Gama, Vasco da, väs'kō dä, Portuguese navigator: b. Sines, Portugal, 1450; d. Goa, India, 24 Dec. 1524. He was the first navigator who made the voyage to the East Indies by the Cape of Good Hope. Bartholomew Dias, a Portuguese explorer, having visited the cape, which he called Cabo Tormentoso, or stormy cape, brought back such interesting accounts of his discoveries that the Portuguese sovereign Emanuel, following the policy of his predecessor, John II., determined to urge discovery beyond the point where Dias left it, and if possible to reach by sea the countries of the Indies. Accordingly an expedition was placed under the command of Vasco da Gama, a gentleman of the king's household, and a skilful and experienced mariner. The fleet consisted of the San Gabriel, flag-ship of 120 tons, the San Rafael of about 100 tons, a caravel of 50 tons, and a store-ship, with a total force of 160 men. The king presented Gama with the flag of the military order of Christ (a white cross within a red), also the journal of Covilham the navigator, who had 10 years before gone to India by way of the Red Sea, and with letters to all known potentates, and to the mysterious Prester John. On 8 July 1497 Gama's expedition departed from Lisbon for the Cape Verde Islands, whence it set sail on 3 August southward along the African coast. For three months the voyagers pursued their way, harassed, as an early English narrator says, with torments of wind and rain. On 7 November they put into a bay called St. Helena, near the cape, where they found the natives «lyttle men, ill favored in the face and of color blacke, and when they did speake it was in such manner as though they did alwayes sigh.» Departing on the 16th, they encountered a succession of tempests such as had gained for the southern promontory of Africa the name of the Cape of Storms. The courage of Gama's companions failed, and they besought him to put back, which he not only refused to do, but put the ringleaders of the movement in irons, and held on his course into the stormy sea. When they were beating about off the promontory, Gama fancied that he saw the spirit of the cape. Camoens has sung this incident as a fact, while moderns, less poetical, say that the apparition could have been nothing more than that peculiar cloud whose sudden envelopment of the cape is the forerunner of a storm. On Wednesday, 20 November, they doubled the Cape of Storms, or rather, as Emanuel himself had named it ere the expedition set out, the Cape of Good Hope. Proceeding along the coast, they touched at various points, among others at Natal. Further north they discovered Mozambique, and came upon a country which exhibited a high stage of commercial advancement, the inhabitants having regularly built ports, with mosques. The natives were Mohammedans, carrying on a trade in pearls, rubies, silver, linen, and spices with Arabia and India. Gama took with him a pilot from this place. On 1 April the explorers discovered the island of Açoutado, which Gama so named from a flogging he gave to his pilot there; and on the 7th the island of Mombassa, where the people who inhabited it were bravely apparelled in silken stuffs and jewelry. As these men tried to cut his cable, Gama seized a boat containing 17 of them, and carried them off to Melinda, 3° south of the equator, where the king of the place entered into the most friendly relations with the Portuguese, and gave them a pilot to conduct them across the Indian Gulf. Melinda was described as a regularly built city, with wide streets and houses of more than one story. The Melindese pilot is reported to have been acquainted with the astrolabe, compass, and quadrant. Under his guidance the voyagers steered 750 leagues across the open sea. In 23 days they arrived off the Malabar coast, and on 20 May 1498 they reached Calicut, the object of their search. Their mission was thus accomplished, and a new route to the East established. Gama's relations with the ruler of Calicut, who was called the Samoudri-rajah (abbreviated to Zamorin) were not of a cordial nature; and therefore, leaving the Indian coast on 15 October, Gama returned to Lisbon, calling at Melinda on the way to take on board an ambassador to Emanuel's court, and arriving in the Tagus September 1499, after an absence of two years and two months. He brought back only 55 men and one ship, a caravel which he had chartered at Cape Verde. The San Rafael had been lost on the coast of Africa, the store-ship burned according to Gama's instructions, the San Gabriel condemned at Cape Verde, and Nicolao Goelho had slipped away with the remaining vessel in order to be the first to tell the great news in Portugal. The king received Gama splendidly, and permitted him to bear the high-sounding title of "lord of the conquest of Ethiopia, Arabia, Persia, and India."

Emanuel immediately fitted out a second fleet of 13 ships, with 1,200 men, under the command of Pedro Alvarez Cabral, to establish trading posts; but failing in its ends, another fleet of 20 ships was placed under command of Gama. This expedition, which was warlike in its character, sailed early in 1502. On reaching Calicut, Gama immediately bombarded the town, enacting deeds of inhumanity and savagery too horrible to detail, and equaled only by the tortures of the Inquisition. From Calicut he proceeded in November to Cochin, "doing all the harm he could on the way to all that he found at sea," and, having made favorable trading terms with it and other towns on the coast, he returned to Lisbon in September 1503 with richly laden ships. He and his captains were welcomed with great rejoicings; "but to Dom Vasco the king gave great favors, and all his goods free and exempt; he granted him the anchorage dues of India, made him admiral of its seas forever, and one of the principal men of his kingdom." Soon after his return Vasco retired to his residence in Evora, and for 20 years took no part in public affairs, either from pique at not obtaining, as is supposed by some, so high rewards as he expected, or because he had in some way offended Emanuel. During this time the Portuguese conquests increased in the East, and were presided over by successive viceroys. The fifth of these was so unfortunate that Gama was recalled from his seclusion by Emanuel's successor, João III., created count of Vidigueira, and nominated viceroy of India, an honor which in April 1524 he left Lisbon to fill. Arriving at Goa in September of the same year, he immediately set himself to correct, with vigor and firmness, the many abuses and evil practices which had crept in under the rule of his predecessors. He was not destined, however, to prosecute far the reforms he had inaugurated, for on Christmas eve following his arrival he died, and was buried in the Franciscan monastery there. In 1538 his body was conveyed to Portugal and entombed in the town of Vidigueira, of which he was count, with all the pomp and honor due to one who had been the king's representative. The important discoveries of Vasco da Gama had the result of enriching Portugal, and raising her to one of the foremost places among the nations of Europe.

Gama'liel ("God is a reward"). Two persons of this name are mentioned in Bible history. The first, Gamaliel, the son of Pedahzur, in the book of Numbers, i. 10; ii. 20; vii. 54, 59; x. 23, as prince or head of the tribe of Manasseh. The other and better known Gamaliel is mentioned twice in the Acts of the Apostles. In both passages he appears as a learned doctor of the law, of the sect of the Pharisees. From the one we learn that he was the preceptor of St. Paul, who was brought up in Jerusalem, "at the feet of Gamaliel." In the other we find him advising the council of Sanhedrim in regard to their treatment of the apostles, and it is the advice given on this occasion which has rendered him famous. "If this counsel or this work," he said, "be of men it will come to naught, but if it be of God ye cannot overthrow it, lest haply ye be found to fight even against God." Ecclesiastical tradition makes Gamaliel become a Christian, and relates that he was baptized by St. Peter and St. Paul; but the story does not appear to be supported by any evidence. He has been identified by scholars with Gamaliel, the son of Simeon and grandson of Hillel, president of the Sanhedrim under Tiberius, Caligula, and Claudius.

Gamarra, gä mär'rä, **Augustin**, Peruvian general; b. Cuzco 27 Aug. 1785; d. Yngavi 20 Nov. 1841. He fought in the Spanish army in 1809–21, then joined the patriots, marched into Bolivia (1827), and effected the Treaty of Pisagua (1828). From 1829 to 1833 he was provisional president of Peru, and later was variously identified with the political disturbances of the time. In 1837 he took a leading part in Chilean opposition to the Bolivia-Peru confederation, and upon the conclusion of a successful campaign became president of Peru (1839). He was killed in battle during an invasion of Bolivia.

Gamba, a stringed instrument of the viol sort, called also viola da gamba, with six strings, weaker in tone and smaller in size than the violoncello, so called because it was held between the knees of the player, as distinguished from viola da braccia, played on the arm. Also an organ stop, the pipes of which are, in continental organs, generally cylindrical, of small scale, and well cut up, but sometimes conical in shape. Its tone is pungent, and not unlike that of a violin or violoncello.

Gambado, or **Gambade**, a leather legging for equestrians; it is wrapped round the leg, reaching from the knee to the foot, and is fastened at the side by clasps.

Gambetta, Léon Michel, lā-ôn mē-shĕl gän-bet-tä, or găm-bĕt'tă, French statesman: b. Cahors, France, 3 April 1838; d. Sevres, France, 31 Dec. 1882. He was of Genoese extraction; was educated for the Church; but finally decided in favor of the law; and going to Paris became a member of the metropolitan bar in 1859. In November 1868 he gained the leadership of the republican party by his defense of Delescluze, a noted republican. In 1869, having been elected by both Paris and Marseilles, he chose to represent the latter city; and in the Chamber of Deputies showed himself an irreconcilable opponent of the empire and its measures, especially of the policy which led to the war with Prussia. On the downfall of the empire, after the surrender of Sedan in 1870, a government for national defense was formed, in which Gambetta was nominated Minister of the Interior. The Germans having encircled Paris, he left that city in a balloon, and set up his headquarters at Tours, from which, with all the powers of a dictator, he for a short time organized a fierce but vain resistance against the invaders. After the close of the war he held office in several short-lived ministries, and in November 1881 accepted the premiership. The sweeping changes proposed by him and his colleagues speedily brought a majority against him, and after a six weeks' tenure of office he had to resign. The accidental discharge of a pistol caused his death. See Reinach, 'Léon Gambetta' (1884); Harrison, 'Leon Gambetta, a Positivist' (1892); Tournier, 'Gambetta' (1893).

Gam'bia, (1) A British colony in West Africa, occupying portions of territory at the mouth of the river Gambia, some of its islands, and about six miles of land on either bank for a distance of 250 miles from the sea, and the navigable waters of the Vintang Creek. It thus forms a narrow strip running through French territory; total area, about 2,700 square miles. The principal settlement is Bathurst, at the mouth of the river. There is comparaively little fertile land, and agriculture is primitive. Gambia differs very little from the other West African settlements in point of unhealthiness. The position of Bathurst, the seat of government, is very unhealthy in the rainy season. There are a number of Anglican, Roman Catholic, and Wesleyan schools in the colony. Cotton cloth is manufactured to some extent by the natives, who also prepare palm-oil, build boats, etc. The principal exports are groundnuts, rubber, beeswax, ivory, hides, gold and palm-oil. The value of imports in 1900 was over $1,385,000 and the exports amounted to $1,410,000. Gambia is a crown colony under an administrator, who is assisted by an executive and a legislative council. The population of the entire region in 1901 was about 90,000, including about 200 whites, the remainder being chiefly negroes. (2) A river flowing through the above colony and giving to the colony its name. Rising in the mountains of Senegal, after a course of about 700 miles it expands into a broad estuary and at Bathurst enters the Atlantic Ocean. For nearly 300 miles it is navigable by seagoing vessels.

Gambier, găm'bēr, **James,** Baron. English naval officer: b. New Providence, Bahamas, 13 Oct. 1756; d. near Uxbridge, England, 19 April 1833. He entered the navy, and off Ushant fought with distinction as commander of the Defence under Lord Howe in 1794. As admiral he commanded the British fleet at the bombardment of Copenhagen in 1807, and was rewarded with a peerage. At the action in Basque Roads in 1809 he refused to act on the advice of Lord Cochrane, was tried by court-martial, and acquitted. He attained the rank of admiral of the fleet in 1830.

Gambier, Ohio, village of Knox County, on the Cleveland, A. & C. R.R., 50 miles north of Columbus. It is noted for its educational institutions, including Kenyon Episcopal College (q.v.), Kenyon Military Academy, Bexley Theological Seminary, and the Harcourt Female Seminary. Pop. (1900) 751.

Gambier Islands, a group of small islands of the South Pacific, about lat. 23° 8' south, and lon. 134° 55' W. The natives are a well-formed race, and have made some progress in civilization. On Mangareva, the largest of the group, some French missionaries settled in 1834, and the islands now belong to France. The total population is about 1,200.

Gambir, găm'bēr, or **Gambier,** called also *Terra japonica,* an astringent substance obtained from the *Uncaria gambir,* a tree of the family *Cinchonaceæ,* cultivated in Sumatra and other islands of the Malay archipelago. It is obtained from the leaves by boiling or infusing them in water, inspissating the resulting fecula, and forming into cakes. The Chinese use it for chewing, and in the western world, principally in Great Britain, it is employed in dyeing and tanning, also medicinally. It is mostly exported from Singapore. It is often considered as one of the articles of catechu (q.v.).

Gamble, Hamilton Rowan, American statesman: b. Winchester, Va., 1798; d. 1864. He was admitted to the bar in Virginia, settling in Missouri 1818, and being elected Secretary of State of that commonwealth 1823. Practising law at St. Louis he became judge of the Supreme Court and was elected a member of the Constitutional Convention 1861 and appointed by it governor, in place of C. F. Jackson, who had become a secessionist.

Gambling, or **Gaming,** the practice of playing for a money stake games depending solely on chance, like roulette, for instance, or those other games into which the element of skill enters, as in the cases of whist or billiards. Strictly speaking, gambling may be understood as gaming in its worst sense, and as implying professional play for a money stake by men who are unscrupulous adepts at so-called games of chance. Gambling has been common among most nations, civilized and uncivilized. The practice of civilized communities in regard to these acts has been far from uniform. The odium of gambling has sometimes been attached to games perfectly innocent in themselves, and these games have been prohibited to the manifest prejudice of the law, which has thus been brought into dishonor and contempt. At other times, governments, tempted by the facilities of sharing in the dishonest gain, have openly and shamelessly encouraged gambling by licensing gaming-houses, or instituting lotteries under their own authority. See Lottery. In England gambling was early made the subject of penal enactments. Statutory restrictions upon games and gaming go back as far as Richard II. In France, public gaming-tables were suppressed from 1 Jan. 1838. Previous to the formation of the new German empire gambling was encouraged by official countenance in several of the principalities of Germany. Baden-Baden, a watering-place in the grand-duchy of Baden, and Homburg, then in the landgravate of Hesse-Homburg, were until comparatively recent times the two most famous resorts in Europe of the frequenters of gaming-tables. Since the suppression of gambling in these places, after the formation of the empire (31 Dec. 1872), the principality of Monaco in Italy has become the last public resort of this species of gambling in Europe.

In the United States the keeping of a gambling-house is indictable at common law as injurious to morals; and most States and Territories have passed laws against gambling, some of them severe and stringent. Yet till 1880 gambling was common and open in many parts of the United States; and it was left largely to societies for the suppression of vice, especially in New York, to stir up the authorities to put the laws in force. In 1881–4 prosecutions and convictions were very numerous; in 1885 almost all the chief cities in the Union followed the example of New York, and since that time the progress of legislation on this subject has been noteworthy in many of the States. Always there is difficulty in legally defining gambling and distinguishing in judicial practice between acts which violate the gambling laws and those which, while presenting some questionable appearances, are yet not obviously to be classed in the same category. As in so many other matters of public policy, there is also a loss of power to the regulative sentiment of the people through want of uniformity or any considerable degree of identity among the laws of various States and sections. Therefore it is scarcely strange that, in spite of all prohibitive legislation and repressive influences brought to bear by public opinion, gambling should, either through connivance of the authorities or by secrecy and evasion, continue to be practised in many of the large cities of the United States. As in all other matters of public interest, the moral sentiment of the community steadily seeks and no doubt gradually finds a controlling expression through its official representatives in the legislative field and in local and general administration. Consult: 'Encyclopædia of the Laws of England'; Brandt, 'Games, Gaming, and Gamester's Law'; Ashton, 'History of English Lotteries'; Bishop, 'On Statutory Crimes' (1901).

Gamboge, găm-bōj' or -booj', a gum-resin derived from *Garcinia hanburyi*, a member of an extremely large family of the eastern tropical countries. The gamboge tree itself is a native of Siam, Cochin-China, Cambogia, from which places the drug is imported to Europe and to the United States. Other forms of gamboge are found in India, China, and the Asiatic Islands that are rarely seen in the American market. The gum-resin is obtained by cutting or wounding the trunks of the trees causing a bright yellow juice to flow. This is collected, usually in bamboo joints and hardens naturally, or is dried over a fire, until a solid mass results, which generally takes the shape of the collecting vessel. In the drug market pipe gamboge, press gamboge, and cake gamboge are recognized. Pipe gamboge is preferred because it is usually clean. As a pigment for painting, gamboge has been known for centuries, and as a purgative it has been used in China as long as history gives any definite information.

The gum-resin contains a large amount of gum, 15 to 20 per cent, and 70 to 80 per cent of a yellow resin-gambogic acid, on which its purgative properties depend. Taken into the body in doses of from two to five grains, it acts as a very active hydragogue cathartic, producing numerous watery stools, with much griping. It is principally valuable when combined with some other drug that tends to diminish the pain, and it is one of the most important ingredients in the compound cathartic pill of the United States Pharmacopœia, which contains one quarter of a grain of the resin. Overdoses cause violent poisoning with intense prostration.

