisions mentioned? Misapprehension there may have been as to the effects of this bill, but it has not been on the side of those who have emphasized its prohibitive features.

I could spend the entire time allotted to me in enumerating useful experiments absolutely prohibited by this bill, but it must suffice to call attention to a few of the more important classes of prohibited experiments.

No scientific man who reads this bill and notes the definitions of the purposes for which experiments are permitted and the enumeration of the few kinds of experiments excepted from certain prohibitions can fail to be impressed with the fact that the whole emphasis is laid on immediate practical utility. The framers of the bill had evidently no broader conception of science than that short-sighted Philistine one which sees no value in scientific discoveries unless they be of immediate practical application. They seem not to know that the foundations of applied science rest on discoveries in pure science made without thought of direct practical utility. Experiments made solely with a view of advancing physiologic and pathologic knowledge without immediate reference to their practical applications are precisely the ones which have yielded the richest harvest of results applicable to the diagnosis and treatment of disease. Such was the history of the discoveries of antitoxin, of the principles of aseptic surgery, of the treatment of myxedema and cretinism by thyroid extracts, and of many other therapeutic and diagnostic procedures based on the results of animal experimentation.

Instead of some simple and comprehensive definition of the purposes for which experiments can be made, such as "for advancement of medical and biological knowledge and promotion of the healing art," we find the clumsy, unsatisfactory and vague phraseology already cited from Section 2, a. The only instance in the entire bill of the recognition of any other immediate purpose of experimentation than one relating to the treatment of disease is the permission granted in this paragraph to perform experiments "with a view to the ad-

vancement of physiological knowledge." The latest bill has even removed the word "physiological," found in all the previous bills, for the designation of one of the kinds of knowledge for the acquirement of which by students demonstrative experiments may be made in illustration of lectures. It is not customary to designate by the epithet "physiological" the kind of knowledge sought for in pathologic and bacteriologic experiments, and nevertheless, by no means all of these experiments are made for the purpose of acquiring knowledge directly "useful for saving or prolonging life or alleviating suffering." There is a science of pathology as well as of physiology. Together they make the foundation of scientific medicine. Each is most surely advanced by its cultivation for its own sake. The ultimate purpose of obtaining knowledge useful to practicing physicians and surgeons is far more likely to be secured by the experimental work of those experts who devote themselves to physiology and pathology as sciences than by experiments made with direct reference to their application to the treatment of disease. It is difficult to say whether the term "physiological" will be interpreted by the administrators of the proposed law in some broad unusual sense so as to include all pathologic, bacteriologic, hygienic and chemical experiments not performed for the immediate purpose of advancing knowledge "useful for saving or prolonging life or alleviating suffering." Certainly no such vagueness and doubt as to the interpretation of the law should have been permitted as regards these important classes of experiments.

The bill provides that the animal must be completely anesthetized during the whole of the experiments and, if the pain is likely to continue or any serious injury has been inflicted, must be killed before recovery from the influence of the anesthetic. (Section 2 c.) The previous bills contained the ridiculous requirement that only ether and chloroform could be used as anesthetics, whereas in the last bill permission is parenthetically granted to use "any other recognized anesthetic." Those acquainted with antivivisectionist writings must have observed the absurd notions contained therein regarding the distinction between anesthetics and narcotics, so far as the production of insensibility to pain is concerned. It is there stated that such narcotics as morphia and chloral, which on account of their prolonged narcotic effects are often useful and most merciful in animal experiments, do not even in large doses render animals insensible to pain. The so-called narcotics are administered to animals in doses relatively much larger than for human beings and in ways securing prompt effects, but to the antivivisectionist none of these is a "recognized anesthetic." I apprehend that the present phraseology of this bill is calculated to leave it to the decision of the Commissioners of the District of Columbia whether the use of certain narcotic substances, although in fact capable of producing insensibility to pain, shall be permitted in animal experimentation. Doubtless the judgment of this tribunal on this question will be eagerly awaited by the medical world. Anesthetics and narcotics differ among themselves in their effects on the circulation, respiration and other functions, and, while ether and chloroform are the most generally useful, the exigencies of a research may require the employment now of one and now of another without introducing any difference in the completeness of the insensibility to pain.

The use of curare as an anesthetic is forbidden by this bill. Curare is not in fact used as an anesthetic by physiologists, but it hardly seems necessary for Congress to pronounce on the question of its anesthetic properties. Bernard, who believed that curare does not produce insensibility to pain and whose theatrical description on this subject is extensively quoted in antivivisectionist literature, correctly stated, in the following words, the only way in which this question can be decided: "Man alone, after recovering from poisoning by curare, could tell, supposing that he preserved his memory, whether or not he had suffered." Since Bernard's experiments, over forty years ago, other experiments have been made, some of which show that curare in the doses used in the laboratory acts on the sensory as well as the motor nerves, and, what is most pertinent to the question, there have been instances reported of the accidental poisoning of men by curare, who recovered and in whom sensation was totally abolished, while the action of the drug was apparent. (Stephen Paget: Experiments on Animals, pp. 243-245. London, 1900.)

There are painful experiments, fortunately very exceptional ones, in which the objects of the experiment would be frustrated by the use of an anesthetic. Such experiments are permitted under certificates by the British law, but are prohibited by this bill—excepting inoculation experiments, tests of drugs, medicines or foods, and experiments relating to the communicability of disease. When one considers that the

discovery of the separate functions of the spinal nerve roots, probably the most fundamental discovery in physiology next to that of the circulation of the blood, is based on experiments under this category, the possible injury to science which may result from the absolute prohibition of this class of experiments is sufficiently apparent.

Perhaps the largest and most important class of useful experiments prohibited by this bill comprises those in which the purposes of the investigation require the survival of the animal for periods of time too long for the practicable continuance of the anesthesia. Nothing in this bill is more curious or more characteristic of the ignorance of its framers in scientific and medical matters than the little list of cases in which it is permitted to dispense with an anesthetic or to allow the animal to recover from the influence of the anesthetic before killing it. To the three exceptions which permit the survival of the animal, enumerated in previous bills, the present bill has added "tests of foods" and "experiments relating to the communicability of disease." The expression, "tests of drugs, medicines or foods," is certainly a very peculiar and, at least to members of the regular profession, unfamiliar designation of investigations in pharmacology and nutrition. It is hard to see why "tests" of other therapeutic procedures than those of drugs, medicines and foods should be excluded from this list, but I suppose that we ought to be grateful for this new concession that animals need not be anesthetized or immediately killed while feeding them during these "tests of foods."

It is difficult to see what of importance is added to this meager list by the insertion, in the new bill, of "experiments relating to the communicability of disease." A communicable disease is of course a contagious disease, and there do not occur to me any important experiments relating to its communicability which do not come under the already permitted class of "inoculation experiments." But if experiments permitting the survival of the animal may be made with reference to the "communicability of disease" why in the name of common sense may they not be made with reference to the study of the causation, the diagnosis, the prognosis, the pathology of disease?

It will be noticed that this singular little group of experiments which constitute the only ones in which the animal is permitted to survive the influence of the anesthetic are all experiments supposed to be of immediate practical utility, although they represent only a very small fraction of such experiments, most of which have just as much claim to be included as those which actually appear in the list. I have already indicated the fundamental error of conception, nowhere, in this remarkable bill, more strikingly manifested than here, which attributes supreme importance to experiments conducted with a view to their immediate, practical application to the treatment of disease.

With the five exceptions—*inoculation experiments, test of drugs or medicines, tests of foods, tests of surgical procedure, experiments relating to the communicability of disease—all physiologic and pathologic experiments in which the ends of the experiment can be attained only by observation of the animal for days or weeks are prohibited by this bill.* Such important experiments as those which have shed light on the processes of digestion by gastric, biliary, pancreatic or intestinal fistula, on the functions and sounds of the heart by the experimental production of valvular lesions, on the functions of the brain and spinal cord, of the kidneys, of the thyroid gland, of the liver and, indeed, of most of the organs of the body by observations extending over some length of time after an experiment, are all prohibited by the conditions of experimentation imposed by this bill. The list of prohibited experiments of this class is so long that I can not attempt to enumerate them. It has been asked whether the experiments on the brain and on the liver, cited by Dr. Keen as the basis for his successful operations, could not be performed under the provisions of this bill. They could not, for they required the survival of the animal after an operation inflicting serious injury, and they were not undertaken as tests of a surgical procedure or with reference to the communicability of disease, but for purely physiologic and pathologic purposes. Nor does this bill permit such experiments as those cited by Dr. Hare, which have led to the successful treatment of myxodema and forms of cretinism. If this bill included no more than the provision forbidding the performance of this class of experiments its enactment would inflict a blow, simply brutal, on biologic and medical science. It is conceivable that the framers of the bill did not know what they were doing when they inserted this prohibitive feature, but that surely does not put the matter in any better light.

It does not seem to me necessary, nor in the limited time is it practicable, to continue with an enumeration of all the useful classes of experiments prohibited by this bill. To some others I have called attention in Senate Document No. 104, 55th Congress, Second Session, but no one has ever attempted anything approaching a complete list of the prohibited experiments. I may here say that it is not clear to me what is meant by the assertion repeatedly made by advocates of the bill, that inoculation experiments are excluded from its operation. They are subject just as much as any other experiments to all its restrictions except that the animal need not be anesthetized during the operation or killed afterward. The magnitude of the concession that an animal—a mouse is the one oftenest used—need not be anesthetized for the prick of a needle or kept unconscious for days or weeks seems to have made an extraordinary impression on the supporters of this bill. Enough has been said to demonstrate that this bill explicitly prohibits many experiments of the highest scientific and practical value, including many which involve less suffering to the animal than some that are permitted. These unambiguous prohibitive features of the bill have been pointed out again and again in published documents but I have never seen any answer vouchsafed to these apparently weighty criticisms, nor do I expect to hear any to-day.

One of the speakers on the other side devoted a large part of his remarks to the subject of vivisection in public schools. The only reply which seems necessary is that the existing law permits only "properly conducted scientific experiments or investigations, which experiments shall be performed only under the authority of the faculty of some regularly incorporated medical college, university or scientific society," and that the Superintendent of Public Schools, on April 24, 1896, wrote, "Vivisection has never been practiced in the schools of the District of Columbia, so far as I have been able to ascertain after the most diligent inquiry. No legislation is necessary on this subject, because the authorities of the schools are radically opposed to vivisection except by experts for scientific purposes, and will do everything in their power, without legislation, to prevent its occurrence in the public schools."

One of the most irrational features of the previous bills has apparently been eliminated from the new or substitute bill printed on March 9, 1900, through the substitution of the words "warm-blooded" for "vertebrate," but there seems to have been some carelessness in carrying out this correction. In Sections 7 and 8 the license under the act is spoken of as one "for the performance of experiments on living animals," and I have already mentioned that Section 3 requires that "every place for the performance of experiments upon living animals" shall be approved and registered. There is also apparently some uncertainty on this point in Section 5. It is charitable to suppose that these slips and uncertainties are not intentional, but if due care had been exercised they would not have appeared.

In looking over the British law on this subject I was impressed by the following provision which would seem to afford experimenters considerable protection against persecution: "A prosecution under this Act against a licensed person shall not be instituted except with the assent in writing of the Secretary of State" (the authority administering this law). I am not a lawyer and can not say whether the omission of a similar safeguard from the present bill is based on legal grounds, but if not, then I do not care to comment on the motives of those who copied so much of the British law and left out this valuable protection to physiologists against unjust and malicious prosecutions.

Although I have not by any means exhausted the objections to this legislation, and have left untouched a number of just criticisms on it, already presented in various public documents, I see no necessity of occupying more time in a discussion of other objectionable provisions, after the hopelessly defective character of the bill has once been made sufficiently clear. I trust that it has been demonstrated to the satisfaction of the members of this Committee that no further legislation on this subject is necessary; that this law, in attempting to restrain abuses, of whose existence there is no evidence, would do far more harm than by any possibility good, by seriously hampering the work of scientific investigators; that many of the leading provisions of the bill are monstrously wrong in principle and would be most detrimental in practice to the interests of medicine and biologic science; that the proposed law is capable of being administered so as to prevent all animal experimentation, and does in fact explicitly prohibit a large number of important and useful experiments.

Before closing I should like to advert to two points which

measures adopted, and from what I know of America and Americans I am confident that no such laws are needed with you. Indeed, my objections to the act as a politician are quite as strong as my objections as a physiologist; the act is stamped with that mark of bad statesmanship, *maldestiniosidad*.

The act took birth in England: 1, from the energy of *doctrinaires* of the upper middle class—the upper ten thousand had nothing to do with it—who had time and funds for public agitation, while men of science and doctors had something else to do and hated agitation; 2, because certain leaders in science and medicine, fearing the strength of the *doctrinaires*, advised a compromise—the compromise has proved to be one-sided. "The report of the commission went beyond the evidence and the bill went beyond the report;" further, some most objectionable features were added to the bill as it was being passed through Parliament at the end of a session. If the act had been limited simply to demanding that no one should perform experiments who had not received a general license to do so, comparatively little harm had been done; it is the special certificates for particular kinds of experiments which give really all the trouble.

But if the time were to come over again I would fight tooth and nail against any act at all, on the ground that all such legislative restrictions are unnecessary, that instances of cruelty, that is, of heedless causing of pain on the part of physiologists, are, to say the least, rare, and that public opinion aided by the ordinary law is quite sufficient to cope with such cases; (if, of course, assume that vivisection is absolutely necessary for the progress of physiology). And much as I hate public agitation, I should throw myself with all the energy I possess into agitating against such measures, sacrificing my little portion of present ease and comfort for the sake of science to come. My advice to you is, accept no compromise whatever, refuse to admit for a moment the need of such a law, and fight against it everywhere, in the newspapers and on the platform, and, if the situation demands it, even imitate your opponents and refuse a political vote to a candidate who will not pledge himself to vote against it. I do not think I can say anything stronger than this last. To repeal a law is a very different thing from opposing the making of one. I scarcely think that I shall live to see the repeal of our act, but if the chance of success ever offers itself I trust I should be ready to carry out for ourselves the advice which I am now giving you.

Yours very truly, M. FOSTER.

Such are the opinions based on actual experience, of the foremost representatives of English surgery, medicine, therapeutics, and physiology, on the effects of the only antivivisection law in operation in any country, a law, moreover, bad enough but still far less repressive than that embodied in this bill. Can you wonder that biologists and physicians throughout this country are so earnest and active in their efforts to prevent the enactment of this bill? The opportunity which the introduction of this bill into Congress has afforded for an expression of the real sentiments of scientific and medical men has served to show the falsity of the assertion current in antivivisectionist writings that there is any material division of opinion in the medical profession concerning the utility of vivisection and the dangers to science inherent in this kind of legislation. I am aware that lists of doctors are reported in antivivisectionist publications purporting to show that many physicians are opposed to vivisection or approve special restrictive legislation. These lists, so far as published with any fulness, contain many names which will not bear scrutiny as to their professional standing. In the most frequently cited of these lists, that collected by the American Humane Society in 1894-95, I do not see how any right thinking person could have approved the statement headed "Vivisection without Restrictions," which is as follows:

Vivisection, or experimentation upon living creatures, must be looked at simply as a method of studying the phenomena of Life. With it morality has nothing to do. It should be subject neither to criticism, supervision, nor restrictions of any kind. It may be used to any extent desired by any experimenter (no matter what degree of extreme or prolonged pain it may involve) for demonstrating the principles of the statements contained in their text-books, as an aid to memory; for confirmation of theories; for original research; or for any conceivable purpose of investigation into vital phenomena. We consider that sentiment has no place in the physiologist's laboratory; that animals have there no "rights" which Man is called upon to notice or respect.

The comparatively small number of names signed, I must believe without due consideration, to this sorry, yet infamous, stuff is adduced by antivivisectionists as representing the proper ratio of physicians opposed to such legislative restrictions as we are considering, while the large number of those who refused to sign it is cited in support of this restrictive legislation. Could anything be more unfair?

I know no one, certainly no scientific man, who believes in

vivisection unrestricted by morality, uninfluenced by judicious criticism and public opinion, without competent supervision, without regard for a serious purpose in making the experiment, without due care in the avoidance of unnecessary suffering, and without subjection to the statute law relating in general to the prevention of cruelty to animals. These are the restrictions which should and do control the practice of animal experimentation. No further legislation is needed to secure them, and no special legislation regulative of this practice has ever been suggested, which would not seriously interfere with useful and proper experimentation and, therefore, prove detrimental to the interests of medical science and art.

Surprise has been expressed that scientific men and the great body of the medical profession in all parts of this country should concern themselves so actively with contemplated legislation which in its immediate effects relates to a very limited area and affects directly the work of probably not more than a dozen men, if indeed of that number. Our solicitude to prevent the passage of this act is not greater than that of antivivisectionists throughout the country to secure it. Our opponents have hitherto signally failed in their repeated efforts to obtain the enactment of similar laws in the various states. They now seek Congressional sanction in the hope that it will promote their "Cause" throughout the country. We know, and scientific and medical men alone can fully know, the dangers to science and humanity which lurk in what may seem to some of you this unimportant bit of legislation. The medical and biologic sciences have advanced in these later years with strides unapproached and in directions undreamed of but a quarter of a century ago. New vistas of knowledge and power have been disclosed, the full fruits of which will be gathered by coming generations. The main cause of this unparalleled progress in physiology, pathology, medicine and surgery has been the fruitful application of the experimental method of research, just the same method which has been the great lever of all scientific advance in modern times. Strange as it may seem at the turning-point of the century, we are here, not as we should be, to ask you to foster and encourage scientific progress, but to beg you simply not to put legislative checks in its way. Our own contributions to this progress may now be small, but America is destined to take a place in this forward movement commensurate with her size and importance. We to-day should be recreant to a great trust, did we not do all in our power to protect our successors from the imposition of these trammels on freedom of research. Our appeal to you is not only in the name of science, but in the truest and widest sense in the name of humanity.

SPECIAL ARTICLE.

RELATIONS OF PHARMACY TO THE MEDICAL PROFESSION.*

V.

As indicated in our fourth article (THE JOURNAL, page 1178) the pharmaceutical preparations of secret composition protected by trade-marked and fancy names are not entitled to medical patronage. There remain now for consideration as allied preparations several other classes, including: 6. Proprietary Pharmaceuticals—preparations under trade-mark or copyrighted names of which the general constituents are known, the purported formulas being represented by enumeration of ingredients more or less intelligibly, without information as to how a similar preparation could be produced.

FORMULA PREPARATIONS.

Preparations of this class, from the fact that the formulas are either printed on the labels or appear in the advertisements, are regarded as unobjectionable by many medical men, while they are condemned by pharmacists, as being impracticable and sometimes as being outright fictions. These positions are, on the part of both physician and pharmacist, often wrong, being based on incomplete information on the pharmaceutical chemistry involved in the preparations of many of them. The formulas have purposely been designed to mislead, or the satisfactory preparation is dependent on a

* The fifth of a series of articles to appear weekly in THE JOURNAL, designed to correct the abuses from advertising and patronizing pharmaceutical specialties.

certain often complicated reaction. A few examples of each kind will illustrate:

A certain make of "tri-iodides" is said to contain "in each table-spoonful as iodids, the alkaloids of 30 grains each of semen colchicum, phytolacca decandra, solanum dulcamara, with 10 grains sodium salicylate." Now, the alkaloid of colchicum is exceedingly rare, those of phytolacca and solanum have yet to be produced on a commercial scale, and it is a well-established fact that the iodids are the most insoluble compounds of the alkaloids—in fact the assay of many alkaloidal drugs is effected by precipitating the alkaloids as iodids. The preparation could not be made from the alkaloids but, by using the fluid extracts of the respective drugs, adding an iodid, probably potassium iodid, the compounds, if formed at all, will be in minute quantities and will be kept in solution by the large amount of liquid and especially the alcohol, since the iodids, as well as the bromids, of the alkaloids, are soluble in liquids of certain alcoholic strength. The formula for this preparation becomes, therefore, exceedingly simple, but on its face it looks very scientific. It is intended to captivate the physician and to mystify the pharmacist.

Of a simpler order is "tongaline," containing tonga, cimicifuga racemosa, pilocarpus, colchicin and sodium salicylate. These are mixtures of fluid extracts of drugs known to contain active principles, but in order to create and maintain a monopoly in their sale, the formulas pretend that they are made from the alkaloids.

FORMULAS WITH "KINK PROCESSES."

A number of formulas are based on a somewhat different plan in that there is a "knack" in the preparation, as illustrated in one of the earliest and best known—the "hypnotic par excellence"—"bromidia." This is said to contain "15 grains each of chloral hydrate and potassium bromide and ½ grain each extract of hyoscyamus and genuine imported extract of cannabis indica in each fluidram." Cannabis indica extract is a complex resinous substance, as insoluble in water as is varnish, and its solution suggested the use of alcohol, and consequently aromatic elixir was employed as the vehicle or solvent, by pharmacists who were asked to compound the mixture by physicians, attracted by the formula, but who preferred to have it compounded by the pharmacist. On standing a short time the liquid separates in two layers, and the superior oily one can but momentarily be mixed with the heavier liquid of much larger volume. The extemporaneous compounding was therefore very unsatisfactory and the originators of the compound have had a monopoly of it for twenty years. It has become exceedingly popular and is extensively used by the laity, especially by dipsomanics.

A PHARMACEUTICAL PROBLEM.

The explanation is very simple. Chloral, in the presence of alcohol, is decomposed by alkalis into alcoholate of chloral, an oily liquid, insoluble in water and specifically lighter than water which, in the presence of syrup—from the elixir—rises to the top of the liquid. Its solvent power is almost as great as is that of chloroform, and it therefore extracts the alkaloidal principles of the hyoscyamus and cannabis, and all the medicinal agents except the potassium bromid will therefore be found in the immiscible top-layer of the liquid. With a large volume of the mixture, say 500 c.c., the amount of alkaloids may be so great as to cause fatal results from an ordinary dose, if the mixture be not thoroughly shaken before taken. Bromid of potassium is always slightly alkaline, it being necessary on the part of the manufacturer in order to insure stability and to produce an alkaline salt, to crystallize it from an alkaline solution. This alkalinity in the presence of alcohol breaks up the chloral hydrate. It has been found that by using water alone as the solvent a perfectly stable solution is obtained, and this is the secret of the "famous" hypnotic. While water has no effect on cannabis extract, the solution of chloral hydrate and potassium bromid in water has solvent properties nearly as great as chloroform, and this solution will therefore extract and hold in solution all the active principles of the cannabis extract, leaving only some inert resin. The following is the formula:

LIQUOR CHORALIS ET POTASSII BROMIDI COMPOSITUS.

R. Chloralis hydratis	
Potassii bromidi, āā.....	5
Ext. cannabis indicæ	1
Ext. hyoscyami, āā.....	
Aque, q. s. ad.....	25

Dissolve the chloral and potassium bromid in 15 c.c. of hot water and add the solution in small quantities to the extracts, previously triturated with a little powdered pumice stone, contained in a mortar; let stand until cold, filter through cotton, adding water if necessary, with a little caramel, and if sweetness be desired, add a very little saccharin.

This is practically the strength of chloral and potassium bromid, which the preparation, as shown by analysis, contains.

A CHEMICAL PROBLEM.

As illustrative of the rôle chemical reactions play, the prescriptions of Dr. Barclay, "arsenauro" and "mercauro," are unique. These appear to be especially commended from the fact "that they are to be prescribed only on prescriptions," etc., and that the formulas are apparently bona-fide—and so they are. Arsenauero is said to "contain in each 10 minims, 1/32 gr. each of arsenic and gold bromids," and "to be a potent reconstructive." Many failures attended the earlier attempts to make a permanent solution, until some medical man and pharmacist in Pittsburg discovered the secret, viz., that the arsenous acid, as ordinarily employed, must be converted into arsenic acid before a stable compound with gold tribromid can be made. The formulas changed hands several times until they reached an adept in exploiting and had quite a run. The National Formulary gives the following, which differs only in containing 1/16 gr. tribromid of arsenic, instead of 1/32 gr.

LIQUOR AURI ET ARSENIUM BROMIDI.

R. Acidi arseniosi.....	2/5
Auri tribromidi.....	3/25
Aque bromi et aque destil, q. s. ad.....	1000

The arsenous acid is added to 135 c.c. of bromin water, contained in a flask, and heated until free bromin has disappeared; then add bromin water until the solution does not become colorless after some time. Heat the solution in a capsule until excess of bromin has been expelled, dilute with water to 900 c.c., dissolve in this the gold tribromid and then add water to make 1000 c.c.

It will be observed that in the first instances here mentioned, there is no originality or skill required in the process, as they are mixtures such as any competent pharmacist should be able to prepare. The "formulas" have directly or indirectly originated with some prescriber and have been appropriated for the purpose of exploitation, monopoly being secured through the use of trade-mark names.

PROTECTION TO INVENTORS.

The two last-mentioned preparations are in an entirely different category. In one, superior pharmaceutical knowledge and skill are required to form a uniform and stable solution of the cannabis extract and chloral and potassium bromid. The successful production was certainly as great an invention as was that of the traditional lever stoveld-lifter and a thousand and one little ideas which have made fortunes for their inventors. It was a pharmaceutical invention, and as such should have been entitled to limited protection through patent on the process. This would have prevented secrecy, protected the original inventor, and made the entire product public property through expiration of the patent. The same may be said of the arsenical preparation. That the arsenous acid must be converted into arsenic acid, as far as applied to this preparation, was, it is believed, an invention, showing originality and chemical skill. If the process had been patented the inventors would have had some protection, the patent would have been valuable and a princely royalty could have been secured for them as compensation. Instead they sold (?) their invention for a "mess of pottage."

The position on this class of medicines should therefore be the same as on the first-named. Their claims for medical patronage based on invention must be proved by patent on

the process. All parties concerned will then be protected, and medical and pharmaceutical literature will be preserved.

A committee of control, as already proposed, would be of great service in protecting inventors and determining the status of these medicinal articles.

The next class to be considered will be Pharmaceutical Specialties.

Therapeutics.

The Treatment of Seasickness.

At a recent meeting of the Northumberland and Durham Medical Society, McDougall (*British Medical Journal*, March 24, 1900, p. 707) described the results he had obtained in the treatment of seasickness by the hypodermic injection of atropin and strychnin. He had employed these remedies in 47 cases, with complete success in forty and with partial success in the remainder. The doses used have been from 1/60 to 1/30 grain of strychnin sulphate and 1/150 gr. of atropin sulphate dissolved in from 10 to 15 minims of peppermint-water. When necessary the dose was repeated in a few hours or on the next day. The injection should be given at the onset of nausea or discomfort, or as a prophylaxis in susceptible persons. The symptoms of seasickness being those of circulatory depression and cerebral anemia, this stimulating treatment is preferable to the use of sedative drugs, as it places the patient in the best position to avail himself of the natural prophylactics—food and exercise.

Dysentery.

Dr. J. O. Samtchouk, a Russian military physician, treats dysentery in the following way: As the first dose, 3iv to v of sodium sulphate are given; about two hours later, 3ii of sodium bicarbonate; two hours later, gr. iv of ergotin. This amount of ergotin is repeated once or twice a day, according to the amount of blood found in the stools. The following is also given:

- R. Bismuthi subnit. gr. iv
- Acidi tannici. gr. ivss
- Quinina sulph. gr. ii

M. ft. One powder. Give three or four such powders a day. After each stool, in old cases, tannin douches are used in addition, 3i to 4 or 5 glasses of warm water. As food, is given a decoction of barley, to which are added butter, eggs and bread. Tea is given for drink. Recovery is said to result in two or three days in recent cases. —*Merck's Archives.*

Treatment of Ozena.

Bonnier recommends the following course of treatment to be carried out by the patient: Twice a day he is to take a nasal douche of boiled water plus a tablespoonful of salt to the liter, using for this purpose a Weber siphon, elevated about two feet above his head. During the douche he should breathe through his mouth, avoid swallowing, and keep the soft palate raised by pronouncing the vowel a. After the douche the patient is to introduce the following ointment into his nasal fossæ, using for each side a bit the size of a bean, while holding his head backward:

- R. Menthol gr. iv
- Acidi borici 3ss
- Vaselinæ alb. 3i
- Olei geran. rosat. gtt. xx

M. ft. Unguentum. Sig. For external use. —*Medical News.*

Formalin-Alcohol in Night-Sweats of Tuberculosis.

At a recent meeting of the Berlin Medical Society, Hirschfeld (*Berliner Klin. Woch.*, 1900, No. 15, p. 326) reported the results of local application of a mixture of equal parts of formalin and absolute alcohol by means of a soft brush or a cotton swab in the suppression of the sweating in cases of tuberculosis. Under no circumstances should all of the clothing of the patient be removed, as the vapor set free from the warm skin would gain access and cause annoyance to the eyes and respiratory organs.

The patient should wear at least a shirt, which can be thrown over his head. In practice the chest and the abdomen are covered with rubber cloth, fastened about the neck, and drawn over these parts and kept in place for an hour after the application is made. This mode of treatment was pursued in 100 cases of pulmonary tuberculosis without unpleasant results in any. In only four of the cases was the desired effect not attained. In some instances a single application sufficed for weeks. In others it had to be repeated. The skin appeared to bear the medicine well. The chest and the abdomen, anteriorly and posteriorly, were painted at one sitting, and the legs, if involved, on the following day. When the head was the seat of trouble, cotton squeezed out of the solution was rubbed on it. The application should not be made to wounds or abrasions of the skin, such as may be induced by a mustard plaster or iodine, and also not to the nipples, the umbilicus, the genitalia and the anus. Slight burning follows the application, but this soon disappears. In persons with a delicate skin the concentration of the application should be lessened. The patient should not be permitted to use the solution himself.

For Intestinal Dyspepsia with Flatulence.

- R. Pepsini puræ
 - Pancreatini, ʒā. gr. xxx
 - Pulv. carbo. liqui
 - Bismuthi subgallatis, ʒā. gr. lx
 - M. Ft. powders xii. Sig. One before each meal.
- Wells: Medical Record.*

Palatable Trional Mixture.

One of the objections to trional is its difficulty of solution and also its unpleasantness of administration when given in the usual method. The following will be found an excellent method of making a palatable mixture.

- R. Trional ʒii
- Ol. amygdal. dulc. ʒi
- Gum acac. ʒiv
- Syrup toltan. ʒi
- Aque aurant. concent. ʒiv
- Aque pur. q. s. ad. ʒiv
- M. Ft. Emulsion.

Given in this way the hypnotic effect is as pronounced, and far more readily obtained than in the present method of administering the drug. —*M. A. H. Thelberg, New York City.*

Tubercular Syphilides.

Dr. A. H. Ohmann-Dumesnil (*St. Louis Med. and Surg. Jour.*) suggests the following local applications for tubercular syphilides:

- R. Acidi salicylici gr. xx
- Ichthyolis ʒiv
- Ung. aque rosæ ʒi
- M. Sig. Apply thoroughly twice a day.

If there be objections to using an ointment, the following, which is but a type of preparations to use, will be found very efficient. It is dry, water-proof, and not easily removed by friction:

- R. Acidi salicylici gr. xx
- Cocaini hydrochloratis gr. ʒi
- Traumaticini or collod. fix. ʒi
- M. Sig. Paint on affected parts twice a day.

After the disappearance of the skin symptoms a bland ointment should be applied at night. An excellent one is the following.

- R. Hydrarg. chloridi mitis ʒss
- Ung. aque rosæ ʒii
- M. Sig. Apply thoroughly at night.

Treatment of Alcoholism.

Morton (*Brooklyn Med. Jour.*, May 26) does not restrict himself to any special drug in the treatment of alcoholic cases, but individualizes his treatment. In some cases he stops the use of alcoholics on the first day and in others continues it for three or four days after admission, though not longer as a rule. He believes in stopping the use of the intoxicant as rapidly as possible, not so soon as to shock the person or start up a delirium. The drugs he prefers are strychnin in small doses to strengthen the heart, a laxative to relieve arterial

congestion, and a sedative like bromid of soda. For old drinkers he gives liquid diet every two hours, occasional baths and rest in bed. He uses chlorid of gold in fractional doses, and hypodermics of strychnia and atropia, with good results, also extract of ipecac in small doses in a glass of whisky three times a day until the patient is thoroughly nauseated. He thinks the saving of life in critical cases is due to the use of heart tonics and nourishing diet given frequently. He does not employ chloral, hyoscyamin or hydrobromate of hyoscin.

Treatment of Influenza.

Johnson (*Med. Review*, May 12) finds that quinin is one of the best preventives of influenza, and irrigation of the mouth and nasal cavities is also of value. Fumigation of the apartments of the influenza patient should be done even before the convalescence. To prevent relapse, the patient should not be allowed to get out of bed within twenty-four hours after complete subsidence of the fever, and in some cases even this is not sufficient. In checking la grippe at the onset diaphoresis is of value and if we can also produce a sialorrhœa it will have a good effect. These combined results may be obtained with pilocarpin. Phenacetin and Dover's powder may be used for their analgesic and diaphoretic effects, and, if pilocarpin is contraindicated, quinin and Dover's powders, hot lemonade and a hot foot-bath may be used. For elimination and cleaning of the alimentary canal, calomel in divided doses is to be recommended. For the pains, headache and neuralgia, he has found the use of salipyrin and phenacetin of value. Quinin and salicylates hold first place as specifics for this disease. For the special symptom of nasal catarrh he offers the following prescription:

R. Mentholisgr. i
Magnesiæ carbonatis levis.....gr. v
Cocainæ muriatisgr. v
Sacchari lactis3iss
M. Sig. As snuff.

As a substitute for the above, finely powdered white sugar and camphor may be used as a snuff. Syringing the nasal cavities with Dobell's solution is good practice. A teasing cough is often relieved by occasionally spraying with

R. Cocainægr. v
Antipyrinʒii
Aque gaultheriæ3ii

The cocain may be omitted. Strychnia is useful in the depression of and after la grippe. He has found asafetida, combined with tonics, of value.

Pruritus Ani.