Gam'brell, James Barton, American Baptist minister and editor: b. Anderson County, S. C., 21 Aug. 1841. He was graduated at the University of Mississippi, and served as a captain of scouts in the Confederate army during the Civil War. He was ordained to the ministry in 1867 and held several pastorates. He served as editor of the 'Southern Baptist Record' for many years, and was elected president of Mercer University, Georgia, 1893.

Gambrinus, găm-brī'nŭs, a mythical king of Flanders, inventor of beer, said, probably incorrectly, to have an original in Jan Primus (or Jan I.), duke of Brabant. He is represented in Germany as Saint Gambrinus, patron of drinking. His figure is familiar in German beer-cellars, often seated astride a cask, a foaming tankard in his hand.

Game-fowls. See COCK-FIGHTING; POULTRY.

Game Laws, are legislative enactments adopted by nations and states to prohibit or regulate the killing of wild animals, birds, and fishes. In Great Britain the game laws are a relic of the forest laws, which in the time of the Norman kings were so oppressive; it being under the Conqueror as great a crime to kill one of the king's deer as to kill one of his subjects. A certain rank and standing, or the possession of a certain amount of property, were for a long time qualifications indispensably necessary to confer upon any one the right of pursuing and killing game. By the Game Act of William IV., the game laws were greatly modified, the necessity for any qualification except the possession of a game certificate being then abolished, and the right being given to any one to kill game on his own land, or on that of another with his permission. Every uncertificated person selling game is also required to take a yearly license. The animals designated as game by this act are hares, pheasants, partridges, grouse, heath-game, or moor-game, black-game, and bustards. These animals (with the exception of hares) are not allowed to be killed at all times, there being a certain season of the year — the close season — during which all and sundry are prohibited from killing game. By an act of 1880 every occupier of land has a right, as inseparable from and incident to the occupation of the land, to kill and take ground game (hares and rabbits) thereon, concurrently with any other duly authorized person, all agreements in contravention of this right being declared void. Game laws of greater or less strictness are in force in many other countries. In Canada the chief restrictions are in regard to killing wild animals during the breeding season.

In the United States wild game whether of forest, field, or stream is perhaps better protected than in any other country in the world. Although there are certain general national laws, 28 States have passed game laws of their own, and as many States have organized societies for the protection and preservation of game. There are 8 national organizations, the most important being the League of American Sportsmen; G. O. Shields, president, New York. The others are: the American Ornithological Union, the National Sportsmen's Association, the National Bird, Game and Fish Protective Association, Bird Protective Society of America, Boone and Crockett Club, International Forest, Fish, and Game Association and North American Fish and Game Protective Society. Nearly every State in the Union has now a Game and Fish Commission and numerous game wardens.

The national game law, known as the Lacey Law, passed by the Congress in 1900, gave to the Department of Agriculture certain powers, by which among other provisions no importation of wild animals, birds, or fishes could be made without a permit from the secretary of agriculture.

Two important Federal laws relating to game were passed during the year 1902: (1) An act amending the tariff act so as to permit the importation of the eggs of game birds for propagation, and (2) an act protecting game in Alaska. The Alaska act, which is the first general game law of the Territory, fixes close seasons and prohibits export and sale, though permitting shipment of specimens and trophies for scientific purposes under regulations made by the secretary of agriculture. Legislative sessions were held in less than one third of the States and Territories, but in nearly every case some changes were made in laws for the protection of game. General game laws were enacted by Kentucky, Louisiana, and Ohio. The adoption of non-export provisions in several States reduces the number of States which permit unlimited export of game to three, all in the South. Three States — Kentucky, New Jersey, and Ohio — adopted the license system, by which non-residents are required to secure licenses to hunt, fixing fees of $10 in New Jersey and $25 each in Kentucky and Ohio. Non-resident licenses at rates ranging from $5 to $40 are now required in half the States and Territories and in nearly all the Provinces of Canada. Arkansas and Oregon, however, require licenses only for market hunting, and New York only from residents of States which demand similar licenses from residents of New York. Louisiana and Missouri do not permit non-residents to kill game within the State. Additional restrictions on the sale of game were adopted in South Carolina, and a statute allowing dealers to hold their game under bond during the close season was passed in New York.

The movement toward securing uniform laws for the protection of song, insectivorous, and other non-game birds made substantial progress during 1902. Alaska, Kentucky, and Ohio extended protection to birds other than game, increasing the number of States which now have a practically uniform law of this kind to 19. A similar law was adopted for the Northwest Territories, Canada, and the legislature of Maryland passed a law of like character for Washington County.

New York in 1902 raised the number of its game protectors from 38 to 50, and New Jersey has given its wardens additional powers to make searches and seizures. In Oklahoma the territorial authorities seized several large consignments of game en route to eastern markets contrary to law, and have taken steps to secure a more stringent enforcement of the non-export laws.

Under the Lacey Act numerous seizures were made of game shipped from the West and Southwest, and proceedings were instituted in a number of cases in State and Federal courts. In some of the cases in Iowa and South Dakota convictions were secured with penalties ranging from $150 to $200. The inspection of foreign birds at the port of New York was made more effective, and special inspection service was established in Hawaii and extended in scope so as to prevent the introduction of noxious reptiles into the islands.

Even more important than the enactment of new game laws has been the work of game commissions and voluntary organizations interested in the practical protection of birds and game. In 1902 important changes were made in the game commissions of Ohio and Vermont, and a new territorial warden was appointed in Oklahoma. Several sportsmen's game and fish protective associations were added to the large number already existing, and new Audubon societies were organized in Louisiana, Nebraska, North Carolina, Oklahoma, and Oregon. Thirty-two States now have Audubon societies, which are formed primarily for the protection of birds other than game. The committee of the American Ornithologists' Union on the protection of birds extended its work along the coast, and now maintains supervision of all the breeding colonies of sea birds on the Atlantic coast from Eastport, Me., to Chesapeake Bay, as well as at some points in Florida.

Practically all the State game laws passed by the various State legislatures prohibit the export of game, hunting, or fishing for commercial purposes, and hunting big game with dogs. In a few States the netting of minnows for bait is also prohibited. The killing of song birds is forbidden in most of the States, but this law does not apply to the hawk, owl, crow, blackbird, and English sparrow. Hunting and fishing in the national Yellowstone Park is prohibited.

While the close and open season for hunting and fishing are well defined in all the States, there is no general statement which can cover the question, the seasons and conditions varying so widely. In Alabama, for instance, deer may be shot for four months only (September to January) in Indiana all the time, and in Illinois no deer can be shot until 10 May 1906. All State game laws are peculiarly adapted to local conditions. See AUDUBON SOCIETY; FISHING; HUNTING.

Game Preserves, or Game Parks, are large reservations of land, usually including mountain and forest, set aside by the government or individuals, for the propagation and preservation of game. Game preserves have been well known in Great Britain and on the Continent for upward of five centuries. Henry VIII. established a royal deer park near Hampton Palace in 1526, and the Duke of Sutherland at the present day owns the largest game preserve in the world. Game preservation in the United States first attracted attention just prior to the Civil War and later when the rapidly increasing settlement of the States threatened the extinction of all kinds of wild game.

The United States government took up the question of game preservation almost as soon as the individual, and the establishment of the Yellowstone National Park in the Rocky Mountains, and the Yosemite National Park in California had as much to do with the protection of big game as in the preservation of forests. In these two reservations the government ranges have endeavored to preserve and protect such large game as the buffalo, elk, and moose. In 1902, President Roosevelt, himself a hunter of big game, declared no less than 12 new national forest reserves, which while largely important to forestry, will greatly assist in the protection of big game. These new reserves have a total area of 14,276,476 acres, which makes a grand total of government parks and reservations of 60,162,525 acres. The new reserves added in 1902 were as follows:

	Acres
The San Isabel, Colorado	77,980
The Santa Rita, Arizona	337,300
The Niobrara, Nebraska	123,779
The Dismal River, Nebraska	85,123
The Santa Catalina, Arizona	155,520
The Mount Graham, Arizona	118,600
The Lincoln, New Mexico	500,000
The Chiricahua, Arizona	169,600
The Madison, Montana	736,000
The Little Belt Mountains, Montana	501,000
Alexander Archipelago, Alaska	4,506,240
The Absaroka, Montana	1,311,600

Of private game parks in the United States, the first of record was that of Judge J. D. Caton, of Ottawa, Ill., the author of 'Deer and Antelope in the United States.' This he established in 1860, for sport and study, bringing together on his large estate many varieties of game animals native to America. In 1889, Austin Corbin enclosed the largest preserve in the United States, and next to that of the Duke of Sutherland, the largest in the world. It is known as Blue Mountain Forest and is situated near Newport, N. H. It contains over 36,000 acres, and is surrounded by a wire fence, 8 feet high, forming an oblong tract 12 by 5 miles, and which is crossed by a mountain range, the peaks of which are 3,000 feet high. Here are miles of wooded slopes, dense forests, and broad meadows, giving food and shelter to all kinds of game animals, from the buffalo, elk, and moose to the smaller species. The experiment has been most successful, nearly all of the animals thriving and increasing rapidly in numbers. In 1870, F. S. Giles laid out the Grove Park reservation, containing 17,000 acres, and this experiment was followed by Dr. W. Seward Webb with a preserve of 9,000 acres at Nebasane, N. Y., in the Adirondacks, and another preserve at Shelburne, Vt. The Litchfield Park at Tupper Lake, N. Y., in the Adirondacks, was established in 1893, with 9,000 acres, and in 1900 hundreds of herds of large game were roaming the mountain forests within this tract. In the same region the Adirondack Timber Company has a park of over 30,000 acres, well stocked with animals. George W. Vanderbilt at his Carolina estate of Biltmore, has 80,000 acres, 6,000 acres of which are enclosed and well stocked with game. A small army of men are engaged here as keepers. In many of the smaller parks particular attention has been paid to game birds, such as the English pheasant, prairie chicken, and wild turkey. A lover of birds imported large numbers of Japanese pheasants for his preserve in Oregon in 1893, the experiment proving a great success. E. C. Benedict, of Greenwich, Conn., has established extensive fish preserves in Long Island Sound, which are the largest and most successful of their kind in this country. Near Plattsburg, N. Y., Paul Smith owns an immense preserve around St. Regis Lake of 40,000 acres. Large numbers of elk were brought here from the West in 1903. William C. Whitney of New York has been active in stocking the Adirondack region with big game, and in conjunction with Dr. F. E. Kendall, of Saranac Lake, has restocked the forests with elk and deer. At Delaware Water Gap, Pa., on the New Jersey side of the Delaware River, Barclay Warburton, of Philadelphia, established in 1902 an extensive deer park, which is one of the most successful in that section of the country.

In Canada there are several large game preserves, prominent among which is the Caughnawaga reservation on the Maquacippi River. The Roberval Club, which has a membership of 300, including both American and Canadian, owns a big game preserve containing 500 square miles, located in the Laurentian Mountains. Henri Menier occupies as a game park the whole of Anticosti Island, in the Gulf of St. Lawrence.

Games. Games are an expression of the play instinct, a distinct species or form of play. A study of them includes a definition of games as distinguished from play; and a consideration of games from historical, educational, and recreative viewpoints. While the term play includes games, so that we "play games," it is technically applied to informal play activities, such as playing horse, playing house, and playing in the sand. In such play there are no fixed rules, no formal mode of procedure, and generally no climax to be achieved. The various steps are spontaneous, not predetermined, and are subject to individual caprice. In games, on the contrary, as in blindman's buff, prisoner's base, or football, there are prescribed acts, subject to rules, generally penalties for the infringement of rules, and the action proceeds in a formal evolution until it culminates in a given climax; which generally consists of a victory of skill, speed or strength. This definition applies to games that require considerable bodily activity, such as those mentioned, and to so-called quiet games, as dominoes, cards, jackstraws, chess, checkers and other board games. Our concern in this article is chiefly with active games.

Among the simplest of active games are singing games, in which the action is mainly a repetition of dance movements, or of some dramatic or descriptive motions, as when the farmer sows his seed or London Bridge falls down upon its victim. More strenuous are the games of chase, such as tag, cat and rat, and

Red Rover; or competitive games of skill, strength or speed, illustrated by relay races and athletic contests. Highest of all, both in their organization and their demands upon the varied powers of players, are team games, of which baseball and football are popular examples. Team games are peculiar to the Anglo-Saxon race; nearly all games of the other classes are of very ancient origin and of wide distribution among the races and nations of men. Indeed, the games of children form a distinct branch of anthropology, ethnology and folklore, and throw much light on early customs from which they are descended; for they come trooping out of the past unconsciously bearing the relics of primitive civilizations, of old religious rites and grim superstitions, of marriage and May-time festivals and «battles long ago.» «Oats, peas, beans, and barley grows» had its origin in a religious rite intended to increase the fertility of the fields; «London bridge,» in the offering of a human sacrifice at the building of a bridge; «Here we go round the mulberry bush» is the survival of a custom, still practised by some of the European peasantry, and known to have existed at least as far back as the early Greeks, of celebrating May day or spring time with the gathering of flowers and marching in procession. This usage prevailed among the American colonists, and from it have come our May basket and May pole customs. Indeed, most of these singing games and many other active parlor games now played by children, such as stage coach, and going to Jerusalem, were used instead of the dance by the young people of the Puritan era. Among the games of religious or superstitious origin tag should be mentioned, which, in its earliest form of iron tag, represented flight from an evil spirit, against whose influence iron was a protection. The little kindergarten game, «I put my right hand in,» is very ancient, and with its chorus «Looby loo» gives evidence of having been part of a religious rite to some deity. In time it became a stately court dance, which rank it held a century ago. From the superstitious customs of divination by lot have come the doggerel «counting out» rhymes used by children the world over for choosing the principal players in games. Familiar are the stanzas of this kind beginning «Ena, mena, mina, mo,» and «Onery, twoery, tickery, tee.» Of similar derivation is the custom of assigning parts by «holders,» in which one child holds a pebble in the closed hand, and another guesses which hand contains it. Courtship and marriage customs are perpetuated in «Round and round the village» and «Little Sallie Waters.» Still other games, for example, «Uncle John is very sick,» come from the ballad days when a versified narrative was sung and acted at the same time;—days when to «sing a dance» and «dance a song» were interchangeable terms.

Athletic games, or competitive trials of individual strength, speed or skill under fixed rules, are probably pre-historic. The mention of them takes one's thought at once to «the glory that was Greece and the grandeur that was Rome.» The Greek games have been immortalized in literature and art; prominent examples of which are the Iliad and Odyssey, Pindar's ‹Odes of Victory,› and, in sculpture, the discobolus or discus thrower, and the wrestlers. These Greek games were played at four stated festivals, the greatest being the Olympic, which became a national festival about 776 B.C., and recurred every four years at Olympia in Elis. The importance of the Olympic festival in Greek national life may be judged from the fact that time came to be reckoned in Olympiads. The Pythian games were celebrated in the third year of each Olympiad, the Nemean games in the second and fourth years of each Olympiad, and the Isthmian games in the first and third years of each Olympiad. All were held in honor of some god. In Homeric times the events in athletic games were chariot racing, boxing, wrestling, foot racing and javelin throwing. The Olympic contests, which came later, were probably confined at first to foot racing; to this other events were gradually added until the pentathlon came into existence, about the 18th Olympiad, and boxing and chariot racing were added in the 23d Olympiad. The pentathlon consisted of leaping, spear throwing, discus pitching, running and wrestling. It thus called for «all-over» work, thereby preventing inharmonious development by over-specialization. A competing athlete was obliged to enter for all five contests and was considered a victor only upon winning at least three of the five events. The best modern athletic games embody these principles in what are called group contests. For instance, in the pentathlon of the Young Men's Christian Association, the 100-yard dash is equivalent to the Greek foot race; throwing the 12-pound hammer is equivalent to discus throwing, the running high jump to leaping; pole vaulting for height is a substitute for hurling the spear, and the one-mile run for wrestling. The prizes for the Greek games had no intrinsic value and were merely symbols of honor, as wreaths or palm branches. The prestige and indirect advantages accruing to a victor, however, became in time so great that contestants spent all of their time training for the games. The entrance of this professional and commercial spirit led to the decadence of the games. A similar degeneration occurred much more quickly in Rome. In these latter days we have had the dramatic spectacle of the revival of the Greek games as international contests, the first of these occurring in Athens in 1896. The countries represented by the contestants in these international games included: Germany, England, Austria, France, Italy, Switzerland, Sweden, Hungary, Denmark, Greece, Australia, and the United States.

No mention of the Greek games would be adequate that did not include the balanced relation which they held to the intellectual, artistic and ethical interests of the time. The contestants were examples of balanced culture, and the festivals drew together the greatest poets, philosophers, orators, and artists whose achievements were there displayed. The tournaments or jousting bouts of the age of chivalry may be cited as a further example of athletic contests of great popularity in which the concern for physical prowess was blended with higher interests. It is notable that the modern organizations which have made physical training most popular, the German Turnverein, the Young Men's Christian Association, and the colleges, also combine these varied elements.

Ranking higher as games than individual contests, because more complicated in their organization and demands, are team games in which opposing groups contest, each as a unit against the other. Each player on such a team has his assigned part or duties, differing from many of the others, but as an individual he is subordinate to the interests of his team. Games of this class are an expression of the fighting instinct, and undoubtedly are a development from the simpler fighting games played by young boys, such as stealing sticks (Scots and English), and prisoner's base, which in turn are supposed to have originated in border warfare. Between these simpler games and the highly developed team games there exists the same differences of organization as between primitive and modern warfare. The former was merely a series of individual combats, the parts enacted by the various contestants being homogeneous, and, the fight once on, very largely a matter of individual initiative. In modern warfare there is greater differentiation of duties, and the individual is subordinated to the organized whole. The team games most popular in the United States are baseball, football, basket ball, cricket, and hockey. Baseball has been called the national game of the United States, as cricket and Rugby football are distinctive of England, golf of Scotland and hand ball of Ireland. Basket ball bears the unique distinction of being the only game of wide and enduring popularity which was deliberately invented. Dr. James Naismith devised the game about 1892, as a result of studying the principles involved in successful games. Though invented for and played by men, it is the only team game that has become popular with women. Competitive adult games largely in vogue, which depend upon skill, rather than upon a combination of skill and organization, are tennis, golf and croquet.

The anthropological tenet, that in his development the child passes through the stages which the race has gone through before him, finds strong confirmation in children's plays and games. "The work of adults in one age of human history becomes the play of children in another." While the play of civilized children, as of savage, shows imitations of current adult activities, nearly all of the games of civilized children would seem to take their players through the primitive culture epochs. Just what this, or the lack of it, may mean for individual development we cannot say; but it may be inferred from the direct training of power which games provide. The value of this training assumes a clearer position in the light of one of the fundamental concepts underlying the science of education, that of the meaning of the long period of human childhood. Prof. John Fiske pointed out in his 'Outlines of Cosmic Philosophy,' and President Nicholas Murray Butler elaborated in 'The Meaning of Education' the significance of the long interval between birth and maturity in the human species as compared with animals. This significance lies in the importance of adaptation to environment as an element of survival. The animal that lives in a comparatively simple environment, and for which reflex actions are sufficient to maintain life, as the chicken that pecks for food, has but a brief period between birth and maturity. The more complicated environment of the human species, intellectual, industrial, sociological, aesthetic, ethical and spiritual, in which intelligence takes the place of reflex action, calls for a much longer period for adaptation.

The function of education is to assist in this adaptation, and it needs not to be said in an age of the kindergarten that play is one of nature's great means of education, and therefore of adaptation. "Animals play," says Karl Groos, "not because they are young: rather they have a period of youth because they need to play." And the same may be said of children. Physically, mentally, morally, socially, play develops the child, and in that development games have an important and often a unique part. All of the games here passed in review give expression to simple instincts which are basic to strong and effective character and therefore help to develop those instincts. Prof. William James says, "All simple, active games are attempts to gain the excitement yielded by certain primitive instincts, though feigning that the occasions for their exercise are there. They involve imitation, hunting, fighting, rivalry, and acquisitiveness, combined in various ways."

Physical development would obviously result from playing active games. Especially in all running games are strength and endurance of heart, lungs, and related organs cultivated. Neuro-muscular development becomes apparent in agility and skill, from the stumbling child who learns to dodge quickly and skilfully to the expert ball player. Sense organs become more acute. Various powers of the mind are likewise developed and strengthened by the demands made upon them. Sense perceptions gain in rapidity and accuracy, so that a player sees or hears more quickly that which comes in his direction or takes place around him; feels more quickly the touch upon the shoulder that makes him "it." Reactions become quicker and more exact, whether they be the simple reactions of ball catching, or the complicated ones involving reason and judgment, as when one grasps the shifting conditions of a rapid game with many players, and with swift decision adapts his own movements to them. For socionomic training games have peculiar potency; they develop power of co-operation; the sense of, and ability for, social relations, for taking a part in a social whole. Selfishness gives way to generous recognition of ability, and acknowledgment of superior ability, in others; and, highest of all, self is subordinated to the interests of a group. This self-subordination is a distinctive feature of team games, and perhaps does more than anything else to give them high rank in the hierarchy of games. It frequently happens in such games that a player must lose an opportunity to make a brilliant display of his own powers for the sake of a larger advantage to his team. True team play of this character does not appear until adolescence, the games common to an earlier age calling for individual play, or the competitive element, or the homogeneous social characteristics of the folk games. The training of the will is another strong educational feature of games. The timid, hesitating child, who at first shrinks from exposed positions or an aggressive part, gains courage and self-reliance; defeat becomes, instead of a discouragement to all effort, a spur to greater; and the inhibitive control required to obey rules and regulations, especially under strong excitement, touches another of the well springs of character. So, from the first, clumsy, timid efforts of the little child, to the skilful team work of the college athlete, at once aggressive and self-controlled, games afford a means of development and training for body, mind and character. Were any of these results objects of conscious endeavor on the part of the players, the recreative element of games would be lost. But their unique power lies in the fact of this recreation — this objective interest which holds the attention involuntarily and renders the training incidental, unconscious and natural. Because of this psychological distinction, the expression "gymnastic games," which is frequently heard, is a contradiction in terms and a misnomer. A mistake also is an occasional tendency to discard gymnastic exercise in favor of games, and *vice versa.* While each is an important part of physical training, psychologically and physically there are essential differences between the two forms of exercise. Gymnastics are taken for the purpose of bodily development, and the mind is continually in the unnatural attitude of consciously directing the automatic processes of muscular co-ordination; games are played for the frolic or the victory, without subjective or utilitarian end. This psychological difference is exactly that between work and play. Physically, gymnastic exercise may be more closely adapted to individual powers and needs than the exercise of games; it can afford more vigorous exercise in a brief time to large numbers in limited space; and it is corrective of posture — of faulty neuro-muscular habits. Games, on the other hand, offer a more natural form of exercise, have a larger emotional content, and in their social and psychological training are not approached by gymnastics.

The recreative element in games, the sheer fun and frolic spirit, and the engrossing interest that springs from primitive instincts, cannot be too highly valued as a relief from the pressure which modern civilization brings to bear upon both children and adults. Especially under city conditions should this be fostered. The paucity of childish play and normal youthful sport in cities, owing to lack of space, is not only pitiable, but tragic in view of all that it may mean for the healthful, balanced development and life of the individual. The growth of indoor games as basket ball and indoor baseball, is admirable because making a virtue of necessity; but the movement to provide playgrounds is still better, for gangs of youthful criminals and depredators are found to melt away before them, and the play and games which they foster belong by inherent right to the open sky and the free air. See Baseball; Basket Ball; Foot-ball; Folklore; Hockey, Etc.

Jessie H. Bancroft,
Director Physical Training, Public Schools, Brooklyn, N. Y.

Gammer Gurton's Needle, a drama by John Still, supposed to have been the first play acted at an English university, is also one of the two or three earliest comedies in our language. In 1575, nine years after it was staged at Christ's College, Cambridge, it made its appearance in print. The plot is very simple. Broad jokes, extravagant language, and situations depending for their fun on the discomfiture of one or another of the actors, gave this play great popularity in its day. Readers of the present time who penetrate behind its quaint and uncouth language will find in it an interesting picture of 16th-century village life.

Gamp, Mrs. **Sairey,** in Dickens' 'Martin Chuzzlewit' (1843–4), a stout and elderly professional nurse with a watery eye and a fondness for spirits. She is loquacious and confidential, and continually refers to the opinions of a fabulous being, "my friend Mrs. Harris." Her amorphous umbrella has furnished the name "gamp" for that type of impedimenta.

Gamtoos (gäm'tōs) **River,** Cape Colony, South Africa, which rises in the plateau of Great Karoo and empties into the Indian Ocean.

Gam'ut (Italian, *gamma;* French, *gamme*), the name given in the system of Guido d'Arezzo to the entire series of musical tones in the natural order of ascent or descent. The musicians of the 11th century made use, to distinguish a succession of tones of several octaves, of the following scale: *A, B, C, D, E, F, G, a, b, c, d, f, g, aa, bb, cc,* etc. *A* represented the lowest note in their instruments; a lower note having been introduced the Greek gamma (Γ) was taken to represent it in order not to repeat any of the previous signs. The gamma being thus the first note of the scale, its name was taken to represent the whole. The *ut* is the first word of a Latin hymn formerly used in singing the scale.

Gananoque, gä-nä-nōk', Ontario, Can., a port of entry of Leeds County, 18 miles northeast of Kingston, on the St. Lawrence River, at the point where it flows from Lake Ontario. It is opposite the Thousand Islands, and has long been popular as a summer resort. It has a fine insular public park, and manufactures machinery and farming implements. Pop. (1901) 3,526.

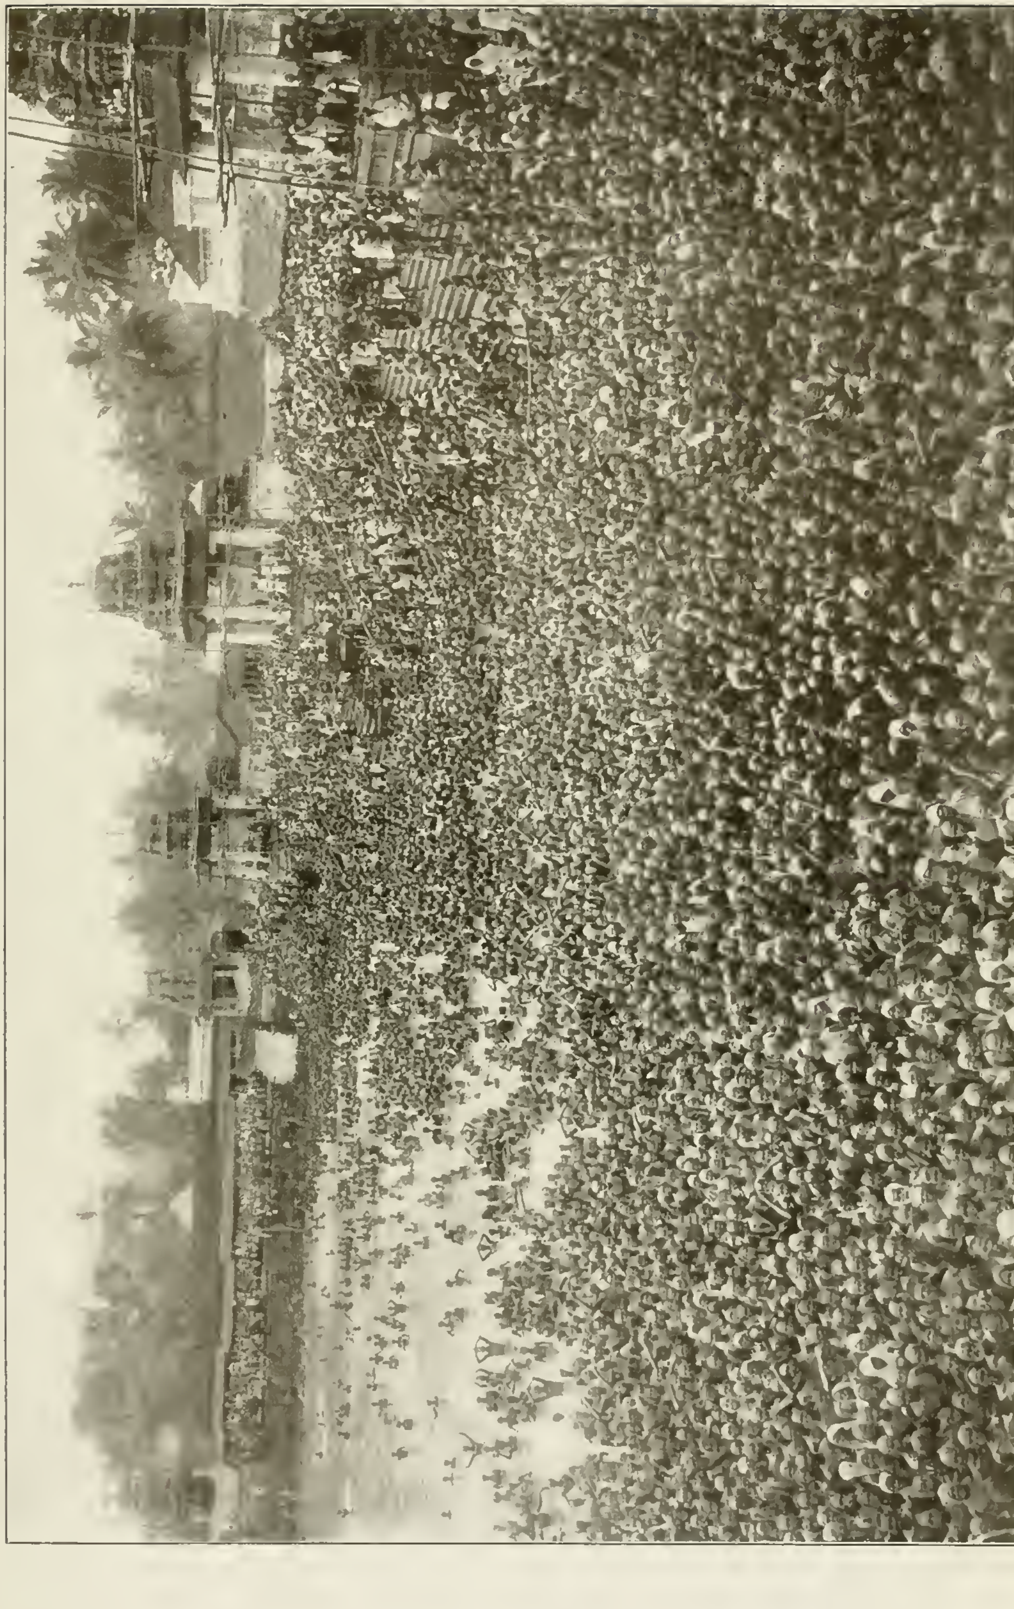
Gándara, gän'dä-rä, Philippines, a pueblo of the island of Samar, situated in the western part of the island on the left bank of the Bachao Bañgahón River. In 1900 it was almost entirely destroyed during an engagement with insurgents; before that it had a large trade. A United States military station and depot for stores is situated eight miles by river from Gándara. Pop. 15,600.

Gando, gän'dō, Africa, a kingdom of the western Sudan, intersected by the Niger, and inhabited chiefly by Fellatahs, with a capital of the same name. It is a most fertile district, the rain being plentiful. Mohammedanism is the prevalent religion. Gando is now comprised partly in British and partly in French territory. Pop. estimated at 5,000,000.

Ganges, gän'jēz, one of the greatest rivers of Asia, and "the sacred river of the Hindus," rises in the Himalaya Mountains, in the province of Garhwal, northern India. It is formed by the junction of two head streams, respectively called the Bhagirathi and the Alaknanda, which unite at Deoprayag, 10 miles below Srinagar, 1,500 feet above the level of the sea. The Bhagirathi which flows from an ice cave in a snow field, 13,800 feet above sea-level, is usually considered the source of the Ganges from its being a sacred stream in Hindu mythology; but the material claims of the Alaknanda are preferable, as it flows farther and brings a larger volume of water to the junction. At Hardwar, about 30 miles below the junction of the head streams, and about 120 miles north-northeast of Delhi, the river is only 1,000 feet above sea-level. Here it enters the great valley-plain of Hindustan, and flows in a southeast by south direction until it discharges itself by numerous mouths into the Bay of Bengal, a distance exclusive of windings of fully 1,100 miles. Its length, with deviations, is calculated at about 1,500 miles. During its course it is joined by a number of large rivers, the principal of which are the Jumna and Son, joining on the right bank; the Ramganga, Gumti, Gogra, Gandak, and Kusi, on the left bank. Some of the principal cities on the Ganges and its branches, descending the stream, are Cawnpore, Allahabad, Benares, Patna, Behar, Murshidabad, and Calcutta. The Ganges is navigable for boats of large size nearly 1,300 miles from its mouths. It is a great feeder of irrigation and navigation canals. (See GANGES CANAL.) Its utmost breadth is about three miles, with a maximum depth of about 30 feet in the dry season, and 60 feet in the wet. Its descent is computed at four inches per mile; its current in the dry season is less than three miles an hour; in the wet season five or six. The quantity of water discharged into the ocean is estimated at 500,000 cubic feet per second during the flood season, and 100,000 during the remaining eight months of the year. Its current brings down a great quantity of mud, which in the course of ages has contributed to form the wide delta which belongs to it in common with the Brahmaputra. The delta, intersected by numerous branches, extends from east to west from 80 to 200 miles, and commences about 200 miles, or 300 by the course of the river, from the sea. A part of it is an uninhabited region called the Sundarbans, overgrown by jungle, infested with tigers and crocodiles. The westernmost deltaic branch of the Ganges called the Hugli, is the only branch commonly navigated by ships; and vessels drawing 26 feet are safely piloted up to Calcutta; the construction of embankments, and continuous dredging, are necessary to keep a clear channel. The Ganges, as the Padna, continues eastward until it joins the Jamuna, the main branch of the Brahmaputra, which flows through the estuary of the Megna, the deltaic boundary on the east, into the Bay of Bengal. The periodical inundation of the Ganges commences about the end of April with the tropical rains. It rises gradually till it attains, near the commencement of the delta, a height of 32 feet above its ordinary level. By the end of July, the flat country of Bengal is overflowed to the extent of 100 miles in breadth, leaving visible little but tops of trees and villages, which are often built on artificial mounds above flood mark. After the middle of August the water begins to recede, and decreases till the period of the next inundation.