Adler's treatment for pruritus ani (*Philadelphia Medical Journal*, May 12) consists largely in paying attention to the removal of the factors complicating pruritus, if such exist, and then giving local treatment for itching. It is important to see that there is a daily evacuation of the bowels, and if necessary, medicine should be used for this purpose. In all cases there is more or less pruritus of the hemorrhoidal veins, and he is in the habit of seeing the patient daily for a time and using an injection into the cavity of 1 to 2½ drams of the following prescription:

R. Fluid ext. hamamelidis.....ʒi
Fluid ext. ergotæ
Fluid ext. hydrastis
Comp. tinct. benzoini, aa.....3ii
Olei olivæ or lini, carbonized (5 per cent.)..ʒi
M. Sig. Shake well before using.

The patient is advised prior to using this injection to remain quiet and resist the sensation of immediate evacuation. On the first visit, if the skin has a very hard and dry surface, he paints around the anus for several inches with a strong (saturated) solution of silver nitrate. If the skin is broken, a little 2 per cent. solution of cocain is used to prevent eruption from this application. The application of silver may have to be repeated two or three times, not oftener, however, than every third day. As soon as the silver is dried he smears over the anus and the cutaneous surface of the parts for a distance of about 2 inches, the official citrine ointment in full strength and repeats on subsequent visits. Over this he uses a wad of absorbent cotton, kept in place with a T-bandage, which is to

be worn all day and over night. If the itching should annoy during the night the patient is advised to use hot water as hot as can be borne, but under no consideration to rub the parts. After using the water he is directed to use a solution of black wash or, what is better in some cases, calomel ointment applied locally. Prior to coming to the office for the next treatment he may wash the parts with castile soap, though this is not essential as a routine practice. No rubbing is to be permitted. For the first two or three weeks the patient is seen daily, then every second day for a like period or longer time; after that once or twice a week will suffice until the disease is conquered. The treatment should be continued for about six months. A definite promise of cure should not be given, and he warns the patient that the itching may return any time, but that it must not be considered a bad sign. Sometimes during the use of nitrate of mercury ointment the parts become sore, presumably from scratching during sleep. Under these circumstances the ointment may be discontinued for a few days and calomel ointment substituted. He has never seen any bad effects from mercury. With a large number of cases thus treated he has not had a single failure.

Medicolegal.

Five Dollars Not Enough for Scalp Wound.—The General Term of the City Court of New York holds, in the case of Levison vs. Bernheimer and others, that an allowance by a jury of five dollars is insufficient to compensate a person for a lacerated scalp wound that a physician washed with bichlorides and bandaged up, where same was found to have been caused by the negligence of the defendants.

Destruction of House Over Sick Person.—The owner of a house who knows that a member of the tenant's family whose term as lessee has expired is sick and unable to leave her bed without danger, the appellate division, second department, of the Supreme Court of New York holds, in Prieser vs. Wielandt, is liable for all the natural and necessary consequences which he might or should have reasonably anticipated from proceeding to demolish the house over such sick person, although no actual blow is struck the latter in the course of the destruction of the building.

Can Recover Compensation Without Certificate.—The Court of Civil Appeals of Texas reaffirms, in the case of Carleton vs. Sloan, that a regular practicing physician, holding a diploma from an accredited medical college chartered by the legislature of the state in which it is situated, who has had such diploma duly filed and recorded in the county of his residence, where he has practiced his profession, can recover for professional services rendered by him, notwithstanding he may have never obtained from a medical board appointed by a district judge of Texas a certificate to practice medicine.

Entitled to Reward for Finding Dead Body.—The Supreme Court of Nebraska holds that the mere fact of being one of a party discovering a dead body for which a reward has been offered is not of itself sufficient to entitle one to share in the reward. It must further appear that the efforts put forth were in conjunction with the party who succeeded in the search, and with whom there was co-operation for that purpose; that such persons were acting in concert, and by their joint efforts the desired end was accomplished. Therefore, the court holds, in Elkhorn Valley Lodge vs. Hudson, where many persons are engaged in the search for a dead body, for the recovery of which a reward is offered, and one acting on his own account, independent of the others, and for the purpose of securing the reward, succeeds in finding the missing body, he will be entitled to the whole of such reward.

Non-Expert Can Not Say About Legal Capacity.—The Supreme Court of Rhode Island says that the uniform practice in that court has been to permit non-expert witnesses to testify to facts which they have observed bearing on the

mental condition of a testator, and then to give their opinions as to his mental condition, derived from those facts. But it holds, in *Hopkins vs. Wheeler*, clearly inadmissible the question whether a certain person was in a condition to make a will, asked of a witness who was not an expert on the subject of mental capacity. It condemns the question because it calls for the opinion of the witness as to the degree of mental capacity required by law for the making of a will.

Valid Contract with Employee.—The Supreme Court of Georgia holds, in *Petty vs. Brunswick & Western Railway Company*, that a contract between an employee and his master, or another acting in the latter's interest, such as a relief and hospital association, by the terms of which contract the employee, when physically injured, whether as a result of his own negligence or not, or when sick, is to receive pecuniary or other valuable benefits, and which stipulates that his voluntary acceptance of any such benefits in case of injury is to operate as a release of the master from all liability on account thereof, is not contrary to public policy. The court considers that such a contract secures to the employee substantial benefits, and that the master has contributed to the fund for the payment thereof constitutes a valuable consideration, as to the employee; and this, it maintains, is true though the employee himself made a small monthly contribution to that fund. So it holds that a contract of this kind is not wanting in mutuality. Furthermore, one who deals with an association as a legal entity capable of transacting business, and in consequence receives from it money or other thing of value, the court holds, is debarred from denying the legality of its existence or its right to contract. This settled, the court then more particularly holds that the acceptance by an injured employee of any benefit under a contract of the kind first-above described is an election on his part to look exclusively to that source for compensation on account of the injury, and amounts to a complete satisfaction of his claim for damages against his master therefrom arising.

Liability for Injury by Private Ambulance.—In *Green vs. Eden* the Appellate Court of Indiana has affirmed a judgment for damages for the injury of a pedestrian by an ambulance. Among other things, the court holds that it can not assume, from an averment that the defendants were operating a "hospital ambulance," that the ambulance was a public vehicle, and being operated for the public good. Nor does it consider that it was necessary to aver that they derived benefit from the operation of the ambulance. But one of their defenses was that they had entered into a contract with the city whereby they bound themselves to keep a hospital ambulance for the use of the city, and to furnish therefor a horse and driver, the ambulance to be under the control of the dispensary surgeon, and all calls coming through the city dispensary must be promptly answered, and that when the injury complained of was inflicted the ambulance was, in accordance with that contract, under the exclusive control and direction of the surgeon in the employ of the city, then and there in charge of the ambulance. Nevertheless, the court not only pronounces inapplicable that line of cases holding that a municipal corporation can not be held liable for damages resulting from the negligent act of a driver of a city ambulance while driving through its streets, but it holds that the defendants could not escape from the results of their alleged negligent acts by saying that when the injury in question occurred the ambulance was under the management, control, and direction of the dispensary surgeon, an employee of the city. The city, through its servant or employee, the surgeon, it holds, could not authorize the defendants, through their servant, the driver of the ambulance, to be guilty of actionable negligence, or recklessness, or carelessness in driving the ambulance through the streets of the city at a high and dangerous rate of speed. Again the defendants argued that the plaintiff had failed to make a case, because it was established that when he was injured the ambulance was conveying an injured person to the hospital, and was being driven at a high rate of speed, at the direction of the surgeon, and that there was necessity for so doing to save life. However, to sustain such a proposition by a judicial decision

would, the court thinks, establish a dangerous precedent. It may be, and doubtless is, it maintains, as necessary and important to protect the life and limb of the innocent pedestrian upon the street, whether child or adult, whether infirm or in the full vigor of years and health, as it is of the person who is being conveyed in an ambulance. And to establish any other rule, it declares, would be to wholly disregard the rights and life of the pedestrian under such circumstances, which it is not willing to do.

Construction of Contract for Cure.—In *Wellman vs. Jones*, the Supreme Court of Alabama had before it an action on a contract which provided that, if Jones, the plaintiff in the court below, would place his brother in a certain named institute, to be treated as a patient addicted to the excessive use of morphin and chloral, and would pay in cash the sum of one hundred dollars to the proper officer of the institute, the party signing this contract would return, on demand, to the said Jones, the said sum of one hundred dollars, provided his brother was not fully and permanently cured by the treatment of said institution of the use and habit of morphin and chloral. This contract, in terms, the supreme court, first of all, declares, was plainly an original undertaking between the said Jones and the defendant, and consequently not open to the defense of the statute of frauds relating to "promises to answer for the debt, default, or miscarriage of another." As shown by the evidence, the brother in question was addicted to the habitual and excessive use of morphin and chloral, and it was of this excessive use and habit, by the terms of the contract, he was to be cured. He entered the institute, and received treatment for that purpose, and, after receiving treatment, he left said institute, claiming that a cure had been effected, but within a short while thereafter returned to his former habit and excessive use of these drugs. This leads the supreme court to say that it thinks the fair and reasonable interpretation to be given to the words "fully and permanently cured," as employed in the written contract sued on, when construed in the light of the attendant conditions and circumstances, was that the patient should be restored to the normal condition of body and mind, with the same will power to resist the desire to indulge in the use of morphin and chloral that he possessed and enjoyed before the habit was acquired. It would be an unreasonable construction of the contract, it maintains, to say that it was the intention of the parties that the patient should be put in that condition that he could never again take the drug—a contract impossible of performance—if by the cure the patient was restored to the normal condition of body and mind and will power possessed before the habit was acquired. But if, as a matter of fact, a cure had not been effected in accordance with the conditions of the contract, the court holds that the plaintiff would not be deprived of his right of action growing out of the failure to cure, although, at the time his brother left the institute, its managing officer, as well as the plaintiff and his brother, were under the mistaken belief that the latter had been cured. Moreover, the court holds that it was no defense to an action on this contract that neither the institute nor its managing officer had a certificate or license from the medical board of examiners to practice medicine or sell drugs, the contract by the defendant being to pay back to the plaintiff the amount paid by him to a proper officer of the institute, in the event a cure of his brother was not effected under the treatment to be given by the institute. There was nothing in this contract, the court says, violative of any provision of the statute against the practice of medicine without a certificate from the board of examiners. Again, so far as the institute itself, a domestic corporation, was concerned, the court says that it is impossible to conceive of a corporation engaging in the practice of medicine, or of conforming to the requirements necessary to obtain a certificate from the board of medical examiners. These provisions of the law can not be applied to a body corporate, and were never so intended. They can only be made to apply to persons or individuals capable of complying with the requirements necessary to obtain the certificate.

Societies.

COMING MEETINGS.

AMERICAN MEDICAL ASSOCIATION, Atlantic City, N. J., June 5-8.

Association of Military Surgeons of the United States, New York City, May 31 to June 2.

American Laryngological, Rhinological and Otological Society, Philadelphia, May 31, June 1 and 2.

New Hampshire Medical Society, Concord, May 31 and June 1.

International Association of Railway Surgeons, Detroit, Mich., May 30 to June 1.

Baltimore & Ohio Association of Railway Surgeons, Atlantic City, N. J., June 1-2.

Conf. of State and Prov. Bds. of Health of N. A., Atlantic City, N. J., June 1-2.

American Academy of Medicine, Atlantic City, N. J., June 4.

American Medical Publishers' Association, Atlantic City, N. J., June 4.

American Medical Editors' Association, Atlantic City, N. J., June 4.

Association of American Medical Colleges, Atlantic City, N. J., June 4.

Medical Society of New Jersey, Atlantic City, N. J., June 4. New Mexico Medical Society, Santa Fe, June 5.

American Association of Acting Assistant-Surgeons, U. S. Army, Atlantic City, N. J., June 6.

Rhode Island Medical Society, Providence, June 7.

Medical Association of Delaware, Rehoboth, June 12.

Massachusetts Medical Society, Boston, June 12-13.

Oregon State Medical Society, Portland, June 26-27.

Colorado State Medical Society, Denver, June 13.

Maine Medical Association, Portland, June 13-15.

South Dakota State Medical Society, Aberdeen, June 14.

Indian Territory Medical Association, Wagoner, June 19-20.

Wisconsin State Medical Society, Milwaukee, June 20.

Third District Branch of the New York State Medical Association, Binghamton, N. Y., June 21.

Second District Branch of the New York State Medical Association, Schenectady, N. Y., June 28.

Oregon State Medical Society.—At the annual meeting of this Society, to be held in Portland, Ore., June 26 and 27, Dr. A. M. Phelps, of New York City, will give two addresses, and operate on cases to illustrate his remarks.

Texas State Medical Association.—B. E. Hadra, of Waco, was elected president of the Texas State Medical Association, at its recent meeting. Galveston was chosen as the meeting-place for the next session, to be held in April, 1901.

Thirteenth International Medical Congress.—During the week of this Congress, to be held in Paris, August 2-9, free admission to the Paris Exposition will be granted to members of the Congress. To secure this, members will receive a special card by applying to the office of the Congress, 21 rue de l'École-de-Médecine.

Brazos Valley Medical Association.—At the recent meeting of this Association, in Caldwell, Texas, the officers elected for the coming year were: president, L. P. Oliver, Caldwell; first vice-president, M. L. Langford, Baileyville; second vice-president, E. S. Ferguson, Camron; secretary, W. B. Briggs, Easterly; treasurer, J. W. Hudson, Milano.

American Proctologic Society.—The following officers were elected by the American Proctologic Society, at Washington, D. C., May 5: president, Jas. P. Tuttle, New York City; vice-president, Thos. Chas. Martin, Cleveland, Ohio; secretary, Wm. M. Beach, Pittsburg, Pa.; executive council, S. T. Earle, Jr., of Baltimore, Md.; A. B. Cooke, of Nashville, Tenn.; J. R. Pennington, of Chicago.

International Congress of the Medical Press.—The sessions will be held in the United States Press Pavilion, Paris Exposition, July 26 to 29. The American delegates are as follows: From the Association of American Medical Editors—Drs. J. M. Mathews and Horace Grant, Louisville, Ky.;

George F. Butler, Alma, Mich.; George H. Simmons, Chicago; C. F. Taylor and H. A. Hare, Philadelphia; Dillon Brown and Daniel Lewis, New York City; Thos. H. Hawkins, Denver, Colo.; Henry W. Coe, Portland, Ore. Those from the American Medical Publishers' Association are: Dr. J. C. Culbertson, Cincinnati, Ohio; J. MacDonald, New York City; Drs. Ferdinand King, New York City; Charles Wood Fassett, St. Joseph, Mo.; Landon B. Edwards, Richmond, Va. Those from the Medical Press Club of the Mississippi Valley are: Drs. I. N. Love, St. Louis, Mo.; Frank P. Norbury, Jacksonville, Ill.; Alexander J. Stone, St. Paul, Minn.; John Puntun, Kansas City, Mo.; Hanan W. Loebe, C. G. Chaddeok, and O. F. Ball, St. Louis. Interesting papers on timely topics will be presented by delegates from the various countries. A symposium on "The American Idea of an International Press Congress" will be read by Dr. Charles Wood Fassett, of the *Medical Herald*, St. Joseph, Mo. Dr. I. N. Love, editor of the *Medical Mirror*, St. Louis, Mo., will present a thesis on "The Relationship of a Medical Editor to the Publisher."

Toronto Tuberculosis Association.—This Association held its inaugural meeting recently. Dr. E. J. Barrick, Toronto, was elected its first president. The objects of the Association were outlined by Dr. Barrick, in his presidential address. An active campaign will be at once pushed toward securing a large membership, first 1000 and then gradually extending until there is something like 5000 members. The city council will be appealed to for the purpose of submitting a bill to the rate-payers at the next municipal elections authorizing the city to expend \$50,000 in the erection of a sanitarium. In addition to this an appeal is to be made to philanthropically disposed persons for contributions, donations and bequests. Then a campaign of education will be enthusiastically prosecuted along the line of showing the people that it will be better to expend money in this direction than for the orphans of the victims of the disease. It is presumed that there are 8000 consumptives in Ontario; and the only sanitarium accommodation provided for these unfortunates is the fifty beds at the Gravenhurst institution. The problem which this Association will try to solve is the bringing of sanitarium treatment within the reach of the other 7950 afflicted ones. It was largely through the efforts of this Association that the Ontario government granted legislation toward helping municipalities in the erection and maintenance of these institutions.

Confederation of Examining Boards.—The National Confederation of State Medical Examining and Licensing Boards, will hold its tenth annual meeting, at the Hotel Traymore, Atlantic City, N. J., Monday, June 4, the morning session at 9:30, the afternoon at 2:30 o'clock. The program includes the following: Address of Welcome, by Hon. F. P. Stoy, Mayor of Atlantic City; Address of Welcome on Behalf of the Medical Profession of Atlantic City, by W. Blair Stewart; Address of Welcome on Behalf of the State Board of Medical Examiners, of New Jersey, by William Perry Watson, Newark; Response, by Vice-President N. R. Coleman; Annual Address by the President—"The Work Accomplished under the Kentucky Law"; "Associate Medical Examining Boards," by Charles A. Groves, East Orange, N. J.; "A Brief Review of the Medical Curriculum of the United States with Special Reference to its Defects and Indicated Modifications, as Demonstrated by the State Medical Examinations of Pennsylvania," by Henry Beates, Jr., Philadelphia; "The New Medical Law of Ohio," by Hon. Maro J. Love, Bloomingville; "The Co-operation of the Medical Profession of the United States with the National Confederation of State Medical Examining and Licensing Boards in Establishing Interstate Reciprocity for the License to Practice Medicine," by Emil Amberg, Detroit, Mich.; Discussion: "What Steps Shall be Taken to Establish a Uniform Standard of Preliminary Requirements in Accordance with the Recommendations Contained in the Report of the Committee on Minimum Standards, Adopted June 5, 1899?" The following members will lead—N. R. Coleman, Columbus, Ohio; William Warren Potter, Buffalo, N. Y.; Augustus Korndorfer, Philadelphia, Pa.; Joseph M. Mathews, Louisville, Ky.

Illinois State Medical Society.

Fiftieth Annual Meeting, Springfield, May 15-17, 1900.

MEDICINE OR SURGERY: ARE THEY SEPARATE? IF NOT, WHICH IS THE SCIENCE, WHICH THE SPECIALTY?

DR. A. C. CORR, East St. Louis, delivered the address of the section on practice of medicine, using this subject. He said that medicine and surgery are inseparable in practice, except in the extremes; that medicine is a science and embraces all that comes under the head of the practice of medicine; that the tendency to be enticed by the glamor of surgery for its mere physical appearances is strong; but physicians forget that tissues have properties that may by a classified derangement constitute a disease and that these properties may be modified by medicines so as to correct the aberration and cure the disease. If surgery arrogates much, medicine must become in a restricted sense a specialty. The well-informed general practitioner is the only one who can comprehend the whole situation, is the safest one to trust, and the best exponent of the science and practice of medicine. None are competent to practice a specialty until they have studied and practiced general medicine for at least ten years.

DR. M. S. MARCY, Peoria, said that not every physician is a surgeon by any means and that the attempts of various physicians to become one have been detrimental to the population. This is especially true since appendicitis has become such a fashionable disease and there is a furor for operating. Owing to this, many lives have been sacrificed by inexperienced practitioners trying to operate on cases of appendicitis.

DR. H. B. BROWN, Decatur, said that the specialist should first be a general practitioner, and as such must necessarily have some knowledge of surgery, although his manual dexterity may not be as fully developed.

DR. R. H. HENRY, Peotone, said that the country doctor must learn to amputate a limb, to ligate an artery, and to perform laparotomy, etc., consequently he is a surgeon in the strict sense of the word, and that every practitioner must qualify himself the best he can to do surgical work.

DR. O. B. WILL, Peoria, said that some practitioners make good diagnosticians, some good therapeutists and others expert operators; and that what is expected of every man is that he will have sense to know, and the honesty to express himself when he does not know.

DR. J. N. NELMS, Taylorville, said that in order to be successful the surgeon must necessarily be a skilled mechanic, and that this requirement should be exacted of him before he graduates. If he has not the aptitude of a surgeon, he should be the first to know it, and people soon learn whether a man is skilful or not in any department of medicine.

DR. A. C. CORR, in closing, said that the essential feature of his paper was to elicit the opinions of members in regard to stopping, or at least restricting, what he designated as premature specialism.

CHRONIC GASTRITIS.

DR. JAMES BRAYSHAW, Berlin, contributed a paper on this subject, and entered a protest against the use of the tube recommended by Hemmeter; for, although it is quite soft, it is provided with a sharp, chisel-like edge around the lower opening, for the purpose of loosening pieces of carcinomatous tissue, and such an instrument is dangerous in the hands of the average practitioner. Fermentation and dilatation, one or both, are usually present in chronic gastritis, but chronic gastritis is not always an accompaniment of the former conditions. In the treatment he recommended lavage, as it not only cleanses the stomach, but stimulates the muscularis. Another method of treatment is the use of abdominal massage; this may be carried out more or less perfectly with the hands, if one is a skilled masseur, or by rolling a metal ball over the abdomen. A method he has not seen recommended, but which has given excellent results in his hands as an adjuvant, is the interrupted and alternating galvanic current passed directly through the walls of the stomach.

OUR MILK-SUPPLY; SOME OBSERVATIONS AT HOME AND ABROAD.

DR. S. E. MUNSON, Springfield, in discussing this subject, considered the milk from the time of its delivery to the conditions influencing its protection. He said that it is absolutely

essential to start with a healthy animal in order to have Nature's milk laboratory give us a supply of pure, wholesome milk. Such laws as we have already regulating disease in cattle should be rigidly enforced, and additional ones enacted. "Only the State can guard against the dirty milk, corrupted or polluted water-supply, impure ice, etc., and nothing but medical supervision will accomplish these objects, and there are no agents so effective as physicians to spread through all classes of the community the educational sense of sanitary decency."

DR. CHARLES B. REED, Chicago, mentioned the work of a legislative committee appointed to investigate the feeding of distillers' slops and brewery grain to cattle. It was found that cattle so fed were markedly tubercular to a greater degree than those that had been fed on so-called pasture food. It was likewise found that where the milk of these cattle was fed to infants and young children, there was a larger portion of infantile alimentary diseases.

DR. FRANK P. NORBURY, Jacksonville, spoke of the satisfactory results obtained in investigating the condition of cattle from the tuberculin test, and pointed out the great necessity and importance of conducting these tests and examinations more extensively, and having them involve all herds from which the public secures its milk-supply.

DR. W. H. KIRBY, Chestnut, said that the value of the tuberculin test had been conclusively demonstrated, and that all physicians should give it their support.

DR. E. H. OCHSNER, Chicago, said that if physicians, through their influence, would make a demand for Pasteurized or pure milk from tested herds, dairymen would supply it.

DR. KATHERINE MILLER, Lincoln, pointed out the necessity of having the milk-cans thoroughly clean, as the source of contamination in many instances can be traced to them.

DR. A. C. CORR, East St. Louis, said it is inconvenient and expensive for men who own small farms and have small herds of cattle to carry out some of the plans and tests mentioned.

NEPHRITIS.

DR. J. W. KELLY, Springfield, read a paper on this subject. He emphasized its prevalence, alluded to the reasons for this, and cited illustrations. He dwelt on the importance of an accurate and early diagnosis, and closed by reporting three instructive cases.

IS PNEUMONIA CONTAGIOUS?

DR. J. T. McANALY, Carbondale, considered this question, and the following conclusions and inferences were drawn: 1. Pneumonia is an acute specific and mildly contagious disease produced by the micrococcus lanceolatus, involving the vesicular structure of the lungs in an exudate of greater or less extent, and is attended by the severe and often dangerous constitutional symptoms due to the toxins produced by the infecting micro-organism. 2. Isolation should always be recommended, and no two patients should occupy the same room at the same time. The aged and children, owing to the great mortality among them and to the enfeebled powers of resistance of the former, should be excluded from the sick-room. 3. The room should be large, and should be kept well ventilated, as pure air is very essential for a pneumonia patient. The danger of vitiated air should be constantly borne in mind, for it is a point to be doubly guarded because of its harmful effects on the patient, and of its dangers to the attendants. 4. The prompt and thorough disposal of all pneumonic sputa is important, for while it may be harmless to-day, it may be dangerous to-morrow. Prophylaxis is clearly one of the most important points to be considered. Since the true nature of pneumonia has been demonstrated by the bacteriologist, we may the more readily appreciate its dangers and guard against the septic possibilities resulting from pneumococic invasions. 5. The rapid increase in our knowledge of bacteriology and the introduction of specific remedies afford ground for the hope that soon we may discover a treatment for this disease as certain and effective as that of antitoxin for diphtheria, or quinin for malaria.

THE EVILS RESULTING FROM NAMING DISEASES FOR INDIVIDUALS.

DR. N. S. DAVIS, Sr., Chicago, read a paper on this subject, bringing out the following points: 1. It is very inconvenient.

2. It is meaningless, i. e., it conveys no information concerning the causes of location, nature or results of the disease.

3. It is unscientific. Disease is necessarily a deviation from the healthy condition of function or structure of some part of the whole of the living body; consequently its name should be suggestive of the nature, and, when possible, also of the chief seat of the disease.

DR. HAROLD N. MOYER, Chicago, said that society owes thanks for this calling of attention to the vicious nomenclature of medicine, and that the time is almost ripe when organized medicine should take some action to abolish the method of naming diseases for individuals.

DR. JOHN H. HOLLISTER, Chicago, emphasized the necessity of creating an urgent demand by the medical profession for greater simplicity of terms, so that they shall be self-explanatory. He expressed the hope that the profession would soon reach the termination of the creation of new names for drugs.

DR. A. C. CORR said that physicians should keep in mind the physiologic action of drugs, in order to counteract the pathologic changes that take place and he able to meet the indications that are required in the treatment of the diseases which are recognized.

DR. T. J. PITNER, Jacksonville, called attention to the fact that in the specific diseases, where we have a distinct bacillus which is recognized as characteristic of and causing the disease, it does not act alone, but is modified by other germs and other pathologic processes which must be considered. Examples were cited.

DIAGNOSIS OF TUMORS OF SPINAL CORD AND ITS MEMBRANES.

DR. FRANK P. NORRURY, Jacksonville, considered this subject and said that disturbed functions of the cord vary in intensity and kind, involving either it or its membranes, or both. But as symptoms of organic disease, and especially tumors affecting the cord or its membranes, are similar, it is necessary to study symptoms in common. Practical diagnosis recognizes the local sequence of symptoms and does not accept as disease, what, in many instances, are purely symptoms. When possible, differential diagnosis considers the pathogenesis of tumors. Defective function is seemingly not commensurate with existing lesions, and in some cases the reverse is true. Symptoms should be systematically considered, and the plan of Eskridge is a good one, viz.: irritation of the nerve-roots; meningeal symptoms; cord symptoms.

Irritation of the nerve-roots begins by changes in sensibility—pain, neuralgia in character; and neuralgia is apt to be the diagnosis. Sensory symptoms, usually unilateral at the beginning, become more pronounced as the neoplasm develops. Segmental diagnosis is of assistance here, as soon as local symptoms appear. Motor symptoms usually give the clue as to localization; numbness, hyperesthesia, and later anesthesia follow along the distribution of the nerves involved; and contracture, spasm and exaggerated reflexes of the extremities are noted.

In regard to meningeal symptoms there are no pronounced differentiating symptoms, except Kernig's sign and muscular rigidity, when the upper cervical region is involved.

The cord symptoms are those of gradual compression of the cord, viz., motor and sensory paralysis, spastic symptoms, vasomotor, trophic and reflex changes, and differential diagnosis as to intradural, intramedullary location requires careful investigation.

The vasomotor and trophic symptoms are sweating, unilateral and profuse; occasional deep capillary flushings, herpetic skin eruptions; bed-sores, and change in the skin and nails.

As to differential diagnosis, caries is to be noted, the great point being the history or presence of tuberculous infection elsewhere. This is suspected in young persons, and especially when there is a clinical history suspicious of tuberculosis. The pain, tenderness, deformity, muscular rigidity, are also points in differentiations. Carcinoma is also to be considered—the history of removal of malignant growth. A case was mentioned with constant bilateral sciatica present; and lumbar carcinoma found after death; also some deformity, etc. Cervico-occipital neuralgia, myelitis, syringomyelia, spinal syphilitic tumor are also to be considered in differentiation.

The observations and conclusions were derived from the study of three cases: One of tuberculous tumor, intramedullary, cervical region; one of sarcomatous, dorsal region, extradural; one of carcinoma, extradural, lumbar region. Post-mortem findings confirmed the diagnosis in two cases.

DR. HUGH T. PATRICK, Chicago, said that the differential diagnosis of spinal cord tumor due to syphilis, as the gumma, had been omitted. He had seen several cases of spinal cord syphilis in Chicago.

DR. ARCHIBALD CHURCH, Chicago, said that he had seen four cases of tumor of the spinal cord, and that the most distinctive symptoms in all had been those of sensation. He regards it as exceedingly difficult to diagnose tumor of the spinal cord, and considers this largely tentative, unless confirmed either by surgical intervention or post-mortem examination. He related a case that had been operated on by Dr. Fenger, where the tumor seriously invaded the cord and produced a destructive myelitis.

DR. FRANK P. NORRURY, in closing, said the three cases reported by him had come under his observation during the last twelve years; and tumor of the spinal cord is a comparatively rare affection, there being only some 220 cases found in medical literature.

CALIFORNIA AS A HEALTH RESORT.

DR. J. H. HOLLISTER, Chicago, in a paper on this subject, considered: persons to be benefited; the locations suited to their various needs; and the proper care of such individuals. No climate in and of itself is curative, but the power for recovery must be inherent with the patient, as the environments at best are only helpful. With certain recuperative powers in the individual, the conditions which may best promote recovery are: a dry soil, with freedom from soil exhalations; a mild atmosphere, pure in quality and nearly uniform in temperature; exposure, with personal comfort, to continuous days of sunshine; wisely directed daily physical exercise; the residence isolated from crowded apartments, with good ventilation, proper drainage, and plenty of sunlight exposure; a liberal bill of fare, well selected and properly cooked; pleasant social relations and diverting pastimes. These are the ideal factors which promise most of helpfulness, so that in no single locality can one expect to unite them all, but such ideal conditions may be more nearly approximated in California than in any location with which we are familiar.

EVERY-DAY HEADACHES.

DR. HUGH T. PATRICK, Chicago, read a paper on this subject. He said that every-day headaches are those of eye-strain, migraine, neurasthenia, infection and intoxication—fever, constipation, indigestion, alcohol, etc. Those from migraine and neurasthenia are incomparably the most frequent, but the headache of the latter is not really a head pain, but nearly always a cephalic distress. The peculiarities, causes, and treatment were considered and several illustrative cases cited. Migraine, if not the most frequent headache, is the most often misunderstood, and its prevalence, nature, cause, peculiarities and variations were discussed; the diagnosis and treatment given, also illustrative cases narrated.

DO WE HAVE SMALLPOX?

DR. H. C. MITCHELL, Carbondale, discussed this question, now that we have an epidemic of smallpox, so mild in character that its fatality is almost *nil*; when such a state of affairs exists, we can rest assured that the diagnosis of smallpox will be questioned by the average physician and laity. The doubt manifested as to the diagnosis of the present epidemic is not because the symptoms are not identical with those of former epidemics, but because of its mildness and low fatality. The mildness of the disease can not be due to its having originated in a tropical country, because it has been clearly shown that in Cuba, where it is supposed to have started, the death-rate was relatively large. It can not be due to climatic conditions in our own country, because the disease prevails in the same mild type both North and South. He believes that this explanation may be offered: The disease is produced by several germs which differ as to the character of their virulence; for example, the pus-producing ones—streptococci and staphylococci. Or that it might be explained

on the hypothesis that smallpox, like measles, diphtheria, scarlet fever and similar diseases, often appears in mild form. This may not be a satisfactory explanation, because in these diseases, when they appear in their mildest forms, there will occasionally be some malignant cases and deaths, while in this instance we have a more fatal disease than any of the others mentioned that has been running for three years with practically no death-rate.

TREATMENT OF THE OPIUM HABIT BY THE BROMID METHOD.

DR. ARCHIBALD CHURCH, Chicago, read a paper on this subject, and said that in the *British Medical Journal*, July 10, 1897, Dr. N. Macleod, of Shanghai, reported seven cases which he had treated by what he called the "bromid sleep." Briefly, the purpose of this treatment is to stupefy the patient utterly for a number of days, during which time the opium is rapidly withdrawn, with also recovery from the physical disturbance secondary to its withdrawal. Macleod states that early in 1897 a neurasthenic woman, addicted to the use of morphin for nine years, by accident, had administered to her 2½ oz. of sodium bromid in something over two days. A profound sleep was induced, lasting several days, and when its effect wore off the craving for morphin had ceased and with it the various disturbances which had led to its use. A few months afterward a pilot, who was addicted to morphin and alcohol, agreed to try the effect of the treatment; no suffering was experienced during the withdrawal of the morphin, craving for which, as well as for alcoholics, disappeared on recovery from the bromid sleep.