That part of the Ganges which lies between Gangotri, the first temple and pilgrim resort on its banks, 10 miles from its source, and Saugor Island, below Calcutta, is held particularly sacred. Wherever the river runs from south to north contrary to its usual direction, and at the junction of its affluents, it acquires a more peculiar sanctity. Its junction with the Jumna at Allahabad (q.v.) forms the most venerated place of Hindu ablution. The Hindus believe that this river rises immediately from the feet of Brahma, and that it possesses great and miraculous cleansing powers on account of its divine origin. There is a scientific basis for this universal faith among Hindus, repeated and careful experiments showing that the river possesses extraordinary but hitherto inexplicable antiseptic qualities.

It is an imperative duty of the Hindus to bathe in the Ganges, or at least to wash themselves with its waters, and to distribute alms, on certain days. Whoever dies on its banks, and drinks of its waters before his death, is thought to be exempted from the necessity of returning into this world and commencing a new life. Whenever, therefore, a sick person has been given over by the physicians, his relations hasten to carry him to the bank of the Ganges, in order that he may drink of the holy water, or be immersed in the river. Such as live too far from the river to admit of this, always preserve some of the precious water, as a sacred treasure, in a copper vessel, that it may be given them in the hour of death. This water is, therefore, a considerable article of commerce in India. It is also customary, after the dead have been burned, to preserve the remains of the bones and the ashes until an opportunity offers of throwing them into the Ganges.



BATHING IN THE GANGES

The name Ganges is derived from *gam*, a Hindu verb signifying "to go." In Hindu mythology the river is personified as the goddess Gangā.

Ganges Canal, The, in India, an important irrigation work and navigable channel, the older portion called the Upper Ganges canal, opened in 1854, and extending, on the right of the Ganges (q.v.) from Hardwar to Cawnpore and Etawah, with a main canal 440 miles long, navigable throughout; and with 2,634 miles of distributaries. The Cawnpore and Etawah terminal lines are now absorbed in the Lower Ganges canal, commenced in 1873, and which continues in its main branch for 260 miles to Allahabad, drawing its supply from the river at Narora, in the Aligarh district. The weir and headworks at Narora include a solid wall, 3,800 feet long, with 42 weir sluices, founded on huge square blocks.

Gan′glion, connective tissue membranes enclosing small amounts of clear synovial fluids. They are usually found where tendons or muscles glide over bony parts, or where the skin, muscles, or fascia are subjected to pressure or to friction. The number, size, and location of these structures are subject to much individual variation. One of the commonest is found on the back of the hand, at the wrist, particularly in people who stretch their fingers widely, as piano players, or as librarians who handle many books, grasping several at a time. In this form is a firm and painless swelling, liable to be caused by any excessive exercise of the wrist, as in playing tennis, golf, etc. This swelling gives the impression that there is fluid beneath the skin, and grandmother's advice to break it with the family Bible or the dictionary is often followed, sometimes with serious results. This forceful method of reduction is foolish, as most of the swellings disappear with rest and the application of heat. If they persist, a surgeon should be consulted. Another very persistent variety of this trouble is found in the knee — causing housemaid's knee, or miner's knee. Obviously the breaking of these tumors by force is out of the question. There are many places in the body in which similar collections of fluid may accumulate, but these rarely cause much inconvenience unless they become infected through some knock or cut. In this event prompt surgical treatment is advisable, and aseptic surgery should be insisted on. A careless and unclean surgeon may render a limb useless.

Gangotri, gän-gō′trē, a square temple, about 20 feet high, erected on the right bank of the Ganges (q.v.), which here forms a small bay, about 10,319 feet above the level of the sea. This spot is regarded by pilgrims as the source of the holy stream, here called the Bhagirathi, which, however, rises 8 miles higher up. The water here is peculiarly sacred, but few pilgrims come so far, and the only dwelling-house in the locality is occupied by the officiating Brahmins, by whom flasks of the holy element are sealed for conveyance to the plains.

Gangrene, găn′grēn, the term applied to death of soft tissue in masses large enough to be seen. There are two forms, differing in causation, appearance, and progress. Dry or senile gangrene results from the gradual occlusion of arteries, the venous return being unimpaired. For weeks or months the toes and feet, the parts most frequently affected, may feel cold or numb, or be actually painful, then gradually the skin becomes dry, then purple and black. The spread is usually very slow. It is particularly a disease of old age, due to the tendency at that period of life toward thickening and stiffening of the arterial walls.

Moist gangrene results from sudden stoppage of the arteries, obstruction of veins, mechanical destruction of the tissues, or from specific infection by germs. This form shows a soft, boggy, bluish mass covered with blisters and emitting the odor of putrefaction. In both forms of gangrene there may be a zone of inflammation between the dead and the living tissue, called the line of demarcation.

Hospital gangrene was formerly very prevalent in military hospitals; a wound becoming infected would quickly change to a gray slough, which in a few hours might involve the entire limb unless prompt removal of the tissue was undertaken. Aseptic surgery has made this fatal disease a thing of the past.

Spreading gangrene is due to infection by a specific germ, the bacillus of malignant œdema, so called from the fact that it generates a gas that puffs up the tissue affected. The spread is rapid, and life is sometimes saved by amputation far above the wound. The treatment of gangrene is usually a matter of amputation, well beyond the affected part. Careful aseptic dressing is imperative, particularly where the condition of the patient is apt to contra-indicate radical cure.

Gangue, găng (Ger. *Gang*, a vein), the matrix or veinstone of ores. These are always included in some stony matter, which forms the principal portion of the veins or beds which are worked for the sake of their metalliferous contents. Quartz is the most common veinstone, and has been called the mother of ores. Calcareous spar is also a frequent predominant material of veins. Sulphate of barytes or heavy spar, and fluor spar, are also often found as gangues.

Gan′ister, a name originally given in England to a particular clay high in silica, used in the manufacture of fire-brick. In this country the term is used more loosely and includes non-plastic rocks that are not clays at all but approach sandstones in character. Ganister may, therefore, be defined as highly silicious material used in the manufacture of fire-brick, more particularly what are known as silica-brick, for lining blast-furnaces, Bessemer converters, etc. The manufacture of such brick is an important industry in Western Pennsylvania. See Clay.

Gannal, gä-näl, **Jean Nicolas**, French chemist: b. Saarlouis, Prussia, 28 July 1791; d. Paris January 1852. He is noted for his invention of the method of embalming by injection.

Gannets, large sea-birds constituting the family *Sulidæ*, of the order *Steganopodes*, characterized by having all the toes connected by webs, the absence of external nostrils and a very short tongue. They are closely related to the pelicans and cormorants, have large powerful bills and feed upon fish, frequenting the sea-coasts of various parts of the world. The common gannet

(*Sula bassana*), to which the name properly refers, is restricted in the breeding season to a few rocky islets on the coast of the British Isles and Iceland — notably the St. Kilda group, and to Bird Rock in the Gulf of St. Lawrence; and their numbers have been much diminished by the fishermen who gather their eggs for food. They nest in colonies among the crevices and ledges of the rocks, and each bird lays a single large chalky white egg. When the young are on the wing they all leave together and scatter widely in search of food, extending their range on our coasts as far as the Gulf of Mexico. In the southern hemisphere are two closely related gannets. *S. serrator* of Australia and *S. capensis* of South Africa. Eight other somewhat smaller species, called «boobies» (q.v.), breed on various tropical islands. The common gannet is pure white with black outer wing-feathers and a buffy suffusion on the head. The young are mottled grayish brown. The other species are similar, many of them with red and blue coloring on the bare skin of the throat and around the eye.

Gan'nett, Ezra Stiles, American Unitarian clergyman: b. Cambridge, Mass., 4 May 1801; d. near Boston 25 June 1871. He was graduated from Harvard in 1820, in 1824 became assistant to W. E. Channing at the Federal Street Church, Boston, and later succeeded to the pastorate. In the Unitarian controversies of 1825–35 he took a prominent though conservative part. He was the first secretary of the American Unitarian Association, its president 1847–51, and president of the Benevolent Fraternity of Churches 1857–62. He was also founder and editor of the 'Scriptural Interpreter,' and an editor of the 'Christian Examiner,' and the 'Monthly Miscellany of Religion and Letters.'

Gannett, Henry, American geographer: b. Bath, Maine, 24 Aug. 1846. He was graduated at the Lawrence Scientific School in 1869; became geographer of the United States Geological Survey in 1882; was geographer of the 10th, 11th, and 12th censuses, and of those taken by the war department in Cuba and Porto Rico in 1899. His publications include: 'Manual of Topographic Surveying'; 'Statistical Atlases 10th and 11th Censuses'; 'Dictionary of Altitudes'; 'Commercial Geography'; etc.

Gannett, William Channing, American Unitarian clergyman: b. Boston, Mass., 1840. He is a son of E. S. Gannett (q.v.). He has held Unitarian pastorates at St. Paul, Minn., and other cities, and has been for some years pastor at Rochester, N. Y. He is the author of: 'A Year of Miracle'; 'Memoir of Ezra Stiles Gannett'; 'The Thought of God in Hymns and Poems' (with F. L. Hosmer).

Ganodonta, a group of primitive mammals regarded as ancestral to the edentates, whose remains are found in the lowest Eocene formations of the western United States. These remains are not numerous nor complete, but plainly exhibit a progressive relationship toward modern Edentata (q.v.). The earliest known is *Hemiganus*, from the Puerco beds of New Mexico, which was as big as a medium-sized dog. A later genus of similar size is *Psittacotherium*; and a still later (Lower and Middle Eocene) is *Stylinodon*. In reviewing the series, says Beddard, we see a gradual diminution of the incisors, a gradual loss of enamel on the teeth generally, and the production of hypsilodont teeth growing from persistent pulps, all of which are features of the later edentates. The progression is gradual, but the forms seem to be a continuous series culminating in the ground-sloths. See PALÆONTOLOGY.

Gan'oid Fishes, an order of fishes founded by Agassiz on the character of the scales of certain fossil fishes, which are bony and lustrous, now regarded as a group-name for a rather heterogeneous series of low and chiefly extinct teleost or «true» fishes. (See ICHTHYOLOGY.) The ganoids were most numerous in Palæozoic and early Mesozoic times, and few and diverse are the surviving forms, which include the paddle-fishes and sturgeons, the gar-pikes, the mud-fishes of African rivers and a few others, all elsewhere described. In this group fall some of the most famous fossil fishes of palæontology, described by Hugh Miller in his 'Old Red Sandstone' and otherwise introduced long ago to the public. The *Pteraspis* and *Cephalaspis* of the Upper Silurian and Lower Old Red Sandstone strata had the head covered with a bony shield, which in form somewhat resembled the carapace of some crustaceans; the body of *Cephalaspis* had bony scales. The berry-bone (*Coccosteus*), the seraphim (*Pterichthys*), and the *Asterolepis* also had a bony shield, the flexible trunk having scales in *Pterichthys*, being naked in *Coccosteus*. The anterior limbs, or pectoral fins, of *Pterichthys* were long, covered with closely fitted plates, and had a complex joint connecting them with the thorax. The garpikes of the American lake region, are the modern representatives of the *Lepidotus*, *Æchmodus*, etc., of Mesozoic strata, and of the Carboniferous *Palæoniscus*. *Polypterus*, the type of this group, is confined to the Nile, and a few other African rivers. The group is most abundant in the Palæozoic strata, *Dipterus*, *Osteolepis*, *Holoptychius*, *Phaneropleuron*, being Old Red Sandstone genera; *Rhizodus*, *Megalichthys* with rhomboidal scales, *Strepsodus* with cycloid scales, Carboniferous. The cœlacanths range from the Carboniferous to the Chalk formations, and are the only members of the order in which the tail is homocercal.

Gansevoort, găns'voort, **Peter**, American officer: b. Albany 17 July 1749; d. 2 July 1812. In 1775 he joined the army which under Montgomery invaded Canada, and in 1776 he was appointed to the command of Fort George. In 1777 he was placed in command of Fort Stanwix, which he gallantly defended against a vigorous siege of 20 days by British and Indians under St. Leger, and received the thanks of Congress for having thereby prevented the co-operation of that general with Burgoyne, and contributed to the defeat of the latter. In 1781 the State of New York raised him to the rank of brigadier-general, which he held till the termination of the war. He afterward filled various important offices under the Federal government. He was successively commissioner of Indian affairs, commissioner for fortifying the frontiers, and military agent. In 1809 he was appointed brigadier-general in the United States army.

Gan'ymede (Gk. Γανυμήδης; Lat. *Ganymedes*), in Greek mythology the son of Tros and of Callirrhoë, a daughter of the Scamander. Zeus sent his eagle from heaven, which carried him off from Mount Ida to the seat of the gods, where he discharged the office of cupbearer to the immortals, Hebe having rendered herself unworthy of this office. This fiction has afforded, both to poets and artists, an inexhaustible supply of subjects. Numerous paintings, statues, cameos, and intaglios, masterpieces of ancient art, have descended to us, upon which this youth, scarcely past the years of boyhood, is represented as of great beauty. The representations of Ganymede are to be recognized by the Phrygian cap and the eagle, which is either standing beside him or carrying him in its talons to Olympus.

Gapán, gä-pän', Philippines, a pueblo of the province of Nueva Ecija, Luzon, situated four miles east of San Isidro, the capital. It is at the junction of several roads, and is the largest town in the province. Pop. 20,200.

Gaper, ga'- or gā'per, a name given to many animals who have great mouths, or in some other way suggest gaping. Thus it is one of the British names for the European soft clam (*Mya truncata*) in reference to the wide separation of the shells, as is characteristic of deeply burrowing bivalves; and it is applied to relatives on the Pacific coast of the United States. Among birds, the broadmouths (q.v.) are called gapers; and among fishes some of the sea-bass, which open their mouths in dying to the widest extent.

Gapes, a disease of young poultry, caused by a parasitic nematode worm in the throat. See Poultry, Diseases of.

Gar, Garfish, or **Gar-pike**, one of two sorts of fish, both long and slender, with a prolonged spear-like snout filled with teeth, and hence bearing such local names as «bill-fish,» «needle-fish,» «bony-pike,» etc.; and «greenbone,» because of the greenish tinge on the bones. The group originally called «gar» was that of the family *Belonidæ* (or *Esocidæ*), allied to the sauries and flying-fish, the type of which is the common European *Belone belone*. This is a swift, voracious fish which darts along the surface picking up little fishes, and especially playing havoc in shoals of young mackerel. It is usually about two feet in length, is often brought to the London market, and forms a wholesome dish, in flavor somewhat like mackerel. The young forms have at first jaws of a normal size, but in growth the lower outstrips the upper. Very similar, but larger, are the «silver» gars, «agujas,» or «needle-fish» of American tropical waters, which offer good sport by their speed and strength, but are hated by practical fishermen whose nets they frequently destroy or damage by their effort to get at imprisoned prey. There are several species, all of the genus *Tylosurus*.

Both these kinds, as well as their Oriental representatives, are often called «gar-pikes» from their pike-like form and voracity; but in the United States this term is suitably reserved for a very different kind of gar, not known in the Old World, and a relic of the ganoid tribe prevalent in the palæozoic seas. This gar-pike represents the family *Lepidosteidæ* (see Ichthyology), and has a long almost cylindrical body encased in an armor of white, bony, enameled rhomboid plates, which are imbricated in oblique rows running downward and backward. The jaws are long, narrow, and furnished with sharp teeth, each of which fits into a depression in the opposite jaw; and are covered with a granulated shagreen-like integument. They have the air-bladder subdivided and used in respiration; no spiracle; strong fins; a heterocercal tail; swim well, and prey upon small fishes. Their own flesh is not edible and they interfere with fishing, and therefore are destroyed freely. They inhabit the rivers and lakes of North America, where the commonest species is the long-nosed gar (*Lepidosteus osseus*). Another, more southerly, is the short-nosed gar (*L. platystomus*); and a great and powerful subtropical species (*L. tristœchus*), reaching 8 or 10 feet in length, and called «manjuari» in the West Indies, is known as «alligator-gar» in the lower Mississippi district. Another species occurs on the west coast of Central America; and another in the rivers of China.

All these gar-pikes frequent shallow, reedy, or grassy places, basking in the sun like the pike, and devouring living prey with great voracity. The manner of seizing prey differs from that usually observed in fishes, and resembles that of reptiles; instead of taking their food at once with open mouth and swallowing it immediately, they approach it slily and sideways, and then, suddenly seizing the fish or other animal, hold it until by a series of movements it is placed in a proper position for being swallowed, in the manner of alligators and lizards; the ball of food is also seen to distend the body as it passes downward, as in snakes.

Gar-pike. See Gar.

Garabit, gä-rä-bē, France, in the department of Lozère, is a picturesque locality on the railway from Marvejols to Neussargues, where the line spans a gorge of the Truyère River, about 10 miles south of Saint Flour. The viaduct planned by M. Eiffel is 1,852½ feet long, and is built partly of girders and partly of masonry. Where it crosses the river at a height of 401 feet, it is supported by an arch, with a span of 541 feet 4 inches. Consult: Eiffel, 'Le Viaduc de Garabit' (1889).

Garancine, găr'an-sĭn, is prepared from the ground root of *Rubia tinctorum* or madder (in French *garance*) by washing it with 8 or 10 times its weight of water acidulated with sulphuric acid, 1 part of acid being used for 100 parts of powder. After digesting for 7 or 8 hours the fluid is run off, and the paste is boiled for 2 or 3 hours by steam with more acid, and then the mass is thrown into cold water contained in a large trough with a perforated bottom covered with cloth to act as a filter. Here it is washed till all the acid is got rid of, and the paste is afterward pressed, dried, and ground to fine powder. It is used for dyeing, and has the advantage over madder (q.v.) of containing a large proportion of coloring matter. It is preferable to madder for mixing with other dyestuffs to produce chocolate and some other shades.

Garay, Juan de, hoo-än' dā gä-rī', Spanish soldier: b. Badajoz 1541; d. South America 1584. About 1565 he went to South America, where he became secretary to the governor of Paraguay, was sent on a voyage up the Paraná, discovered a vast territory, and founded near the river the town of Santa Fé de Vera Cruz. He defeated the Charruas Indians not far from the Uruguay, received the commission of lieutenant-general, and was appointed (1576) governor of Asuncion. In 1580 he re-founded the city of Buenos Ayres on its previous site, and subsequently did much to improve the condition of neighboring native tribes. Having landed in an unfamiliar region on a journey up the Paraná to Asuncion, he was there killed by hostiles.

Garbage is kitchen refuse and table waste, offal, or discarded material from the preparation and use of human food. Assembled, it is an ever-varying mixture of animal and vegetable food waste, the nitrogenous or proteids being largely in excess of the non-nitrogenous properties. Garbage decomposes rapidly in the open air and becomes offensive, especially in warm weather. When thrown upon the ground and allowed to decompose, or when used as a fertilizer in a raw state, it may contaminate sources of water supply, and thus become a menace to public health. In country districts and in most towns and small cities it is used as food for domestic animals, and when fresh no more proper disposition of it can be made. When the material is allowed to become partially decomposed before feeding, and where caustic solutions are used for the cleansing of cooking utensils, etc., the mortality caused thereby, particularly among hogs, is so serious as to preclude its use. American cities produce from one half pound to one pound per day for each person. European cities produce less than one half of this amount for each person. Analysis of American city garbage shows moisture 70 per cent to 80 per cent; grease, 2 per cent to 3 per cent; and solids, principally wood fibre, 18 per cent to 28 per cent. Garbage from European cities contains more of solids and less of moisture and grease.

Compared with the garbage of New York city, British garbage contains about 25 per cent and German about 50 per cent less water. Practically, France has no garbage.

No other problem so far encountered has so troubled city officials and boards of health as the disposal of garbage. The thoughtless citizen throws it in the street, or leaves it in his back yard until his neighbors rebel, or he burns it in his range or furnace and has more trouble with his neighbors. He puts it with ashes and other refuse and it is dumped on a vacant lot, or a depression in the ground is filled with it, and injunction proceedings are brought by near-by residents; protests and complaints of every description are made to councilmen, heads of departments, and boards of health. Newspapers take it up, and everyone who can possibly be held accountable is abused. The first attempts at collection and disposal are crude and imperfect. All kinds of household wastes are put together in boxes or barrels and teams are hired to cart it away. In some cases the city owns the horses and wagons required for the work. This lasts until there is no longer a dumping place within hauling distance. In a few instances it has been taken to sea in scows and dumped in deep water. This is found objectionable, as the lighter portions float to shore. Total destruction of the material is the next resort. Inventors and promoters take advantage of the situation, and it is proposed to burn or utilize the material at huge profit. Corporations are formed, stock is sold, and plants are built for final disposal. Then there are indignation meetings and injunction proceedings. No one wants a garbage-disposal plant near his property. Should it be completed and started, it is generally closed within a year, either by injunction or owing to the lack of funds for its operation. The country is strewn with such wrecks. From one to a half dozen can be found in almost every city. Many are so utterly worthless in practice as to approach very nearly to the ridiculous. Others are admirable in design and construction, but fail on account of insufficient returns or excessive cost of operation. Much has been learned, however, through these failures.

It has been found that when garbage is mixed with ashes, paper, and other household waste, final disposal is rendered very difficult, the mass being unfit for filling, fuel, or fertilizer. Leading American cities separate household waste into three parts, namely, "food waste," "combustible waste," and "non-combustible waste." By this means final disposal is more readily effected, each class of waste having properties of commercial value when kept separate from the others. Most European cities do not attempt a separation, excepting it be at the plant where final disposal is effected. In some cases the whole mass is passed through what are termed "destructors," burning the unconsumed carbon found in the ashes, and the combustible portions of other household waste. This system of final disposal has not been found satisfactory in American cities, and has been equally unsatisfactory in some European cities, particularly on the Continent, where, as in America, it is found that much additional fuel is required in order to maintain a proper temperature in the furnaces. Many of them have, therefore, been abandoned altogether, and attention has been turned to some form of utilization as being more reliable and less expensive.

Engineers have struggled manfully with the problem, and have been ably seconded by men of means and energy. It would scarcely be possible to name in this connection all those who have contributed to the development of principles, systems, and apparatus which go far toward the practical solution of this difficult problem. Much impetus was given to effective practical development of the principle of utilization by the determined efforts of the late Col. Geo. E. Waring, New York's indomitable commissioner of streets. After a most exhaustive investigation of the whole subject, and a thorough inspection and test of every system of disposal then in existence, both in Europe and America, Col. Waring became thoroughly convinced that utilization was right in principle and practice, and proceeded at once to have the garbage of the city of New York disposed of in this manner.

Prior to this time there were successful utilization plants in Philadelphia, Pa., St. Louis, Mo., and Detroit, Mich. The system adopted by Col. Waring, and which is now in use in many of the principal cities of the United States, is first, thorough sterilization by subjecting the material to the action of live steam in enclosed vessels, condensing all vapors and passing insoluble gas through flame. By this treatment the structure of the material is broken down,— even bones are disintegrated,— the liquids carrying the oils and greases being separated from the solids by mechanical means. The further preparation of the ingredients, by which they are put in commercial form or finally disposed of, varies greatly in the different plants. In some cases the liquids are evaporated, in others they are allowed to run into sewers or water courses. In a number of the plants the solid portions are used for fuel; in others they are acidulated or dried and prepared as a base for commercial fertilizers. The greases are sometimes extracted by the use of a solvent, and reclaimed by evaporation, the solvent vapors being condensed and also reclaimed to be used again. The principles involved are not new, having been applied for many years to the treatment of slaughter-house waste. In its application, however, to the greater subject of garbage disposal, much new apparatus has been invented, and the plants have been equipped to handle very promptly a vast amount of the material; the plant which disposes of the entire garbage of the Greater New York having a daily capacity of more than 2,000 tons, and the plants located in Philadelphia, Pa., Boston, Mass., Newark, N. J., Baltimore, Md., Washington, D. C., Detroit, Mich., St. Louis, Mo., Cleveland, O., and in some of the smaller cities, are of sufficient capacity to dispose of all the garbage produced in the respective cities within 12 hours of delivery at the plant. It is this prompt and effective disposal that has rendered the utilization systems so popular in the large American cities. The entire work of collection and disposal is, in most cases, done by contract. The plants are owned by contractors, the cities in some cases collecting the garbage and delivering it upon the contractors' cars or boats for transportation to the place of final disposal. The contractors have expended vast amounts of money in perfecting the systems, and certain features, processes, etc., are kept secret. As they are private enterprises, no statement can be made as to returns from the sale of the products, but it is known that reasonable dividends are paid, and that the contracting companies are in a sound condition financially, while the citizen who notes carefully the service rendered is well satisfied with the results.

The state of the art as to final disposal would seem to preclude the utilization systems in cities having a population of less than 50,000, excepting where a combination plant can be used, thus disposing at one plant of all garbage, dead animals, slaughter-house waste, butchers' scrap, etc. Where this cannot be effected, it has been found that burning is the only safe and effectual means of disposal.

Many of the failures, both in incineration and utilization, are due to the improper location of plants. While it should be perfectly clear to everyone that such plants should be so located as to cause the least possible property loss or inconvenience to the people, yet it should be recognized that every city must have a place for final disposal of its waste, and, once properly located, it must be recognized as such. Though plants for final disposal, when properly designed and operated, have not proved a nuisance to near-by residents, nor a menace to public health, yet the assembling at one point of the material is objectionable and should be restricted to a section for such purposes. See Wastes, City, Disposal of.

Much has been written on the subject by both European and American engineers, principally in the form of papers read before some of the engineering societies, and published in engineering journals. Valuable information can be obtained from the files of such journals. Very little of such material, however, has been put in book form. In a small volume published in 1897, entitled, 'Street Cleaning and Its Effects,' by Col. Geo. E. Waring, interesting and valuable data is assembled, a portion of which bears directly on this subject, and in an English publication entitled 'The Economic Disposal of Towns' Refuse,' W. Francis Goodrich gives a very good description of European and American burning methods, with illustrations, plans, and tables well arranged. His data on the subject of utilization is, however, inaccurate and misleading and does not correctly set forth the true state of the art at the present time. A most comprehensive treatise on the subject is 'The Wastes of a Great City' by John McGaw Woodbury, commissioner of street cleaning, New York, in Vol. XXIV., p. 387, 'Scribner's Magazine' (1903).

Charles Edgerton,
President Sanitary Product Company.

Garborg, gär'bôrg, **Anne**, Norwegian novelist: b. island of Time, Jæderen, 25 Jan. 1851. He was educated at Christiania, published anonymously in 1873 his essay, 'Ibsen's "Emperor or Galilean,"' in 1877 founded the 'Fedraheimen,' a liberal journal which he edited until 1882, and in this as well as 'Den syttende Maj,' another periodical, urged the adoption of a national language for Norway. On this subject he wrote also: 'The New Norwegian Language and the National Movement' (1887). His best-known work was done in his stories, originally written in the popular tongue and largely rendered into Swedish and Danish. They are of the realistic vein so common to Scandinavian writers, and include: 'A Freethinker' (serially in 'Fedraheimen' (1878); 'Men' (1886); 'Weary Souls' (1891); 'Fred' (1893).

Garção, Pedro Antonio Correa, pā'drō än-tō'nē-ō kōr-rā'ä gär-sän', Portuguese poet: b. Lisbon 29 April 1724; d. there 10 Nov. 1772. As a lyric poet he stands very high; while his satires, odes, and epistles,— upon the models of Horace,— are dainty and spiritual. He also wrote successful dramas. The Portuguese esteem him for the perfection with which he employed their language in his works. The 'Hymn to Dido' is one of his most popular productions. He was arrested for a personal satire, and died in prison after a long captivity.

Garcia, Diogo, dē-ō'gō gär-sē'ä, Portuguese navigator: b. Lisbon 1471; d. Madrid 1529. In 1526 he sailed with three vessels from Cape Finisterre for South America, in the employ of the company established at La Coruña for the spice trade. He explored the Uruguay (1827), and the Paraná to 27° S., defeated the Indians who had besieged Sebastian Cabot on the latter river, and in 1528 left for Spain. About 1532 he is said to have made a voyage to the East Indies. His account of his Brazilian explorations appeared in Vol. XV. of the 'Revista do instituto histórico é geográfico do Brasil.'

Garcia, gär-thē'ä, **Manuel del Popolo Vicente**, Spanish vocalist and composer: b. Seville, Spain, 22 Jan. 1775; d. Paris 10 June 1832. After acquiring a considerable reputation as a tenor singer in Cadiz and Madrid, in 1808 he obtained great success at the Italian opera in Paris, and afterward proceeded to Italy, where he was received with equal favor. From 1816 to 1824 he was constantly engaged as a singer, either in Paris or London. In 1825, with a select operatic company, composed in part of members of his own family, he crossed the Atlantic and visited New York and Mexico. On the road between Mexico and Vera Cruz he was robbed of all his money; and after his return to Paris was compelled to open a class for singing, as his voice had become greatly impaired by age and fatigue. Many of Garcia's pupils reached a high degree of excellence, but none equaled his eldest daughter Maria, afterward Madame Malibran (q.v.). He was less successful as a composer, though several of his works, such as 'The Caliph of Bagdad,' were much admired.

Garcia, gär-thē'ä, **Manuel**, Spanish professor of singing in England: b. Madrid, Spain, 17 March 1805; d. London, England, 1 July 1906. He was a son of the preceding. He invented the laryngoscope, and published: 'Memoire sur la voix humaine' (1840): 'Traîte de la Chant' (1841) ; 'Hints on Singing'; etc.

Garcia y Iniguez, gär-se' ä ē-nē'gēs, **Calixto**, Cuban patriot: b. Holguin, Cuba, 14 Oct. 1836; d. Washington, D. C., 11 Dec. 1898. In 1868, with Donato del Marmol and Carlos Manuel Cespedes, he organized the revolution known as the "Ten Years' War." In the early part of the struggle he won the battle of Santa Maria and recaptured Jiguani. In recognition of his services Garcia was appointed brigadier-general under Gomez (q.v.), and subsequently succeeded that officer as commander-in-chief of the Cuban army. In 1873 he was captured and carried as a prisoner to Spain. In 1879 he returned to Cuba to start "The Little War," but was again captured and kept in Spain under police surveillance for 15 years. In 1895 he escaped and came to New York, where he fitted out a filibustering expedition, which failed to reach Cuba on account of the wreck of the vessel. Later he was successful in landing in Cuba with arms and supplies. He was given the command of the forces in Camaguey and Oriente, where he held almost complete possession, and in 1898 gave valuable aid to the American forces at the capture of Santiago. At the close of the Spanish-American war he was made chief of the commission to discuss with President McKinley the future of Cuba.

Garcia Moreno, gär-sē'ä mō-rā'nō, **Gabriel**, Ecuadorean politician: b. Guayaquil, Ecuador, 1821; d. Quito 6 Aug. 1875. He was educated at Quito and in Europe, became professor of chemistry in the University of Quito, and in 1857 its rector. In 1859, upon the overthrow of the Roble's government, he was chosen a member of the provisional government, and in 1861 president for a term of four years. He declared himself dictator in 1864, subsequently relinquished the title and office, though he maintained virtual control of affairs, in 1869 led a revolution, and became again dictator, and in 1875 was elected president for a six-years' term. Before his inauguration he was fatally wounded by assassins.

Garcia de Quevedo, gär-sē'ä dā kā-vā'dō, **José Heriberto**, South American author: b. Coro, Venezuela, March 1819; d. Paris June 1871. Educated in France and Spain, he settled in Paris, and was killed in the communard insurrection of 1871. Among his poems are: 'To Columbus'; 'To Liberty'; 'To Pius IX.'; 'Frenzy'; 'The Life to Come'; and 'The Proscript.' His dramas were well received. He wrote the novels 'The Love of a Girl' and 'Two Duels Eighteen Years Apart.'

Garcilaso de la Vega, gär-thē-lä'sō dā lä vā'gä (properly Garcias Laso de la Vega), Spanish poet: b. Toledo 1503; d. Nice 14 Oct. 1536. According to an account given in the 'Historia de las Guerras Civiles,' the Garcilasos received their surname from their combats with Moorish heroes, in the great valley of Granada, called *La Vega*. Garcilaso soon found his proper sphere. His genius was kindled by the study of the ancients, particuarly of the Romans. Boscan had already begun to transplant the versification of the Italians into Spanish poetry. Garcilaso followed his example, and succeeded so well that he is still ranked among the best Spanish poets. Most of the events of his life may be learned from his own works. He lived for a long time in Italy, and afterward traveled through part of Germany, in the service of Charles V. In 1529 he was engaged in the expedition against Soliman, and in 1535 in that against Tunis. In the latter he received a wound in his arm, after which he remained some time in Naples. In 1536 he commanded 30 companies of infantry, and accompanied the imperial army against Marseilles. Spanish poetry is highly indebted to him; for without his aid Boscan, a foreigner, would never have succeeded in his innovations, more particularly as he had a formidable adversary in Christoval de Castillejo. His writings consist of eclogues, epistles, odes, songs, sonnets (in which he imitated Petrarch), and some smaller poems. An edition of his works, with notes, appeared in 1765, and Herrera's commentary (1580), with notes by Azara (1765).