He also gave the histories of two other cases treated by the Macleod method: in the first, the result was excellent; the second, which might have been a successful result, so far as the bromid treatment was concerned, terminated fatally, perhaps by the bromid aggravating a nephritis. The method of administration, which has been gradually developed as the result of the experience of Macleod and his own observations, was formulated thus: The drug should be given only in the daytime; 120 grains of sodium bromid in a half tumbler of water, every two hours, until an ounce is given in the same way, and this may be sufficient, or it may be necessary to continue the doses in the same way on the third day. Macleod says a safe rule is to cease the administration of the bromid after twenty-four hours, when drowsiness is so profound that the patient can not be aroused, or when aroused is incoherent. If the sleep continues or becomes deeper, no more bromid will be needed. It is to be remembered that the bromid acts in a cumulative manner. After the second or third day, when the bromid is withdrawn, the drowsiness, in some cases actually coma, tends distinctly to deepen for forty-eight hours, so that the fully-developed sleep presents a rather alarming condition to any one not familiar with it. For two or three days there is difficulty in feeding the patient, and swallowing is sometimes impossible, so that rectal alimentation is required. During this treatment, there is apparently a tendency to aspiration pneumonia, so that feeding by the mouth becomes doubly dangerous. Any septic condition in the pharynx or in the antra communicating with the mouth should contraindicate the treatment. The poisonous effect of the bromid apparently falls on the respiratory and cardiac centers, so that a weak heart or impaired pulmonary conditions would furnish reasons against the method. From the case of nephritis, that he had reported as terminating fatally, it is strongly suggested that bromid of sodium in large quantities acts harmfully upon the kidneys, if they are diseased, and therefore any degree of nephritis should be a contraindication to this line of treatment. Three deaths being occurring in twelve cases, although in each instance attributable only remotely to the bromids, and occurring where it had been used in extraordinary doses—doses that can no longer be advised—show that the plan of treatment is very far from being simple and without danger. However, as compared with the difficulties of the ordinary methods that are pursued in correcting the addiction to morphin, it seems to be of very definite value in well-selected cases; and can then be used without hesitation, under appropriate safeguards.

(To be continued.)

Association of American Physicians.

Twenty-sixth Annual Meeting, Washington, D. C., May 1-3, 1900.

President, Dr. E. G. Janeway.

ACID INTOXICATION.

DR. C. A. HERTER, New York City, in a paper on "Experimental and Clinical Study of Acid Intoxication," referred especially to the presence of oxalic acid and oxalates in the urine, and said that animals kept on a mixed diet have 67 mg. of oxalates in twenty-four hours' urine, while those on a diet of milk are free from oxalates; and that dogs fed on a sugar diet in the course of a few weeks are taken with intermittent diarrhea and gastric disturbances, with oxalates in their urine, and that all this goes to show that the oxalates are formed within the body. He concludes that this is done in the stomach and that it is probably due to an organized ferment.

DIABETES.

DR. J. B. HERRICK, Chicago, presented a paper on this subject and spoke of the low specific gravity of the urine in some cases, it being influenced by the large amounts of fluids taken. He has had cases with specific gravity as low as 1004, and has found albumin and casts not uncommon in diabetic urine, the latter being unusually abundant preceding coma.

URIC ACID AND EPILEPTIC ATTACKS.

DRS. JAMES J. PUTNAM and F. PFAFF, Boston, presented a paper entitled "Communication on the Relation of Uric Acid Secretion to Epileptic Attacks," and said that there is no difference in the amount of uric acid secreted during or between the prooxysms.

CASE OF ACUTE ASCENDING PARALYSIS, SHOWING HEMATURIA AND PYRINURIA.

DR. CHAS. G. STOCKTON, Buffalo, N. Y., read a paper on this subject, in which he reviewed the history of a case of this quite fully. He said that the claret-colored urine was not due to any of the indican bodies, for they were absent, but that there was a relationship of the pigment to the inflamed condition of the spinal cord.

INFREQUENCY OF TRANSMISSIBLE DISEASES IN CHILDHOOD.

DR. A. C. ABBOTT, Philadelphia, presented a paper on the "Relative Infrequency of Acute Transmissible Diseases During the First Year of Childhood: with a Discussion of the Probable Reason for the Same." By means of a number of statistical charts, he was able to show that acute infections, especially of measles and scarlatina, are relatively rare in children under one year of age, and very rare in those less than six months old. He thinks that this immunity is due to the mother's milk.

RECURRENT VOMITING IN CHILDREN.

DR. J. P. C. GRIFFITH, Philadelphia, in a paper on this subject reviewed the histories of four cases, and said that recurrent vomiting, often called cycle vomiting, is too little discussed. Of the cases under consideration, the third and fourth were fatal; the first, mild, and the second, very severe, but recovery took place. The symptoms were as follows: vomiting almost incessant, with obstinate constipation, not relieved when the bowels were opened; exhaustion marked, but no abdominal pain; they appeared to be at the point of death, but quickly recovered.

DR. CHAS. G. STOCKTON said that the character of the vomit had not been given and that in his cases it was pure gastric juice.

DR. JOHNSON, Washington, D. C., had a case in which the vomit was like coffee grounds.

PULMONARY TUBERCULOSIS.

DR. E. L. TRUDEAU, Saranac Lake, N. Y., presented a paper entitled "Sanitarium Treatment of Pulmonary Tuberculosis and Its Results," in which he spoke of the advantages of the sanitarium treatment over the old routines, and mentioned as especially necessary: good climate, well-regulated open-air life, proper food and care in regard to daily habits. He said that the incipient stage of pulmonary tuberculosis is not generally recognized; and that the X-ray, together with the tuberculin test, are valuable in aiding to make a diagnosis.

DR. NORMAN BRIDOE, Los Angeles, said that three-quarters of his cases were managed best by treatment outside of the sanitarium.

DR. FRANCIS KINNICUT, New York City, reported a case of phlegmonous gastritis and exhibited some specimens.

ORGANISM AND LESIONS OF ACTINOMYCOSIS.

DR. J. H. WRIGHT, Boston, considered this subject, and said that this disease goes frequently unrecognized, and it is much more common than one would suppose. He considers it a subacute or chronic process, and spoke of the difficulty in making cultures of these organisms; he showed a number of specimens by lantern slides and said that it was not necessary to stain a fresh specimen of one of the rays in order to make a diagnosis.

SPOROTHRUX.

DR. L. HEKTOEN, Chicago, read a paper entitled "A New Pathogenic Fungus" (Sporothrix), which was first described by Schenck, and gave the history of a patient who was inoculated with this new organism by a punctured wound of the fingers, due to an iron nail, and said that several different cultures produced the same organism.

PERNICIOUS ANEMIA.

DR. RICHARD C. CABOT, Boston, presented a clinical study of 110 cases; and in speaking of its etiology said that the disease is more common in males, that late middle life is predisposed to it, and that the menopause bears no relationship to the disease. The symptoms are relatively constant in all of his cases, viz., hemorrhage of the nose and mucous membranes, muscular weakness, shortness of breath, gastrointestinal irritation, which is paroxysmal, some slight fever, about 99 F., frequent myelitis together with the blood changes. He thinks that treatment is hopeless, that the average duration of the disease is from two to three years.

BLOOD FINDINGS IN PERNICIOUS ANEMIA.

DR. FRANK BILLINGS, Chicago, read a paper entitled "Report of Cases of Pernicious Anemia with Special Reference to the Blood Findings." He showed some very interesting charts that illustrated the rise and fall of the polychromatophiles and the nucleated red corpuscles, together with the color-index, and brought out their relationship to the periods of improvement and decline. He spoke also of the increased number of eosinophiles accompanying apparent improvement.

NOTES ON CASES OF PERNICIOUS ANEMIA.

DR. F. P. HENRY, Philadelphia, reported five cases, three of which had autopsies; some had paralysis of the extensor muscles of the extremities, though this is rather uncommon. His theory is that in this the blood of man reverts to that of the cold-blooded animals.

DR. H. A. HARE, Philadelphia, said that he thinks a great many changes in the form of the blood-corpuscles takes place in health, and suggested work in this line, because we know more about the pathology of blood than about its normal changes.

DR. WM. H. THOMSON, New York City, spoke of Hunter's theory of pernicious anemia, which makes it due to suppuration at the roots of the teeth.

DR. W. H. THAYER, Baltimore, Md., said that he thinks that a diagnosis could not be made by the blood count alone.

DR. DACOSTA said that the length of remissions is often as long as eight and ten months.

STRONGYLUS INTESTINALIS.

DR. W. S. THAYER, Baltimore, Md., gave a report of "Two Cases of Diarrhea Associated with the Presence of Strongylus Intestinalis in the Stools," and said that the character of the diarrhea was interesting inasmuch as it was never painful, and appeared to be the first described in the United States.

FILARIA.

DR. W. T. COUNCILMAN, Boston, read the report of a case of filaria and showed specimens of the adult parasite. The patient, who was a native of Barbados, had several live adult filaria in his left testicle and also in the blood.

THE ELIMINATION OF DELETERIOUS SUBSTANCES FROM ANTI-TOXIC SERA.

DR. W. H. PARK, New York City, read a paper on this subject, in which he said that antitoxins are of the nature of globulins, because they give the same clinical reactions, and when there is an increase in the number of toxins in the blood there is also in the globulins. He spoke of the deleterious effects

that the sera of certain animals have on the individual and suggested that only those animals he used which by experiment have been found not injurious.

VARIETIES OF DIPHTHERIA BACILLUS.

DRS. F. F. WESTBROOK, WILSON and McDANIEL, Minneapolis, Minn., presented a paper on this subject. Dr. Westbrook illustrated with several water-colored charts, and divided the diphtheria bacilli into three groups, viz., granular forms, barred forms and solid color forms, and said that some of them are able to change their shape through morphological development.

ADDISON'S DISEASE.

DR. W. W. JOHNSTON, Washington, D. C., presented a case of Addison's disease that has been under treatment with suprarenal extract. The patient has shown a marked improvement by an increase in weight, though this is due as much to rest as to the treatment.

VENOUS THROMBOSIS AS A COMPLICATION OF CARDIAC DISEASE.

DR. WM. H. WELCH, Baltimore, Md., considered this subject and reported four cases. Cultures taken from the thrombus after death were infected, while cultures from other parts of the body were not. He reviewed the literature of twenty-three cases.

CIRRHOSIS OF LIVER.

DR. SIMON FLEXNER, Philadelphia, presented a paper entitled "The Nature of the New Tissue in Cirrhosis of the Liver and Its Distribution." He said that the pathology is not well understood, but that the introduction of special stains has made the study of elastic tissue possible; and that in studying the distribution of the elastic tissue, staining has been combined with a process of digestion and in this way he has been able to separate some of the different kinds of connective tissue.

MULTILOCULAR CYSTOMA OF PANCREAS.

DR. R. H. FITZ, Boston reported a case in which the cysts were successfully removed by operation, and the patient recovered.

DEGENERATED ECHINOCOCCUS CYSTS OF PLEURA.

DR. CHAS. CARY, Buffalo, N. Y., presented a paper on this subject and told of a patient who had never been out of the United States.

MINOR FORMS OF CARDIAC DILATATION.

DR. BEVERLY ROBINSON, New York City, discussed this subject and spoke of three types in which the disease is found, viz., the young anemic girl, the fat woman, and the nervous woman about the age of 40.

GRAVES' DISEASE WITHOUT EXOPHTHALMIC GOITER.

DR. WM. H. THOMSON, New York City, read a paper on this subject and said that it is a distinct disease, not an undeveloped exophthalmic goiter; that tachycardia is the first symptom to appear and the last to disappear; and that there were often sensory and motor disturbances. He spoke also of the gastric disturbances and said that he believed the disease to be of a gastrointestinal origin.

PERICHONDRITIS OF LARYNX.

DR. M. H. FUSSELL, Philadelphia, discussed this subject and exhibited a patient and a specimen. He said that only 7 per cent. of cases of typhoid fever are thus affected.

APPENDICITIS AND TYPHOID FEVER.

DR. H. A. HARE, Philadelphia, read a paper entitled "The Attitude of the Physician and Surgeon to Appendicular Symptoms. Complicating Typhoid Fever," and cited cases that he has had simulating appendicitis, which after twenty-four hours became typical typhoid fever.

Southern Medical Association.—This Association met in Sparta, Ill., May 11 and 12. The following officers were elected for the ensuing year: president, F. T. Grinstead, Cairo; first vice-president, H. L. Gault, Sparta; second vice-president, A. A. Dean, Campbell Hill; secretary, A. B. Ormsby, Murphyboro; assistant secretary, Emmett Bottom, Murphyboro; treasurer, A. Tilford, Menard.

American Gynecological Society.

Twenty-fifth Annual Meeting, Washington, D. C., May 1-3, 1900.

President Dr. George J. Englemann, of Boston, in the chair.

OPERATION FOR PRIMARY VAGINAL CARCINOMA.

DR. WILLIAM R. PRYOR, New York City, read a paper on "Operation for Primary Vaginal Carcinoma, Applicable also to Cancer of the Rectum in Women," in which he mentioned the fact that cancer of the vagina is very rare, involving usually its posterior wall, and extending underneath the rectum, then to the vaginal structures and to the uterus. He described the operation as performed by him in two cases, where he removed all the organs in which recurrence was apt to take place, and worked from above downward. The steps being: 1. The general preparation of the patient. 2. The incision from the umbilicus to the pubes. 3. The ligation of the vessels and ligaments. 4. Dissection of the bladder from the cervix and entrance to the vagina anteriorly. 5. Removal of the vagina and the entire rectum. 6. Ligation of the obturator artery to prevent anastomotic circulation being formed.

The technique of the operation was illustrated by drawings.

DR. PAUL F. MUNDÉ considers it fortunate that these cases are rare; he has never seen but two, and says that he has curetted and cauterized, but does not think that radical work repays for the slight benefit received.

DR. R. S. SUTTON, Pittsburg, Pa., had seen but one case in thirty-four years, and does not favor radical operations. He thinks that the pathology of cancer should engage our attention instead of a new method for its removal.

DR. E. VAN DE WARKER thinks that nothing has been gained by operations for cancer.

DR. E. E. MONTGOMERY, Philadelphia, believes that the great frequency of recurrence of malignant disease, where it involves the vagina, and extends into the parametrial tissue and the broad ligament, makes questionable the operative treatment. He has seen patients in whom he felt that an operative procedure would result favorably, but in whom there was an early return of the disease, while in other cases of extensive destruction of the cervix, the patients lived several years without recurrence.

FECAL FISTULA.

DR. I. S. STONE, Washington, D. C., read a paper on this subject. He regards fecal fistulae one of the most distressing and annoying of post-operative sequela, and thinks that possibly the larger number of them follow in the wake of appendiceal abscess, and that there can be no routine treatment. Mention was made of certain methods that he believes are followed by the best results, for instance in cases in which the cecum and ascending colon are greatly thickened and firmly bound by adhesions, a section of the ilium may be taken as near the caput coli as convenient and transplanted, or an end-to-side anastomosis may be made to the transverse colon. He gave his successful experience in two cases of recto-abdominal fecal fistulae of long standing. In all of these that are persistent any foreign body must be removed, and all attempts at skin closure, by cauterization or by curettement are generally successful; and in all cases where a fistula connects with the superficial coil of intestine, the method of Greig Smith may be tried before resorting to radical operation. Recto-abdominal fistulae should, if possible, be converted into recto-vaginal fistulae, and closure of the tract secured before temporary fistulae are allowed to close.

DR. A. F. CURRIER, New York City, has seen but one case of fistulae of the small intestine and this was finally cured by section of the small bowel. He believes that in these cases, including the small intestine, it is not wise to wait, and in those situated low down, he does not advocate hasty operative procedures, having seen a number of cases where by waiting, Nature instituted a cure.

DR. C. P. NOBLE, Philadelphia, has seen a number of fecal fistulae, all but four of which closed spontaneously, three remained obstinately open, and one recovered after operation.

DR. A. P. DUDLEY, New York City, said that in operating for cancer and in breaking up the adhesions, he has broken the small intestine in two and put in a Murphy button, that was afterward recovered, having worked down to the rectum, and out through the fistula behind the uterus. Although he had expected the woman to die, the fistula healed and she recovered.

DR. P. F. MUNDÉ referred to three cases of fistulae resulting from the intestinal opening of the intestines in order to relieve an obstruction to the bowels that was tending to general peritonitis following some abdominal operation. He agreed with Dr. Currier that in fistula in the small intestine it is well to wait, but in the same condition in the large bowel, the abdomen should be opened.

DR. M. D. MANN believes that we are almost always obliged to open the abdomen in fistula of the small intestine, and that further treatment will depend on the opening; if it is close to the mesentery it will be dangerous to sew it, and if large it should not be sewed for fear of stricture.

DR. I. S. STONE, in closing, said that the Society seems agreed as to the danger of opening the abdomen in these conditions, and that it should be done only after every special method has been employed.

DR. W. L. BURRAGE, Boston, reported 137 operations which were performed on diseased uterine appendages, with the object of preserving one ovary, or portion or portions of one or both ovaries with their tubes, or as much of the tubes as was reasonably normal in appearance. He gave the results in 85 of these, the table being divided into the more severe and the less severe. By comparison it was found that in the majority of the former gonorrhoea and syphilis were more prevalent, that the symptoms had resulted more frequently from difficult labors, or abortions, and that the tubes were closed; whereas they were open in all but one of the less severe. Pregnancy followed operation in four of the more severe, and in 11 of the less severe. Anatomical cure was reported in 33 out of 57 cases, and symptomatic cure in 60 out of 85. In women of both classes, who have borne children, subsequent pregnancy may be expected in 35 per cent., whereas in previously sterile women, it may be looked for in only 5 per cent.

DR. A. P. DUDLEY said that in a case of double pyosalpinx he had taken the tube off and left the ovary hanging, then brought the uterus up and split the fundus in two; and he was absolutely sure that the ovary had grafted, and that the patient is now menstruating every twenty-eight days. He had had five cases in all, in which, not being able to save any of the tubes, he had planted the ovary, and in all he was sure it had grafted, as every portion of the discharging stricture had been analyzed.

DR. H. N. VINEBERG, New York City, said that the class of cases in his hands, which had given the poorest results had been those in which the lesions had not been very severe.

DR. M. D. MANN, Buffalo, N. Y., mentioned a case in which one tube and ovary were entirely removed, and the others were in bad condition. The tube was opened, and after breaking up the adhesions, left, together with the ovary. Four children have since been born, three girls and one boy. This is interesting in the matter of sex in regard to one ovary.

DR. J. RIDDLE GOFFE said that he was approaching his one hundredth case of conservative work on appendages, which had been very largely through the vaginal, rather than the abdominal, incision.

DR. W. L. BURRAGE, in closing the discussion, said that he has operated twice in cases where there was no symptomatic and anatomical cure, and that there were several other cases, where operation was needed but the patients would not submit and he had used the cautery. He has had in his experience pronounced neurasthenia in patients past the age of 33 years, and in those cases either complete removal or no operation is indicated, as they do not do well after resections.

INTERNAL SECRETION OF OVARY.

DR. A. W. JOHNSTONE, Cincinnati, Ohio, in a paper on this subject, said that retained secretions are the cause of nearly all conditions. For if it is a lack of an internal secretion that

causes the nervous menstruation disturbances of the menopause, why is it that delayed menstruation in a child-bearing woman will produce identically the same symptoms as those of the menopause? This is apparent to all in our every-day work, and has occurred so often that he believes that if a woman's menstruation is delayed for any reason except pregnancy, she is apt to have symptoms closely approximating those of the change of life. This leads him to believe that the internal secretion of the ovary is a myth.

THE TECHNIQUE, INDICATIONS AND ULTIMATE RESULTS OF SUTURING THE ROUND LIGAMENTS TO THE VAGINAL WALL FOR RETROVERSIONS AND FLEXIONS OF THE UTERUS.

DR. HIRAM N. VINEBERG, New York City, described in detail the technique because he felt that the method was not correctly understood. The patient is prepared as she would be for a vaginal hysterectomy, and when the uterus is unusually large and heavy, or the utero-rectal ligaments are put on high tension by anteverting the uterus, it is wise to employ a single uterine fixation suture in addition to the round ligament sutures. To avoid the possibility of dystocia in the event of pregnancy this should not be placed too high up on the uterine wall. Any operation on the cervix that may be called for is now done, and the posterior vaginal wall or perineum subjected to any plastic operation that may be deemed necessary. The patient is kept in bed for twelve days, when the round ligament sutures may be removed and also the uterine sutures, if they are present.

In 64 per cent. some surgical work on the adnexa was found necessary. In 53 consecutive cases the results show no mortality; in 48 cases convalescence was uneventful, and in only 1 was there absolute failure, the uterus being found in retroversion six weeks after the operation.

DR. A. F. CURRIE said that fixation can be done through the abdomen, and his plan is to limit the operation to those cases in which a later one is necessary.

DR. R. S. SUTTON hopes that soon the abdomen will not be opened as often as it is now, and that pelvic diseases may be attacked almost exclusively by the vaginal route.

DR. J. W. BOVÉ considers that the Alexander operation possesses an advantage over the shortening, inasmuch as it does not require the opening of the peritoneal cavity.

DR. J. RIDDLE GOFFE expressed the belief that we will not have to wait long until all pelvic work will be done through the vagina. He believes that laparotomy is not justifiable until it is found impossible to relieve the patient by a vaginal incision. In only one case within the last few years has he been compelled to resort to laparotomy to complete the work.

DR. HIRAM N. VINEBERG thought that the cases may require to be selected for the vaginal route, and that some are best approached from the abdomen.

PREGNANCY IN LABOR.

DR. J. CLARENCE WEBSTER, Chicago, offered for inspection some casts illustrating the anatomy of pregnancy in labor, also models used in gynecologic teaching. Many clinical observations made by him in regard to the topography of pregnancy had been reproduced in frozen sections.

DR. BUCKMASTER spoke of a method of reproducing the process of an operation by paraffin.

ANASTOMOSIS OF URETERS WITH INTESTINES.

DR. REUBEN PETERSON, Chicago, considered this subject and gave a historical and experimental research. He presented first an exhaustive review of the literature, then a description of his experiments, from which, together with the work of others, general conclusions were drawn. The most striking fact is the exceptionally high mortality attending the operations; out of 60 dogs operated on by the various experimenters, where one ureter was implanted in the intestine, there was a mortality of 61 per cent.; out of 65 dogs undergoing bilateral ureteral anastomosis, there was a mortality of 87 per cent. The majority of the deaths resulted from peritonitis. The method which calls for the least amount of suturing of the ureter itself is found to give the best results. He gave a short abstract of the 28 uretero-intestinal anastomoses in man, showing that the primary mortality of 32 per cent. is high.

EVOLUTION OF TECHNIQUE IN TREATMENT OF FIBROID UTERINE TUMORS.

DR. H. A. KELLY, Baltimore, Md., in this paper referred to his method of controlling the uterine vessels, which he considers a remarkable advance on any that has preceded. He briefly detailed his method of dealing with very difficult cases, such as large adhering tumors, and gave the following ways of dealing with them: by median sagittal incision of the uterus with the tumor; by a corona bisection of the uterus with its cervical portion; by a bisection of the tumor alone. The principle of the operation is the same in all cases. The best method of enucleation is to seek at first to isolate and ligate the ovarian vessels of one side and to expose the uterine vessels, then cut across the cervix, clamp the opposite uterine artery and the round ligament, and lastly, the ovarian vessels.

GYNECOLOGY IN THE LAST QUARTER OF A CENTURY.

DR. GEORGE J. ENGLEMANN, Boston, in his presidential address, gave a historical review of the various periods in gynecology in the last quarter of a century. The trend of modern medicine is toward research for cause and prevention, and the main cause of suffering is found on the great waves of a woman's life—puberty, menstruation, labor, and the menopause.

INTRA-ABDOMINAL AMPUTATION OF THE UTERUS; A MODIFICATION OF HYSTERECTOMY.

DR. F. H. DAVENPORT, Boston, in a paper on this subject, stated that the indications for hysterectomy are quite well established, and that interest is now centered on the technique. In a young married woman, whenever possible, he prefers to leave the cervix, and for suitable cases, chooses the abdominal route; he operates by the vagina for cancer, either of the cervix or body. The essential feature in which his method differs from that usually employed is that the uterine arteries are not ligated.

KELLY'S METHOD OF REMOVING THE FIBROID UTERUS VIA ABDOMEN.

DR. A. LAPHORN SMITH, in speaking on this subject, said that the advantage of Kelly's method lies in the fact that the operation is commenced on the easy side, and after securely tying the ovarian, round ligament and uterine arteries, and separating the bladder, we cut across the cervix and roll the tumor out, thus obtaining plenty of room to tie the arteries from below upward. Another great advantage is that there is much less danger of injuring the ureters. He lays even greater stress than does Kelly on the importance of feeling for each individual artery, and tying it before cutting it, and then putting on a second ligature. He strongly advises the use of chromicized catgut, and just as firmly opposes leaving the ovaries and tubes and myomectomy, and he holds the opinion that all fibroid uteri should be removed as soon as discovered, because a woman with a fibroid is liable not only to hemorrhage, but to reflex disturbances of digestion and circulation. He objects to a preliminary curetting, because it is unnecessary, and when done is seldom effectual, and also to vaginal morcellation which is not to be compared with Kelly's method.

He strongly advises the closure of the abdomen with through-and-through silk-worm gut sutures, left in for three or four weeks, for then, if not tied too tightly, and redressed with boric acid in abundance, the one dressing, or at most two, will suffice.

BRONCHIAL DISEASE AND ETHER ANESTHESIA IN ABDOMINAL SURGERY.

DR. THADDEUS A. REAMY does not think that bronchial disease is invariably a contraindication for anesthesia in abdominal surgery. He said that his personal experience with surgical anesthesia covered 8000 cases; his obstetrical work, 3000 deliveries; and that 2000 of these were under chloroform anesthesia. Although he much prefers ether, he has never lost a patient under either ether or chloroform. He mentioned as the proper conditions in the administration of both, the preparation of the patient; the temperature of 98 to 100 F. in the operating room, where the anesthetic should be administered; the placing of the chest and trunk of patient lower

than the pelvis; and of the pure quality of the ether, and the inhaler that must permit of the re-inhalation of the vapor, no more to be used unless the operation lasts more than forty minutes. He has witnessed but one case in which pneumonia was probably induced by ether inhalations, but has seen bronchitis, both acute and chronic at once cured as a result. He would not employ ether in the presence of emphysema.

DR. MALCOLM MCLEAN emphasized the importance of the high temperature of the room and spoke against any confusion that would make it necessary for more ether than would otherwise be required.

DR. T. A. REAMY regards conversation in the room of great disadvantage. His rule is to allow no one to speak until the patient is unconscious. He emphasizes the fact that the room must be hot and the ether given in the operating room.

RELATIONSHIP BETWEEN DYSMENORRHEA AND APPENDICITIS.

DR. ARCHIBALD McLAREN, of St. Paul, Minn., considered the influence of pelvic and inflammatory conditions on menstruation. In 200 laparotomies, he had 158 cases where inflammatory appendages had to be removed and in 40 per cent. the appendix showed evidence for removal, but does not advocate doing so always. The technique of his earlier operations was given; in later years he has adopted the method of Kelly.

DR. A. J. C. SKENE said that the relation of appendicitis to dysmenorrhea was a new idea to him, and explained certain observations for which he had previously been unable to account.

DR. A. LAPHORN SMITH'S experience coincides with that of Dr. McLaren. He had often been called in consultation with two doctors, one being of the opinion that the condition was salpingitis, and the other appendicitis; and since he has had more experience he agrees with both.

PELVIC ASYMMETRY.

DR. PHILANDER A. HARRIS, Paterson, N. J., demonstrated the utility of a certain chart for the determination of pelvic asymmetry by a very simple method of external pelvimetry. He exhibited the instrument and urged a more frequent use of the pelvimeter, and also showed photographs illustrating the advantages of employing a certain background in the photography of pathologic specimens.

The officers for 1900 are: president, E. Van de Warker; vice-presidents, Charles Jewett and R. B. Maury; secretary, J. Riddle Goffe; treasurer, J. Montgomery Baldy. Chicago was selected as the next place of meeting.

German Congress of Internal Medicine.

Wiesbaden, April 21, 1900.

ENDOCARDITIS.

The two principal subjects discussed: "Treatment of Pneumonia" and "Endocarditis," were ably handled by Koranyi, Pel and Litten, but nothing new was presented except Litten's classification of endocarditis. He rejected the anatomic divisions: verrucose, ulcerative, etc., as endocarditis may occur and kill before vegetations or ulcerations have appeared, and they are not characteristic of any clinical manifestation. He proposes a classification based on the clinical evolution and the degree of virulence of the micro-organisms, distinguishing three varieties: the benign, the malignant nonpurulent, and the malignant septicopyemic. Benign endocarditis occurs in the course of an infectious disease: rheumatism, chorea, gonorrhoea, purpura, typhoid or the eruptive fevers, diphtheria, pneumonia or tuberculosis, or it may be of ex-influenza or traumatic. It is not a morbid entity but merely a localization of the infective process. The anatomic manifestations may be verrucose or ulcerative, and there are usually metastases, which may be simple bland infarcts, or suppurative emboli in consequence of the participation of pyogenic micro-organisms. If the agents of the infection are unusually virulent they may induce the second variety, malignant nonpurulent endocarditis, which is generally fatal, while the benign terminates in recovery. The third variety, malignant septicopyemic endocarditis, is merely one manifestation of the general invasion of the organism. Traumatic endocarditis may

develop sooner or later after a trauma, even without external manifestations of injury to the thorax, and may remain benign and heal, or may lead to chronic valvular defect. It is also liable to become complicated with secondary pyogenic infection and assume the malignant septicopyemic form. Wassermann believes that any kind of bacterium settling on the endocardium may induce endocarditis, and that the benign or malignant character is not due to the virulence of the germ, but rather to finer biologic processes such as Ehrlich has demonstrated in his research on the hemolysins. His, of Leipsic, reported observations in which acute gonorrhoea had an aggravating effect on pre-existing valvular affections. Jurgensen asserted that the share of the myocardium in the cardiac complications of infectious diseases has been underestimated, and remarked that the character of acute articular rheumatism has altered in his experience of late years. There is less fever and swelling of the joints, and the pains extend through the diaphyses. The course is more insidious; the functional disturbances of the heart occur earlier and more frequently; respiration is accelerated and he has observed nervous phenomena, choreic, cataleptic or reflex.

EXPECTORANTS.

In discussing expectorants, Naunyn recommended potassium iodid in pneumonia and rebellious bronchitis with certain limitations, and Senator reported extremely favorable results from the use of hot water, which he administers in bronchitis and rebellious catarrh in the form of hot alkaline mineral waters.

CARCINOMA OF ALIMENTARY CANAL.

Boas reported that he had become convinced from his study of two hundred cases of this affection that the influence of heredity is much overrated. On the other hand, his belief in the noncontagious character of carcinoma has been rudely shaken by twenty-two observations on its occurrence in persons living together. He proclaimed the necessity of prophylactic measures, especially in regard to the dejecta of carcinomatous subjects, and articles they have used, dishes, toilet articles, etc. Meat-eaters predominate in his experience, but vegetarians are quite frequently affected. Alcoholic antecedents were noted in 40 per cent. of his observations. Traumatism, he adds, may unmistakably favor or arouse carcinoma of the alimentary canal, and likewise phthisis, diabetes, and syphilis.

New York County Medical Association.

CONTINUATION OF DISCUSSION ON DR. HOWARD KELLY'S PAPER ON "THE PRESENT STATUS OF OPERATIONS FOR CANCEROUS UTERI."

(Concluded from p. 1220.)

DR. H. J. BOLDT, New York City.—When your president requested me four months ago to take part in the discussion of Dr. Kelly's paper, I accepted with pleasure, not because I thought that I would be able to add to the value of the discourse, so far as treatment was concerned, because I knew that what the gentleman would speak about would be thoroughly weighed and studied, to enable him to contribute something of real value to the profession, but as I desired to add my opinion, based on the observation of a considerable number of cases. Fortunately the time given me has been sufficient to enable me to make an inquiry from all accessible surviving patients who have been under my care with cancer of the uterus.

The question as to what are the ultimate results in treating cancer of the uterus can only be answered intelligently, if the extent of the invasion of the cancerous neoplasm be defined in the individual case; the operator should differentiate these cases with regard to the prognosis, guiding himself by the ascertainable local extension. We must look on cancer of the uterus as a local disease in the initial stages; therefore, we are in a position to say that if the malignant neoplasm is diagnosed during such early stage, before it has gone beyond the uterus, the ultimate result as to final cure is good in the hands of an operator who is a master in the technique of performing hysterectomy. Unfortunately, however, it is but seldom that

patients are seen in the beginning stages; they do, however, increase in the practice of those who, on the slightest suspicious symptom, make a careful examination of such patient, and who, in all submitted to an abrasion of the uterine mucosa, have the scrapings carefully examined by a competent pathologist. The scrappings, in giving a prognosis, must also be considered as an important factor; the older the patient, the better is the prognosis, always with the proviso that the case is one very favorable for a radical operation. Women under 30 years, unless the neoplasm is in its incipient stage, give an unfavorable prognosis as to ultimate freedom from the disease. Its seat has also a bearing on the prognosis. The most favorable cases are, so far as my own experience goes, malignant disease of the uterine body; next favorable, cancer of the vaginal portion; then cancer of the cervical mucous membrane. The most unfavorable variety is the cervical cancerous nodule.

The method usually adopted in citing the value of treatment for cancer of the uterus loses greatly by neglect of consideration of the points noted. It is obvious that it is an injustice toward any given therapy to quote, for instance, that of 100 cases of cancer of the cervix operated on by vaginal hysterectomy, 50 patients are alive after one year; 30 after 2; 10 after 3; 8 after 4; 1 after 5 years. For the purpose of arriving at an accurate prognosis, as to the ultimate results, we should know what the form or variety of cancer was; which part of the cervix was the seat of the neoplasm; how much progress the disease had made at the time of operation; the age of the patient operated on, and then the description of the operative technique adopted in the respective instance. As an illustration permit me to cite an instance: A nullipara, 26 years old, presented herself with an epithelioma of the portio vaginalis, twenty-seven months ago. The vagina was appreciably infiltrated about one-fourth of an inch from its junction with the cervix. The parametria were free on the right side; on the left there was a slight thickening of the base of the broad ligament, which did not impress me as malignant, on account of the lack of a board-like, unyielding hardness. After rapid removal of the readily breaking down neoplasm, with a sharp curette, and subsequent cauterization, the upper half of the vagina was detached and closed over the portio by a continuous suture; the bladder, with the ureteral terminations, was well pushed out of the field of operation by a large gauze strip; the parametria were ligated as far from the cervix as possible and the uterus removed *in situ*, with the adnexa. The patient is still free from any evidence of recurrence.