Garcilaso (Garcias Laso) de la Vega, surnamed the Inca, Spanish historian: b. Cuzco, Peru, 1540; d. Spain 1616. He was the son of Garcilaso de la Vega, one of the conquerors of Peru, and Elizabeth Palla, a princess of the race of the incas. His mother taught him the Peruvian language, and is said to have inspired him with the idea of writing the history of his ancestors. His great work on the history of Peru is in two parts: the first bearing the title of 'Historia de las Antiquedades y Conquista de Piru; Primera Parte de los Comentarios Reales que tratan del Origen de los Incas, etc.' (1609); the second being the 'Historia general del Peru' (1616). He wrote also 'Historia de la Florida (1609).

Garcin'ia, so called after Laurent Garcin (d. 1752), a Franco-Oriental traveler, is the botanical name for a genus of guttifers, the typical one of the tribe *Garcinieæ*. It consists of opposite leaved trees, with a yellow resinous juice, and generally unisexual flowers with four sepals, four petals, many stamens in from one to four bundles, and a 2 to 10-celled ovary with a single seed in each cell. The fruit of *G. mangostana* is the highly-prized mangosteen. The fruits of *G. pedunculata, G. cornea,* and *G. kydiana* are also eaten, but are not greatly valued. The *G. kola* of tropical Africa yield fruit and seeds similar in properties to the kola-nut. *G. cambogia* and other species of the genus furnish Gamboge (q.v.).

Garda, gär'dä, or **Benaco, Lake,** the Italian *Lago di Garda,* and the *Benacus Lacus* of the Romans, is an extensive and beautiful lake in north Italy, 33 miles long from north to south, by 3 to 11 miles broad, and 213 feet above sea-level. It forms part of the boundaries of the provinces of Verona, Mantua, and Brescia, while its north extremity enters the Austrian territory of Trent, in the Tyrol. It receives the Sarca, almost its only affluent, at its north end, and is drained by the Mincio, which issues from its southeast end near the fortress of Peschiera, and conveys its waters to the Po. Storms are not infrequent, and are sometimes violent. It is well stocked with excellent fish including salmon-trout, trout, eels, and pike. Garda is the largest lake in Italy, and attains a depth of over 1,000 feet in many places. Its shores are covered with villas and steamboats ply on it regularly between the ports of Riva, Desenzano, and Peschiera, which with Gardone-Riviera, Garda, Malcesine Salo, and the beautiful promontory of Sirmione are its most popular resorts.

Garde Nationale, gärd nä-sē-o-näl, a guard of armed citizens instituted in Paris 13 July 1789 for the purpose of preserving order and protecting liberty. At first it numbered 48,000 men, but was increased to 300,000 when it was organized throughout the whole country. Acting as a royalist and reactionary force, it was crushed by Napoleon in 1795. It was reorganized by the Directory and by Napoleon and again under the Bourbons, to whom, however, it was a source of such disquietude that it was dissolved by a royal ordinance in 1827. Under Louis Philippe it was resuscitated in its old form and contributed to his overthrow. In 1851 the national guard was again reorganized, but in 1855 it was dissolved. In 1870 the national guard of Paris was again formed for the defense of the city against the Prussians. The resistance of a section of the guard to the decree of disarmament issued under M. Thiers led to the communal war, at the close of which the guard was declared dissolved by the National Assembly (1871).

Garden, Alexander, Scottish scientist: b Charleston, S. C., about 1730; d. London 15 April 1791. He was graduated from Aberdeen; became a professor in King's College, New York (now Columbia University), and in 1755 established himself in medical practice at Charleston. From 1783 he was in London, where he became vice-president of the Royal Society. The botanical genus *Gardenia* (q.v.) was named in his honor by Linnæus. He wrote various papers on topics of botany and zoology.

Garden, Alexander, American soldier: b. Charleston, S. C., 4 Dec. 1757; d. there 29 Feb. 1829. He was for a time aide-de-camp to Gen. Greene. He wrote 'Anecdotes of the Revolutionary War in America, with Sketches of Character of Persons the most distinguished in the Southern States for Civil and Military Services' (1st series, Charleston, 1822; followed by a second series), which is one of the authorities for the history of the period, containing information hardly to be found elsewhere.

Garden. The earliest known gardens are those of Solomon which are described as having been of quadrangular form, surrounded by high walls. They contained aviaries, wells, and streams of water. The gardens of Cyrus and other Persian monarchs were of great extent, and generally laid out in romantic situations. They were also distinguished for the great diversity of their uses and products. The first allusion to terraces in gardens is to be found in the description of the celebrated hanging gardens of Babylon, anciently reckoned among the wonders of the world. Their construction is variously ascribed to Queen Semiramis and to Nebuchadnezzar. Diodorus and Strabo have given descriptions of them. They are said to have formed a square with an area of nearly four acres, and rose in terraces, supported on masonry arches, to a height of 75 feet. They were irrigated from a reservoir built at the top, to which water was lifted from the Euphrates by a screw. Fountains and banqueting-rooms were distributed throughout the numerous terraces; groves and avenues of trees, as well as parterres of flowers, diversified the scene; while the view of the city and neighborhood was extensive and magnificent. Most of the elements of a modern architectural garden are alluded to in connection with those of Babylon. The grove of Orontes, described by Strabo, must be regarded as a park or large garden in the picturesque style; it was nine miles in circumference.

In ancient Greece, gardening was rather a neglected art at first, but in process of time great advance was made. The vale of Tempé, the Academus at Athens, and other public gardens, were extremely elegant, and were ornamented with temples, altars, tombs, statues, monuments, and towers. The Greeks copied their gardening from the Persians; and the Romans, in their turn, copied that of the Greeks. Little is known of the early style of Roman gardening; the vast edifices projecting into the sea, and the immense artificial elevations, are apparently ridiculed by Cicero and Varro. About this time, however, began the cultivation of odoriferous trees and plants; and the planting of trees adjoining each other, whose odors assimilated, was then as much a study with the gardener as the harmonious blending of colors at the present day.

The early French and Dutch gardens were evidently adopted from the description of Pliny's garden. The use of glass in the construction of conservatories was early known to the Greeks and Romans; and the "Gardens of Adonis," mentioned by some of their most eminent authors, were probably of this kind. Gardening, like all the other arts, languished during the Dark Ages, but with the revival of learning, the invention of printing, and the Reformation, it began again to flourish. The art was revived and patronized by the family of the Medici in Italy; and their gardens which were of the geometric and architectural style, long served as models for most of Europe. It continued to be imitated in France, Germany, and Great Britain till the introduction of the English or natural style. In garden architecture very little progress, as far as hothouses are concerned, has been made in southern Europe, the warmth of the climate rendering them all but useless. There are, however, plant houses in many places in Spain and Portugal. The French and Dutch gardens resemble each other closely; symmetry and profuse ornament are the characteristics of both. The Dutch style is eminently adapted to the nature of the country, where there are no inequalities of surface, as in England. The French style seems to have arisen about the middle of the 17th century, during the reign of Louis XIV. The most celebrated gardener of the period was Le Nôtre, who laid out the famous gardens of Versailles. Le Nôtre's style spread rapidly into other countries. The first erection of hothouses in France occurred toward the end of the reign of Louis XIV., by M. Fagon, in the Jardin des Plantes. The first magnificent attempt at hothouse building was that of Francis I., of Austria, in 1753. They were in five ranges, extending altogether to the length of 1,290 feet, many of them being 30 feet high. From about 1760 landscape gardening, and the adoption of the English style, rapidly spread into France, Germany, and Russia, where it still prevails. See FLOATING ISLAND; FLORICULTURE; GREENHOUSE; HORTICULTURE; BREEDING, PLANT; FLOWERS; CROSS-FERTILIZATION; ETC.

Garden City, N. Y., a village on Long Island in Nassau County; on the Long Island R.R.; 18 miles east of New York. It was founded by Alexander T. Stewart as a residential town. It is the seat of the Protestant Episcopal bishop of Long Island, and contains the Cathedral of the Incarnation. Here are also the Cathedral Schools of St. Mary and St. Paul. Pop. (1901) 800.

Garden of the Gods, a small region in Colorado, near Colorado Springs, in which are seen some of the most striking effects of erosion ever found upon the globe. The "Garden" covers an area of about 500 acres, within which are strangely sculptured sandstone rocks, red and white, forms of grotesque magnificence — columns, "cathedral spires," and giant figures sometimes appearing almost as if made in human likeness. To many of these shapes have been given distinctive names suggested by their various formations. The road into the "Garden" enters through the huge "Gateway" of red rock-masses more than 300 feet in height.

Gardener Bird. See BOWER-BIRDS.

Gardening, Landscape. See LANDSCAPE GARDENING.

Gardiner, gärd'nėr, **Asa Bird,** American lawyer: b. New York 30 Sept. 1839. He was educated at the College of the City of New York and New York University; during service in the Civil War attained the rank of captain and received a medal of honor for bravery; was professor of law in the United States Military Academy in 1874–9, and became district attorney of the County of New York in 1897. He has practised law in New York, and held important posts in the Society of the Cincinnati and other organizations.

Gardiner, Frederic, American Protestant Episcopal clergyman: b. Gardiner, Me., 11 Sept. 1822; d. Middletown, Conn., 17 July 1889. He was graduated from Bowdoin College in 1842, from the General Theological Seminary, New York, in 1845; was rector of Trinity, Saco, Me., 1845–7; rector of churches at Bath (1848–53) and Lewiston, Me. (1855–6); and in 1865 became professor of the literature and interpretation of Scripture in the Gambier (Ohio) Theological Seminary. In 1867 he was appointed professor of the Old Testament language and literature in Berkeley Divinity School (Middletown, Conn.), and in 1883 of New Testament interpretation and literature in that institution. He founded (1880) the Society of Biblical Literature and Exegesis, and published: 'The Island of Life' (1851); 'Diatessaron' (1871); 'The Old and New Testaments in their Mutual Relations' (1885).

Gardiner, John, American lawyer: b. Boston 1731; drowned off Cape Ann 15 Oct. 1793. He was a son of Sylvester Gardiner (q.v.). He studied law at the Inner Temple, London, and was admitted to practice at Westminster Hall. He formed an intimacy with Churchill and Wilkes, and was junior counsel of the latter at his trial in 1764, and also appeared for Beardmore and Meredith, who for writings in support of Wilkes had been imprisoned on a general warrant. In 1766 he procured the appointment of attorney-general in the island of St. Christopher, where he remained until after the American revolution, when he returned to Boston. After residing there a few years, he removed to Pownalborough, Me., which place he represented in the Massachusetts legislature until his death. As a legislator he distinguished himself by his efforts in favor of law reform, particularly the abolition of special pleading, and the repeal of the statutes against theatrical entertainments. In connection with the latter subject he published a 'Dissertation on the Ancient Poetry of the Romans,' and an accompanying speech. The abolition of the law of primogeniture in Massachusetts was due to his efforts. He was one of the most influential of the early Unitarians of Boston, and participated in the change of King's Chapel from an Episcopal into a Unitarian Congregational Church.

Gardiner, John Sylvester, American Episcopal clergman: b. Haverford West, South Wales, England, June 1775; d. Harrowgate, England, 29 July 1830. He was a son of John Gardiner (1731–93) (q.v.); accompanied his father to the West Indies, and subsequently studied in Boston, and in England under the celebrated Dr. Parr. Returning to America, he became a candidate for orders in the Protestant Episcopal Church, and in 1797 was ordained. In 1805 he became rector of Trinity Church, the chief Episcopal parish in Boston, with which he remained connected until his death. He was an accomplished scholar, and a forcible preacher. In the establishment of the 'Boston Anthology and Monthly Repository,' for which he was a frequent writer, he contributed materially to the dissemination of literary taste and culture in Boston. He was also one of the founders of the Boston 'Athenæum.' He wrote the ‹Jacobiniad,› a satire in prose and verse directed against the liberal clubs of Boston, to which, being in politics a strong Federalist, he had an antipathy.

Gardiner, Lion, English settler in America: b. 1599; d. 1633. After service in the English army, he came to America in 1635 as the representative of a land company which had a patent of territory at the mouth of the Connecticut. He built a fort to which he gave the name of Saybrook, compounded from the names of Lord Say and Sele and Lord Brook, two of the patentees, and remained in charge until 1639. He made on an island, called by him the Isle of Wight (now Gardiner's Island, township of Easthampton), the first English settlement within the limits of what is now the State of New York, and there he lived in baronial style.

Gardiner, Samuel Rawson, English historian: b. Ropley, Hampshire, 4 March 1829; d. Sevenoaks, Kent, 23 Feb. 1902. He was educated at Christ Church, Oxford, studied also at Edinburgh and Göttingen; was professor of history at King's College, London, in 1871–85, historical lecturer for the University Extension Society in 1880–94, and examiner in the Oxford final history school in 1886–9. He was elected to a research fellowship by All Souls, Oxford, in 1882, and to a similar fellowship by Merton in 1894. On Froude's death (1894) he declined appointment to the Oxford regius professorship of modern history. It is for his work of research in the history of England from 1603 to 1660 that he is best known. The results were published in instalments later assembled in various collective editions. In the course of his investigations he examined minutest details with extraordinary care. He inspected the scene of most battles which he described; he thoroughly familiarized himself with the state papers of the Record Office, and, for the study of the state papers foreign and the contents of other national archives, learned six continental languages. It is stated that he was the only one that ever read the entire collection of Thomasson tracts in the British Museum. Though himself a Liberal in politics, his writing was wholly judicial and impartial. Perhaps no other English historian ever labored more enthusiastically for historical truth. His style is clear and well-ordered, and in later volumes vigorous and often impressive. He was the first to describe in full the period of Commonwealth and Protectorate from an unprejudiced viewpoint, and he was also the first satisfactorily to explain the beginnings of the Cavalier party and the rise of the civil war. He was fortunately enabled to utilize many newly discovered sources. His work was not at first popular, but its worth was later fully recognized. In 1882 he received a civil-list pension of £150. The titles of the larger divisions of his great undertaking are: ‹History of England from the Accession of James I. to the Disgrace of Chief Justice Coke› (1863); ‹History of England from the Accession of James I. to the Outbreak of the Great Civil War› (1883–4); ‹History of the Great Civil War› (1886–91); and ‹History of the Commonwealth and Protectorate› (1894–1901), in three volumes, a fourth to be completed by Firth. He wrote also ‹Cromwell's Place in History› (1897); ‹Oliver Cromwell› (1899); and other works, including: ‹The Thirty-Years' War› (1874); ‹The First Two Stuarts and the Puritan Revolution› (1876) ‹Introduction to the Study of English History› (with Mullinger, 1881); ‹Constitutional Documents of the Puritan Revolution› (1889); ‹Student's History of England› (1890–2); ‹School Atlas of English History› (1891); ‹What Gunpowder Plot Was› (1897).

Gardiner, Sylvester, American physician: b. Kingston, R. I., 1717; d. Newport, R. I., 8 Aug. 1786. He studied medicine in London and Paris, subsequently practised his profession in Boston, and opened there a drug establishment, from which the New England colonies were chiefly supplied. He was one of the early promoters of inoculation for the smallpox, and a liberal contributor for the erection of King's Chapel, Boston. He became possessed of large tracts of land in Kennebec County, Maine, and about the middle of the century was instrumental in establishing there the settlement of Pittston, a portion of which was subsequently set off into a separate town, under the name of Gardiner, where he built and endowed Christ Church. He retired from Boston on its evacuation by the British troops, but returned to the United States at the close of the Revolutionary War, and passed the rest of his life there.

Gardiner, Me., a city in Kennebec County, on the Kennebec River, and on the Maine C. R.R., six miles from Augusta. It has admirable water-power, valuable manufacturing interests, and an assessed property valuation of $4,000,000. The ice-cutting industry employs 1,000 people, with an annual output valued at $75,000. Pop. (1900) 5,501.

Gardiner's Island, N. Y., an island in a bay of the same name at the northeastern extremity of Long Island. It is part of the township of East Hampton, Suffolk County, and has an area of 3,300 acres, mostly undulating pasture land. It was colonized by an English family of the name of Gardiner in 1639 and is in possession of lineal descendants of the original settlers. Captain Kidd (q.v.) buried part of his treasures on the island in 1699, but they were recovered in the same year by the colonial authorities.

Gardner, Elizabeth Jane, American artist: b. Exeter, N. H., 1842. She was a pupil at Paris of Bougereau, Merle, and J. J. Lefebvre, and has exhibited much in the United States and foreign countries. Among her works are several portraits: ‹Cinderella›; ‹Fortune-Teller›; ‹Moses in the Bulrushes.›

Gardner, Ernest Arthur, English archæologist: b. London 1862. He was educated at Cambridge University, and was director of the British School of Archæology at Athens, 1887–95. From 1884 he has been engaged in archæological researches in Athens, Paphos in Cyprus, Megalopolis, and elsewhere, and has lectured and written much upon Greek art and archæology.

Gardner, Eugene C., American architect: b. Ashfield, Mass., 28 March 1836. He was principal of the Academy at Tallmadge, Ohio, 1852–62. He then removed to Northampton, Mass., where he resided 1863–8, engaged in architectural work, going to Springfield, Mass., in the latter year, editing ‹The Builder› 1885–7, and writing for the ‹Springfield Republican.›

In 1901 he was elected a member of the Massachusetts House of Representatives. Among his works are: 'Homes and How to Make Them'; 'Illustrated Homes'; 'Home Interiors'; 'The House that Jill Built'; 'Town and Country School Houses'; and 'Common Sense in Church Building.'