Suppose the technique would have been such as we frequently see employed even at this day; curetting of the disintegrated neoplasm followed by extirpation of the uterus, the operator keeping close to the cervix, for fear of injuring the ureters; I doubt whether the result obtained could have been achieved. Suppose even moderate malignant infiltration of the parametria had been present, then I do not believe that there would still be freedom from the evidence of a recurrence. The cauterization after curetting, with subsequent resection of the vagina and covering the malignant surface with the loosened portion, prevents the chances of an implantation or vaccination infection, to which George Winter has called attention. Again, the probability of a good ultimate result would be still better, if the patient's age, at the time of operation, had been double.

Let us view cancer of the supravaginal portion of the cervix for a moment. Experience has taught us that the peculiarity of cancer of the uterus is that, in its early stages, it will not encroach by dissemination to other anatomic segments or parts of the uterus from where it had its primary origin. A patient with beginning carcinoma of the cervical endometrium consults her family physician on account of leucorrhœa and the discharge may occasionally be slightly intermixed with blood; the examination reveals an intact os externum of the portio, while about the vaginal portion nothing abnormal seems to present itself to the examining finger; she is dismissed with a prescription for some remedy like ergot or hydrastis canadensis and ordered to take douches. About three months later she is examined again. By that time a crater may have formed in the cervical cavity, the supravaginal portion be invaded in its

entirety and the parametria affected; the probability is that it is too late at such a stage to do a radical operation with the prospect of a good ultimate result. Not infrequently such cases are sent to the specialist as beginning cases of cancer, whereas the beginning was four to five months previously, and that was the proper time for operation.

The patients who have a hard carcinomatous nodule in the supravaginal portion of the cervix do not present any symptom until the neoplasm begins to break down, and it is then always too late to do radical work, because the parametria are generally extensively involved; it is by mere accident that such patients are seen early enough to do a hysterectomy, which will promise a good ultimate prognosis. I can not emphasize it too strongly, that we should invariably think of malignant disease, and use every method known in arriving at a diagnosis, to make sure that cancer is *not* present before dealing lightly with the respective patient. The same precaution holds good for disease of the corporeal endometrium, causing slight atypical bleeding or prolonged menstruation. We should never be satisfied with doing a curetting if there is the *slightest* suspicion, unless the microscopic examination of the scrapings shows an absolutely negative result. In making such curetting, it should also be remembered that a dull instrument is inadequate and that the mucosa must be removed from *all* portions of the interior, including the uterine cornua. I have never seen a case in which, if the microscopic examination showed cancer in one part of the scrapings, no matter how small, the examination of the extirpated organ did not verify the diagnosis. True, sometimes opinions may differ, but this is not the fault of the microscope but rather of the examiner; it is also true that a patient may have cancer and nothing has been seen in the scrapings to show it; this again is not the fault of the examiner, but it is due to the operator, hence the precaution noted, to remove from *every* part of the lining membrane.

Let us now turn to the results obtained by the speaker from radical operations for cancer of the uterus. The operation has been performed 131 times, 5 by the abdominal route and 126 by the vaginal. From the latter method 8 deaths ensued, as the direct result of the operation, making nearly 6.35 per cent. direct mortality. These are to be divided into: 3 from shock—1 of the latter had an extensive cardiac lesion, as determined a few hours after death, this taking place about three hours subsequent to operation; the lesion consisted of myocarditis and calcareous degeneration of the aorta, which was diagnosed before operation; 1 foreign body pneumonia, also determined, or rather, verified by autopsy; in 1 patient the ureters were probably tied—unfortunately an autopsy could not be obtained to verify or dislodge the suspicion; 3 died of septic peritonitis.

If we analyze the cases operated on for cancer of the uterus by vaginal hysterectomy, more than two years ago, we find the following result: total number of patients, 111; direct mortality, 5.4 per cent.; mortality from recurrent cancer, 34.2 per cent.; living with recurrence, 2.7 per cent.; deaths from other causes than cancer, 2.7 per cent.; no report obtainable, 30.6 per cent.; living and free from any evidence of recurrence, 24.3 per cent.

Year.	No. of cases.	Direct mortality.	Deaths known from recurrence of cause.	Deaths from other causes after recovery from operation and discharge of patient.	Living with recurrence.	No report obtainable.	Living and free from evidence of recurrence.

Until April 1.	126	8	40	3	6	35	31

So far as the radical operation by the abdominal route is concerned, I have not yet arrived at a positive opinion. Of the 5 patients operated on, 3 died as a result, although one of these was early in my career, when the Freund operation was first made known and the technique then employed could not be called radical, as now understood, if the method is employed at this day. Yet it must be conceded that abdominal hysterectomy as advocated by Riess, Clark, and Kelly, in this country, with extirpation of the retroperitoneal glands and lymphatics, is more grave and must necessarily give a larger percentage of direct mortality, and it is still a question with me whether the ultimate results from the operation will justify the procedure. When, in 100 cases operated on by radical measures, more than two years shall have elapsed from the time of operation, the statistics of that series will undoubtedly throw the balance in favor of one or the other method.

In instances of *beginning* cancer, in fact so long as the parametria are not involved, vaginal hysterectomy, properly performed, gives a fair percentage of ultimate recoveries.

It is my opinion that with the use of the hot iron, galvano-cautery or paquefin cautery, the ultimate results will still be bettered. That this seems correct is illustrated by the published results of Byrne and Mackenrodt. With the limited personal experience which I have had with the method, I feel justified in agreeing with those authors.

In doing a vaginal hysterectomy, one must consider that it is for malignant disease, and must operate as far away from the uterus as can be done with comparative safety; the disintegrated structures should be rapidly removed with a sharp curette or spoon, and be thoroughly cauterized, charred, with a hot iron, before beginning the removal of the organ. The uterus should be removed *in situ*, unless a part of the vagina is resected and covered over the cervix. Subsequent to the operation, the administration of some form of arsenic is beneficial. The patients, during the first year after operation should be examined not less than once a month; during the second year, once in two months. Should there be the slightest infiltration of a suspicious character, then we should thoroughly cauterize with an actual cautery. One patient with cancer of the portio with a recurrence in the scar has been treated in this manner three times since her primary operation in 1896, with satisfactory result.

The question whether ligatures or clamps should be used in performing vaginal hysterectomy should not be dealt with in an offhand way; each has a place, especially so in hysterectomies for cancer; each has its advantages and disadvantages. The practical advantages which I have found with the exclusive use of the ligature method are: the patients suffer much less pain after operation, in fact it principally amounts only to the effects caused by the anesthetic; the convalescence is hastened materially—there is less liability to produce cystitis from catheterization. Theoretically it is a more surgical operation. For practical results, however, I have not found it superior to the clamp method, that is so far as the direct mortality and the remote results are concerned. What, on the other hand, are the advantages of clamps? The time consumed is greatly diminished—this is of very great importance with patients who are not robust; it is much easier to perform; one can generally work farther from the uterus. Theoretically, there is less danger of secondary infection—this, however, has not been borne out in practice in my hands.

I use ligatures exclusively, when the uterus is freely movable and if the vagina is sufficiently large, so that they need not be applied closely to the cervix, with the proviso that the patient's general condition is such that the greater amount of time consumed is of no consequence. When these requisites are not present, I deem the use of clamps safer, both for direct and remote results. The greatest danger of any vaginal method, when operating for cancer, is the injury of the uterus. This complication is more surely avoided by the abdominal method.

Dr. E. E. TULL said that since 1890 he had operated on 20 cases of carcinoma uteri, in all of which the diagnosis had been confirmed by microscopic examination. Four of the patients are now living and 2 of them were operated on ten years ago.

Dr. HIRAM N. VINEBERG said that out of about 12,000 cases

of diseases of women seen by him in dispensary practice there has only been about 12 of cancer of the uterus. The majority of these women had borne many children and had suffered extensive lacerations; hence cervical laceration can not be considered an important factor in the production of cancer. He suggested modifying Dr. Kelly's method by making a longitudinal incision in the anterior wall of the vagina, through which the uterus can be delivered without any necessity for entering the peritoneal cavity posteriorly.

Dr. GEORGE TUCKER HARRISON expressed the opinion that a patient should not be considered cured until five years have elapsed without recurrence. On this basis, 15 or 20 per cent. have been cured. The reason 80 per cent. or more were not cured was that the diagnosis had not been made early enough.

Dr. JOSEPH E. JANVRIN said that four years ago he had reported 16 cases of cancer of the uterus that had originated in the cervix in which, by the despised and old operation of skinning out the uterus, he succeeded in saving 12 patients—at least at that time this number had been well for three years or more. Two of these are well and living at the present time; one is well after twelve years. In every instance the disease of the cervix was well marked, yet he secured 37.5 per cent. of cures. Of 4 in whom the disease had extended down on the vaginal mucous membrane, 3 were cured. Vaginal hysterectomy should be restricted in those in which the disease is only in the cervix or in the adjacent mucous membrane, and to adenoma and carcinoma uteri in their early stages. For all other cases he would advise abdominal or abdomino-vaginal hysterectomy.

Dr. J. RIDDLE GOFFE said that he considers the vaginal operation the only justifiable one in cancer of the uterus, because of the liability to inoculate the freshly exposed tissues by other methods. His first objection to Dr. Kelly's technique is the turning of a carcinomatous cervix up into the peritoneal cavity, for this is simply inviting a dissemination of the disease in the peritoneum. He also objects to the method of quadrisection of the uterus, on the same ground. He would not hesitate to take out the whole vagina if this seems necessary in order to cut wide of the disease.

Dr. RALPH WALDO believes that where the disease has lasted more than six months it is probable that recurrence can not be avoided. He prefers the vaginal operation, using ligatures.

Dr. JOHN BYRNE, New York City—I deem it a privilege, no less than a pleasure, to have been afforded an opportunity of listening to this welcome and masterly résumé of personal experience by one whose opinions on any subject connected with surgical gynecology are worthy of every confidence and the fullest consideration. The difficulties oftentimes encountered in arriving at a correct diagnosis in the incipient or early stages of uterine cancer, and more especially where the disease has its origin in the fundus, are matters familiar to all, and the author's emphatic words touching the necessity for microscopic investigation in all doubtful cases are of the utmost importance, because while they sound the alarm, they preach the gospel of true conservatism.

Than cancer, in the broadest sense of the term, there is, perhaps, no other disease in the whole range of human afflictions more justly dreaded, nor is there another for the relief of which more so-called cures, from condurango to hysterectomy, have been lauded and resorted to, and from the days of Hippocrates to the present time. If the unhappy victim of this malady be a woman, and her sexual organs the seat of the disease, it is, indeed, hard to imagine a fate more pitiable, or an ebbing life so fraught with intolerable distress and utter hopelessness.

We are here to-night solely in the interest of these unfortunate victims of torture and despair, to consider, and, if possible, to decide, as to the best ways and means, through which we may contribute toward their relief and the prolongation of their lives. Such being our object then, it is to be hoped that the consideration of this important subject will not, as too often happens, be conducted in a slipshod or mere perfunctory manner, and that clinical facts, and not visionary theories, however plausible, shall constitute the basis and grounds of this discussion.

At this juncture in our friendly interchange of views, and as

time is precious, I fear the author of this valuable paper, as well as those who may have been impressed by the brilliant and attractive glitter of the work of one who concededly occupies a high place in the ranks of pelvic and abdominal surgery, and your humble servant, will have to shake hands, and for the time being, metaphorically speaking, part company.

With regard to the operative treatment of cancer of the cervix uteri, and to which limited sphere only my remarks apply, I have practically nothing to add to what I have stated over and over again, but more particularly in my critical analysis of the statistics of hysterectomy eight years ago, contrasting the results of this operation with those obtained by me through the agency of the electric cautery. I believed then, and I am now more than ever satisfied that if the time should ever come when the advocates of total hysterectomy, as the remedy *par excellence* for cancer of the cervix, can be coaxed, cajolled, or in any other manner persuaded to follow my method of operating, and then, and in this way only, become qualified to endorse or condemn, this vital question may reach a settlement. Judging from the past, however, we have too often been made to suffer from a surfeit of mono-ideal and sometimes monotonous intellectual pabulum, varied only by occasional changes of place and utensils, from vagina to abdomen and back again, and dished up, I had almost said slaughtered, by the irrepressible advocates of pelvic evisceration. In fact, any unsophisticated outsider might reasonably suppose that the entire body of gynecologists had settled down to the conviction that for cancer of the cervix, be it much or pathologically infinitesimal, nothing short of total ablation of the offending but doomed organ is to be considered.

Indeed, so universal of late years has this short-cut to the solution of difficult and complex problems become that gentlemen of more conservative, sometimes called obsolete, views, have been made to feel that they had no standing in court, and deeming silent discretion the better part of outspoken disapproval, have usually, and perhaps wisely, kept quiet.

In this way those of up-to-date ways and methods, occasionally having novelty, if nothing more, to commend them, in attending society meetings, if the subject for discussion happened to be cancer of the uterus, and being well primed and equipped for a one-sided contest, could always air their opinions and display their uterine trophies unchallenged and unhampered, as in the good old days of wholesale oophorectomy. So, my friends, in spite of the courteous invitation extended to me to attend this meeting and to participate in the discussion of one of the most important, yet open, questions in the whole range of gynecology, I confess I do so with no little diffidence and reserve if not a feeling akin to obtuseness on my part.

Regarding the relative merits of hysterectomy, vaginal or abdominal, and removal of the diseased part by the cautery knife, not loop nor galvanic snare, which I have many years ago discarded as less efficient, and very thorough dry roasting of the remaining cavity, four years ago I made what I fondly hoped at the time might prove to be the final effort to induce members of the American Gynecological Society to give this method of treating operable cases of cancer of the cervix uteri a fair and practical test. On that occasion, however, the remarkably strict application of a rule governing time compelled me to desist at an important point in my remarks. In consequence of this, or perhaps from a lack of interest in the subject, the discussion was less full than I had reason to expect. A committee of three was named, however, to investigate the subject, and to send cases, or invite me to operate, but up to the present time *three patients only* have been referred to me, all in too advanced a stage to warrant even a satisfactory hysterectomy. I offer this statement in order to suggest what I have often been inclined to fear, the probable futility of every effort toward popularizing the galvanocautery.

With regard to the technique of vaginal or abdominal hysterectomy, as so lucidly described by Dr. Kelly, I have nothing to say, nor indeed does it properly belong to the subject of our inquiry to-night, except in so far as certain steps in such operations may influence primary mortality. By far the most vital and far-reaching question, and in fact the only one expressed or implied by the title of the paper, is what is the best treat-

ment for uterine cancer, or, in other words, which of the two methods of operating now under consideration insures to the patient the longest period of exemption from a recurrence of the disease? As to primary danger from hysterectomy, there need be no contention on this point. In the hands of an expert operator, the extirpation of a cancerous uterus, as I have before said, need not be and has not been followed by a ratio of primary disasters sufficient to for a moment cause doubt as to the admission of such a procedure *per se* to the domain of legitimate surgery. On the contrary, the very large proportion of recoveries should be looked on as one of the many brilliant examples of modern surgery, and of which any reasonable operator ought to feel proud. Were it not, therefore, for the groundless assumption of those who have been persistently trying to minimize the difficulties, as well as the dangers of these operations, by quoting the phenomenal success of a few favored ones only, the question of primary mortality need hardly be considered. So when in 1892 I undertook the analysis of published statistics up to that date, my main object was, if possible, to disentangle and sift from the chaotic mass some grains of truth regarding the period of exemption from recurrence of the disease obtainable through hysterectomy.

Therefore, whether the death-rate due to this operation be 5 or 15 per cent., or, as in cases treated through the agency of the electric cautery, less than 1 per cent., need not trouble us at present, and does not seriously affect the more important questions regarding the degree to which life may be prolonged by either method, and the period of exemption from recurrence, assured or obtainable.

To any one who may undertake to glean facts and truth from the ingeniously and marvellously constructed statistical reports on the results of hysterectomy for uterine cancer, the task will be found to be one of extreme difficulty, and in some instances almost impossible. In some, I regret to say, will be found a strained, yet unsuccessful, effort to divert attention from leading and vital issues to a tabulated but unwarranted summary, while in others the perversion of figures is so manifestly, and it would seem purposely, resorted to to obliterate the tracks of disaster, that it will often be found hard to pursue this line of investigation with any degree of patience. As neither the occasion nor time will permit me to go into details, for which I would refer to Volume xviii of the "Transactions of the American Gynecological Society," I will merely state as a sample of what may be learned by any one who will take the trouble to interpret reports on recurrences after hysterectomy for cancer up to 1892, and subsequent experience will in no material point justify any modification, the following: In summing up all the facts obtainable regarding the results obtained in 235 cases treated by a number of leading operators in Germany, France and elsewhere, we found but 63, or 27 per cent. of the whole, in which relapses were noted, while nothing whatever is said of the fate of 172, or 73 per cent. of the whole number operated on and tabulated as follows: One had no recurrence for 8 years, 1 none for 7, 1 none for 6, 7 none for 5, 17 none for 4, 15 none for 3, 19 none for 2, 2 none for 1 year. An average exemption from recurrence or death for 63 patients out of 235 was three years and nearly four months.

From reports like this, and it is a fair specimen of what is available, no possible trustworthy data can be gleaned, because if, for example, to each of the 172 patients, or those of whose fate we are told nothing, we allow even one year of life, which would be far in excess of what all records warrant, we have in the aggregate 381 years of exemption for 235 patients, or one year, seven months and thirteen days only for each.

Again, at the International Congress in Berlin, in 1890, Olshausen reported 163 cases of hysterectomy for cancer at the University Womans Klinik, 42 only of whom were living at the end of two years, and of the entire number who escaped death from the operation, namely 155, 19 only were free from recurrence.

Facts like these, and the records of every country with them, may be modified to an inconsiderable extent by the rare and more happy experiences of able and exceptionally fortunate surgeons like the indefatigable author of the paper under consid-

eration, but I contend that they should be well pondered over and not dismissed, as they have been heretofore, with the vain hope that by improved technique and greater familiarity with these operations better results may yet be reached. It should also be remembered that, although a more or less perfect technique must and has lessened primary mortality, it can not likely influence, and has not materially, the great liability to recurrence, due mainly to traumatic infection, against which we can devise no reliable safeguard. To this latter defect and the unavoidable mauling of outlying tissues, often in an early but unrecognizable stage of cell proliferation, and thus more responsive to traumatic irritation, are we to attribute the great and well-known liability to recurrence after hysterectomy. Truly, the most noteworthy fact in the history of this operation is that a very large majority of women suffering from uterine cancer may submit to it yet live for a time at least.

Regarding my own experience in the treatment of cancer of the cervix by the electrocautery, covering a period of thirty years, I have but little to add to what is already of record. During the last ten years, what the advocates of hysterectomy would consider operative cases, i. e., those in which the disease is found to be limited to the cervix proper, the vaginal surroundings intact, and the whole organ fairly movable, have been comparatively few and rare. Consequently, of late years, most of my work in this line has consisted of a free use of the curette, trimming the ragged edges by cautery knife and thoroughly roasting the cavity. In this class of cases, when it is found that the disease has extended beyond the os internum, the sharp or the serrated curette is also freely used, but in exceptional cases only is actual cauterization carried to the fundus proper.

Several patients, at least five, of this advanced and otherwise hopeless case, operated on in this manner from ten to fifteen years ago, are now known and reported by reliable physicians to be perfectly well. Similar results in so-called inoperable cases are by no means rare in my experience, as my hospital colleagues well know. As for cancer of the cervix proper and uncomplicated, my reports and predictions of 1872, 1875, 1889, 1892 and 1894 have been fully confirmed and substantiated. In other words, in cancer of the cervix at an early stage or of circumscribed degree, excision by the cautery knife and deep and thorough dry roasting of the cavity by the dome-shaped electrode, while absolutely free from danger, insures a longer, if not a permanent, respite from recurrence than any other known means. Again, in more advanced cases, deemed at all operable by the most reckless advocates of hysterectomy only, the free use of the curette followed by electrocauterization as I have so often described, advised and resorted to will always be found to be a safe and palliative measure, and will often insure a nonrecurrence of several years.

Without going into details, and as the clinical grounds and basis of these statements, and the results of long and careful observation, I can simply say that in 100 cases of strictly cervical cancer, permitting of supravaginal excision by the cautery knife, and further dry-roasting of the cavity, the great majority will be followed by a permanent cure, while, in less favorable ones, an average longevity and freedom from relapses of from seven to eight years may reasonably be expected. In the more advanced class, always premising that the corpus be not involved, the results, as stated, are strictly in accordance with my experience.

The seemingly paradoxical assertion that the extirpation of the diseased part of a carcinomatous uterus by electrocautery, besides being absolutely free from danger, should also give better results than extirpation of the entire organ has usually been met with the simple *non credo* of those who fail to reflect on the peculiar effects and properties of the agent employed. My explanation of this apparent enigma, supplementary as it is to clinical facts, may be found in the volume of "Transactions of the American Gynecological Society" for 1892, and is as follows:

I am of the opinion that in the parametric tissue of many cancerous uteri, and much beyond what might seem to be the limit of disease, there exist some morbid cell changes due to faulty nutrition, or cancer germs, but, in so undeveloped a state

as to be inappreciable even by the aid of the most powerful microscope. Under such circumstances there is surely nothing unreasonable in surmising that cell proliferation, hitherto slow, or almost dormant, would be hastened, and that formative processes, so responsive to any kind of irritation, would be roused into active life through the traumatic stimulus of an operation, and the exposure of more or less raw surfaces. On the other hand, in the progress of an amputation by cautery, and where the heated knife is so long and repeatedly applied—for such operations must be slow—the effects of the heat on outlying structures may be imagined by the shriveled and comparatively small size of what had been, before operation, a voluminous cervix. In no other manner do I think it possible to explain certain phenomena following these operations by galvanocautery, e. g.: 1, absence of fever and almost all pain, pelvic or peritoneal; 2, the almost universal immunity of the scar tissue after cauterization from secondary attack in the event of recurrence of the disease, and 3, in the case of relapse, the long respite obtained from reappearance of the disease in remote parts, even in the more unpromising cases of undoubted circum-uterine infiltration.

Why, it may be asked, have phenomenally successful results obtained through the agency of the electrocautery failed thus far to convince theoretic skeptics wedded to the glamor of more sanguinary methods? Why will gentlemen still declare there is but one remedy for cancer of the cervix uteri? Why will they persistently declare that there is positively no place for any treatment other than hysterectomy? And why will editors of journals published in the interest of gynecologic progress, in reviewing the treatment of uterine cancer, and supposed to be *au fait* in leading questions touching the subject, continue to insult our intelligence by stating in an *ex cathedra* fashion, that though the treatment of uterine cancer by hysterectomy "is eminently unsatisfactory," yet that "it is the best procedure now at our disposal?" Why will gentlemen still persist in palming off the base coin of obsolete methods as mine, and talk of removing a cervix by the galvanic snare, an instrument which I have not employed ten times in twenty years? Finally, where, I would ask, can we find, throughout the pages of gynecologic literature, a shadow of warrant for the dictum that hysterectomy, with its ghastly and life-curtailing record, is the only surgical procedure admissible in cancer of the uterus? These and many similar questions I shall not waste your time in discussing, but merely submit them for your own consideration and possible solution.

In the light of startling facts like those I have barely touched on, is it not marvelous to think that at this late day so few, if indeed any, of our numerous and otherwise progressive gynecologists should have accorded to the electrocautery a reasonably fair and practical trial? Those who have reluctantly admitted its claims to serious consideration have, for the most part, done so through the representations of others rather than from an adequate practical knowledge of its worth or possibilities. Hence it is not surprising that in nearly all past discussions on the treatment of uterine cancer by the galvanocautery, the most outspoken doubters and the most zealous advocates of any or every other method of operating have usually been those least qualified to judge. Whether the essential attribute of an umpire, i. e., the power or skill to compare or contrast, is wanting, opinions regarding the relative merits of any two or more methods of operating for uterine cancer, for example, as between the galvanocautery and hysterectomy, must necessarily be worthless, and should have no legitimate claim to consideration.

Within the last few years, however, owing to the substitution of the dynamic for the chemical current, the less frequent use of the troublesome and fitful battery, and the comparative facility with which the most delicate, as well as the most extensive, operations may now be conducted, by hospital surgeons especially, there is no longer any valid excuse for culpable apathy or indifference.

There is every reason to hope, therefore, that intelligent, unbiased and honest investigation, so long desired, may yet unfold the whole truth, and thus remove every doubt as to the rare exceptional and special efficacy of the electrocautery and the gradual abandonment of hysterectomy in the treatment of cancer of the cervix uteri.

ETIOLOGY, PATHOLOGY AND SURGICAL TREATMENT
OF TUBERCULOSIS OF THE KIDNEY.

In the absence of a specific remedy for the treatment of tuberculosis, the clinician must avail himself of all those measures that have proved in any way helpful. While it is universally admitted that the tubercle bacillus is the exciting cause of the disease, it is recognized that the conditions, as yet undefinable, that render possible the manifestation of its activity, are scarcely less important. The mere presence of the bacillus does not constitute tuberculosis, but this consists rather in the reaction that takes place between the invading micro-organism and the attacked tissues. The disease is to be averted by preventing dissemination of tubercle bacilli, and by rendering the tissues resistant to their invasion; and the indications for treatment are the extrusion, destruction, encapsulation of the bacteria, or otherwise rendering them innocuous, the neutralization of their effects, and the repair of lesions. The tubercle is a local formation, and its removal would constitute the most certain means of cure. Unfortunately, however, the lesion is not single, nor always circumscribed, while often it is situated in an inaccessible organ, or is otherwise not susceptible of excision. Of the several situations in which such intervention is feasible and sometimes promising, the kidney is one; and the results thus far attained in this connection are most encouraging. An important requisite for successful treatment is, here as elsewhere, early diagnosis.

A most interesting discussion of the subject of tuberculosis of the kidneys, with especial reference to etiology, pathology and surgical treatment, has been entered into by Newman¹. It is pointed out that renal tuberculosis may occur as acute miliary, as localized, or as chronic tuberculosis or caseous nephritis. Healthy kidney-tissue is thought, by reason of its abundant blood-supply, although it is more vulnerable than other portions of the urinary tract, to possess a remarkable power of destroying organisms introduced into its substance or of eliminating them from the system. Tubercle bacilli may, thus, be found in the urine of persons suffering from tuberculous disease of bone, the lungs, or other organs, in the absence of morbid structural change in the kidneys.

The natural power of the kidneys to destroy or eliminate micro-organisms may be impaired as a result of local disease or hemorrhage or traumatism. The kidneys may become invaded by tubercle bacilli through

the blood-stream, the tuberculous particles being so small as to be stopped only in the ultimate capillaries, where they give rise to numerous miliary deposits; or through infective emboli entering a branch of the renal artery, and the tuberculous virus becoming disseminated throughout the area of its distribution. Invasion may take place also along the lymphatics of the kidney from foci in the lower urinary tract; by contagion along the lumina of the excretory ducts: by contiguity from adjacent diseases.

Infection by way of the blood-stream may result in obstruction of the capillaries or in tuberculous emboli of the arteries. In cases of acute miliary tuberculosis of the kidney, the bacilli are conveyed by the blood-vessels and are widely distributed. The disease is always associated with tuberculosis of other parts, and attacks children more commonly than adults. The condition usually escapes recognition during life, as it does not give rise to distinctive symptoms. A tuberculous embolus in the kidney may undergo caseation or become encysted. The disease is generally unilateral, and involves only a portion of the kidney-substance, although there may be more than a single focus. At first, the lesion is limited to the substance of the kidney, but in the further progress of the case, the tuberculous process is carried forward through other channels, unless a conservative inflammatory action closes the lymphatics and prevents extension. If the caseous material breaks down, rapid destruction of the organ may result.

Tuberculous pyonephritis may arise in several ways. Thus, the primary focus may be in the kidney-substance itself. If the ureter becomes blocked by tuberculous thickening of its walls, by impaction of masses of debris, by cicatricial stenosis, or by twisting, pyonephrosis will be likely to result. Primary tuberculosis of the pelvis of the kidney is less common than secondary infection. With tuberculosis of the kidneys there are usually associated inflammatory changes in the mucous membrane of the pelvis, the ureter and the bladder.

Tuberculous infection of the kidneys by way of the lymphatics, from foci in the lower urinary tract, is not uncommon. Such ascending renal tuberculosis is characterized by early obstruction to the escape of urine from the pelvis, with symptoms and signs indicative of hydronephrosis or pyonephrosis. Extension by contagion along the lumina of the ducts occurs in cases with ascending tuberculous lesions. Infection by extension of disease from adjacent organs is uncommon.

Statistics show that tuberculosis, both primary and secondary, occurs in the kidneys in about 5.6 per cent. of all cases of tuberculosis. The renal localization seems to be more common in children, in the proportion of nearly three to one. The presence of pyuria, together with renal symptoms in men, should always suggest examination of the genital organs and the prostate for tuberculosis, and association with rapid emaciation, anemia, elevation of evening temperature, and rapidly

¹ The Lancet, February 24, March 3 and 10.

progressive marasmus should arouse suspicion of tuberculosis. The presence of pain depends on whether the pelvis and the ureters are involved or not. Vesical irritability, as manifested by incessant and painful micturition, is a frequent, and almost characteristic, symptom. Strangury also is often present. A swelling may be appreciable in the loin if the kidney is enlarged. Careful analysis and microscopic examination of the urine are necessary for early diagnosis. Polyuria is often one of the first indications of a tuberculous lesion in the kidney. Hematuria may occur long before, as well as after, the development of a gross renal lesion. It is rarely profuse. The urine contains albumin, but no tube-casts. The detection of the tubercle bacillus is extremely important. Ureteral catheterization may be necessary to determine whether the disease is situated on one or both sides.

Tuberculosis of the kidney must be differentiated especially from renal tumors, septic pyelitis and pyonephrosis, and renal calculi. The prognosis is most unfavorable, the more so if the disease is not limited to one kidney, but extends to the ureter, the bladder or the other kidney. When the disease is localized in one kidney, or in only a part of the kidney, the tuberculous material may be discharged or may dry up into a firm caseous mass, while the other kidney undergoes compensatory hypertrophy.

It must be admitted that spontaneous recovery may take place, or the progress of the disease may be checked. Some time elapses between the onset of primary tuberculosis of one kidney and the invasion of other parts, and it is in this interval that the surgeon can intervene with advantage. A number of cases are on record in which life has been prolonged for a considerable time by surgical treatment, or good health has been conferred for a number of years. Nephrotomy may be practiced if the disease is limited to a small area, or has formed a single cavity that can be drained. Should recovery not ensue, we can then resort to nephrectomy. This should be undertaken as a primary operation when the disease is extensive and little can be hoped for from incision and drainage. When operative intervention is deemed advisable, symptomatic treatment should be employed. The internal administration of boric acid, salol, ammonium benzoate, and also of antipyrin and extract of hyoscyamus, frequently affords relief from vesical irritability. Strangury may be alleviated by the employment of preparations of opium by the rectum, or of warm sitz-baths; and when the urine has become alkaline, calomel given by the mouth exerts a beneficial effect.

THE DEVELOPMENTAL CYCLES OF THE ORGANISM OF MALARIA.

In order to understand the peculiar and complicated developmental cycles of the malarial parasites, it is necessary to consider the organisms most closely related to them, namely the coccidia, because the details concern-

ing these are much better known. As there is no change of host in the case of the coccidia, the process is not so complicated as in the malarial parasites. Shorn of a wealth of detail, the developmental cycle of the coccidia runs somewhat as follows, according to the recent review, by Lühe,¹ of the investigations of sporozoa, with especial reference to the malaria parasites and related organisms. As is well known, coccidia are found rather frequently in the intestinal tract and the liver of vertebrate and other animals. Examining the feces of an infected rabbit, for instance, there are found encysted parasites of varying size, which Schaudinn and other prominent investigators in this line call "oocysts;" they have a double contoured membrane and a unicellular content, called "sporont." The further changes are readily followed in the moist chamber. The unicellular contents divide into a certain number, commonly four, or "sporoblasts," which in turn become "sporocysts" by the appearance of a protected membrane around each spore. Each sporocyst forms two nucleated sickle-shaped bodies, the so-called "sporozoites." And now the sporocyst may remain latent for several months without losing the power to develop further, hence it has also been called lasting spore. Further development takes place only when it is taken into the digestive tract of a suitable animal; then the membrane is dissolved and the sporozoites penetrate into epithelial cells. The form of multiplication just described is termed "sporogony."

In the host, however, multiplication does not take place according to this type. After much controversy the zoologists practically agree that in the host multiplication takes place by fission. The sporozoites may develop and subdivide into numerous sickle-shaped organisms, called "merozoites." As the mother organism of the sporocyst is called "sporont" so the mother organism of the merozoites is called "schizont." This mode of reproduction is termed "schizogony," and it alone can explain the massive infections sometimes observed in animals and which consequently are the result of a sort of auto-infection. Schaudinn has shown that the schizonts rapidly form merozoites, and that multiplication in this manner at first goes on at a great rate. Later, when the host has become weakened and the conditions of the nourishment of the numerous parasites unfavorable, then another mode of reproduction is resorted to, and the sexual coccidia appear. Some of the merozoites grow to form larger, female cells, the macrogametes, and others form the so-called microgametocytes, the nucleus of which rapidly subdivides into a number of nuclei that become surrounded with a small amount of protoplasm and leave the mother cell as spermatozoa—microgametes. The copulation between the macrogamete and microgamete occurs according to the same principles as in the impregnation of the eggs of metazoa. The result of the copulation is the oocyst, the starting-point of sporogony.

Sporogony secures the preservation of the species and

¹ Cbl. f. Bakt., Abth. i, 1900, xxvii, 367.

the spread of the infection, while schizogony increases the infection of the host. Coccidia consequently present alternating, sexual and non-sexual generations.

Lühe then recounts step by step the development of our present knowledge of the mode of infection of human malaria and the rôle played by certain mosquitoes, especially *Anopheles claviger*, as one of the hosts necessary for the development of the malarial organism. These things have been described from time to time in these columns. The reproductive method first understood of the malarial organisms corresponds to the schizogony of the coccidia. The sexual processes that lead to multiplication by sporogony were first recognized by McCallum, who demonstrated the copulation of the male and female elements. Reproduction by schizogony takes place in the blood of the warm-blooded host—man. Sporozoites pass into the red corpuscles, develop into schizonts, which divide into merozoites. The merozoites may and ordinarily do repeat this process. After a time, however, they form sexual individuals and in pernicious human malaria these assume the crescent and oval forms characteristic of this affection.