Gardner, George Clinton, American engineer and railway official: b. Washington 1834; d. Richmond Hill, L. I., 12 Aug. 1904. He studied at Columbia for a time, in 1850 became connected with the survey establishing the United States and Mexican boundary from the Gulf of Mexico to the Pacific. In 1856 he was commissioned by the government assistant astronomer and surveyor of the Northwest boundary, and in this survey, for establishing and marking the 49th parallel, he gained considerable distinction. His determinations along this line form the initial points of the United States land surveys. He resigned in 1869, and subsequently was prominently identified with various railway interests. He was general manager of the Mexican National Construction Company, the Mexican National Railroad Company, and the Texas-Mexican Railroad Company, constructing much of these lines, and was connected also with other railways.

Gardner, Percy, English archæologist: b. Hackney, Middlesex, 24 Nov. 1846. He was educated at Cambridge University, was Disney professor of archæology there in 1880, and has been professor of classical archæology at Oxford from 1887. Among his publications are: 'Samos and Samian Coins' (1882); 'The Types of Greek Coins' (1883); 'New Chapters in Greek History' (1892); 'Manual of Greek Antiquities,' with Jevons (1895); 'Sculptured Tombs of Hellas' (1896); 'Exploratio Evangelica' (1899); 'Historic View of the New Testament' (1901); 'A Grammar of Greek Art' (1905).

Gardner, Mass., a town in Worcester County, including the villages of Gardner Centre, South Gardner, and West Gardner. It is situated about 25 miles north of Worcester, on the Fitchburg division of the Boston & M. R.R., two branches of which pass through the town, intersecting at the station in Gardner Centre. Gardner is the trade centre of an agricultural region, and has a large chair-manufacturing industry, with establishments employing about 3,000 people. Almost every known kind of chair is made here, and the products of this manufacture are shipped to all parts of the United States and to many foreign countries. The town has two good parks and an excellent public library. Pop. (1900) 10,813.

Garefowl, or **Great Auk**. An extinct auk (*Plautus impennis*), much like the existing razor-bill, but larger (nearly the size of a goose), with a larger bill and relatively smaller wings. It was black above and white below, with a conspicuous white patch in front of the eye. It was an expert swimmer and diver, but unable to fly on account of the very small size of its wings. The habits of the garefowl were those of auks generally, but its range was limited on the American coast to the vicinity of Newfoundland. It seems never to have lived north of the Arctic Circle; but its bones in shell-heaps testify to its former occurrence, at least in migrations, southward as far as Florida. These birds bred on small islands off the coast of Iceland, and on the Orkneys and Hebrides. Early in the 19th century they disappeared from these haunts, mainly through the persecution of fishermen and sailors who had for years killed them for food, bait, and feathers; but they lingered somewhat longer in the gulf of Saint Lawrence. Cartier's vessels visited Funk Island in 1534, and the crews easily filled two boats with the birds which they knocked down with sticks; and their abundance was mentioned as one of the inducements for settlers to come to Newfoundland. For many years the colony was ruthlessly harried, yet a few pairs survived until about 1840. A small breeding-place remained in Iceland until 1844, when the last few pairs were killed as museum specimens. The skins of this auk have been sold for $650, and an egg for $1,500. Seventy-eight specimens of the bird were preserved in museums throughout Europe and America in 1903. Consult: Newton's 'Dictionary of Birds,' article 'Garefowl,' and articles by F. A. Lucas in 'Report United States National Museum for 1887–8,' and for 1888–9.

Garfield, James Abram, twentieth President of the United States: b. Orange, Cuyahoga County, Ohio, 19 Nov. 1831; d. Elberon, N. J., 19 Sept. 1881. On his father's side he was of English Puritan descent; on his mother's, Huguenot. The father, a native of New York, settled in the "Western Reserve" in 1830, and died in 1833, leaving his widow with four small children, James being the youngest. Garfield's boyhood was passed amid the harsh but by no means destitute conditions of frontier life. He worked hard on the farm, helped in the support of the family, attended school three months each winter, and read and re-read every book which fell in his way. For a short time he was a driver and steersman on the Ohio Canal. Supporting himself chiefly by teaching, he studied successively at Geauga Seminary 1849, Eclectic Institute, Hiram, Ohio (now Hiram College), 1851–4, and Williams College, Mass., entering the junior class in 1854 and graduating with high honors in 1856. Returning to Ohio, he taught the classics at Hiram Institute 1856–7, and became its president 1857–9. Coincident with his teaching he studied law, was admitted to the bar in 1859, and, resigning his presidency, was elected to the Ohio State senate. The Civil War breaking out, he threw himself enthusiastically into the Northern cause, was commissioned lieutenant-colonel of the 42d Ohio, and given command of a brigade, with orders to operate as an independent force in eastern Kentucky, December 1861. With a force of 1,100 men and no artillery he signally defeated 5,000 Confederates under the veteran general, Humphrey Marshall, driving them from fortified positions of their own choosing, 10 Jan. 1862. For this exploit Lincoln promoted him brigadier-general. Subsequently he took part in the battle of Shiloh, in the operations around Corinth, and served with distinction on several courts-martial at Washington, one being that of Gen. Fitz-John Porter (q.v.). Appointed chief of staff to Gen. Rosecrans, February 1863, his notable services at Chickamauga (see CHICKAMAUGA, BATTLE

JAMES ABRAM GARFIELD.

TWENTIETH PRESIDENT OF THE UNITED STATES.

OF) caused Lincoln to make him a major-general, 19 Sept. 1863. In 1862 his home district had elected him to Congress. Thus, within six years he had been president of a college, State senator, major-general, and representative-elect, a combination of honors without parallel in the national annals. Upon the advice of Lincoln and Stanton he resigned his major-general's commission 5 Dec. 1863 and took his seat as a representative on December 7. In this field his talents and genius found their true sphere. He stepped to the front at once, taking a prominent part in every debate of importance, and becoming an authority on questions of finance, tariff, education, and constitutional rights. Always the champion of sound money, his speech in March 1866 clearly outlined the policy which resulted in the resumption of specie payments 1 Jan. 1879. An eminent contemporary has well said of Garfield's speeches that they are a compendium of the political history of the time, and would give a connected history and complete defense of the important legislation of the 17 eventful years that comprised his legislative career. He was eight times re-elected to Congress, serving on such important committees as those on military affairs and on ways and means, and was the first chairman of the committee on banking and currency. In the Reconstruction period he steadily opposed the theories of President Johnson (see JOHNSON, ANDREW); in 1876 he went to New Orleans at President Grant's request to watch the counting of the Louisiana vote, and in 1877 was chosen by acclamation one of the two members of the Electoral Commission allotted to the House of Representatives. In the 45th Congress Garfield displayed masterly qualities as a leader of opposition. His speech at Faneuil Hall, Boston, in 1878 on the national finances was circulated by thousands as a campaign document. On 13 Jan. 1880 the Ohio legislature unanimously elected him United States Senator to succeed Hon. Allen G. Thurman (q.v.), and his last speech in Congress was delivered 23 April 1880. At the Republican National Convention at Chicago, 2–8 June 1880, he headed the Ohio delegation, nominated John Sherman (q.v.) for the Presidency, opposed the nomination of Gen. Grant for a third term, and was himself nominated on the 36th ballot as a compromise candidate. Contrary to all precedent, Garfield himself took part in the campaign that followed, making some 70 speeches in all, chiefly extemporaneous. At the November election he received 214 electoral votes to 155 given his Democratic opponent, Gen. Hancock. The first months of Garfield's administration were disturbed by the opposition of the New York senators to certain of his appointments. Senators Conkling and Platt claimed the right to control the Presidential appointments in their State. This the President refused to concede. The senators resigned and appealed to their legislature to vindicate their attitude by a re-election, but failed to get it. On the morning of 2 July 1881, while in the Baltimore & Potomac station at Washington, on his way to New England, where he intended to deliver the commencement address at Williams College, President Garfield was shot by Charles Jules Guiteau (q.v.), a disappointed office-seeker For weeks he lingered between life and death, suffering the greatest agony but bearing it with a magnificent fortitude that won the admiration and sympathy of the civilized world. A removal to Elberon, N. J., in the hope that the sea air might benefit him was of no avail. Blood poisoning set in on 15 September, and he died on the 19th at 10:30 P.M. In February 1882 an impressive memorial service was held in the House of Representatives, the Hon. James G. Blaine delivering a commemorative address, which, for eloquence, dignity, and truth, has rarely been equaled on such occasions. Garfield's body lies in a beautiful cemetery in Cleveland, Ohio, a stately monument marking the spot. His life was the fullest realization of the opportunities of American citizenship. Rising from nothing, by his own exertions he won high places in various spheres and filled them all adequately and with dignity.

No definitive 'Life' has yet appeared, the biographies of Garfield by J. M. Bundy, C. C. Coffin, and J. R. Gilmore (all 1880) being incomplete and unsatisfactory. His 'Works' have been edited by Prof. B. A. Hinsdale (1882–3).

W. N. C. CARLTON,
Librarian Trinity College, Hartford.

Gargano, gär-gä'nō (ancient Garganus), a mountainous peninsula, the «spur» of Italy, in the province of Foggia, jutting out into the Adriatic Sea, and attaining in Monte Calvo a height of nearly 4,000 feet. Bee-keeping is yet as generally engaged in as in the time of Horace. The district is visited mainly by pilgrims to a shrine of Saint Michael on Monte Saint Angelo. It is about 50 miles long and 27 miles broad.

Garguntua, gär-gan'tū-ä, the hero of Rabelais' satire, so named from his father exclaiming «*Que grand tu as!*» «How large (a gullet) thou hast!» on hearing him cry out, immediately on his birth, «Drink, drink!» so lustily as to be heard over several districts. It required 900 ells of linen for the body of his shirt, and 200 more for the gussets, 1,100 cow hides for the soles of his shoes, and he picked his teeth with an elephant's tusk.

Gargoyle, Gargoil, or **Gurgoyle** (French *gargouille* = the weazand of the throat), in architecture, a quaintly-formed head of a man or animal, employed as a decorative spout for the rain-water from a roof. The most common form was that of a dragon projecting from the roof-gutter, but the varieties are innumerable. They were used in all styles of architecture, and are many of them of a most hideous appearance.

Garfield Monument, a monument erected as a memorial to President Garfield, in the Lakeview Cemetery at Cleveland, Ohio. See CLEVELAND.

Garibaldi, Giuseppe, joo-sĕp'pĕ gä-rē-bäl'-dē, Italian patriot: b. Nice, France, 4 July 1807; d. island of Caprera, Italy, 2 June 1882. His father being a poor fisherman, he received little education, and for a number of years was a sailor on various trading vessels. In 1834, being condemned to death for his share in the schemes of Mazzini, he escaped to Marseilles and finally went to South America. In the service of the Republic of Rio Grande against the Brazilians he became known as a brilliant leader, and with his famous Italian legion he subsequently gave the Montevideans such effective aid against Buenos Ayres as to earn the title of "hero of Montevideo." In 1848 he returned to Italy, raised a band of volunteers, and harassed the Austrians till the re-establishment of Austrian supremacy in Lombardy. In the spring of 1849 he proceeded to Rome to support Mazzini's republic. He was appointed to command the forces, but the odds were overwhelming, and after a desperate defense of 30 days Garibaldi escaped from Rome with 4,000 of his followers. He reached the United States, and was for several years in command of a merchant vessel. He then purchased a part of the small island of Caprera, off the north coast of Sardinia, and made this his home for the rest of his life. Latterly the subscriptions of his admirers enabled him to become owner of the whole island.

In the war of 1859, Garibaldi and his Chasseurs of the Alps did splendid service; and on the revolt of the Sicilians in 1860 he crossed to the island, wrested it after a fierce struggle from the king of Naples, recrossed to the mainland and occupied Naples, where he was proclaimed dictator of the Two Sicilies. He readily acquiesced in the annexation of the Two Sicilies to Italy, and declining all honors retired to his island farm. In 1862 he endeavored to force the Roman question to a solution, and entered Calabria with a small following, but was taken prisoner at Aspromonte by the royal troops. He was soon released, however, and returned to Caprera. In 1864 he received an enthusiastic welcome in Great Britain. In 1866 he commanded a volunteer force against the Austrians in the Italian Tyrol, but failed to accomplish anything of consequence. Next year he attempted the liberation of Rome, but near Mentana was defeated by the French and pontifical troops, and was again imprisoned by the Italian government, but soon pardoned and released. In 1870 he gave his services to the French republican government against the Germans, and at the end of the war was elected a member of the French Assembly, but speedily resigned his seat and returned to Caprera. Rome now became the capital of united Italy, and here in January 1875, Garibaldi took his seat in the Italian Parliament. The latter part of his life was spent quietly at Caprera. After 1870 he wrote two or three novels of very mediocre quality. His autobiography was published in 1887, and translated into English with a supplementary biography in 1889.

Garibaldi (fish), a small, brilliantly colored, edible fish (*Hypsypops rubicundus*), scarlet when adult, which dwells in rocky pools along the coast of southern California, hiding and finding its food among the seaweeds.

Garigliano, gä-rēl-yä'nō, a river in southern Italy, formed by the junction of the Liri and Sacco near Pontecorvo. It flows southeast and southwest, and after a course of 40 miles falls into the Gulf of Gaëta.

Garland, Augustus Hill, American lawyer: b. near Covington, Tenn., 11 June 1832; d. Washington, D. C., 26 Jan. 1899. He opposed secession as a policy, but was afterward elected to the Confederate Senate, which office he held till the close of the War. In 1874 he was elected governor under the new Constitution of Arkansas, and in 1885 became attorney-general in the cabinet of President Cleveland.

Garland, Hamlin, American novelist: b. West Salem, Wis., 16 Sept. 1860. His works include: 'Main Traveled Roads' (1891); 'A Spoil of Office'; 'Prairie Folks'; 'Jason Edwards' (1891); 'A Member of the Third House' (1892); 'Prairie Songs' (1893); 'A Little Norsk' (1893); 'Crumbling Idols' (1894); 'Rose of Dutcher's Coolly' (1895); 'Wayside Courtships' (1897); 'The Eagle's Heart' (1901); 'Captain of the Gray Horse Troop' (1902); 'The Tyranny of the Dark' (1904); etc.

Garland, Landon Cabell, American educator: b. Livingston, Va., 21 March 1810; d. 1895. He was graduated at Hampden-Sidney College, Virginia, was professor of chemistry at Washington College in that State 1830–3, at Randolph-Macon College 1833–5, and became president of the latter in 1835. In 1847–53 he was professor of astronomy and mathematics at the University of Alabama, in 1855–66 its president; later was professor of physics in the University of Mississippi, and chancellor of Vanderbilt University.

Garlic (*Allium sativum*), a species of onion cultivated in Europe since the year 1551. The leaves are grass-like, and differ from those of the common onion in not being fistulous. The stem is about two feet high, terminated by a head composed principally of bulbs instead of flowers; the flowers are white; the root is a compound bulb, consisting of several smaller bulbs, commonly denominated cloves, enveloped by a common membrane. Garlic has a strong, penetrating odor, and a pungent acrid taste. It differs from the onion only by being more powerful in its effects. In warm climates, where garlic is considerably less acrid than in cold ones, it is much used both as a seasoning and as food. In the south of Europe, particularly in Spain, and among Italians in the United States, it enters into the composition of almost every dish, not only among the common people, but among the higher classes of society. At all times, however, while it has been prized by some nations it has been detested by others, as by the ancient Greeks. Its cultivation is easy, and it is reproduced by planting the radical or floral bulbs. Its medicinal virtues are celebrated.

Garlic, Oil of. When the leaves, seeds, or bulbs of garlic and other allied plants are distilled with steam, about 0.2 per cent of a brown oil, with acrid taste and strong disagreeable odor, passes over. By purification it is obtained as a pale yellow oil having the odor of garlic, and it is then found to consist of the sulphide of allyl $(C_3H_5)_2S$. This oil is nearly related to the pungent oil of mustard, C_3H_5NCS, an isomer of the sulphocyanide of allyl, and is of much interest chemically, but it is of no importance from an industrial point of view.

Garman, Harrison, American naturalist: b. Lena, Ill., 27 Dec. 1858. He was graduated at the State Normal University and studied later at Johns Hopkins University. He has held many professional positions, among them being entomologist and those of professor of zoology and entomology at Kentucky State College, 1892–6, and State entomologist of Kentucky since 1897.

Garman, Samuel, American naturalist: b. Indiana County, Pa., 5 June 1846. He was graduated at the Illinois State Normal University in 1870, and became assistant in herpetology and ichthyology in the Museum of Comparative Zoology, Cambridge, Mass., in 1873. His works include: 'The Reptiles and Batrachians of North America'; 'Chlamydoselachus'; 'The Evolution of the Rattlesnake'; etc.