The maturation of the sexual forms ordinarily takes place in the stomach of the blood-sucking mosquitoes. Here copulation takes place, and the resulting body—called "ookinete"—passes into the intestinal wall of the mosquito, where it forms innumerable sporozoites which ultimately collect in the salivary glands of the insect where inoculation of the warm-blooded host results during the act of stinging. And now multiplication by schizogony again begins. It will be seen that, stated in this simple manner, the developmental cycles of the malarial organisms correspond accurately to those of coccidia, the essential difference being that in the case of the malarial organism the sexual cycle is connected with the change of host and runs its course in the mosquito.

The intracorporeal parasite seen in the blood of quartan malaria, for instance, is a sporozoite; as it grows it becomes a schizont—sporulating body—and the "spores" formed as it breaks up are the merozoites of the zoologic nomenclature.

It would be of lasting service to all present and future students of malaria and malarial parasites if the writers on subjects connected with reproduction of the organisms would agree as far as possible to the use of the same nomenclature. In a matter as complicated as this with phases subject to different interpretations, entire unanimity in nomenclature is not to be expected, however. The mere mention of the group of malarial organisms suggests a large list of synonyms. Lühe points out that according to the law of priority, which is the only one applicable in cases of this sort, the correct name is *plasmodium malariae*. This name ought therefore to be used in the interests of uniformity and simplicity.

Druggists of Vienna have agreed to charge a special rate for putting up prescriptions marked *pro paupere*, by the physician.

ETIOLOGY OF ACUTE ARTICULAR RHEUMATISM.

In a recent review of the infectious diseases, Packard¹ considers the various theories in regard to the etiology of acute articular rheumatism. There is little or no foundation for the humoral and the nervous theories. The principal support of the humoral theory was the similarity between articular rheumatism and gout, the joints being affected in both. The lactic-acid theory grew out of this apparent relationship. But the fact that lactic acid may cause articular pain and swelling does not prove that it is the cause of acute rheumatism, because there is more to rheumatism than articular inflammation. How should the excessive production of lactic acid be explained? The nervous theory was the outgrowth of the similarity between the joint affections of acute rheumatism and of certain nervous diseases. There is no good reason to be advanced in favor of nervous joint centers. There is no real evidence of any relationship between rheumatoid arthritis and acute articular rheumatism, hence no support of the nervous theory is to be derived from comparing these two diseases with each other. Packard points out the confusion in nomenclature that has come from calling the secondary arthritis of such diseases as gonorrhœa, scarlet fever, and pyemia rheumatism; at the same time such names as gonorrhœal rheumatism, etc., give a suggestion as to the probable nature of acute articular rheumatism. There are a number of affections, such as lumbago, certain forms of wry-neck, etc., that are called "rheumatic" largely because they are painful, but there is not the slightest connection between acute articular rheumatism and these troubles. Either the term "rheumatism" should be restricted to these disorders, or else they should be designated by more appropriate terms.

Acute articular rheumatism is a distinct clinical entity. There is considerable resemblance between the general manifestations of acute articular rheumatism and pyemia, only that in pyemia there is no difficulty in studying the organism at work.

The efforts to discover the cause of acute articular rheumatism have thrown much light on arthritis of various kinds. It need not be stated that the infectious arthritis of pneumonia, of gonorrhœa, and of a number of well-recognized infections, is not acute articular rheumatism.

Packard then reviews the principal reports of bacteriologic work in acute articular rheumatism. Without going into details suffice it to say that the results reported by the various investigators are so contradictory that no definite conclusions can be drawn. The organisms that have most claim for consideration are the bacillus of Achalmé and the diplococcus of Triboulet. The diversity of the bacteriologic findings has led to the suggestion that acute rheumatism is not an etiologic entity, but that it may be produced by a number of different organisms. Packard finds the view advanced by Singer

¹ *Progressive Medicine*, March, 1900.

to be attractive, namely, that our disease is a modified pyemia, the difference between the two being one of degree rather than of kind. It has been pointed out that attenuated organisms have a certain affinity for joints. Packard also dwells on the relation of angina to rheumatism, the angina being regarded as an evidence of the entrance of the moribific agent into the body at the tonsils; further that the lymphadenoid tissue of the faucial mucous membrane may lessen the virulence of the organisms before they reach the internal organs. This theory is strengthened by Manfredi's experiments on the influence of lymphadenoid tissue on bacteria. Manfredi and his pupils² show that lymph glands may retain microbes for a long time, the virulence being more or less reduced. This theory is an interesting one, and it is strengthened in a measure by the fact that pyogenic cocci are reported present rather frequently, relatively speaking, in the joint and other lesions of rheumatism, but if the disease is a mild form of pyemia we would have a right to expect that pyogenic cocci would be found in the lesions far more constantly than has been the case up to this time.

There are many features of rheumatism that speak in favor of the phenomena being produced by a toxin or toxins: the frequent, in fact, common, absence of bacteria from the articular exudate, the evanescent character of the joint symptoms, the completeness of recovery of the affected articulations. Packard sums up the evidence somewhat as follows: Rheumatism is an exogenous disease; the part played by cold and wet in its production must be regarded as productive of a general lowering of vitality, permitting infection of some kind, whether specific or produced by various organisms can not now be settled. There is much to favor the view that pyogenic cocci of reduced virulence are frequently the cause of the disease. And it is also possible that bacterial toxins absorbed from some hidden bacterial focus produce the articular and some of the other phenomena of the disease.

On the whole it seems that this undesirable uncertainty and vagueness of our knowledge concerning the etiology of acute articular rheumatism may give way to clearer notions only through patient, thorough, clinical and bacteriologic study of larger series of cases. There is excellent room here for investigations of high practical and scientific value.

OPERATIVE RELIEF OF SUPPRESSION OF URINE OF LONG STANDING.

Interference with the discharge of urine may result from mechanical or functional causes. Obstruction of the urinary passages at any point—by a calculus, a stricture, a neoplasm, a twist or a kink, or by pressure from without—will have this effect; as may also disease of the kidneys, by preventing the secretion of urine. Suppression of urine at times results from reflex influences. Deficient elimination of urine, from whatever cause, will

be followed by the development of uremia, although the skin, the bowels and the lungs may for a time vicariously assume the functions of the kidneys. This period is usually not a long one, and generally rather short, but an interesting case in which it extended over sixty hours, and relief was afforded by operative intervention, is reported by Jaffrey.¹

The patient was a man, 53 years old, who had felt ill for several weeks and for a short time had complained of pain in the left loin and a dragging sensation in the region of the left kidney. Micturition was frequent and the urine had appeared normal. Anuria, however, set in, with acute tearing pain in the left groin and lumbar region, together with frequent vomiting. Applications of hot fomentations to the loin and the administration of diuretics internally failed to afford relief. On introduction of a catheter into the bladder after suppression had been present for two days, only a little blood-stained mucus was obtained. No definite tumor could be developed on palpation at first, owing partly to thickening of the abdominal walls and their rigidity, but on the third day, a well-defined tumor could be felt and was thought to be the distended kidney, probably hydro-nephrotic. The catheter again failing to afford relief, the kidney was exposed through an opening in the loin and found to contain not urine, but rather more than a pint of blood-clot and serum between the perinephric fat and the kidney itself. Blood was present also between the capsule of the kidney and the cortex. The kidney was larger than normal, much congested and when incised it bled freely. The pelvis of the kidney was filled with blood-clot. No calculus and no other possible cause of obstruction could be detected. Irrigation was practiced, a drainage-tube introduced and the wound sutured and dressed with cyanid gauze. Urine was discharged through the tube, which slipped out of place, and was not restored, and in thirty-six hours practically all of the urine was being passed by the natural channels. The patient was out of bed on the sixteenth day and left the hospital three weeks after entrance, quite well. The nature of the influences responsible for the suppression of urine in this case is not clear, although it is suggested that it may have been due to a small calculus or to kinking or to compression of the ureter by the blood surrounding the kidney or finally to congestion of the kidneys.

ATTEMPTED CONTROL OF SECTION ON MATERIA MEDICA.

The action taken by THE JOURNAL in regard to the proprietary and secret nostrums is having the effect of arousing to action those interested in these products. They are actively at work with the object of getting control of the Section on Materia Medica, Pharmacy and Therapeutics of the AMERICAN MEDICAL ASSOCIATION next month, and to accomplish this they are sending circular letters broadcast. Those addressed are editors of certain medical journals whose support comes

² Virchow's Arch., 1899, 155, 335; Zft. f. Hyg. u. Infektionskr., 1899, xxx, 64.

¹The Lancet, March 3, p. 612.

only from their advertising pages, drug journals, and physicians whose influence they are hoping to get. Well-known secret nostrum houses of St. Louis and New York are especially energetic, and spare neither postage stamps nor even telegraph tolls. Many of the letters have been forwarded to THE JOURNAL by those who received them, although it has not been favored with any sent direct by the gentlemen managing the enterprise. When THE JOURNAL took up the fight against secret nostrums, it expected opposition and is not surprised at the first skirmish of the battle. But we can assure the gentlemen that they need not be in the least afraid that the "German chemical houses" will get control of the Section, any more than will the secret-nostrum houses. It will be controlled in the future, as in the past, by physicians of standing in the profession.

DOES NOT TAKE A JOKE.

An English medical statistician, in reporting on the mortality of his district, for 1899, took the occasion to suggest that the predominance of male births was influenced by the patriotic enthusiasm aroused by the present war. This was apparently offered as a facetious comment and it was accepted as such by the council receiving the report. Our British contemporary¹ that gives us the item does not appear to take it kindly as such. It not only ironically congratulates the council on its sense of humor, but gravely proceeds to remark that the figures are too small to afford any sound conclusions, and that a still greater fallacy is involved since it is impossible to suppose that maternal patriotic zeal could have affected the sex of unborn children in the last two or three months of pregnancy. Hence it says: "absurdities of this kind will do nothing to advance the position of the medical officer of health as an instructor of the community." The humor of the suggestion appears to have been comparatively innocent; at the worst it is only a matter of taste, but the serious consideration it has received has a still funnier side.

EPILEPSY, RICKETS, AND THE LYMPHATIC CONSTITUTION.

The association of idiopathic epilepsy—*grand mal*—with the lymphatic constitution—persistence of thymus gland, hyperplasia of lymph nodes, and of spleen—has been emphasized of late by Ohlmacher. The association of lymphatism and of idiopathic *grand mal* has been so strikingly frequent in the autopsies in Ohlmacher's laboratory at Gallipolis, Ohio, that a thorough study of the literature bearing on persistent thymus and on the lymphatic state became necessary. The clinical condition of thymic asthma, or laryngismus stridulus, of infancy is connected on the one hand with the lymphatic constitution, of which enlarged thymus is often but a part, and on the other hand clinicians are wont to associate it with rickets. Tetany and infantile convulsions are also referred to "the rickety diathesis." With these considerations in view, and guided also by gross pathological evidences of rickets in some of the epileptics, Ohlmacher was led to think more and more of the relation of idiopathic *grand mal* and rickets; and, all things

considered, he became convinced that rickets plays an important rôle in the development of epilepsy.¹ Ohlmacher² refers, with a certain sense of satisfaction, to the fact that Gowers in 1885 had reached the same conclusions from purely clinical data obtained from a careful study of the infantile period of ninety-eight cases of epilepsy. Gowers was so strongly impressed with the apparent influence of rickets on the development of epilepsy that he was led to suggest that a considerable proportion of cases of epilepsy are really within the range of preventable diseases. There is reason, then, for continued effort toward clearing up the relationship of rickets, epilepsy, and the lymphatic constitution. We are as yet in the dark as regards the essential nature of rickets, and the lymphatic state. But at all events, infant hygiene and feeding should be brought up to the highest standard so as to do what can be done, in the light of our present knowledge, to prevent epilepsy and other neuroses that seem to have some connection with such diseases of infancy as rickets.

THE PLAGUE AND COMMERCIAL INTERESTS.

The San Francisco Board of Health started out right when the bubonic plague first developed in that city, and courageously did its duty in spite of bitter opposition. But in the more recent developments it has certainly laid itself open to censure. Two weeks ago³ we noticed the discovery of another case of the plague in San Francisco's Chinese quarter, the account being sent to us by telegraph by our regular correspondent. Shortly after his telegram was received, another came in which we were requested not to publish the matter, as the merchants' association there desired it kept out of the papers. Developments show that the merchants succeeded and that while they kept a knowledge of the conditions out of the general newspapers—a report of the case appearing exclusively in THE JOURNAL—the disease spread. Secrecy in this instance meant half measures in fighting the disease, whereas the most energetic steps, those which could only be carried out openly, were demanded. The penny-wise policy has proved to be a pound-foolish one for the business men of San Francisco. We have frequently asserted that there is no danger of the plague spreading in this country, even though it came to our shores, but if secret half-hearted measures are to be adopted in deference to commercial interests, then a different story may have to be told. The San Francisco Board of Health has been abused by the newspapers and will be in the future, probably, but none the less its duty is to protect the people against the spread of the disease, even if commerce should temporarily suffer by the publication of the actual conditions.

MEDICAL SOCIETIES.

A British contemporary,⁴ remarking on the fact that some 700 medical societies are entitled to representation at the AMERICAN MEDICAL ASSOCIATION, says that the United States must be the "happy hunting-ground" of medical organizations. It further states the fact that

¹ Bulletin of Ohio Hospital for Epileptics, Vol. 1, Nos. 2 and 3, 1898.

² Am. Jour. of Insanity, April, 1900.

³ THE JOURNAL, May 5, p. 1141.

⁴ Medical Press and Cir., May 2.

¹ Med. Press and Cir., May 2.

the figures given do not represent the total, and mildly deprecates the mighty burden of literature that must be thrown upon the profession if all the societies regularly publish proceedings. The local American medical society is an institution that is not fully understood by outsiders, but it is nevertheless a very important and valuable reality. Were its possibilities fully developed, and had every one of the thousands of counties an organization, the numbers would still more astound our contemporary. There would be, however, less danger of wasted or buried wisdom than it seems to think; such societies are or should be local stimulants of scientific medical work, but not necessarily publishing bodies. That society proceedings do sometimes bury valuable papers, so far as the general knowledge of their contents is concerned, may still be occasionally true, but it is certainly less so now than at any former time. The greater evil, if it is an evil, at the present is the over and over republication of the same articles. In any case the danger from multiplication of local centers of scientific medical progress and thought is not in this or any other respect as yet a serious one, although the same can not be said of the district, tristate and seminational bodies.

THE PLAGUE.

The newspaper reports of new cases of plague in San Francisco are not surprising; in fact they are no more than was anticipated. Any of our Pacific ports in direct communication with the Orient and with a specially segregated Mongolian quarter are liable to the same possibilities, and inland cities with similar elements in their population are also not free from danger. The influx of Japanese was never greater than at the present time, and it may be that in this is our greatest danger. Plague is now, however, a pandemic; it has reappeared in Egypt, it exists in South Africa, South America, Australia, China, Japan, Russia, and Persia as well as in India, where it has extended itself, being malignant in the eastern portion of that country, in Calcutta as well as in Bombay. It is therefore a universal danger and one that should receive the attention of sanitarians everywhere, as, with the greatly expanded modern methods of communication, no city with extensive commercial relations can be considered altogether safe. There is one cheerful side to the picture, however, and that is that modern methods of sanitation are a far better protection than those in vogue in the past and that thus far the plague has gained no lasting foothold in any European city. Better modern civilized habits of life have also apparently robbed the disease of many of its terrors, for our race at least. In Hongkong, where it was long epidemic and where the mortality was about the highest known, it was treated by the European community almost as a negligible quantity and its ravages were almost, if not quite, exclusively among the native population. We now know many things in regard to the disease that we did not know before, and while there is not the familiarity that breeds contempt, it may rationally relieve us of much of the senseless fear of this disease that has prevailed in the past. The possibilities of preventive inoculations are also to be con-

sidered when calculating the dangers, and we can safely say that if health authorities do their duty the recurrence of anything like the Middle Age epidemics is a very remote probability in any country inhabited by civilized whites. What the plague can do in a country like India at the present time is an object-lesson of the need of due precautions and healthy living on our part. It may be we will find it a necessity to do more than we have done in the past to prevent an undue influx of unassimilable Orientals, with their habits and diseases, over our boundaries.

ANTIVIVISECTIONISTS AND THE "BRITISH MEDICAL JOURNAL."

A peculiar libel suit against the *British Medical Journal* has just been decided in London, in favor of the defendant. One Adams, the editor of an antivivisection publication, discovered a "mare's nest" in a government report, and thought he could make a point against experimenters in that they had, as he supposed, obtained authorization for experiments on animals without anesthetics, but had employed them. He wrote to the Home Secretary in regard to the matter, and received a specific reply that he was mistaken as to facts. Not satisfied with this he sent an insulting circular letter to the gentlemen mentioned in the report, and a number of others, inferentially charging them with bad faith or incompetence in obtaining certificates authorizing experiments without anesthesia and afterward using it, and saying that he should accept their silence as assenting to the accuracy of his inferences. This communication, of which it was said by the trial judge in his summing up that "a more impertinent letter was never written by one man to another," was sent out to over seventy gentlemen, forty-one of whom had no connection whatever with the experiments referred to. A copy or copies of it naturally came to the hands of the editor of the *British Medical Journal* who, in what appears to us to be exceedingly temperate comments, mentioned the writer as an "irresponsible editor," which was the basis of the libel suit just concluded. The evidence showed that the reports and letters were easily understood by any one who wanted to understand them, and that there was no reason for the inferences drawn except the desire to find fault. There are several strange features in this case: one, that this editor who, as the evidence shows, was by no means careful as to imputations about others, should have felt himself libelled by the extremely temperate criticism of the *British Medical Journal*. As the judge remarked, the difficulty in dealing with the case was because the defendant was not the plaintiff, and the whole proceeding is perhaps an illustration of the general state of mind of these especially self-righteous zoophiles. Another feature illustrating this and their methods is the fact that, failing a charge of cruelty, he made one of bad faith, fraud, or ignorance because giving pain was avoided. This antivivisectionist was certainly hard to please. It is not always fair to judge a class by one of its representatives, but this is only an extreme case, if it is that, of the usual methods of the antivivisectionists. There is a general family likeness in them all; they are

all too ready to distort facts, and employ the *suggestio falsi* on the very slightest basis of inference. The petty malignancy shown in the course followed by the plaintiff in this suit is still another evidence of what numerous other facts have illustrated in the past, that excessive zoophily exists often in inverse ratio to philanthropy.

Medical News.

PROGRESS OF THE PLAGUE.—At a meeting of the San Francisco Board of Health and the attorneys of the Chinese Six Companies, May 22, a letter was drawn up for posting in Chinatown to the effect that the Board will not force the Chinese to submit to inoculation and that only those volunteering will receive the prophylactic injection. A house-to-house canvass of Chinatown will be made, to discover, if possible, any hidden cases of the disease, and to thoroughly cleanse the disease-breeding spots. As noted in our editorial columns this week, the Board has endeavored to keep the actual conditions from the public, but on the 21st it admitted, in a circular to the other state boards, that there had been nine deaths from bubonic plague, all Chinese found dead in Chinatown. No further cases are known, but every precaution to prevent the recurrence of the disease is being taken. Rio Janeiro, Brazil, is also a suspected plague center, several cases of the disease being officially reported, and eleven suspicious ones on the 22d. The plague has also appeared in a Persian village near Bagdad, and in Persian Kurdistan, where there have been 122 deaths. The sanitary council has met in extra session at Constantinople to consider these facts, and the Bassorah authorities have been ordered to draw a sanitary cordon around Suleimanic. Cases of plague have also been reported on vessels arriving at Barcelona from Manila, at Assyr, Rangoon and Matrah in Oman. The *St. Petersburg Med. Woch.* states that advices from Tokio, Japan, announce that Kitasato has discovered a second plague bacillus. The existence of a second casual agent explains the conflicting results with Yersin serum, and Kitasato hopes to be able to produce a new plague serum which will be effective in the cases in which the Yersin serum fails.

PENNSYLVANIA. Philadelphia.

AUTHORITIES OF ST. TIMOTHY'S HOSPITAL have appointed Drs. William C. Todd and James Libard visiting physicians.

HEIRS OF THE LATE PERCIVAL ROBERTS have donated \$50,000 for an addition to the St. Timothy's Hospital as a memorial to him.

THE ANNUAL COMMENCEMENT EXERCISES OF THE JEFFERSON MEDICAL COLLEGE were held May 15. Over 100 candidates received their diplomas. The degrees were conferred by Hon. William Potter, and the presidential address was made by Dr. James D. Moffat, president of Washington and Jefferson College.

THE PHILADELPHIA ALUMNI OF THE MEDICO-CHIRURGICAL COLLEGE held their annual exercises May 18, in the clinical amphitheater of the hospital. The principal address was delivered by Adj.-Gen. Thomas J. Stewart. A banquet followed, at which the principal speakers were: Thomas J. Stewart, Dr. Henry Fisher, and Dr. Frank Hachlin.

THE NUMBER OF DEATHS IN THIS CITY during the past week was 535, an increase of 41 over the previous week, and an increase of 152 over the corresponding period of last year. The principal causes of death were: apoplexy, 22; nephritis, 33; pneumonia, 75; measles, 22.

THE BOARD OF TRUSTEES OF THE PHILADELPHIA POLYCLINIC have

recently appointed Dr. James Thorington as professor of diseases of the eye. This is a new chair in that department.

DR. J. M. DA COSTA has been chosen orator for the annual commencement exercises at Yale Medical College. His subject will be "Questions of To-day in Medicine."

MR. W. B. SAUNDERS announces that he has associated with him in business Mr. F. S. Hopkins and Mr. F. F. Legner. The former has been manager, heretofore, of the subscription, and the latter of the publication, department. The firm will be known as W. B. Saunders & Co.

ON THE AFTERNOON OF MAY 14, a fire broke out in a building adjoining the Germantown Hospital and for a time threatened that institution. The loss was about \$1000.

COLLEGE SUED BY STUDENT.

A student in one of the medical colleges recently entered suit against that institution for \$2500 damages for refusal of the defendant to allow the plaintiff to take the final examinations. The student claimed that he entered this college in 1896, but was subsequently compelled to finish his course at another institution. The college maintained that he was in arrears for his tuition and had failed in certain requisite studies. The jury, after being out all night, failed to agree and was discharged.

NEW YORK.

New York City.

AT THE NEW YORK POLYCLINIC, Drs. Francis J. Quinlan and R. C. Myles have been elected professors of laryngology and rhinology.

MILK BOOTHS.

The board of estimate and apportionment has appropriated \$4000 for the construction of two ornamental booths, one for Central and the other for Tompkins Park. They are to be used for dispensing the sterilized milk and infant food supplied by Nathan Straus, and are to cost \$1400 each. By the end of this month Mr. Straus proposes to have fifteen milk booths in operation in this city. These are to be provided with proper facilities for cooling and preserving the milk.

CLOSING OF TRINITY HOSPITAL.

For the first time in the twenty-seven years of its existence, Trinity Hospital has been closed, and it will not reopen until October 15, as it is necessary to make extensive alterations in the building. The fact that in the fall it is to be placed in charge of trained nurses has probably given rise to the rumor that this step was taken as a convenient way of retiring the Angelican Sisters of St. Mary, who have been in charge all these years.

THE BICYCLE AND CONSUMPTION.

The long-distance cycle riding of William R. Brown is of a different kind from that to which the public has been treated in the past, for a decidedly novel feature has been introduced—a long-distance bicycle ride with the object of demonstrating its value as a consumption cure. This man has pluckily pedaled away in the face of all sorts of difficulties and discouragements, and in a ride of nearly 148 hours has covered 1400 miles through mud and rain. He was off his wheel only thirty-seven hours altogether, and his total sleep amounted to 1½ hours. On the completion of his fourteenth century, several physicians examined him. They not only found him to be in fit form to continue his ride, but he had only lost 3½ pounds from the commencement of the ride. The respirations were 22, the pulse 60, firm and regular, and the temperature normal. He seemed no more exhausted than most persons at the completion of a single century. The remarkable thing about his weight was its increase, he having gained 3½ pounds in the last two days.

BURNED WITH CAUSTIC POTASH.

A dastardly assault was recently made on the wife of Dr. John J. Cronin. As she opened the door of their residence, in answer to a ring, a slender woman, dressed in black, and closely veiled, asked in a lisping voice if Dr. Cronin was in. On being told that he was not, she hesitated a moment, and then pulling out a small bottle from the folds of her dress, said, "I called to give him this," and pulled out the stopper and dashed the contents, a solution of caustic potash, in Mrs.

Cronin's face. The police were at once notified, and detectives put on the case. They found that less than an hour before the assault the woman in black had called on Mrs. Cronin's mother and had asked where the Doctor lived. From what the mysterious woman said it was evident she was well acquainted with the family. Mrs. Cronin was removed the next day to the Manhattan Eye and Ear Hospital but it is thought probable that she will lose the sight of one eye.

DAMAGES AWARDED A PATIENT.

A case of much medicolegal interest, and one that has been in the courts for five years, has just been decided. It is the suit of Miss Helen D. Ward, to recover \$30,000 damages from St. Vincent's Hospital for injuries resulting from the carelessness of a nurse in burning Miss Ward while the latter was still under the influence of ether after an operation. She entered the hospital in February, 1894, and paid \$25 a week for board and \$3 a day for the services of a special nurse. The operation was performed by her own physician and was entirely successful, but the burn on her leg, it was alleged, eventually compelled Miss Ward to undergo an operation to save her leg from amputation. The suit was first brought in March, 1895, and came to trial three years later. The judge directed a verdict for the defendant, on the ground that the hospital was a charitable institution and, therefore, not liable for the negligence of employees. The case was appealed, and in April, 1899, the judges of the appellate division unanimously ordered a new trial, holding that Miss Ward was a pay patient, and the action was not brought because of negligence, but for alleged breach of contract. At the second trial, last December, the jury disagreed. The third trial was last week, and as a result, the plaintiff was awarded \$10,000 by Judge Gildersleeve and a jury of the supreme court. The decision is totally at variance with all precedent, and is likely to open the way for numerous suits against hospitals for real or fancied grievances.

MARYLAND.

DR. T. ROSS PAYNE has been appointed health officer of Baltimore County, to succeed Dr. H. Burton Stevenson.

DR. H. O. WALTON has been appointed health officer and physician to the jail of Anne Arundel County.

DR. CHARLES F. DAVIDSON of Queenstown has been appointed health officer of Queen Anne County.

DR. C. L. CECIL, the local health officer of Charles County, has contracted smallpox.

DR. O. H. W. RAGAN, Hagerstown, has been appointed health officer of Washington County, vice Dr. J. McPherson Scott.

DR. CHARLES A. WELLS, Hyattsville, has brought suit against the Baltimore and Ohio Railroad for \$6000 for injuries received at a railway crossing.

DR. CHAS. L. MABBELDT has been appointed sanitary officer of Catonsville; and Dr. J. C. Schofield, of Highlandtown and Canton, both in the same county.

DR. H. BURTON STEVENSON, secretary of the Baltimore County Board of Health, reports the smallpox outbreak at Sparrow's Point, a suburb of Baltimore, as checked. There are still 9 cases at the quarantine hospital, and 16 in the detention hospital.

Baltimore.

DR. I. EDMONDSON ATKINSON has resigned the chair of therapeutics in the University of Maryland.

DR. JOHN A. SCHULTE has been appointed vaccin physician and health warder, vice Dr. J. J. Valentine.

DR. G. W. TRUITT, a member of the late legislature, has been appointed chief clerk by the new state insurance commissioner. The salary is \$2000.

THE REGISTER of the Johns Hopkins University, recently issued, shows that there were 231 students enrolled in the medical school, of whom 20 were in special courses.

THE SPRING state medical examination of applicants to practice medicine commenced May 16, and continued four days. Eighty-three persons were examined.

AT THE Hebrew Hospital, Dr. A. L. Rettaliata has been re-elected resident physician in charge. Drs. Jos. Blum and Sidney Cone have been added to the visiting staff, and Dr. Jos. Seligman has been put in charge of the dispensary.

MR. HENRY WATERS presented to the city the keys and deed to the public bath-house at 131 and 133 South High street, May 17. Mr. Eugene Levering, president of the Public Bath Commission, made an address showing the necessity of public baths in crowded neighborhoods.

FIRST KOREAN DOCTOR.

THE feature of the commencement exercises of the Women's Medical College, May 14, was the graduation of Dr. Esther Pak Kim, of Seoul, Korea. She is the first medical graduate in America from her native country, and the occasion was regarded as of sufficient importance to be observed officially by the representatives of Korea in Washington, two of whom were present. She will become a missionary in her native land.

ILLINOIS.

Chicago.

THE CAPITAL stock of the College of Physicians and Surgeons has been increased from \$100,000 to \$217,000.

DR. CLARENCE L. WHEATON, owing to illness in his family, is going to Colorado to engage in the practice of medicine.

THE REGULAR quarterly examination of the Illinois State Board of Health will be held at the Great Northern Hotel, July 11-13.

DR. G. FRANK LYDSTON has been appointed professor of genito-urinary surgery in the Chicago Clinical School vice Dr. F. Kriessl.

DR. R. R. CAMPBELL has returned from the Pacific Coast, where he has been for the past five months on account of his wife's health.

THE NEW FRANCIS Willard National Temperance Hospital, at 167 South Sangamon Street, was opened May 17. The hospital will accommodate thirty patients, and has twelve nurses in attendance.

DR. JACOB FRANK sailed for Europe May 19, via the Hamburg-American liner *Graf Waldersee*. He goes as a delegate from the AMERICAN MEDICAL ASSOCIATION to the International Medical Congress that meets in Paris in August, where he will also read a paper.

A DIET kitchen for infants and children will soon be opened at Thirty-second and Wallace streets, in the building of the Rouse Mission of the Trinity Episcopal Church. Its object will be the provision of pure modified milk, modified foods, fruit juices and meat extracts for poor children. It will be under the medical direction of Dr. Geo. T. Palmer, and Dr. Marcus P. Hatfield will be the consulting pediatrician, while the detail work of the kitchen will be in the hands of the trained nurses of St. Barnabas Guild.

OHIO

DR. C. A. PROBST, Columbus, secretary of the State Board of Health, sails for Europe, June 5.

THE MEDICAL staff of the Cincinnati Hospital, represented by Drs. Eichberg, Packer and Holt, together with the board of trustees, have just selected the site on Price Hill for the hospital for consumptive and other contagious diseases. The legislature has granted \$25,000 for the purpose, and a two-story brick, fifty feet in length and thirty in width will be erected.

VIRGINIA.

THE EXECUTIVE committee of the State Central Hospital, near Petersburg, has accepted the plans for the new addition to the main building, which will accommodate 160 patients and cost about \$18,000.

Richmond.

SEVENTY-FIVE received the degree of M.D. at the commencement exercises of the University College of Medicine, recently.

AT THE commencement exercises of the Medical College of Virginia, May 10, forty received the degree of doctor of medicine. Dr. Chas. A. L. Reed, Cincinnati, made the address.

KANSAS.

TEN YEARS' PRACTICE QUALIFIES PHYSICIAN.

THE supreme court has decided that under the provisions of chapter 68, laws of 1870, enacted "to protect the people from empiricism and to elevate the medical profession," a physician

who had practiced medicine for ten years prior to the taking effect of the act is qualified, but ten years of practice after the passage of the act confers no right on the practitioner. In this decision the supreme court reverses Judge Monroe, of Hays City, who held, in the case of the State vs. Wilson, that Dr. H. L. Wilson had complied with the law by practicing for ten years after its enactment.

Topeka.

AT THE last meeting of the city council the salary of the city physician was reduced from \$200 to \$50, the regular monthly salary. This is on account of the abatement of the smallpox epidemic, as there are now only fifteen cases in the city.

HOSPITAL DONATION.

Rev. Chas. Sheldon has offered to give the city \$1000 on condition that the council appropriate a like sum for the purpose of erecting a detention hospital to be operated in connection with the city jail. The city has accepted his offer, and work on the hospital will be commenced at once. Dr. Sheldon's donation is from his share of the profits resulting from the Sheldon edition of the *Capital*.

DELAWARE.

THE TRUSTEES of the state hospital at Farmhurst have re-elected Dr. John J. Black, New Castle, president; Dr. Paris Carlisle, Frederica, secretary.

THE MEDICAL Examining Board has elected Dr. Irving Valandigham, Middletown, president, and Dr. J. H. Wilson, Dover, secretary.

TENNESSEE.

A CLASS of sixty was graduated from the Chattanooga Medical College, at the recent commencement.

A CONSOLIDATION of the *Memphis Lancet* with the *Memphis Medical Monthly* is announced, and in deference to the seniority of the latter journal the name of the new publication will be the *Memphis Medical Monthly*.

IOWA.

DR. J. C. SHRAEDER, Iowa City, has been elected president of the State Board of Health.

NINETY-TWO applicants have passed the medical examination and been granted certificates to practice medicine in the state.

NEBRASKA.

FIFTEEN STUDENTS were granted diplomas from the Omaha Medical College, at the commencement exercises held early in the month. David R. Kerr, chancellor of the University of Omaha, conferred the degrees, and Prof. Henry Ward, of the University of Nebraska, addressed the class on "The Physician as a Scientist."

CALIFORNIA.

DR. J. F. KITCHINGS, Oakland, has been re-elected president of the State Board of Health.

DR. DRIESBACH SMITH has resigned as assistant in the Napa State Hospital, and will be connected with the Asylum for the Insane, at Livermore.

Los Angeles.

THE TOTAL number of deaths in Los Angeles for April was 142, or an annual rate per 100 of 16.54 per cent. Twenty-six were from pulmonary consumption, 2 of the persons being natives of the Pacific Coast. There were 281 cases of contagious diseases, as follows: diphtheria, 19; scarlet fever, 14; typhoid fever, 20; measles, 228.

DR. STANLEY P. BLACK, professor of histology, bacteriology and clinical microscopy, medical department of the University of Southern California, is suffering from a serious attack of blood poisoning, there being special involvement of the glands under the pectoralis major and along the clavicle. Infection occurred through a slight wound in the finger while handling pathologic specimens.

CANADA.

DR. D. A. SHIRRES, Montreal, has returned from Baltimore, Md., where he has been carrying on research work in neurology.

LAST WEEK the death-rate in Montreal was more than usually heavy, 151 being registered. Of these, five were from typhoid fever.

THERE IS an epidemic of diphtheria in the barracks of the Northwest Mounted Police stationed at Regina. The disease was brought in by recruits. The hospital is full.

LIEUT.-COL. GEORGE STIRLING RYEBSON, Canadian Red Cross Commissioner in South Africa, has been appointed British Red Cross Commissioner with Lord Roberts' headquarters.

DR. COLIN A. CAMPBELL, of the house staff of the Toronto General Hospital, has been appointed surgeon to the S. S. *Tartar* of the Canadian Pacific's line from Vancouver to Yokohama.

DR. ALFRED A. LOEB, who was graduated from McGill last spring, and who has since occupied the position of house physician of the Philadelphia Maternity Hospital, has been re-elected.

FIFTY HOUSES in Montreal are placarded with scarlet fever notices. The civic hospital still continues full of these patients. So far the health officer is at a loss to account for the prevalence of the disease.

THE FOLLOWING practitioners are at the head of the movement in Montreal to establish a free consumption sanitarium for the city: Drs. LeCavallier, Mignault, Adams, Campbell, Johnston, Hervieux, Marsolais, Lesage and Dube.

THE TORONTO osteopath was up for trial last week and got off "scot free." The daily papers are reaping the benefit of it by the appearance of his card in their columns. Apparently we have not heard the last of osteopathy in Ontario.

THE "CANCER DOCTOR" and his practitioner friend of this city, who, it will be remembered, were to be tried at the May assizes, for manslaughter, are now breathing easier, the grand jury having found "no bill."

THE DOMINION government is shortly to appoint a quarantine officer at Windsor. The necessity for this is shown by there having been 2700 cases of smallpox in Illinois, whence there is much travel into Ontario.

PASSENGERS on the R. M. S., *Empress of India*, which is held in quarantine off Williams Head, near Victoria, B.C., are not permitted to leave the boat, pending instructions from Ottawa, there being a rumor that either plague or smallpox had appeared among the 100 steerage passengers.

TWO PHYSICIANS of Montreal are being sued for \$1099 damages, by a laborer who received a railway injury to one foot. His claim is that his foot was amputated while under the influence of an anesthetic, although promise was given that the operation would not be performed.

DR. MCCARREY, milk inspector of Montreal, has reported that the milk-supply is much purer than that of the spring of 1899. A year ago twenty-five dealers were summoned for supplying an inferior quality; so far this season only two have been similarly dealt with.

TORONTO UNIVERSITY is advertising for two professors for the medical department. On account of the death of Dr. J. Elliott Graham, the professorship of medicine and clinical medicine is vacant, and the professorship of pathology also by the resignation of Dr. John Caven.

THE SECRETARY of the Provincial Board of Health of the Province of Quebec has issued a statement of the smallpox situation in that province. Since the outbreak of the disease in the lower part of the province, in January, there have been 230 cases and only two deaths. At the present time there are thirty cases.

DR. PAUL A. GILLESPIE, a graduate of Toronto University, who was referred to in these columns some time ago as President Kruger's physician, having been commandeered at the outbreak of hostilities for service in the Boer hospital corps, has again become associated with the British service after the taking of Boshof by Lord Methuen's forces. Previous to the war he was a practitioner in Winburg, Orange Free State.

TRINITY MEDICAL COLLEGE.

So far as Trinity is concerned, the session is finally closed. On the 17th inst., between fifty and sixty were made recipients of diplomas making them Fellows of Trinity Medical College. At the commencement exercises, held that afternoon,

the Dean of the College, Dr. Geikie, presided, and as usual, gave some good, sound, practical advice to the graduating class. In the evening the members of the class held their class dinner. On the following day Trinity University conferred about seventy degrees in medicine; and the Trinity Medical Alumni Association held its eighth annual reunion. Dr. Allen Baines, Toronto, was elected president for the ensuing year.

MONTREAL GENERAL HOSPITAL.

Dr. F. G. Finley, the secretary, has presented his annual report, showing that the work of the past year was greater than at any other time, though the receipts have fallen away to some extent. The ordinary income amounted to \$76,421.72, and the expenditure to \$81,570.75. The income was \$1605.23 less than the previous year, while the expenditure was \$1082.50 more. The total number of in-door patients treated to a conclusion during the year was 2824, an increase of 94 over the preceding year. Of these, 189 remained over from the preceding year, and 2810 were admitted during the year; and 175 remained in the hospital at the end of the year. There were 2629 discharged, and 195 died in the hospital, making a total of 2824 treated during the year. The average number of patients in the wards during the year was 167; the average number of days in the hospital was 21.3; and the aggregate number of days in the hospital by all patients was 60,078, a decrease of 2966 over the previous year. Of the in-door patients treated to a conclusion, there were 1795 males, and 1029 females. The death-rate was 6.5 per cent., or, excluding 106 dying within three days after admission, 3 per cent. In the out-door department there were 37,373 consultations, an increase of 2295. The medical superintendent, Dr. Von Eberts, was appointed again to the position. In consequence of the resignation of the president, F. Wolferstan Thomas, Esq., Mr. James Cathern was elected president.

Correspondence.

Improvements in Medical Education.

CHICAGO, May 19, 1900.

To the Editor:—I have within the past few years been delivering special lectures at medical schools both in the East and in the West, and during that time I have made some observations concerning the state of medical education in this country, which, though not new to the readers of THE JOURNAL, may, nevertheless, be of interest to them. It need hardly be said that, wherever I went, I found such an *esprit de corps* among the members of the profession as, in spite of their many differences in theory and practice, constituted them a real brotherhood. There was also manifested in the schools an earnestness and candor which argues well for the future. The good work accomplished was so patent that I may be excused from dwelling upon it at any greater length. In pointing out some of the defects in the present system of medical education, I do not intend to assume the rôle of a carping critic. My sole object is to be of service to the cause of scientific medical practice.

In viewing the present system one does not have to seek long to find the root-cause of most of its defects. This lies to a large extent in the method of organization and conduct of the medical schools. The almost universal type of organization and conduct of the medical schools is that of a stock company. The school is owned and controlled by a few leading physicians who constitute themselves its professors. These stockholders, who usually have a large private practice, hire instructors in pathology, chemistry, etc., at salaries as low as possible. They elect as dean or secretary of the school a good business man who knows how to secure a large number of students and so can make the institution a paying investment—for the stockholders. In some cases, when this has been accomplished, the stock is then "watered" in order that it may be sold at a greater profit to new professors, and these in turn repeat what their predecessors have done. By a little play on words such a corporation might be styled "a traction company," organized for the purpose of *driving*

large dividends. Even without dividends the stockholder-professor regards it a paying investment.

From this brief description it is clearly seen that the money does not go to the hard-worked and poorly-paid laboratory man. The institution, on the contrary, is founded and run to further the selfish ends of the professor. Moreover, in such a school the leading professors, being general practitioners, consider themselves capable of teaching everything or anything, and hence such anomalies as the following are not uncommon: Dr. —, professor of physiology, hygiene and demonstrator of anatomy; Dr. —, professor of obstetrics and preventive medicine; Dr. —, professor of children's diseases and medical jurisprudence.

Then, too, the professor, being a busy practitioner, does not have time to prepare for his classes. On his way to college he "thinks up" what he will give the boys in his morning lecture. Or he studies a text-book and gives it to them just as he read it the night before. I have seen such a professor, after a busy day, bolstered up in bed "bucking up" for the next morning's recitations. I have also read stenographic notes on lectures, every point of which was presented in the same manner and in the same order as found in some well-known text-book on the subject. Knowing the text-book used, the entire course could have been arranged by an undergraduate.

Furthermore, I have heard lecturers spending much time in describing laboratory methods, who could scarcely tell a staphylococcus from the ameba coli. I found one who could not even focus the microscope. He was the "head" professor, and his income from practice was \$25,000 a year, gained largely through college association. (The bacteriologist and pathologist, devoting most of his time to the school, received \$600 a year.) In a recent report on the financial condition of a certain college, it was shown that its receipts were \$32,000. The expenses were \$6000, leaving a net profit of \$26,000.

It is clear that under such actual conditions as those outlined above, where the selfish financial principle is at the basis of the medical institution, the departments which require the largest expenditure of money for equipment will be the most hampered and crippled. This will be most keenly felt by the laboratory of the school, the place where all scientific work must begin. If the graduates of our institutions have not been deeply grounded in modern laboratory methods, how can we hope for real progress in the medical profession? It is also clearly seen that under such circumstances the real workers in the institution will be continually underpaid, and so there will be no stimulus toward proficiency. Only inferior talent will thus be attracted to such positions. Moreover, where the personal and selfish interest governs the faculty, all appointments will be conditioned by it, rather than by the sole condition of fitness and competency.

But to see the worst features of the present system, one must view it from the standpoint of the student. And in the first place a protest must be made against the prevailing didactic lecture and quiz method, which employs, almost exclusively, the one intellectual faculty—memory. We need to cultivate in the student the truly scientific method, *which emphasizes inductive reasoning based on observation and experiment*. One recent graduate not long ago remarked to me: "I do not remember one thing my professor taught in his didactic lecture, but the clinics I can remember very distinctly, not only the cases, but even the details of diagnosis, pathology, and therapeutics." The old method is a suspension of ideas in the mind in such a way that they do not become incorporated with past or present practical experience. Thus the student contracts a sort of "dyspepsia of the mind," or "cerebral indigestion." Moreover, by it the student's attention is directed away from the empirical and practical to the theoretical. He conceives the notion that the only equipment which a successful practitioner needs is a scalpel, scrap-blank and pencil, and a mahogany-top table. The thirty patients in his two hours a day in the business center is the outcome of this faulty educational method. Only an infinitesimal amount of what he has been taught can be put to any practical use by him. Nor is the student given the ability to acquire the right kind of practical knowledge. In the post-graduate work

I have been enabled to observe the results of these methods of education on the new as well as old graduates and find the grossest ignorance in matters relating to laboratory equipments, scientific medicine, and the physical methods of diagnosis and treatment.

This leads me to insist that all medical students should be given a practical knowledge of: 1. Hydrotherapy in all its many branches and forms. The physiologic effects of heat and cold constitute so vast a field that they ought to be known by the M.D., no matter what branch of medicine he takes up. I have known students who did not know the difference between the action on the system of water at 40 C., and of water at 55 C. 2. Hot and cold air baths have a place in therapeutics that can not be ignored by the educated physician. Only the ignorant product of the recitation room shuns these practical methods and relegates them to the domain of empirical quackery. 3. Medical gymnastics, such as physical exercise, massage, etc., is now a necessity in medical education. Under the direction of a competent physician grounded in the science and practice of medical gymnastics it would be of far-reaching value to the school, both for the professors and students, if for no other purpose than the personal benefit derived by the hard brain-racked student; the daily exercise of this branch of medical education would be a god-send. It would be a conservative and expedient policy, but the advantages are not confined to such narrow and selfish ends as the physical welfare of the student. Other professors on the faculty of such a school would soon become practically interested, to their own benefit as well as that of their patients. Students would learn to give massage to each other. The recent valuable work of Schott's method of cure for diseases of the heart is only another illustration of the wide application of the physical and mechanical supplementing the hydrotherapeutic method of treatment of this otherwise incurable disease. Take only the same time to teach this method as is required to teach the action of the digitalis series, and it will be far more valuable. Other physical methods, such as are used in the exploration of the cavities and organs of the body by means of sounding instruments, etc., for both diagnostic and therapeutic purposes, should also be taught in the medical school. Early education in those physical methods not only interests the student in "theory and practice" but develops a taste for exploration and investigation.

Electricity was formerly the useful property of quacks. Medical science has raised it to a high place in therapeutics. Electricity used internally and externally in all forms of application should be taught theoretically as well as practically. The therapeutic advantages of the electric light have recently added another useful form of electricity that may displace many drug prescriptions, but with greater success in the beneficial results derived. Finsen has shown most marvelous results from the use of the light in lupus.

Dietetics in all its branches is practically neglected in medical schools. That part of dietetics concerning the chemistry of cooking and the preparation of food is as unknown to the medical student as if the study did not belong to the science of medicine. It has a wider application and perhaps more necessary use than any single branch. Books on dietetics can not teach cooking and preparation of food. It must be learned in the diet kitchen. Discharge the cooks in the hospital and give each student an opportunity under an educated chef. If the old methods of instruction are thus supplemented by these more modern ones, the medical schools of our country will have taken a distinct step forward and the men who graduate from them will be fitted to gain the confidence of the public even more than they have in the past. If, at the same time, our medical schools could not only be affiliated with, but *incorporated into* the colleges and universities of the land, the mercenary spirit would, to a large extent at least, be wiped out, and the effect of a scientific atmosphere would be wholesome to both professor and student. In this way petty jealousies and rivalries which often result in the establishment of new schools with no endowment, poor teachers, and low entrance requirements, would be eliminated, and the standard of the whole profession raised.

FENTON B. TURCK, M.D.

Book Notices.

TREATMENT OF DISEASES OF THE NERVOUS SYSTEM. A Manual for Practitioners. By Joseph Collins, M.D., Professor of Nervous and Mental Diseases in the New York Post-Graduate Medical School. Illustrated by Twenty-three Engravings. Cloth. Pp. 602. Price, \$5. New York: William Wood & Co. 1900.

This volume is practically a manual on nervous diseases, in which special attention is given to therapeutic methods. It begins with a section on the etiology and the prevention of nervous diseases, followed by a somewhat longer one on the general application of the remedial measures. The bulk of the book is taken up with the consideration of the special forms of diseases and the remedies and measures applicable to them. It will be seen, therefore, that it is far more than merely a therapeutic work. The first section, on cause and prevention, is a very judicious summary of the general facts as known in regard to etiology and the prophylaxis of these disorders, and calls for no further special comment. In the second section the author's views are plainly expressed on the subject of serumtherapy, and he seems to believe that thus far only the thyroid is really of decided value. As regards the use of the bromids, probably the most misused drugs in the Pharmacopœia, he makes no mention of their occasional excitant effect, nor is it mentioned in his special article on epilepsy. In asylum practice this is sufficiently common to be noticed, and it is a little remarkable that while it has been observed by some of the very earliest experimenters, it has been such a late discovery by some of our leading neurologists. The author's opinion of hydrotherapy is a judicious one, and the same is true as regards electricity, where he certainly does not follow the extreme opinions of some specialists. Massage is more briefly treated, but on the whole we can agree with Collins in his estimate of its use; the same is true of his remarks as regards hypnotism. The treatment of special disorders, which takes up the greater part of the book, may be said to be according to the latest light on this subject, and a safe guide to the general practitioner. There is no mention, however, of the Baccelli method in the treatment of tetanus with carbolic acid, with which some remarkable results have been reported of late. Nor is the use of cannabis indica in migraine so entirely obsolete as might be inferred from its lack of mention. As regards the surgical treatment of epilepsy, he holds the view that is probably now held by the majority of those who have had experience with the disease, that it is practically useless as regards any permanent benefit and that even when the disease can be localized it is questionable whether serious surgical operations, such as trephining, is often justifiable, at least in those very recent cases. The present claims of some ophthalmologists are hardly more than mentioned.

Excepting in the discussion of a few disorders, such as headache, very little in the way of prescriptions and formulas is given. The treatment is stated in a general way, and any one who looks here for special prescriptions is liable to be disappointed.

Dr. Collins writes in a very lively and readable style and it sometimes even appears that the style gets away with him a little. One or two of his expressions seem a little odd, for example such as that on page 113, where it would seem that he is calling male masseurs ancille. These few minor criticisms, however, do not imply any depreciation of the work as a whole; we have nothing but commendation for the book, and it will be a most valuable addition to the library of every general practitioner.

A DICTIONARY OF TERMS USED IN MEDICINE AND THE COLLATERAL SCIENCES. By Richard D. Hobblyn, M.A. Thirteenth Edition. Revised Throughout, with Numerous Additions. By John A. P. Price, M.D., Late Physician to the Royal Hospital for Children and Women. Cloth. Pp. 838. Price, \$1.50. Philadelphia: Lea Brothers & Co. 1900.

This is an American reproduction of the well-known English work which has the sanction of long favor, this being its thirteenth edition. Special attention appears to be given to

the etymology and correct Latinity, etc., of the terms here included. It is not as full as some American dictionaries even of similar size, but we do not believe there have been many important omissions.

MANUAL OF ORGANIC MATERIA MEDICA AND PHARMACOLOGY. An Introduction to the Study of the Vegetable Kingdom and the Vegetable and Animal Drugs. Comprising the Botanical and Physical Characteristics, Source, Constituents, Pharmacopœial Preparations, Insects Injuries to Drugs, and Pharmacal Botany. By Lucius E. Sayre, B.S., Ph. M., Dean of the School of Pharmacy. Second Edition. Revised. With Histology and Micro-technique by William C. Stevens, Professor of Botany in the University of Kansas. With 574 Illustrations, the Majority from Original Drawings. Cloth. Pp. 684. Price, \$4.50. Philadelphia: P. Blakiston's Son & Co. 1899.

This volume is clearly intended as a work for the pharmacist, to the physician it will be of use simply for reference. It is practically a treatise on medical botany. The section on animal remedies is short and includes only the older pharmacopœial preparations. In this edition the author has left out the chapters on elementary botany, from the earlier one, and replaced them by an extensive section on histology and microtechnique. This, with some other alterations mentioned in the preface, ought to make it still more useful to the large class for whom it has been prepared. Its very numerous illustrations are a useful aid to the text, and the book as a whole appears to be a very valuable treatise on its specialty.

A MANUAL OF MODERN GASTRIC METHODS, CHEMICAL, PHYSICAL AND THERAPEUTICAL. By A. Lockhart Gillespie, M.D., F.R.C.P.E., F.R.S.E., Lecturer on Materia Medica and Therapeutics in the School of Medicine of the Royal College, Edinburgh. With a chapter on the Mechanical Methods Used in Young Children. By John Thomson, M.D., F.R.C.P., Assistant Physician, Royal Hospital for Sick Children, Edinburgh. Cloth. Pp. 175. Price, \$1.50. New York: William Wood & Co. 1899.

This book seems to be very well fitted to meet a want. Most general practitioners have little practical experience in some of the methods of gastric diagnosis and treatment here described, the utility of which in certain cases is undeniable. The author has described them in a way to be clearly intelligible, and where his text requires it has supplied the needed illustrations. The book is one to be safely recommended to any one who treats gastric disorders, as giving information not so readily picked out of the larger works on the subject, and in a very convenient form. The reputation of the author is a guarantee of its accuracy in details.

MENTALLY-DEFICIENT CHILDREN. Their Treatment and Training. By G. E. Shuttleworth, B.A., M.D., Medical Examiner of Defective Children, School Board for London. Second Edition. Cloth. Pp. 180. Price, \$1.50. Philadelphia: P. Blakiston's Son & Co. 1900.

The first edition of this little work being out of print and still in demand, Dr. Shuttleworth has reproduced it in this volume, with the addition of a couple of chapters giving an account of an official inquiry in which he took part, on the systems of education of the feeble-minded. The results of this inquiry were embodied in a statute which is printed in the appendix. The book has been and will continue to be one of the best brief accounts of its subject in our language, and it is well that it has again been made available.

PROGRESSIVE MEDICINE. A Quarterly Digest of Advances, Discoveries and Improvements in the Medical and Surgical Sciences. Edited by Hobart Amory Hare, M.D., Professor of Therapeutics and Materia Medica in the Jefferson Medical College of Philadelphia. Assisted by Charles Adams Holder, M.D., Assistant Demonstrator of Therapeutics in the Jefferson Medical College. Volume I, March, 1900. Surgery of the Head, Neck and Chest. Infectious Diseases, Including Acute Rheumatism, Croupous Pneumonia and Influenza. Diseases of Children. Pathology. Laryngology and Rhinology. Otology. Cloth. Pp. 428. Price, \$2.50. Philadelphia: Lea Brothers & Co. 1900.

The first number for the year, of this quarterly serial in book form, includes the usual digests, as indicated in the title. The first of these is a valuable résumé of the general literature, by Chalmers DaCosta, which is both critical and full, and will

be found to be a most useful one. The second, by F. A. Packard, on infectious diseases, deserves equal commendation, and is noticed editorially in this issue. Blackader's digest on diseases of children is well done, though the literature is not so full as in the two above noticed, and the section on pathology, by Hektoen, is, as might be expected, thorough and complete, as regards the chief advances within the past year. The two concluding sections, on laryngology and rhinology, by A. Logan Turner, and otology by Robert L. Randolph, while in the main useful critical résumés of papers that have appeared, contain more omissions, if we may use an idiom, than any of the others in the book. A comparison with the recent published work of Head and Andrews will show this. As a whole the volume fully keeps up the reputation of the series.

ON FRACTURES AND DISLOCATIONS. By Professor Dr. H. Hefnerich, of Griefswald. Illustrated with 69 Plates and 126 Figures in the Text. Drawn by B. Keilitz. Translated from the Third Edition, by J. Hutchinson, Jr., F.R.C.S., Surgeon of the London Hospital. Cloth. Price, \$3. New York: William Wood & Co. 1899.

This English translation is from the third edition of the German work, and as such it will be of value to American readers. The usefulness of illustrations is well shown by the fact that three-quarters of the book is thus taken up, the text filling less than 150 pages.

Association News.

Board of Trustees.—There will be a meeting of the Board of Trustees of the AMERICAN MEDICAL ASSOCIATION in Room 237, Hotel Dennis, Atlantic City, N. J., at 10 a. m., Monday, June 4, 1900. Alonzo Garcelon, M.D., President.

Membership Receipts.—Members attending the Atlantic City meeting, and who have paid their dues for 1900, are reminded of the necessity of taking their receipts with them if they wish to avoid annoyance when they register.

The Official Program.—In order to avoid misunderstandings and to protect the interests of advertisers, attention is called to the fact that there is but one official program. This program is copyrighted by the Board of Trustees and contains no advertising matter.

Delegates to the Meeting of the American Medical Association.—Secretaries of societies are requested to forward the names of delegates as soon as possible after these are appointed or elected. George H. Simmons, M.D., Secretary, 61 Market St., Chicago.

General Business Committee.—The first meeting of the General Business Committee of the AMERICAN MEDICAL ASSOCIATION will be held at the Hotel Dennis, Atlantic City, N. J., on Monday, June 4, at 4:30 o'clock, in room 238. Subsequent meetings of the Committee will be held at the same place and hour, every afternoon, during the meeting of the ASSOCIATION, unless otherwise directed by the Committee. In order that the business of the ASSOCIATION may be effectively transacted, it is very important that all the members of the Committee should attend all its meetings. L. DUNCAN BULKLEY, Acting Secretary.

Railroad Rates for Atlantic City Meeting.—As previously announced in these columns, the Trunk Lines Association and the Central Passenger Association have granted one and one-third fare rate on the certificate plan for the Atlantic City meeting. Tickets will be on sale in the territory of these Associations from May 30 to June 7, and good to return to June 23. Action has also been taken by the Western Passenger Association and the same rate announced from all points in its territory, tickets also to be sold on the certificate plan, the dates of sale being May 30 to June 5. The return limit was made June 12 by this Association, but on account of the later limit allowed by the others, it will probably be changed to correspond with that of the Trunk Lines and Central Passenger Associations. The certificates will be signed at Atlantic City by Dr. W. Blair Stewart, N. E. Cor. Pacific and North Carolina Avenues, and a special agent

will be present on June 6, 7 and 8. The territory covered by the two first-named includes practically everything north of the Ohio River and east of the Mississippi from Cairo to St. Louis, thence east of a line drawn from St. Louis to Chicago, through Jacksonville, Decatur, Gibson, etc. The Western Passenger Association's territory to which the certificate plan usually applies comprises points west of Chicago, Peoria and St. Louis, including Oklahoma, Indian Territory, Kansas, Colorado, Utah, Nebraska, South Dakota, Minnesota, Wisconsin, Iowa, most of North Dakota and Missouri, and northern Michigan and northern Illinois.

Deaths and Obituaries.

JACOB R. WEIST, M.D., Richmond, Ind., died after only a few days' illness, May 14, aged 66. He received his degree in 1861 from Jefferson Medical College, and in 1862 was appointed assistant-surgeon of the Sixtieth Ohio infantry, and later was transferred to the Fourth Ohio cavalry. He subsequently became chief operating surgeon in the First Division of the Eighteenth Army Corps and finally was medical inspector and medical director of the Twenty-fifth Army Corps. He was a frequent contributor to medical journals on subjects of surgery and hygiene. He served as city health officer of Richmond, and as secretary and president of the Wayne County Medical Society, and as president of the Indiana State Medical Society. He was a member of the AMERICAN MEDICAL ASSOCIATION and represented the ASSOCIATION in the International Congress in London in 1881. He was one of the projectors of the American Surgical Society, and served as its first secretary.

EDWARD C. HUSE, M.D., Rockford, Ill., died May 14, aged 65 years. He was born in Massachusetts, and after graduating at Harvard, taught school until 1861, when he went to New York and attended the College of Physicians and Surgeons. Soon after receiving his degree he located in Rockford, where he had since remained. He has been a frequent contributor to medical journals, and in great demand for expert testimony.

LEWIS P. LAYTON, M.D., died at his home in Buffalo, N. Y., May 14, after a lingering illness of eight years. He was born in Erie County in 1819, and received his early education in the Springville Academy. In 1845 he was graduated from the Geneva Medical College, and immediately began the practice of medicine in Buffalo. He held many positions of honor in the medical fraternities and in local politics.

WILLIAM R. RAMSEY, M.D., Norristown, Pa., died in that city May 13, aged 68 years. He was assistant-surgeon, U. S. A., during the Civil War, and was in charge of the field-hospital at the battle of Gettysburg. He was later transferred to the frontier, and on his return practiced in Hazleton and Norristown.

EDWARD F. UPHAM, M.D., Randolph, Vt., died of apoplexy, at his home, April 15, aged 75 years. He was pension examiner for twenty-six years and had several times been president of the Vermont Medical Society, and was a member of the AMERICAN MEDICAL ASSOCIATION.

EDGAR BOLLES, M.D., Macomb, Ill., died May 14, aged 63 years. He was born in Ohio but spent most of his early life in Illinois. He was graduated from the Detroit Medical College in 1869, and after being an assistant to a physician there for some time located at Macomb.

ROBERT F. GRUBAUGH, M.D., Mansfield, Ohio, died very suddenly May 15, aged 36 years. He was graduated from the Western Reserve Medical College at Cleveland in 1888, and had since practiced medicine in Mansfield. He was secretary of the North Central Ohio Medical Society.

R. G. FURST, M.D., Lockhaven, Pa., died May 13, aged 28 years. He was a graduate of the University of Pennsylvania and for two years was connected with St. Joseph's Hospital in Philadelphia.

J. V. HARRIS, M.D., Canton, Ill., died May 7, aged 61 years. During the Civil War he served in the Sixty-fifth Ohio Vol. Inf. He was graduated from Rush Medical College, in 1871, and had since practiced in Canton.

C. W. SYDNOR, M.D., died in Stratsburg, Va., May 11, aged

67. He served as surgeon in the Stonewall Brigade of the Confederate Army.

ARCHIBALD MITCHELL, M.D., formerly a practitioner of Kingston, Mich., but lately a resident of Los Angeles, Cal., died May 17. He graduated from the Medical Department of the University of Michigan in 1872.

WILLIAM SOULE, M.D., Jewett City, Conn., died May 15, from injuries received by being thrown from his carriage five days before. He was born in Chaplain, Conn., August 24, 1827, and was graduated from Yale University in the Class of 1851.

CHARLES H. VOORHEES, M.D., Jefferson Medical College, 1850, died at his home in New Brunswick, N. J., May 13. He served in the Union Army during the Civil War, and was for a time in Libby Prison.

DEATHS ABROAD.

We note the deaths of:

S. Saxtorph, professor of surgery at Copenhagen.

L. H. Petit, M.D., Paris, editor of *Revue de Tuberculose*.

G. Planchon, M.D., Supt. of Paris Ecole Sup. de Pharmacie.

P. Sgrasso, Privat-doctent of ophthalmology at Naples.

E. van Millingen, professor of ophthalmology at Constantinople.

E. Grimaux, *agrégé libre* at the Paris Faculté de Médecine.

K. v. Limbeck, professor of internal medicine at Vienna, known for his research in experimental pathology.

Dr. Apostoli, of Paris, whose name has been so prominently connected with the application of electricity to gynecology.

Miscellany.

Early Diagnosis of Tuberculosis.—Landouzy compares the rectal temperature immediately after a walk of three or four hours in the afternoon and morning. If the temperature in the afternoon is higher than in the morning, he considers himself justified in affirming the existence of tuberculosis. Bozzolo also called attention, at the recent Antituberculosis Congress, to the significance of albuminuria as a precursor of tuberculosis, also of tachycardia *sine materia*; rheumatoid pains; certain forms of anemia, and zona.

Climate and Tuberculosis.—Lannelongue's recent experience with guinea-pigs and climate is disconcerting, to say the least. As described in the *Semaine Méd.* of May 2, he inoculated 150 guinea-pigs on the same day, with cultures of the Koch bacillus, and under identical conditions; he sent 50 to the mountains, 50 to the seashore, and placed the remaining 50 in the laboratory cellar, where they were deprived of light and almost of air. The last-named batch survived the longest and in larger numbers. The same experiment was repeated twice on the same number and with the same results each time.

Deprivation of Salt with Bromid Treatment.—THE JOURNAL has referred to the advantages claimed by Richet and Toulouse for hypochloruration, as they call it, which is, reducing the amount of salt in the food during the treatment of epilepsy with bromids. They assert that the effect of the bromids is much enhanced by the absence of salt; and in a recent communication (*Jour. de Méd. de Paris*, April 29), Toulouse states that adults, as a rule, eat too much salt, and thus inflict unnecessary labor on their kidneys, and that more is needed with a vegetable diet than with a mixed one. He reports tests with a diet containing 2700 calories, 20 gm. nitrogen and 2.19 gm. salt. This was given to twenty adult epileptics, all old, established cases, for a period ranging from 21 to 208 days, while 1.7 to 5 of bromid was administered. The subjects did not appear to suffer in any way from the deprivation of their usual quantity of salt. The tabulated results of the tests show a remarkable decrease in the number of seizures during the hypochloruration, falling from 99 to 2; 25 to 0; 67 to 13; 47 to 2, etc., although in many instances a larger amount of bromid had been administered during the control period. In eight cases there were no seizures nor vertiges after the first fifteen days of salt reduction.

Disinfecting Steamer "Sanator."—By courtesy of *Marine Engineering*, we present illustrations of the disinfecting steamer *Sanator*, for the U. S. Marine-Hospital Service. In the March number of this publication, C. M. Green, First Assistant Engineer R. C. S., Superintendent of Construction M. H. S., describes this vessel as an interesting example of unusual marine construction, just completed, for service at Havana. The *Sanator* is provided with the most improved disinfecting and fumigating machinery, the whole plant being a decided improvement on that of the *Protector*, which, during

pine and decked with Oregon pine, the use of wood being necessary from the fact that a steel hull is quickly corroded by the solution of bichlorid, used in considerable quantities on the vessel and which can not be kept out of bilge. Her dimensions are as follows: Length over all, 161 ft. 6 in.; length from forward edge of stem to after edge of stern post, 149 ft. 11 in.; beam, extreme on water line, 32 ft.; depth of hold from top of deck beams at side to top of ceiling at keelson, 12 ft.; depth from top of main deck beams at side to top of keel, 13 ft. 3 in.; camber of deck beams, 6 in.; draft, normal, for-

DISINFECTING STEAMER SANATOR FOR U. S. MARINE HOSPITAL SERVICE AT HAVANA, CUBA.

VIEW IN AFTER END OF HOLD OF S. S. SANATOR LOOKING TOWARD STARBOARD SIDE.

the fall of 1898, thoroughly demonstrated the efficacy of a floating disinfecting plant by its successful and rapid disinfection of troops and troop-ships at Montauk Point. The *Sanator* is undoubtedly the most complete floating disinfecting plant in the world, and is a low-powered steam vessel capable of making a maximum speed of eight knots an hour. Her hull is framed of Delaware oak, planked inside and out with yellow

ward, 7 ft. 3 in.; draft, normal, aft, 8 ft. 3 in.; displacement, normal, 640 tons; displacement, tons per inch at L. w. L., 9.4 tons; distance center to center of frames, 26 in.; depth of keel below bottom planking, 9 in. There are two steam chambers located side by side for disinfecting, their forward ends projecting through the bulkhead into the infected compartment of the hold. They are cylindrical, about sixty inches in diam-

eter outside and sixteen feet long, and each is constructed with an inner and outer steel shell, these 1 $\frac{3}{4}$ inches apart, forming a steam jacket. The chambers are built to carry a working pressure of 10 pounds per square inch. They are covered with magnesia and fitted with a complete system of steam and exhaust pipes, drains and traps. Near the bottom and through each runs a double track of angle iron with movable extensions, to transfer-tables at both ends, and along these tracks can be moved cars of light wrought-iron construction containing the goods to be disinfected. These cars are provided with removable galvanized wire trays, brass hooks, and galvanized-wire folding baskets for use according to the character of the goods to be disinfected. They are loaded with infected goods or clothing while on the transfer-tables in the infected compartments, and then pushed into the steam chamber where the disinfection is accomplished, after which the doors of the chamber are opened and the cars brought out on the after transfer-tables and unloaded, the disinfected materials being then taken up the after hatch. The length of time for disinfection depends on various conditions, but usually occupies about thirty minutes for each chamber. Steam is

Medical Women in Italy.—Fifteen women graduated at the Italian universities between 1870 and 1897 in medicine and surgery, and one has been appointed "commune physician" at Montiglio, the first woman to fill this position. She is the daughter of Dr. Musso and completed her studies at Pavia and Zurich.

Experiments on Human Beings.—The recent discussion in the German Parliament, of Neisser's inoculations of a few prostitutes with syphilitic serum, was the occasion of a violent attack on the profession as a whole and denunciation of all experimental research, by a number of lay representatives of some prominence. Among those who replied, Ministerial Director Althoff, also a layman, protested against attributing to all, the faults of a few, and exclaimed: "The faults will nowhere meet with such severe disapproval as in medical circles, for physicians, in self-sacrifice and devotion to the welfare of suffering humanity, surpass all the other citizens of the state, and set them the noblest example." Virchow proclaimed the absolute necessity of finally testing remedies on man after conclusive tests on animals: "The conscience of the physician

AFTER-ENDS OF DISINFECTING CHAMBERS—CARRIAGE PARTLY RUN OUT IN FOREGROUND.

kept in the jackets of the chamber during the operation so that the materials disinfected are thoroughly dried before being taken out. Four cars and four transfer-tables are provided. There is also an apparatus for generating formaldehyde gas and ammonia gas, and the vessel is to be provided with four Kinyoun-Francis autoclaves, which are portable formaldehyde gas generators and can be taken into the cabins or rooms of a vessel alongside, for disinfecting purposes. There are two sulphur furnaces in the forward hold compartments and sulphur bins holding forty barrels of sulphur. The bichlorid of mercury apparatus, an 1800-gallon steel tank, is located in the hold amidships on the starboard side, and above this in the dock house is a 40-gallon mixing tank with connections for steam and water, as well as a connection to the large tank below. The proper quantity of the chemical is mixed in the small tank and allowed to flow into the large one, into which has already been pumped a requisite quantity of water for making the solution. Then there is a pumping apparatus, and by means of a 2-inch hose, and spray nozzles, the solution can be sprayed even in any part of a vessel alongside.

tells him what is right and what is wrong, and a code of ethics of the medical sciences is gradually being evolved, over the entire world, which as time goes on will prove more effective, more beneficent in its results, and be more respected than the deliberations of any peace conference." Kollé, in the *Deutsche Med. Woch.*, March 15, reviews various instances of experiments on man. The most audacious on record, and without any previous experience with animals, was the inoculation of millions of healthy persons in India with small-pox virus from patients with smallpox, which was practiced for centuries by the priests. A number of persons died as the results of these inoculations but the few were sacrificed for the benefit of the many, with the consent of the authorities. Jenner inoculated a healthy person with virus from an animal suffering from a disease the nature of which he only surmised, and Pasteur had the courage to inoculate a man with rabies. Mothers sometimes send their children "to catch the measles," and yet measles has quite a high mortality. Innumerable are the instances in which physicians have experimented on themselves, and Billroth used to say that the road to our successes

leads over mountains of corpses. If laymen would divert their attention to charlatans, who, as has been shown by some recent occurrences, borrow from the medical arsenal and give mercury and other strong drugs in enormous, toxic doses, the world would be benefited, while these attacks on the regular profession tend to impair the confidence of the public in trained physicians and thus they fall an easy prey to ignorant, unscrupulous quacks.

Alterations of the Skin in Lymphatic Leucemia.—Histologic study of three cases at Neisser's clinic showed enormous deposits of lymphocytes in the interstices of the corium and subcutaneous tissue, sharply defined from the subpapillary vessels, with little mitosis, but with the lymph vessels filled with lymphocytes as in functioning lymph glands, while a lack of proliferation was evident in the lymph glands. Pinkus concludes that these accumulations of lymphocytes are not due to proliferation alone, but rather to a diminished consumption of lymphocytes. In his illustrated report in the *Arch. f. Derm.* (L. I), he asserts that an emigration of the lymphocytes from the vessels is improbable, and that it is much more likely that the accumulation of cells is due to cell-division on the spot. In lymphatic leucemia a considerable portion of the lymphatic tissue throughout the body may proliferate and produce large tumors at certain predisposed points. The qualitative and not the quantitative alterations in the blood decide the diagnosis. He distinguishes four varieties: 1. True (smooth) leucemia tumors of the skin, never found except with lymphatic leucemia, and histologically identical with the alterations in the internal organs in this disease. 2. Kaposi's lymphodermia perniciosa. 3. Sarcoma and leucemia have frequently been observed associated, and in "round-celled tumors," leucemic depositum, lymphosarcoma of mycosis fungoides are differentiated by clinical appearance. 4. It is difficult to determine the connection between mycosis fungoides and leucemia. The affection known by this name in Germany has scarcely anything to do with leucemia, but in France a protracted, diffuse erythrodermia with violent pruritus, has been noted, always connected with lymphomatosis and finally leading to the development of tumors if the patient survives to this terminal stage. Pinkus is inclined to classify this with lymphodermia perniciosa, and identify it closely with leucemia, noting its characteristics as: 1. erythrodermia; 2. diffuse thickening of the skin, mostly in the face and leontiasis, occasionally actual tumor-formation, and 3. lymphocytenia co-existing or not appearing until the cutaneous phenomena have long existed.

EXAMINATION QUESTIONS.

The following questions were presented at a recent examination of candidates for license to practice medicine in Illinois:

ANATOMY.

1. Name and locate the muscles of the eyeball. 2. Locate and describe the iliocecal valve. 3. Give the origin and distribution of the median nerve. 4. Name the membranes of the brain and spinal column. 5. Describe the heart. 6. Give origin and insertion of the gastrocnemius muscle. 7. Describe the alimentary canal from the duodenum down. 8. Describe the arch of the aorta. 9. Name the articulations of the malar bone. 10. Describe the anterior tibial artery.

BACTERIOLOGY AND PATHOLOGY.

1. How would you determine the presence of the tubercle bacilli in a specimen of sputum? 2. Give the characteristics of the bacillus tetani. 3. What are supposed to be elements of resistance or protective forces possessed by the human body against parasitic infections and intoxications? 4. Give the characteristics of the malarial organism. 5. Name the six pus cocci. 6. What is the pathology of chronic endocarditis? 7. What is the histologic structure of sarcoma? 8. What is the pathology of locomotor ataxia? 9. What are the blood changes in anemia? 10. What is thrombosis? What is embolism?

CHEMISTRY.

1. What is analysis? 2. Define simple or elementary and compound matter. 3. What is the principal atom having linking function? 4. What two kinds of molecules can be chemically distinguished? 5. How are multiples of atoms expressed in chemical notation? Example. 6. What is a base? 7. What is the difference between an atom and a molecule? 8. When are traces of albumin indicative of renal lesion? 9. What is the function of hemoglobin? 10. Give Haines' test for sugar in urine.

GYNECOLOGY.

1. Describe the minute structures of the endometrium. 2. Give the nerve and blood-supply of the ovaries. 3. What are the causes of sterility? 4. How would you give a vaginal douche? 5. What is the treatment for acute pelvic peritonitis? 6. How would you diagnose a small subperitoneal fibroid of the uterus from a salpingitis? 7. Give the successive steps in the operation for curettage

of the uterus. 8. What are the causes of dysmenorrhœa? 9. What disease of the uterus may result from childbirth? 10. What is the treatment for carcinoma of the uterus?

HYGIENE.

1. Wells, cisterns, lakes and rivers are the usual sources of drinking water. In your judgment, from which of these sources is the water most pure and why? 2. Name at least one source of contamination of lake and river water. 3. Some of the sources of contamination of well and cistern water. 4. Give a concise statement of the means to which you would resort to prevent contamination of drinking water in the several ways mentioned. 5. Mention some of the more usual constituents that render drinking water unfit for use. 6. What bacilli usually found in water show evidence of fecal contamination. 7. What physical properties may drinking water present to the senses and yet be non-potable? 8. Give as full an answer as you can of diseases traceable to water contamination. 9. Why are cases of typhoid fever rare in a new country, and why common in an old settled country? 10. In contrast to typhoid fever, why is malarial fever common in newly settled countries and relatively rare in old?

MATERIA MEDICA AND THERAPEUTICS.

1. Name four of the most important cardiac tonics and describe their physiologic action. 2. State the difference between a cholagogue and hepatic stimulant, also name examples of each. 3. Give the dose of fluid extract of ergot and describe its therapeutic action. 4. Name the alkaloids of *nux vomica*. 5. Describe the therapeutic and physiologic action of selenium and give the dose of the tincture. What is Crede's ointment, and in what cases would you recommend its use? 6. Describe the action and use of bromoforn, and give the dose for a child 2 years old. 8. What drugs contraindicate the use of oils and fats in case of poisoning? 9. What would you do in a case of poisoning with Paris-green? 10. Write a prescription suffering from membranous croup and outline the general treatment.

MEDICAL JURISPRUDENCE.

1. As regards cause, the subject of abortion has been divided into natural, artificial and criminal. A woman has aborted under somewhat suspicious circumstances. Name some facts that would induce you to think the abortion belonged to the class natural. 2. Some that would indicate the class artificial. 3. Some that would cause you to suspect criminal intent. 4. Name some conditions that would justify the bringing on of artificial abortion, what authority should be secured? 6. In case of death following criminal abortion how would you go about establishing the fact? That is, what proofs would you expect to find? 7. A woman, evidently of recent birth, is found dead. What is your opinion of a woman who is said to be its mother. In case of an examination what proof would you expect to find in the alleged mother's condition? 8. And in the event the mother had meantime died, what further proofs of maternity upon post-mortem would you expect to find? 9. To what is the term inquired it is sometimes necessary to ascertain whether a woman has borne children at a more or less remote period. How could this fact be proven? 10. How soon can one pregnancy follow another? And what is the shortest time on record between two conceptions?

OBSTETRICS.

1. What are the blood changes in pregnancy? 2. What is the treatment of varicose veins in pregnancy? 3. What vein is always contracted? 4. What are the varieties of uterine contractions? 4. What is the danger if the external and internal os uteri contract without the uterus contracting itself? 5. How would you assist in delivering the head, pelvic presentation? 6. What is "hour-glass" contraction of the uterus? How would you treat such a case? 7. What is retroversion of the uterus? What are the effects of retroversion and what is the treatment? 8. What would you do if the head was arrested in the inferior strait, pelvic presentation? 9. How would you diagnose a case of shoulder presentation? 10. How would you treat such a case? 10. What is placenta previa? Give treatment.

PHYSIOLOGY.

1. From what layer or layers of the blastoderm is the liver developed? 2. What nerves control the action of the heart? 3. Give the minute anatomy of the large intestine. 4. Describe the colored and colorless blood-corpuscles: a. As to proportion. b. As to size and composition. c. As to function. 5. Describe the respiratory changes in the blood and tissues. 6. Describe the nervous apparatus of respiration. 7. Give summary of the digestive changes in the large intestine. 8. Describe the two kinds of supporting material for the medullated nerve-fibers of the white matter of the spinal cord. 9. Name the different columns and tracts of the spinal cord and which are of ascending and descending degeneration. 10. Give in full, the distribution of the gray matter in both brain and cord.

PRACTICE.

1. Name the diseases with which uremia may be confounded and give diagnosis and treatment. 2. Give causes, symptoms and treatment of acute neuritis. 3. Etiology, pathology and physical signs of eccentric hypertrophy of the heart. 4. Give the differential diagnosis of pleurisy, periphrenic pleurisy, lobar pneumonia and phthisis. 5. Give the pathology, etiology, physical signs and treatment of chronic dilatation of the lung. 6. Chronic dilatation of the stomach, its causes, physical signs, symptoms and treatment. 7. How would you diagnose a case of bubonic plague? 8. Outline the differential diagnosis between varicella and vaccinia and outline the general treatment of the former. 9. The causes, symptoms, complications and differential diagnosis of scarlatina. 10. Write what you know of cirrhosis of the liver.

SURGERY.

1. What is hydrocele? Give treatment. 2. What are the main treatments of fractures? 3. What is adhesion and what is effusion? 4. What are aneurysms? How do you treat them? 5. What are the indications for ovariotomy? 6. How do you treat lateral curvature of the spine after the former? 7. Enumerate the different classes of fractures. 8. What is Pott's disease? Give treatment. 9. What symptoms characterize joint wounds? Outline your treatment. 10. Describe amputation of the knee-joint, lateral flap operation.

NEW PATENTS.

Patents granted of interest to physicians, May 1-8. 649,055. Apparatus for making extracts, Frederic A. Anderson, London, England. 649,284. Molding meat extracts, Henry J. Dunn, London, England. 649,257. Fracture apparatus, Charles F. Dyson, Hiram, Ohio.

649,202. Apparatus for making barium oxid, Walther Feld, Lintz-on-the-Rhine, Germany.
 649,305. Medicinal compound and making same, Ludwig O. Helmers, Hamburg, Germany.
 649,062. Disinfecting device, Louis and M. H. Levett, New York City.
 32,373. Design, Springs, Samuel C. Stearns, Detroit, Mich.
 649,718. Surgical splint, Lorenz A. Deuther, Buffalo, N. Y.
 649,826. Medicated hat-pad, Byron A. Eldred, Boston, Mass.
 649,692. Vesicant, Heinrich Hebling, London, England.
 649,521. Medicated vapor injector, Hosca W. Libbey, Boston, Mass.
 649,646. Umbilical truss, David S. Plum, El Dorado, Cal.
 649,493. Surgical instrument, Frederick A. Stohlmann and L. G. Pfarre, New York City.
 32,665. Design, massage instrument, Daniel B. Stevens, Toronto, Ont.

Queries and Minor Notes.

PRACTICE IN MEXICO.

CHICAGO, May 20, 1900.

To the Editor:—Will you kindly inform me as to the requirements for the practice of medicine in Mexico, and oblige.

B. R.

ANSWER:—A foreigner, in order to be allowed to practice in Mexico with full legal privileges—signing birth and death certificates, etc.—must pass the full examination that is required of a Mexican graduate; this examination, in the foreigner's case, is likely to be rigid, and is in the Spanish language. A full account of the requirements was given in THE JOURNAL OF Dec. 23, 1899.

The Public Service.

ARMY CHANGES.

Movements of Army Medical Officers under orders from the Adjutant-General's Office, Washington, D. C., May 11 to 17, 1900, inclusive.

Charles Bruning, acting asst.-surgeon, previous orders directing him to proceed from New Orleans, La., to Tampa, Fla., and thence to Havana, Cuba, revoked.

NAVY CHANGES.

Changes in the Medical Corps of the U. S. Navy for the week ending May 19, 1900.

Asst.-Surgeon J. C. Thompson, detached from the *Bennington* and ordered to naval hospital, Mare Island, Cal., for treatment.

Asst.-Surgeon E. O. Huntington, detached from the *Newark* and ordered to the *Bennington*.

MARINE-HOSPITAL CHANGES.

Official list of the changes of station and duties of commissioned non-commissioned officers of the U. S. Marine-Hospital Service for the seven days ending May 10, 1900.

Surgeon Preston H. Bailhache, granted leave of absence for 10 days from May 25.

Asst.-Surgeon J. G. Cobb, directed to rejoin station at Fort Stanton, N. M., visiting Liberty and Saranac Lake, N. Y., and Rutland, Mass., en route.

Asst.-Surgeon John W. Kerr, relieved from duty at San Francisco quarantine and directed to proceed to Hongkong, China, for duty.
 Asst.-Surgeon C. W. Vogel, relieved from duty at Immigration Depot, New York City, and directed to proceed to San Francisco quarantine, Cal., and report to the medical officer in command for duty and assignment to quarters.

Asst.-Surgeon J. W. Amesse, relieved from duty at Detroit, Mich., and directed to proceed to Honolulu, H. I., and report to Surgeon D. A. Carmichael for duty.

Asst.-Surgeon A. J. McLaughlin, relieved from duty at Stapleton, N. Y., and directed to report to the medical officer in command, Immigration Depot, for duty.

Asst.-Surgeon B. H. Earle, relieved from duty at Chicago, and directed to proceed to Detroit, Mich., and report to the medical officer in command for duty and assignment to quarters.

Asst.-Surgeon E. J. Lloyd, relieved from duty at Mobile, Ala., and directed to proceed to Chicago, Ill., and report to the medical officer in command for duty and assignment to quarters.

Asst.-Surgeon John D. Long, relieved from duty at Boston, Mass., and directed to proceed to Stapleton, N. Y., and report to the medical officer in command for duty and assignment to quarters.

Acting Asst.-Surgeon E. E. Field, granted extension of leave of absence for two days.

Hospital Steward Charles W. Stephenson, relieved from duty at Chicago and directed to proceed to Evansville, Ind., and report to the medical officer in command for duty and assignment to quarters.

HEALTH REPORTS.

The following cases of smallpox, yellow fever, cholera and plague, have been reported to the Surgeon-General, U. S. Marine-Hospital Service, during the week ended May 19, 1900.

SMALLPOX—TYPE STAFFS

Alabama: Mobile, May 5-12, 2 cases.
 Indiana: Evansville, May 5-12, 2 cases.
 Kansas: Wichita, May 5-12, 4 cases.
 Kentucky: Covington, May 5-12, 2 cases.
 Louisiana: New Orleans, May 5-12, 57 cases, 14 deaths.
 Maine: Portland, May 5-12, 1 case, 1 death.
 Massachusetts: Chicopee, May 5-12, 1 death.
 Michigan: Detroit, May 5-12, 2 cases.
 Nebraska: Omaha, May 5-12, 6 cases.
 Ohio: Cleveland, May 5-12, 19 cases, 1 death.
 Pennsylvania: Pittsburg, May 5-12, 2 cases.

South Carolina: Greenville, May 5-12, 3 cases.
 Utah: Salt Lake City, May 5-12, 2 cases.
 Washington: Tacoma, April 28 to May 5, 1 case.
 Wyoming: Sweetwater Co., May 4, 6 cases; Uintah Co., May 4, 4 cases.

SMALLPOX—FOREIGN.

Austria: Prague, April 22-28, 16 cases.
 Belgium: Antwerp, April 22-28, 1 case, 1 death.
 Canada: Manitoba, Winnipeg, April 1 to May 12, 11 cases 1 death; Quebec, Nouvelle France Co., March 31 to April 1, 5 cases.
 China: Hongkong, March 22 to April 7, 6 cases, 3 deaths.
 England: Liverpool, April 22-28, 9 cases, 3 deaths; London, April 22-28, 6 cases, 1 death; Southampton, April 28 to May 5, 5 cases.

France: Lyons, April 14-21, 2 deaths.
 Gibraltar: April 22-28, 8 cases, 2 deaths.
 Greece, Athens, April 22-28, 8 cases, 2 deaths.
 India: Bombay, April 10-17, 72 deaths; Calcutta, March 25, 39 deaths; Kurrachee, April 6-15, 9 deaths.
 Italy: Rome, March 22 to April 7, 2 deaths; Venice, April 14-21, 1 death.

Japan: Formosa, Tamsui, March 24-31, 134 cases, 2 deaths.
 Mexico: Chihuahua, April 28 to May 5, 3 deaths; Mexico, April 1-29, 57 cases, 42 deaths; Vera Cruz, April 28 to May 5, 8 deaths.
 Spain: Corunna, April 22-28, 1 death.
 Russia: Moscow, April 7-21, 5 deaths; Odessa, April 22-28, 7 cases, 2 deaths; St. Petersburg, April 14-21, 31 cases, 9 deaths; Warsaw, April 14-21, 2 deaths.
 Scotland: Glasgow, April 22-28, 19 cases, 2 deaths.
 Spain: Valencia, April 22-28, 1 case.

YELLOW FEVER.

Cuba: Havana, May 7, 1 case.
 Mexico: Vera Cruz, April 28 to May 5, 10 deaths.
 CHOLERA.
 Arabia: Oman, March 10, present.
 India: Bombay, April 10-17, 26 deaths; Calcutta, March 18-24, 101 deaths.

PLAGUE.

Egypt: Alexandria, May 9, reported.
 India: Bombay, April 10-17, 533 deaths; Calcutta, March 18-24, 878 deaths; Kurrachee, April 8-15, 480 cases, 402 deaths.
 Japan: Foshan, Tamsui, March 24-31, 106 cases, 74 deaths; Osaka, April 13, 2 deaths.
 New Caledonia: Numea, Dec. 17 to April 4, 123 cases, 17 deaths.

CHANGE OF ADDRESS.

Dr. C. T. Allen, from Shiloh to Tobaccoport, Tenn.
 Dr. L. F. H. Bahrenburg, from Pemberville, Ohio, to 19th Ave. and 83d St., Bath Beach, Brooklyn, N. Y.

Dr. F. E. Bennett, from Fair View to Galesburg, Ill.
 Dr. G. F. Butler, from Chicago, Ill., to Alma, Mich.

Dr. C. M. Braidwood, from Detroit to Lapeer, Mich.
 Dr. A. Cornelius, from 589 Van Buren to 525 S. Robey St., Chicago.

Dr. H. Cook, from 155 Adams St. E., Detroit to Pewamo, Mich.
 Dr. O. N. Carter, from Sandhides, Va., to Lebanon, Mo.
 Dr. H. F. Conally, from McGregor to Bruceville, Texas.

Dr. P. Conlan, from Omaha to Columbus, Neb.
 Dr. M. H. Coan, from Wyandotte to Leslie, Mich.
 Dr. W. R. Cothern, from 354 S. Hoyle St., Chicago to Melvin, Illinois.

Dr. H. C. Castor, from 340 to 184 N. State St., Chicago.
 Dr. S. T. Carzwell, from Homerville to Fowittown, Ga.
 Dr. J. H. Dyer, from Shelbyville to Wartrace, Tenn.

Dr. W. E. Duncan, from 603 W. 63d St., to 6058 Kimbark Ave., Chicago.

Dr. D. W. Detwiler, from 2099 Harvard St., to 1800 Wabash Ave., Chicago.

Dr. W. E. Frank, from Trivoli to Itasca, Ill.
 Dr. J. F. Fox, from Redland to Mulhro, J. T.

Dr. J. K. Frankish, from Philadelphia to Gwynedd, Pa.
 Dr. O. A. Fliessburg, from 102 Washington Ave., South to 1312 7th St., South, Minneapolis, Minn.

Dr. A. P. Griggs, from Atlanta, Ga., to 2027 3d Ave., Birmingham, Ala.

Dr. E. Gleitsman, from 654 N. Hoyle Ave., to 710 Fullerton Ave., Chicago.

Dr. W. A. Hibbs, from Delphos, Kans., to Lead, S. D.
 Dr. D. V. Jones, from Port Gibson to Hernando, Miss.

Dr. F. G. Johnson, from Brooklyn to Paoli, Wis.
 Dr. T. W. Little, from Long Grove to Morley, Iowa.

Dr. B. F. Long, from Baltimore, Md., to McCoyville, Pa.
 Dr. V. F. Lassagne, from Chicago to Eureka Springs, Ark.

Dr. R. Pedden, from Detroit to Fetsko, Mich.
 Dr. W. M. Phelps, from 529 Van Buren to 120 E. Kalb St., Chicago.

Dr. A. E. Perkey, from Presbyterian Hospital to 393 S. Leavitt St., Chicago.

Dr. W. C. Ramsey, from Everett Block, Akron to Hopedale, Ohio.
 Dr. G. P. Ramsey, from Crawfordville to Newtown, Ind.

Dr. W. A. Scott, from Thomasville, Ala., to Swanton, Ohio.
 Dr. W. T. Seymour, from Polo, Ill., to Reedburg, Wis.

Dr. I. J. Spear, from 2338 Eutaw St., to Ray View Asylum, Indiana Department, Baltimore, Md.

Dr. Le Roy Southmayd, from Virginia City to Great Falls, Mont.
 Dr. E. E. Stewart, Care Merck & Co., from New York City to 67 Prospect St., East Orange, N. J.

Dr. E. B. Schrock, from Ostrander to Yellow Springs, Ohio.
 Dr. H. C. Sulcher, from Colorado Springs to Denver, Colo.

Dr. J. A. Tyler, from 229 N. Champlin to 221 N. 6th St., Columbus, Ohio.

Dr. C. A. Thlxton, from 1617 to 1707 Preston St., Louisville, Kentucky.

Dr. N. A. Upechurch, from Moulas, Ga., to Summerfield, Fla.
 Dr. W. C. Weswell, from Burksville, Ill., to Warrenton, Mo.

AMERICAN.

1. **Scarlatinal Miliaria.**—After noticing this peculiar eruption in scarlatina and reporting cases, Griffith suggests that the often expressed view that miliaria is an indication of severity in scarlatina may not be tenable, as there seems to be no connection between the two. Apparently different causes act to produce the efflorescence and the vesiculation and, contrary to the opinion of certain writers, there seems to be no necessary relation between the amount of scarlatinal peeling and the degree of miliarial eruption. He favors the view of Thompson, that the development of miliaria in scarlatina depends largely on some peculiarity of the skin rather than on any intensity of the scarlatinal rash or other factor, and the observation of Henoch, as to a family tendency to miliaria in scarlatina seems to support this view. It is possible to have embarrassment of diagnosis from miliarial eruption in scarlatina, and in one of his cases the presence of other instances of the disorder was the leading factor deciding the diagnosis.

2.—See abstract of this article in our Therapeutics Department of this week.

3. **Nose and Throat Diseases in Life Insurance.**—Ingals concludes, from a study of the facts, that examinations of the nose and throat will not usually aid the life insurance examiner, but that in a limited number of cases it may cause him to reject persons otherwise acceptable, who are likely to develop diseases within a short time that will greatly reduce their expectancy of life. Hence such examination should be made whenever the personal or hereditary history and the general appearance or quick pulse leads the examiner to suspect the beginning of pulmonary or cardiac disease.

6. **Intestinal Indigestion.**—Porter describes the physiology of intestinal digestion, and, in concluding says that for the most perfect working of the alimentary canal, the system must daily produce a laxative mixture composed of bile, glycerin and soap, and when it fails to do so the common symptoms of constipation appear. This is a point to be kept in mind in the management of every case of intestinal indigestion, if the best results are to be secured.

9. **Internal Hemorrhoids.**—Monroe claims that the hypodermic injection method, although it has received its share of condemnation, is a good one, that will cure in certain cases and when properly used is perfectly safe. He discredits the deaths reported by Andrews and says that he has found him to be mistaken in some instances. For small hemorrhoids, especially in the perineal form, found so often in females, he believes there is no better treatment; and it can also be used successfully in all tumors that are above the sphincter muscle. He uses 1 dram of a saturated solution of Calvert's carbolic acid, and 3 drams of olive-oil mixed by placing the bottle in warm water, injecting from 5 to 10 drops into each tumor. He admits that there may be accidents, such as abscess or fistula but thinks that talk of heart-clot is nonsense. The preparation of the patient for this method of treatment is the same as for any other; and a weaker solution than the one given should not be used. If the sloughing is extensive or abscess or other troubles follow, they should be treated as though coming from any other cause.

10. **Galvanocautery in the Nose.**—Douglass has studied, microscopically, the effect of the galvanocautery in the nose, in order to determine the reason why this method has fallen

into disfavor, and he finds that the action of the cautery tends to form a cone of burned tissue, deepening toward the deeper structures. If it is used superficially over wide areas there results an extensive destruction of the epithelium, including the hyaline membrane. If the cautery point is rapidly pushed deeper into the tissue, the superficial effects with wide devastation of the epithelium and hyaline membrane are not noticed, and the area of reaction is more circumscribed; hence the cautery should not be used superficially or over a large surface, but should be rapidly introduced into the deeper structures and immediately drawn forward or backward. Another practical point is that the cautery point, on being placed against the epithelial surface should either not be heated or else heated only to a moderate degree—just sufficient to allow the cautery point to pass the epithelium and hyaline membrane. After this, greater heat can be turned on and the deeper structures, vessels, glands and hypertrophic masses destroyed to the bone. The old and time-honored "linear" method of cauterizing must be forsaken, since the hyaline membrane and epithelium are injured by a less degree of heat than the deeper structures. We have by the use of the superficial method, the broad based wedge or sloughing that defeats the real purpose, which is to reduce the hypertrophic parts and leave as little disturbance as possible on the surface. This method must, therefore, be discarded, except where it is desired to produce a superficial effect. In all other cases, we must use the cautery point so as to spare these superficial tissues as much as possible. He suggests a stiff wire electrode to penetrate the external tissues at a moderate heat and to be repeatedly inserted at different points along the hypertrophy. The method would vary a little according to the locality. On the septum a single puncture should be made, and that only in a case where there is dilatation of the venous sinuses of the tuberculum septi, the only condition which he thinks would require cauterization. Necrosis of the cartilago septi is very apt to result from its disturbance. On the anterior end of the inferior turbinate and posterior ends of both inferior and middle turbinates several punctures should be made in as nearly a circular series as possible. The posterior tip of either turbinate should be punctured from the posterior pharynx, a palate retractor being used. The part of the ethmoid known as the middle turbinate should perhaps seldom be cauterized, except at its posterior end, and sometimes at the anterior end, on account of its close relation to the ethmoidal cells, and theirs to the dura mater. Pachymeningitis or ethmoiditis is the danger to be avoided.

12. Stricture of the Ureter.—Cumston describes the methods of performing internal and external urethrotomy. He does not believe in the routine use of the permanent catheter in the latter operation, for he thinks that it is injurious. The only proper treatments in the case of stricture are dilatation with sounds, internal urethotomy, and, in exceptional cases, external urethrotomy. Temporary dilatation is useful in the stage of exudation or early part of the connective tissue stage, but forcible dilatation is not advised. It is also used as a preparatory treatment for internal urethrotomy, which should be employed in those cases that have a valve-like or bridge-shaped form, and where the connective tissue encircles the canal. This should be done to a limited extent only, and only after being treated unsuccessfully by dilatation. Internal urethrotomy is simply an operation intended to pave the way for future treatment by dilatation. The incision made in this way, heals rapidly, but in cases of external urethrotomy, healing takes place with interposition of cicatricial tissue between the edges of the walls of the urethra; and consequently there is an actual increase in the caliber, which can be made permanent by the subsequent passage of bougies, even if this cicatricial tissue should contract somewhat. If external urethrotomy is performed, and the central end of the urethra can not be found and there is complete retention of the urine; or if in case of traumatic stricture, the cicatricial tissue extends as far back as the neck of the bladder, there is but one method, and that is posterior catheterization. The technique of the operation is described, and caution given in regard to the antiseptics; he recommends the use of urotropin to render the genito-urinary

apparatus antiseptic, and special care to be taken with instruments and applications.

13. Lumbar Puncture.—In locating the point of lumbar puncture, three things should be considered: 1. That there is ready entrance of the needle into the subarachnoid space. 2. That the tapping is made at the point least likely to admit of damage to the nervous structures. 3. That the fluid obtained is as rich in sediment as possible. In regard to the first requirement, it is sufficiently well met by entrance through any of the lumbar spaces or through the lumbosacral space; and injury to the cord can be avoided by entering at some point below the third lumbar vertebra. The last requirement is best fulfilled by tapping in the lumbosacral space, and when the patient is a child, he would have the puncture made while in a sitting position. The essential point is to secure the greatest possible degree of ventral flexion of the spine. General anesthesia is usually unnecessary and asepsis should be as complete as possible. In very fat or muscular patients where the bony prominences are indefinite, the most satisfactory means of locating the vertebra is by taking a line between the highest points of the iliac crest, that regularly crosses the fourth vertebral spine, and the method of puncture is described. In children the fluid is reached at a depth of 2 to 3 cm., and in adults from 4 to 7 cm. There are rarely any accidents; sometimes the fluid does not flow when one is sure the needle is in the canal, but this may be due to its being plugged while being introduced, or to the contents being of a gelatinous character, as in a case reported by Paekard. A little blood stain from injury of a small vein is unimportant. More serious accidents, when they have occurred, have generally been caused by the rapid withdrawal of a large quantity of fluid.

14. Hay-Fever.—Douglass recommends the use of suprarenal gland extracts, both locally and internally, for a long period of time, in the treatment of hay-fever. He thinks that it is generally best given internally in the tablet form—5 gr. of saccharated, dried suprarenal gland administered at first every two hours, day and night, until some giddiness or palpitation is observed, or until the local examination of the nasal membrane shows that the remedy is controlling the vasomotor paralysis. After this has been done it may be given at longer intervals—probably every three hours, then every six, then twice daily, continuing in this way through the hay-fever season. If the symptoms reappear, the quantity may be again increased until they are again controlled. When used locally, it should be applied either by means of a spray or on pledgets of cotton saturated with a 6 to 12 per cent. solution. There is no other remedy used which is as useful as suprarenal gland, for it fulfills all the indications better than any other that has been introduced.

17. Bottini's Operation.—Meyer reports 12 cases in addition to those previously given, and says that 30 Bottini operations have been performed on 24 individuals, and that he finds that they show 38 per cent. cured so far, 29 per cent. much improved, 8 per cent. benefited; and a mortality of 8 per cent. directly due to operation, and 8 per cent. indirectly due to it. These cases were not selected but were operated on as they came along. One of the deaths was due to anterior incision, a method which he has since abandoned, and he thinks that in the future he can reduce the mortality.

18. Diabetes Mellitus.—The diet for diabetic cases is best ascertained by putting the patient on a standard one, taking besides the indefinite albuminous and fat-producing matter, a definite amount of carbohydrates—say 60 grains; then collecting a twenty-four-hours' urine, beginning after the first breakfast. The amount of sugar can be ascertained by polarization and titration, or by polarization before and after fermentation, to find out also the amount of substances which turn the plane to the left. In all mild cases and in non-diabetic glycosuria, we have no sugar, and in these after a period of four or five days, the daily allowance of carbohydrates is increased and the urine of the last day of such a period collected as heretofore; and this is continued until the presence of sugar is found in the urine, and we know the tolerance of the system for carbohydrates. In all cases where the glycosuria is found, the

amount of carbohydrates in the patient's diet is reduced and it is kept as free from them as possible, until the condition has disappeared, when they are increased again, and so on. Where it is impossible to suppress the glycosuria even by the strictest diet, a certain amount of carbohydrates is allowed, because it would be impossible to keep the patient from taking some, as they are essential to life. It is also of great value to know in each case the fluctuation of glycosuria within twenty-four hours, so that the distribution of the carbohydrate food can be thus controlled. To make a good diathetic list, one must know the percentage of carbohydrates in the various articles and how to substitute them. Kraus thinks that a moderate amount of carefully selected alcoholics can be used, but care should be taken to avoid any toxic effect. Balneotherapy is rather favored, since it has its advantages in taking the patient away from home to a place where proper care can be exercised, some of the alkaline-muriatic waters have also a good effect. In other cases, especially neurasthenics, it would be better to send the patient to the seaside or to some high, bracing altitude, where he can find sufficient accommodation to follow the diet prescribed.

19. Functional and Organic Heart Murmurs in Infancy.—The denial by Hochsinger and Soltmann, of the existence of functional murmurs in the first three years of life, is noticed by Jacobi, who reports a case in an infant 13 months old. He has taken care to avoid confusing it with extracardial murmurs, an error which has been committed. This is undoubtedly rare in infants under 2 years of age, but as the lungs grow and there are present tumors or adhesions between the pleura and pericardium, the murmur may appear soft or grating, and is generally heard anteriorly only. It is rhythmic, not synchronous with contraction of the heart; strong on deep inspiration; disappears when there is no breathing and is less audible in a recumbent than in an erect position. While murmurs in most cases mean organic disease, the converse is not true, and he reports a case illustrating this. Most murmurs mean organic lesions, either in the valves or in the myocardium, but in children there are conditions which occasionally make the diagnosis somewhat difficult. In persistence of the ductus arteriosus, there is a loud systolic murmur over the sternal end of the second left intercostal space, extending upward into the vessels of the neck, mainly on the left side and audible posteriorly in the left interscapular space. There is a characteristic dullness, nearly oblong, along the left margin of the sternum to the clavicle. The diagnosis is embarrassed by complications with valvular anomalies, but when not so complicated patency of the duct is compatible with a fairly long life. In congenital stenosis of the pulmonary arteries, there is a systolic murmur in the sternal part of the second left intercostal space, which is not transmitted into the carotid, unless there is a defect of the ventricular septum. There is sometimes a full feeble second pulmonary sound, with club fingers, and hypertrophy of the right ventricle, but when atresia of the artery exists these are absent, and the right heart is small or rudimentary. Jacobi has never found an absence of the ventricle unless it was complicated with stenosis of the pulmonary artery. He can not verify the statement of hooks that pulmonary stenosis with defect of the septum is characterized by hypertrophy of the heart; for the opposite condition is characteristic. Another class of cyanotic cases is due to arrest of development of the common arterial trunk, which did not separate into the aorta and pulmonary artery; and in these he found little or no hypertrophy. The loud murmur is heard over the sternum, a little to the right and left, at about the second or third ribs, and is very audible posteriorly. There are some very loud murmurs, that are audible at a distance; these are more common in adults, and always systolic, generally attributed to hypertrophy and believed to be muscular. In a few cases, he thinks there is no increase and the phenomenon is due to torn and swinging papillary muscles. Not unfrequently the general condition is better than the noise would appear to suggest. Organic murmurs are not always audible, they may decrease with the increase of the pulse and may disappear from compensation or recovery; but the disappearance does not prove the murmur functional. Myocardial changes are mainly caused

by anything that gives rise to hypertrophy and dilatation. The senile heart is very apt to exhibit hypertrophy and dilatation connected with atheromatous degeneration of the coronary and minute nutrient arteries causing muscular disturbance. What we call debility of the heart is due to a great many different conditions—intoxication, nephritis, etc. It is not functional, but is the result of organic lesions. In infants and children, myocarditis is mostly parenchymatous, and the most intense and persistent myocardial changes occur after la grippe and diphtheria. The alteration is never uniform, and that is why arrhythmia is so frequent; but no matter how many causes, either in the heart or nerves or distant organs, its most frequent origin is myocarditis. Special forms of arrhythmia are duplication of the heart sounds, which is a suspicious symptom, as it proves the exhaustibility of the heart muscle. Jacobi thinks it is apt to be caused by trouble in the myocardium, or lack of muscular myocardial coaptation.

23. *Ibid.*

24.—*Ibid.*

25. Tropical Ration.—Munson discusses the standards of diet and says that from the individual conditions that occur, we are obliged to use general averages, and he gives various tables showing the dietaries for different climates and their physiologic constituents.

26. Use and Abuse of Phosphorus.—Mettler restates the facts, as to the physiologic action of phosphorus in the system, and mentions its therapeutic uses. He considers it a reconstructive stimulant to all tissues and a special stimulant and nutritive to those of the nervous system. When required for the latter purpose the most satisfactory preparation which he has found is the phosphorus itself, prepared in elixir, or pill. For general tonic effects, he prefers the hypophosphites, especially the glycerinophosphates; while for gastric and hepatic troubles, acid salts are to be employed. Phosphate of soda is almost specific in its action on the liver, and in that class of mild neuroses dependent on hepatic insufficiency, he uses this first. He has found a small dose of phosphorus useful in certain forms of insomnia, due to an overtaxed and ill-nourished brain. In neuralgia, he has not found it very efficacious, but in functional impotence it is advantageous, as also in the early stages of locomotor ataxia. It is important, however, not to administer too large doses or continue it for too prolonged periods of time.

27.—See abstract in our Therapeutics Department this week.

29.—This article has previously appeared elsewhere: See title 88, p. 738, and title 82, p. 991.

35.—This article also appears in another journal: See title 151, this week.

44. Esophageal Diverticulum.—Two cases of this condition are reported by Richardson, both of which were successfully operated on, making a total of 16 patients thus treated, out of 56 that have been reported. The operation has been successful, and the only alternative to it, where this is impossible, is gastrostomy. In favorable cases after the removal of the pouch, the esophagus should be immediately sutured and the external wound, if closed, should be reopened on the first indication of infection. As a rule it is better to employ temporary wick drainage. Girard's method of invaginating the diverticulum, so that its internal surface projects into the esophagus, is mentioned, and he says that he has been successful with it in his practice, he, however, does not believe that it is advisable since it must produce more or less obstruction, and one that would seem more dangerous than the opening of the tube. The pathology and etiology are described, and while these pouches are called pressure diverticula, a constriction of the esophagus has not been observed in the cases reported, and so far as known, no recurrence has taken place after the excision.

45. Post-Diphtheritic Stenosis of the Larynx.—According to Rogers, the most common cause of post-diphtheritic stenosis, necessitating long-continued intubation, is a hypertrophy of the subglottic tissues, accompanied by a chronic in-

inflammation. Intubation is not the cause, as it occurs without the operation, and less often there is an ulceration and subsequently a formation of cicatricial tissue and contraction. This can not be credited to the intubation as a rule, but it may follow tracheotomy. The frequency of the post-diphtheritic stenosis is, according to Dillon Brown, about 1 in 75 or 100 cases. Others have met it less frequently, and a reasonable estimate of the average in hospital experience would seem to be about 1 per cent.

46. **Surgery of the Stomach.**—Delatour reports several cases of gastrotomy and gastroenterostomy, and one of gastrectomy in which a patient lived twenty-one months and gave birth to a living child.

47. **Ligation of the Subclavian Artery.**—Halsted reports a successful ligation of the first portion of the subclavian artery for aneurysm of the third portion. The operation was complicated by the anomalous position of the subclavian vein, lying along the artery throughout its whole course, and the right subclavian seemed to start directly from the arch of the aorta. He attempted to perform the operation without resection of the clavicle, but believes that doing so would be generally advisable, as in his case he had to make a resection before he finished. This is, he thinks, the second case on record where the patient survived the operation; and so far there has been no appearance of the radial pulse since operation was performed. 52.—See abstract in THE JOURNAL of May 13, 1899, p. 1053.

53.—*Ibid.*, April 28, p. 1070.

54. **Eye Defects.**—Huizinga calls attention to the need of watchfulness and treatment for conditions of visual defect that are very often neglected; and warns especially against consulting opticians instead of ophthalmologists for the remedy of these conditions.

55. **Albuminuria.**—The conditions in which albumin is present in the urine are pointed out by Kennedy: nephritis in its different forms, the functional albuminuria which occurs in the lithemic and hemoglobinuric forms and the neurotic type. He mentions last the extrarenal albuminuria, accompanying disturbances in the urinary organs, and cystitis, that may also be due to oxaluria.

56. **Malaria.**—The technique of examination for malarial parasites is described by Woldert, and the products which may lead to error in the diagnosis are mentioned. They are: the refractive bodies seen in the red corpuscles, the karyokinetic figures of the leucocytes, and the vacuoles and products of blood disintegration.

57. **The Electrocautery in Nose and Throat Diseases.**—Dabney has found the electrocautery useful in broad hypertrophies over the turbinated bones, with erection of the turbinated tissue, and in cases where there is loss of tone of the vasoconstrictors of the blood-vessels of that region. He rarely uses it on the septum, as only two conditions ever call for it; one a marked thickening of the so-called tubercle of the septum, where two or three linear cauteries have been useful; and the other frequent hemorrhages from erosion of the lower anterior part, not attributable to other disturbances of the circulation. He thinks, however, that it is less valuable in this condition than is claimed. In the throat, the conditions most helped by the electrocautery are the deep-seated follicular tonsil inflammation, the so-called "granular sore throat," necrosis of the fauces, and enlargement of the veins at the base of the tongue, and the so-called "lingual tonsil."

58. **Pancreatic Digestion.**—Rachford's paper is a study in comparative anatomy, showing the peculiarities of the bile and pancreatic openings into the small intestine in carnivorous and herbivorous animals, respectively. He thinks that the physiologic inference is that fats and proteids require a retarding in their passage through the duodenum, in order that they may be acted on by the bile and the pancreatic juice before they reach the alkaline succus entericus of the jejunum and ileum. This physiologic inference from anatomic facts is supported by laboratory experiments that have been previously published.

61.—This paper appeared elsewhere: see abstract in THE JOURNAL of April 21, ¶ 81, p. 991.

66. **Hyperkeratosis Lingualis.**—This condition, according to Goodale, consists histologically in a papillary enlargement and a small round-celled infiltration of the corium, together with protoplasmic reticulation, nuclear degeneration, and excessive keratin formation in the epithelium; the latter on its superior surface being prolonged upward to form filamentous processes, containing peculiar refractile pigmented granules, with which a characteristic bacterium stands in intimate association. It is of interest to note that the hypertrophy affects all layers of the mucous membrane and reaches its greatest development in the posterior and central portion of the dorsum. The condition appears to be primarily of the nature of a chronic inflammation with secondary alterations in the epithelial cells.

67. **Cysts of the External Auditory Canal.**—Somers describes a case where one of these cysts was removed. They originate: as retention cysts of the existing glands; or by the independent formation in the tissues, through softening and liquefactive changes, the material so produced compressing the cells in the immediate vicinity, and these undergoing changes, ultimately forming the cyst wall. Or they may be produced by collection of fluid between connective-tissue cells, these areas forming into one large cavity and the surrounding tissues combining into a retaining wall. Still another way is by the formation of the fibrous tissue wall around a foreign body. They are almost always located at the junction of the cartilaginous with the osseous canal, where the glands abound.

68. **Suprarenal Extract.**—Bates concludes, from six years' experience with suprarenal extract, that it is a powerful and unobjectionable astringent, but that it does not mix with other substances and must be prepared fresh whenever needed. In nose and throat disease other remedies should also be employed. He thinks that its being a natural secretion of the body prevents its causing physiologic disturbance, and that we have no other substance that can take its place.

75. **The Chemistry of Cow's Milk.**—This paper gives a careful comparison of human and cow's milk and the author's method of preparing infant food from the latter. He siphons from the bottom of a bottle of fresh milk, three-fourths of its contents into an ordinary double boiler, and adds 1½ teaspoonfuls of essence of pepsin, then warms slowly to blood heat and keeps it there until thoroughly curdled; then heats with constant stirring, until the temperature of 155 F. is reached, strains while hot, and dissolves in the whey a heaping teaspoonful of sugar of milk and the white of one egg. When this is cold he pours the sweetened whey back into the milk bottle and mixes it thoroughly with cream and top milk, and then pasteurizes the mixture. If this is found too laxative the quantity of milk sugar should be reduced. He has found this method a good one in most cases, and for the home modification of cow's milk for infants it is freely recommended.

76. **Hemorrhoids.**—Campbell operates for hemorrhoids by gradually dilating the anus and irrigating by the bichlorid solution. He then pulls the hemorrhoid out with forceps, severs the lower attachment with blunt-pointed scissors, and dissects it up from its submucous attachment until it is attached by a small pedicle containing the vessels. This is ligated with fine catgut and the hemorrhoid cut away. The operation is completed by suturing the incised edges with catgut and inserting a piece of iodoform gauze for drainage, with a sterilized gauze pad applied and retained by a T-bandage. The third day the bowels are opened by a suitable aperient, and this is continued as long as necessary. The patient sits up on the tenth day and is about on the fourteenth. He has found this uniformly satisfactory in twenty-five cases where he has used it. It does not produce the contused wounds and charred surface which are results of the ligature and cautery operations, and leaves a clean sutured out and the rectal surface as complete and perfect as ever.

77.—See abstract in our Therapeutics Department this week.

80. **Hot Bath in Abdominal Diagnosis.**—The methods of inspection in abdominal examination are more or less interfered with by the rigidity of the abdominal wall, or sometimes

simply by its thickness. In such cases the patient is often anesthetized for the purpose of completely relaxing the tissues. Deck calls attention to a method that is not only safer, but truly superior to anesthesia for this purpose, which is simply immersing the patient in a hot bath. Its advantages are less risk, less disagreeableness, and complete control of the patient's respiration, thus calling into play the powerful action of the diaphragm. The only difficulty is that it requires a bath-tub and a large quantity of hot water; and that in cold weather the patient needs a gradual cooling before going out of doors. The bath-tub should be long enough for the patient to lie almost flat, or at least with his knees drawn up. The temperature should be gradually raised from 100 to 110 F., or even a little higher.

81. **Intraligamentous Growths.**—Hawkins describes these growths and reports eleven cases.

85. **The Longitudinal Wire Suture.**—The advantages of this method of suturing the opening in the radical operation for hernia are given by Harris, as follows: it can be easily and certainly sterilized, is of non-glyseroseous character, maintains an accurate coaptation of the edges without constricting the tissue within its grasp, and is easily removed after its functions have ceased. The wire is threaded to a curved, round, non-cutting needle and introduced along the edges of the structure. The first enters the skin about 1 to 2 cm. from the inner angle of the incision and passes directly down to the inner edge of Poupart's ligament. The needle takes a grasp of this structure not to exceed 1 cm. in length in a longitudinal direction, but so as to cross some of its fibers. It then enters the conjoined tendon and the inner edge of Poupart's ligament, thus going from side to side until the entire length is traversed. It then penetrates the external oblique and skin and comes to the surface 1 to 2 cm. from the outer angle of the incision. This is not an over-and-over stitch, for when the wire is pulled tight it is perfectly straight. Each grasp of the needle should be about 1 cm. in length and no kinks should occur in the wire. When there is considerable space external to the cord, caused by early divergence of the muscles from the ligament, it is advisable to take one or more grasps of the suture external to the cord. A sufficient opening should be left to permit the passage of the cord without obstruction. The first wire having been introduced, the cord, which has been held to one side, is now restored to its normal position. The second wire taking the edges of the divided external oblique passes from without inward, closing the wound over the cord, leaving but an opening for it to pass into the scrotum. The cutaneous edges are now closed by a third wire, and the operation is finished. The ends of the wire, which are left long, are folded over pads of gauze, and a strip of adhesive plaster crosses over each end of these, fixing them to the body so that they can not slip and draw out. Sterilized gauze dressing is then applied. This operation is applicable to a large proportion of cases of inguinal hernia, and the size is immaterial so long as we have firm tendon and structures.

95. **Chorea.**—Punton notes our lack of knowledge in the pathology of chorea and discredits the general belief of its necessary connection with rheumatism or endocarditis. Heart disease is more often found as a sequel than a cause, and he thinks that the disease is more important than it is generally considered, and believes that rest and arsenic are practically the best and most reliable remedies, used together with a general tonic treatment and attention to details.

97. **Pulmonary Complications of Typhoid Fever.**—Edson discusses the possibility of pulmonary disorders occurring with typhoid, and illustrates them by cases. He says that pneumonia is most frequent and may be a pure typhoid infection, and gives the points of diagnosis between such and the complicating pneumococcal disorders. The initial chill in typhoid is not so marked, there is less pain, dyspnea and cough, and if the sputum is not rusty the suspicion of typhoid is increased. Early diarrhea and enlarging of the spleen are in favor of typhoid, but only the trained judgment can make a perfect diagnosis before the rose spots appear or the Widal reaction is present. Other pulmonary disorders that may complicate ty-

phoid are pleurisy, abscess, tuberculosis and catarrhal pneumonia, which is usually an avoidable complication.

98. **Climate and Treatment.**—Denison argues for the importance of climate in the treatment of tuberculosis, and thinks that it should stand first in the remedies to be used. Next to this he values outdoor life and exercise, then good feeding, medical supervision, inhalations, local medication, surgical interference, and special medication based on antitoxin treatment. However, in lasting results there is no single agency equal to suitable change of climate.

99. **Acute Coryza.**—The prevention of catarrhal disorders, according to Black, is best done by recognizing the fact that the skin is the natural covering of the body; and that we should not keep air away from it. He does not mean that we should go nude, but that the clothing should be such as will admit of a free passage of air to the skin. Underwear should be worn for only sanitary reasons and not for warmth. Wool should not be worn next the skin, but only for outer garments, while the material used for underwear should be linen, very loosely woven. The other clothing should be little heavier in winter than in summer, and when out of doors the overcoat should be in proportion to the severity of the weather. He claims he has put these theories into practice for five years with good results.

107. **The Therapeutic Use of Yeast.**—In 1899, T. Landau reported cases of leucorrhoea treated with local applications of yeast, and Mitchell has followed up the method and gives an account of eight cases thus treated. The summary does not show the brilliant results obtained by Landau, but justifies continuing the trial of this method. Of the eight cases, only one was entirely unaffected and that was of syphilis and the discharge not of local origin. No unpleasant after-effects were noticed.

119. **Post-Febrile Insanities.**—Bauduy finds, from an analysis of the symptoms and literature, that in the etiology of post-febrile insanity we have heredity causing unstable nervous equilibrium; disorders of the nerve centers themselves, of which fever is often only a symptom; anemia, the result of febrile processes or excessive and prolonged temperature elevation causing irritable weakness; toxic perturbation of the nervous nutrition by the retaining of waste matter causing blood changes, and, lastly, microbial invasions of the nerve centers producing a caecetic condition of these organisms.

120. **The Fetal Theory of Eclampsia.**—Von der Hoeven supports the theory that the blood poisoning in fetal eclampsia is largely due to the toxins from the fetus. This would explain the fact of its greater frequency in the case of twins, and the other peculiarities of eclampsia in primiparae. The intoxication of the child is often overlooked because of the special attention given to the mother, and the coma of the infant is mistaken for quiet sleep.

121.—This paper appeared elsewhere: see abstract in THE JOURNAL of April 7, ¶ 1, p. 863; also of April 14, title 125, p. 925.

123. **Nervous Prostration.**—Raney reiterates his well-known views in regard to eye-strain as a cause of headache and other nervous symptoms, especially those that go under the name of nervous prostration.

124. **The Missile and the Weapon.**—This article is a medico-legal study of bullets and firearms. The author shows the peculiarities of bullets as affected by the arms through which they are sent, and also the facts that can be learned from inspection of the weapon itself.

130. **Hemoglobin Estimate.**—Tallquist describes a method which is mentioned in the eighth volume of "Nothnagel's Handbuch," and that consists in placing a drop of blood on a piece of filter-paper and letting it spread there, judging of the amount of hemoglobin from the strength of the color. He has made a scale which is illustrated here in this article. It consists of ten different colors with regular interspaces to about 10 degrees, each according to the hemometer; the strongest color corresponds to the normal blood, the lightest to that caused by pernicious anemia. The blood is obtained in the usual way, by pricking a clean finger, and the drop must

amount to enough to make the stain on the filter-paper show a 5 or 6 mm. diameter; it must spread equally and slowly and the examination must be made by direct light so that the comparison can be immediately after the stain has lost its humid gloss. It is necessary to make the examination by daylight, and the paper must be perfectly white and smooth, corresponding in thickness to about fifty-five leaves to 1 c.c. Tallquist notices the fact that in specimens of pernicious anemia of a high degree the color spot on the paper will appear surrounded by an uncolored or slightly colored ring. This occurs only when the number of blood-corpuscles has gone down to about half what is normal.

132. **Pernicious Anemia.**—Ball discusses the general subject of pernicious anemia, and mentions especially the ignorance of all authorities in regard to its etiology. In its beginning it is hard to recognize, for the blood condition is not marked until the anemia is considerably advanced. The prognosis should be extremely cautious; the morbid anatomy is not characteristic. The best treatment seems to be the use of increasing doses of arsenic, rest in bed, systematic feeding, massage for the muscles, and a daily flushing of the colon.

133. **Anesthesia.**—The conclusions deduced by Magaw from experience with over eleven hundred cases of anesthesia and from a study of the subject generally are: 1. Ether kills slowly, giving plenty of warning, while with chloroform there is not given time to say goodbye. 2. If ether is given with plenty of air and the drop method, there are few, if any, bad results. 3. Firmness with a hysterical patient assures the anesthetizer more success in gaining confidence of the patient. 4. An anesthetic is dangerous as long as it is in use. 5. The mortality can be diminished by the careful selection of the anesthetic. 6. The surgeon should make the choice. 7. In most cases where artificial respiration is resorted to, it is usually the fault of the anesthetic or the method used.

148. **Facial Neuralgia.**—Belt recommends the placing of the hand, on the opposite side to that on which the neuralgia occurs, in a basin of hot water as hot as can be borne; and reports several cases of relief with this method.

151.—This article also appears in another journal: see title 35, this week.

FOREIGN.

British Medical Journal, May 5.

Secondary Suture of the Brachial Plexus. WILLIAM THORBURN.—The case reported is one of injury to the brachial plexus, situated in an accessible region of the neck external to the scalenus medius, the motor fibers above that level intact, those below it paralyzed and sensory fibers all paralyzed. The plexus was torn across and hopelessly contused in that region, but its roots were not torn away from the spinal cord. The operation was done by opening the posterior triangle of the neck, the clavicle pulled to one side, the main roots of the plexus dissected out of the cicatrix and the peripheral ends, to some extent artificially, separated into five cords which were attached to the higher ends without tension. Four years after the operation there is partial return of motor power, with occasional sensation of heat and cold and at rare intervals pain; sensation exists in the arm, but the localization of touch is defective. The wasting of the muscles still continues to a certain extent, but improvement is even now progressing. The author thinks that it is probably the only case as yet recorded of secondary suturing of the brachial plexus.

The So-called "Stave of Thumb," or Bennett's Fracture. GEORGE THOS. BEATSON.—The author calls attention to the fact that fifteen years ago, E. H. Bennett proved that fracture of the metacarpal bone of the thumb is more common than that of any other of these bones, and that it is not as usually believed, "just above the middle," but is situated at the base of the bone. The fact has not received the recognition that it should and is hardly mentioned in modern text-books. It somewhat simulates a dislocation, and the pain and swelling that accompany it so mask crepitus that the injury is generally regarded as "sprain of the thumb," and the dislocation is serious. He reports a case in which the X-ray revealed the

condition as described by Bennett, which was completely relieved by extending and thoroughly abducting the thumb and then applying a plastic splint to it. The point he calls attention to is that sprain of the thumb should be subjected to Röntgen rays, as otherwise Bennett's fracture is likely to be overlooked.

The Lancet, May 5.

Then and Now; or the Influence of Modern Surgery on Medical Practice. FRED J. SMITH.—After prefacing his remarks with some statements in regard to the possibility of zeal outrunning discretion in modern methods, which he illustrates by some of the prophylactic fads of the day, the author speaks of the progress which has been made in regard to cancer, and sums up by saying that we have gained but little in clinical diagnostic precision, much in scientific knowledge, and most of all in our power to smooth the path to the grave, by means of hypodermic medication and operative relief. In gastric ulcer he believes in operative interference if the hemorrhage reappears after a trial of medicines and remedies, and would urge it on the third repetition or confirmed persistence of hemorrhage. When the diagnosis is uncertain he would insist on rest in bed with "slop" diet, and if on resumption of active life the symptoms recur, he would suggest operation, and on the third recurrence, most strongly urge it. With gall-stones, he thinks an operation is required if there is a large stone, too large to escape by the natural routes, if there is an accumulation of smaller ones causing trouble and if any suppurative has occurred around a stone of any size. The question is to diagnose these conditions. The recurrent attacks of local pain, associated with jaundice or not, almost certainly associated with a gall-bladder large enough at least to be felt, are the strongest evidences of stone too large to pass and of the accumulations of the smaller ones. The symptoms of suppuration in this region are somewhat misleading and the presence or absence of leucocytosis would be of aid. In ascites he believes the proper method is to have the abdomen opened by the surgeon, when purges, diaphoretics, and diuretics have had a fair chance, or when there is no time to use them, owing to the urgency of the case. He thinks this better than tapping and more scientific, and it is far safer for the patient. He has never seen death arise from simple exploratory laparotomy, but peritonitis has occurred from paracentesis. It assists and clears up a doubtful diagnosis, allows removal of removable cause at one sitting and patients who are usually considered incurable have recovered after laparotomy. He thinks these five facts constitute an unanswerable case in favor of laparotomy against canular drainage, at least once in the course of every case. As regards appendicitis, he holds that we must operate instantly in fulminating cases, as soon as we are reasonably certain of pus in less acute ones, and after subsidence of the attack in milder ones. In the treatment of renal troubles, tuberculosis, if not generalized, should be very carefully diagnosed before interfering. We must ascertain by every means in our power which kidney is affected and if the other is sound. He would still advise a month's course of creosote treatment, which in his experience is the only drug method that has any influence on the tuberculous internal lesions. As regards stone in the kidney, when it is once definitely diagnosed, it is our duty to operate as speedily as possible before consecutive changes occur. Bacteriologic examination of the urine, administration of a few small doses of turpentin, and X-ray photographs are the means he mentions for the diagnosis. He does not think much of dietetic and water treatment, and believes a simple exploratory operation is justified in all cases.

Effect of Alcohol on Human Brain. VICTOR HORSLEY.—The author reviews the facts in regard to the influence of alcohol on the brain. The researches on the reaction period by Kraepelin are referred to, and they show that it is a depressant, although there may be a temporary increase of activity. The influence of the drug may be due to loss of cerebellar controlling influence as well as dissolution of the cortical cerebral constituents. The direct effect on the nerve cells themselves

is noticed, and while the action is a chemical one, he shows from the researches of Nissl and others that its effect on them is direct. From a scientific standpoint, he believes that it can not be true that the small doses of alcohol such as people take at meals have practically no deleterious effect. From a scientific standpoint total abstinence must be the course, if we are to follow the plain teachings of truth and common sense. It is the part of the scientist to point this out and the part of the politician to adopt it as a whole.

Vasectomy Relative to Enlarged Prostate and Bladder Atony. REYNALD HARRISON.—The writer sums up his conclusions relative to vasectomy as follows: 1. Vasectomy has been shown to be especially effectual in the earlier stages of prostatic hypertrophy in effecting shrinkage of the gland and the restoration of the natural process of micturition. 2. In cases where there is evidence to show that the prostate has in the course of degeneration assumed the form and structure of a fibrous growth the conditions are such, provided the symptoms of obstruction warrant the adoption of other measures than catheterism, as to render some form of prostatectomy preferable to either vasectomy or castration. 3. Where, as a consequence of sudden or protracted prostatic obstruction, secondary changes have taken place in the bladder itself, in the form of sacs, pouches, or trabeculation, the possibility of restoring its natural function by any means is extremely unlikely. Under such circumstances the induction of shrinkage of the enlarged gland will do good in affording a readier access for the catheter and in removing spasm, pain or hemorrhage connected with this or other similar processes. In a further communication he hopes to illustrate the practice of vasectomy under various conditions.

Bulletin de l'Académie de Médecine (Paris), April 17 and 24.

Diagnosis of Rabies in Dogs. NOCARD.—The lesions described by Van Gehuchten as specific of rabies in dogs (see THE JOURNAL, page 811) have been thoroughly investigated by others and Nocard reports that they were found constantly in dogs dying from rabies. But in animals killed at an early stage of the disease, the lesions were so slight as to be unreliable for the diagnosis. Consequently, when a person has been bitten by a dog in which these lesions are found, the diagnosis of rabies is imperative, but the absence of these lesions, when the animal was killed at once, does not convey any certainty that the animal was not rabid.

Vaccin from Goats. HERVIEUX.—The vaccin derived from cow-pox in the goat possesses approximately all the properties of vaccin from heifers, and Hervieux consequently recommends the goat for this purpose in countries where it is difficult to procure cattle. Tested on 250 soldiers in Kabyle the goat vaccin was successful in 78 per cent.; ordinary cow vaccin in 85 per cent.

Profound and Lasting Analgesia of the Eye with Dionin. A. DARIER.—In Darier's experience with iritis, keratitis, arthritic ulcers, iridocyclitis and episcleritis, accompanied with much pain, the application of ethylmorphin hydrochlorate or dionin, relieved and banished the pain in a few moments. A rapid improvement of the lesions was also noted in most cases. He found it very effective in a case of glaucoma, relieving the pain and improving vision from 1/16 to 1/4 in thirty minutes. He instills a 5 per cent. solution, two or three drops every few minutes until chemosis occurs. It smarts at first and then all pain is relieved. The result was negative in only one case in his experience, and in this no chemosis occurred; the patient was evidently refractory. The action of the dionin is strictly local.

Bulletin de la Soc. Med. des Hop. de Paris, April 5.

General Arsenical Melanoderma. ENRÍQUEZ.—A few instances are on record of a general pigmentation resembling Addison's disease, but less diffuse, appearing in spots and patches while respecting the extremities and face, which followed the prolonged use of Fowler's solution. In an observation described in the *Bulletin* last June, and in another more recent issue, the pigmentation still persists, although less intense, notwithstanding suspension of the arsenic. In the latest case the melanoderma was accompanied by dryness

of the throat and slight conjunctivitis, and the hands and feet assumed a lichenoid appearance.

Further Facts to be Learned with the Methylene Blue Test. F. WIDAL.—The author describes the modifications in the renal permeability of a patient, "more cardiac than Brightic," under the influence of medicinal and hygienic measures. The permeability of the kidneys for potassium iodid, at first subnormal, was restored to normal with milk diet, rest and theobromin. Methylene blue was not eliminated at all at first, but permeability improved until the blue appeared in the urine in an hour. C. Achard and A. Clerc have been studying absorption and the influence of medicines, by means of the blue test on normal subjects and others with interstitial or lead nephritis, who took each morning, fasting, a pill of 5 eg. of methylene blue, for several days. The curves show that the normal subjects eliminated the largest proportion at first, followed by a period during which all eliminated alike, and then elimination ceased in the normal but continued for a while in the rest. The period of elimination varied from forty-seven or fifty hours in the normal to eighty or 186 in the nephritic subjects. The uneliminated blue evidently accumulated in the blood in the latter, at first, until the blood became so concentrated that the same amount of blue passed through the kidney—without any change in its permeability—as passed in normal conditions without the previous accumulation in the blood. This mechanism suggests the need of caution in estimating the condition of renal permeability from elimination of the normal principles of the urine. They may become accumulated in the blood in case of deficient permeability, and then be eliminated in approximately normal amount, even with complete suppression of the functions of one kidney.

Pulmonary Gangrene After Gastroenterostomy. J. L. PEXROT.—Pulmonary or pleural accidents in the course of cancer of the stomach have been noted, and attention has been called to their exceptional frequency after gastroenterostomy. An observation is described in which pulmonary accidents followed a successful gastroenterostomy for commencing cancer of the pylorus accompanying an old gastric ulcer. Bronchopneumonic foci in the right lower lobe first appeared, then adjacent serofibrinous pleurisy, then putrid evolution of the brouchopneumonic foci and perforation of one into the pleural cavity, with sudden, fatal pneumothorax. The writer ascribes this train of accidents to septic emboli from the gastric ulcer, the microbes probably mobilized more or less by the operation. The gangrenous foci had many points of resemblance with pulmonary infarcts: site, shape, etc., and also recalled the gangrenous pulmonary foci of embolic origin noted in the course of otitis of the middle ear in children. Whether microbial infection proceeds by way of the veins or lymphatics the lung is soon reached, and its capillary system arrests the infection and serves as a filter to prevent general septicemia. The accidents in these cases are similar to the pulmonary granula observed sometimes after curetting a peripheral tuberculous focus, but in the former instance, the mobilized microbes are anaerobic saprophytes, microbes of putrid fermentations, such as flourish in old gastric lesions and alimentary stasis. The process described is evidently one of the most important reasons for the high mortality after surgical intervention on the stomach. It also suggests the advisability of thorough lavage of the stomach before operating and the benefits of an exclusive milk diet for a few days beforehand; also the necessity of waiting several days before returning to alimentation through the mouth. Although the peritoneal serosa may be amply cicatrized in forty-eight hours, the gastric mucosa is open to microbial infection.

Technique of Radiography of Fractures. G. CONTRE-MOULINS.—Conditions should be identical and determined beforehand, for radiographic interpretation to be exact and capable of comparison. This result can be obtained by having a perpendicular line from the Crookes' tube always coincide with the center of the plate and pass through the center of the fracture. By this means the misleading effect of the oblique

rays will be abolished and the position of the bones accurately shown. Two radiographs at 90 degrees, one anteroposterior, the other lateral, will thus give accurate information in regard to the fracture, and can be repeated indefinitely with identical results. If impossible to get the member in the perpendicular line, the tube and plate can be slanted, but always retaining the same relative position.