Garner Case, 1856, the most tragic of the fugitive-slave cases. Simon Garner, his wife, and his son Robert, slaves of John Marshall of Kentucky, and Robert's wife Margaret and their four children, slaves of A. R. Gaines, ran away, crossed the Ohio on the ice, and took refuge with a Cincinnati colored man. Gaines tracked them, secured a warrant, and with a deputy marshal and a band of assistants attacked the house. After a desperate fight the fugitives were overpowered, one of the posse being badly wounded; but Margaret, who had shared in the conflict, found time before her capture to murder one of the children, severely cut the throats of two others, and considerably bruised the baby, to keep them from returning to slavery. In sympathy with them, and to establish their freedom as denizens of Ohio, a Cincinnati judge issued a writ of habeas corpus, and the grand jury indicted Margaret for the murder of her child, and her husband and his father as accessories. The United States fugitive-slave law of 1850 prevailed, however; the slaves were given back to their owners and sent down the river. On the voyage Margaret jumped overboard with the baby; she was rescued, but the child was lost, at which she expressed satisfaction.

Garnet. See GEMS.

Gar'nett, James Mercer, American philologist: b. Aldie, Va., 24 April 1840. He was graduated at the University of Virginia in 1859; served in the Confederate army during the Civil War; and was professor of English language and literature in the University of Virginia 1882–96. He is the author of: 'Translation of Beowulf'; 'Elene and Other Anglo-Saxon Poems'; 'History of the University of Virginia.'

Garnett, Richard, English poet and librarian: b. Lichfield, Staffordshire, 27 Feb. 1835; d. London, 13 April 1906. He was appointed in 1851 assistant in the printed book department of the British Museum, became superintendent of the reading-room in 1875, but resigned in 1884 to devote himself more exclusively to the printing of the 'Museum Catalogue,' of which he had had charge from its commencement. He published: 'Primula: a Book of Lyrics' (1858); 'Egypt and Other Poems' (1859); 'Poems from the German' (1862); 'Relics of Shelley' (1862); 'Idylls and Epigrams' (1869); 'Selections of Shelley's Poems' (1880); 'Letters' (1882); 'Life of Carlyle' (1887); 'Life of Emerson' (1887); 'Twilight of the Gods' (1888); 'Life of Milton' (1890); 'Iphigenia in Delphi' (1891); 'Poems' (1893); 'William Blake: Painter and Poet' (1895); 'The Age of Dryden' (1895); 'One Hundred and Twenty-four Sonnets from Dante, Petrarch and Camoens' (1896); 'Richmond on the Thames' (1896); 'Life of Edward Gibson Wakefield' (1898); 'History of Italian Literature' (1898); 'Essays in Librarianship and Bibliography' (1899); 'The Queen and Other Poems' (1901); 'Essays of an Ex-Librarian' (1901); etc. He also contributed extensively to the magazines and cyclopædias. He resigned from the Museum in 1899.

Garnett, Robert Selden, American soldier: b. Essex County, Va., 16 Dec. 1819; d. Carrick's Ford, Va., 13 July 1861. Graduated from the United States Military Academy in 1841 and made brevet 2d lieutenant of artillery, he served on the northern frontier during the Canadian border disturbances, and distinguished himself in the war with Mexico (1846–8), receiving the brevet of major for his conduct at Buena Vista. He was transferred to the Seventh infantry in 1848, fought in Florida against the Seminoles, and was commandant at West Point in 1852–4. In 1855 he was promoted major of infantry, and in 1856 commanded the expedition against the Indians of Puget Sound. At the outbreak of the Rebellion in 1861 he resigned his commission, and was made adjutant-general, with colonel's rank, to organize the Virginia forces. Shortly afterward he was appointed brigadier-general, C. S. A., and given command of the troops in the western part of Virginia. While endeavoring to retreat to Beverly, he was overtaken by the Federals at Carrick's Ford, Cheat River, and took command of a detachment with which he sought to cover the retreat. His force was routed, and he was killed during the combat.

Garnett, Kan., city and county-seat of Anderson County, on the Pottawattomie River, and on the Missouri P. and the Atchison, T. & S. F. R.R.'s, 45 miles northwest of Fort Scott. It has good educational institutions, including a United Presbyterian college. There are large manufactures of furniture, and also of cheese. Pop. (1900) 2,078.

Garnier, Jean Louis Charles, zhŏṅ loo-ē shärl gär-nē-ā, French architect: b. Paris 6 Nov. 1825; d. 4 Aug. 1898. He was a pupil of Levieil and Lebas at the Beaux-Arts, won the Prix de Rome in 1848 with his design for a conservatory of arts and industries, traveled in Italy, Turkey, and Greece, and in 1861 won the competitive prize for plans of the new Paris Opera. In 1863–74 he superintended the construction of this costly and important work, whose chief feature is its grand staircase, but which is by some thought to be overladen with accessories of painting and sculpture. In addition to this, his principal achievement, he designed buildings public and private at Paris and elsewhere. He was the author of: 'Travers les Arts' (1869); 'L'habitation humaine,' with Ammann (1892); and editor 'Le nouvel Opéra de Paris' (1876–81).

Garnier, Marie Joseph François, commonly known as FRANCIS, French explorer: b. Saint-Etienne 25 July 1839; d. Hanoi, Tongking, China, 2 Dec. 1873. He entered the French navy, served in the war with China in 1860–2, and became a civil officer in the newly established colony of Cochin-China. In 1866 he was appointed to assist Capt. Doudart de Lagrée in an exploring expedition which set out from the coast of Cambodia and proceeded through Yunnan to Shanghai, the purpose being to open a highway of trade. Garnier explored the river Mekong, and, on the death of Doudart de Lagrée, assumed command of the expedition, which he brought successfully along the Yang-tse-kiang to Shanghai. The geographical societies of France and Great Britain bestowed numerous honors upon him. He took part in the defense of Paris in 1870–1, and again undertook explorations in China. The governor of Cochin-China empowered him to negotiate a treaty with the viceroy of Tongking. Upon the refusal of the viceroy to open negotiations, Garnier captured Hanoi, the capital, and achieved further victories with a force of but 120. He was finally killed in an ambush. His 'Voyage d'Exploration en Indo-Chine pendant 1866–8' (1873) is a notable book.

Garnierite, a green, amorphous mineral, one of the most important ores of nickel. It is a hydrous silicate of nickel and magnesium, the ratio of the two metals varying widely. It is soft and very brittle and has a specific gravity of 2.3 to 2.8. It is extensively mined in New Caledonia, and also occurs in large quantities in Douglas County, Ore., and Jackson County, N. C. It was named after the French geologist, Garnier.

Garnishment, in law, a process by which a third person, in whose possession the effects of the defendant are attached, is warned not to turn over such effects to the defendant, but to appear in court and give information. This process is controlled by statute in the States where it exists, and the demands of the statutes must be fully met by any plaintiff seeking to make use of the process. The process is called in some States trustee process, in others factorizing, and in still others attachment, the more general title. The third party, who is known as the garnishee, is liable for only such property as is not encumbered by trusts and may be delivered by the officer serving said process. Virtually, the process is a secondary suit brought by the suing creditor against the third party, or garnishee, the creditor claiming the rights of the defendant in the primary action.

Garofalo, Benvenuto, bān-vā-noo'tō gä-rō'fä-lō (originally Benvenuto Tisi da Garofalo), Italian painter: b. Ferrara 1481; d. there 6 Sept. 1559. In this city and in Cremona he cultivated his talents for painting; but the masterpieces of art in Rome exercised the greatest influence upon him. In the year 1505 he is said to have returned to Rome, and to have formed a very close intimacy with Raphael, who often made use of his assistance. He afterward painted for Alfonso I., in his native city. Garofalo's works show the influence of all the schools, particularly of the Lombard, and still more so of Raphael's, whom he surpassed in coloring. Most of his works are at Rome. Several of them, however, are in the galleries of Vienna and Dresden.

Garonne (Lat. *Garumna*), a river of southwestern France, the chief one of that section; rising in the Pyrenees, at the foot of Mount Maladetta, in the Val d'Aran, within the Spanish border. It enters France at a distance of 26 miles from its mouth. The Garonne flows in a general northeasterly direction through the department of Haute-Garonne to Toulouse, whence it proceeds in a northwesterly course. Some 20 miles below Bordeaux it forms a junction with the Dordogne; it then takes the name Gironde, and enters the Atlantic Ocean by an estuary of 50 miles in length. The complete length of the river is about 400 miles. Ocean-going steamers may ascend to Bordeaux, and the river is navigable to Toulouse and beyond. From Toulouse the Canal du Midi extends to the Mediterranean. Several destructive floods have taken place, that of 1875 having caused special damage. With its 32 tributaries the Garonne offers a system of waterways navigable for more than 1,400 miles, — a total exceeding that afforded by any other French stream. The total drainage area approaches 38.000 square miles.

Garrard, Kenner, American soldier: b. Cincinnati, Ohio, 1830; d. there 15 May 1879. He was graduated from the United States Military Academy in 1851, was made brevet 2d lieutenant in the artillery, but in 1852 was transferred to the dragoons, and after service, largely in the Northwest, was made captain of cavalry in 1861. During the early part of the Civil War he was in the commissary-general's office at Washington, and in 1861–2 commandant at West Point. In September 1862 he was commissioned colonel of the 146th New York volunteers, which he commanded at Fredericksburg, Chancellorsville, and Gettysburg. For services in the last named battle he was brevetted lieutenant-colonel. In 1863 he was promoted brigadier-general of United States volunteers, and afterward he participated in the combat at Rappahannock Station and the Mine Run operations. He took part, also, in the invasion of Georgia, was brevetted colonel for services in the expedition against Covington, Ga., and from December 1864 to July 1865 commanded the second division of the Sixteenth army corps. He distinguished himself by his efficiency in the battle before Nashville, and in the operations against Mobile; led the storming column which finally captured Blakely (9 April 1865); and was in command of the district of Mobile in August–September 1865. Mustered out of the volunteer service in August 1865, he was assistant inspector-general of the department of the Missouri in 1866, and in November 1866 resigned from the army, being at that time major, with the brevet of major-general for gallant and meritorious services in the field during the Rebellion.

Garrett, Alexander Charles, American Protestant Episcopal bishop: b. Ballymot, County Sligo, Ireland, 4 Nov. 1832. He was graduated from Trinity College, Dublin, in 1855; was ordained priest in 1857; held the curacy of East Worldham, Hampshire, in 1856–9; was a missionary in British Columbia in 1859–69; rector St. James', San Francisco, in 1870–2; and dean of Trinity Cathedral, Omaha, 1872–4. In 1874 he became missionary bishop of northern Texas, and subsequently bishop of Dallas. His publications include: 'The Eternal Sacrifice'; 'The Philosophy of the Incarnation'; 'Historical Continuity.'

Garrett, Edmund Henry, American artist: b. Albany, N. Y., 19 Oct. 1853. He was a pupil in Paris of Laurens, Boulanger, and J. J. Lefebvre, and exhibited much in America and at the Paris Salon. In 1890 he received a medal at Boston. He also published: 'Romance and

Reality of the Puritan Coast' (1897); and 'The Pilgrim Shore' (1900).

Garrett, John Work, American railway official: b. Baltimore 1820; d. 1884. He studied at Lafayette College, became a director of the Baltimore & Ohio Railroad (1857), and its president, greatly developed the road, and made it during the Civil War a most important medium for the transportation of Federal supplies and troops.

Garrett, William Robertson, American educator: b. Williamsburg, Va. 12 April 1839. He was graduated from William and Mary College in 1858, studied law in the University of Virginia, served in the Confederate army, was long occupied in educational work in the South, and was State superintendent of public instruction in Tennessee 1891–3. In 1895 he became professor of American history in Peabody Normal College, and in 1899 dean of the institution. He has published 'The South Carolina Cession and the Northern Boundary of Tennessee' (1884); 'History of Tennessee,' with Goodpasture (1900).

Garrick, David, English actor: b. Hereford, England, 19 Feb. 1717; d. London 20 Jan. 1779. His grandfather was a French refugee, his father a captain in the army. He was educated at the grammar school at Lichfield. He gave an early proof of his dramatic tendency by inducing his school-fellows to act the 'Recruiting Officer,' in which he himself took the part of Sergt. Kite, being then only 12 years of age. Later he was placed with a brother under Dr. Samuel Johnson. In 1741 he joined Giffard's company at Ipswich, where under the name of Lyddal he played with uniform success.

At this time the stages of the metropolis were but indifferently supplied with leading performers, so that when Giffard, who was manager of a theatre in Goodman's-fields, introduced his accomplished recruit there, 19 Oct. 1741, the effect was immediate and decisive. He judiciously chose the part of Richard III., which did not require that dignity of person in which he was deficient, while it gave him scope for all the strong marking of character and changes of passion in which his principal excellence consisted. He at the same time adopted a natural mode of recitation, which was a daring innovation on the part of a new performer before audiences accustomed to the artificial declamation of the school which preceded him. He afterward visited Dublin, where his success was even greater than in the metropolis, and in 1745 became joint manager with Sheridan of a theatre there. In 1746 he was engaged for the season at Covent Garden, and at its close purchased Drury Lane, and opened it 15 Sept. 1747, with the 'Merchant of Venice,' to which Dr. Johnson wrote a prologue for the occasion. This period formed an era in the English stage, from which may be dated a comparative revival of Shakespeare, and a reform both in the conduct and license of the drama. In 1749 he married Eva Marie Violetti (1724–1822), and his married life seems to have been happy. The remainder of his theatrical career was an uninterrupted series of success and prosperity. He had written, while an actor, his farces of 'The Lying Valet'; 'Lethe,' and 'Miss in Her Teens'; and in 1766 he composed, jointly with Colman, the excellent comedy of 'The Clandestine Marriage.' The year 1769 was signalized by the famous Stratford jubilee — a striking proof of his enthusiasm for Shakespeare. It occupied three days at Stratford, and its representation at the theatre lasted for 92 nights. The last part which he performed was Don Felix in 'The Wonder,' for the benefit of the theatrical fund. At the conclusion of the play he addressed a brief farewell to the audience. The general feeling with which this was delivered and received rendered it truly impressive. His remains were interred in Westminster Abbey, his funeral being attended by a numerous assemblage of rank and talent. As an actor Garrick has rarely been equaled for truth, nature, and variety and facility of expression, for which his countenance appears to have been admirably adapted. Expression and the language of passion formed his great strength, as he was equaled by many of his contemporaries in the enunciation of calm, sentimental, and poetical declamation. His literary talents were respectable, but not eminent; besides the pieces already mentioned he wrote some epigrams, a great number of prologues and epilogues, and a few dramatic interludes, and made many and sometimes judicious alterations of old plays. A collection of his works was published in London (1768–98), and his correspondence 1831–2. See Knight, 'Life of David Garrick' (1894).

Gar'rigan, Philip Joseph, American Roman Catholic prelate: b. Cavan, Ireland, 8 Sept. 1840. While he was still very young the family came to America and settled in Massachusetts and in the schools of that State he received his elementary education. He afterward studied at Saint Charles' College, Maryland, later taking an ecclesiastical course at Saint Joseph's seminary, Troy, N. Y., where on 10 June 1870 he was ordained priest. He was then appointed assistant in Saint John's Church, Worcester, Mass. In 1873 he became vice-president of the Troy Seminary and after three years was recalled to the diocese of Springfield. In 1888 he was chosen vice-rector of the Catholic University, Washington, D. C., and continued to hold the vice-rectorship until 21 March 1902, when Pope Leo. XIII. selected him for the newly-created episcopal see of Sioux City. He was consecrated bishop at Springfield, Mass., 25 May 1902. Though but two years established, the diocese now (1905) has a Catholic population of 50,000; 103 priests; 123 churches; 45 parochial schools; 1 hospital, and a Young Ladies' Home.

Garrison, George Pierce, American historical scholar: b. Carrollton, Ga., 19 Dec. 1853. He was educated at Sewanee College, Tenn., and the universities of Edinburgh and Chicago; became instructor in English and history in the University of Texas in 1884, assistant professor of history in 1888, and professor in 1897. He has published: 'The Civil Government of Texas' (1898); etc.

Garrison, Wendell Phillips, American editor: b. Cambridgeport, Mass., 4 June 1840; d. South Orange, N. J. 27 Feb. 1907. After graduation from Harvard (1861), he became literary editor of the New York 'Nation' in 1865. Among his publications are: 'What

Mr. Darwin Saw in His Voyage Around the World' (1879); 'Bedside Poetry' (edited, 1887); the 'Life of William Lloyd Garrison,' his father, with his brother, F. J. Garrison (1885); 'The New Gulliver' (1898).

Garrison, William Lloyd, American reformer: b. in Newburyport, Mass., 12 Dec. 1805; d. New York 24 May 1879. He was apprenticed to a shoemaker, but eventually became a compositor on the Newburyport 'Herald,' an occupation which suited his taste; he soon made himself master of the mechanical part of the business, and when only 16 or 17 began to write for the 'Herald.' His contributions, which were anonymous, were favorably received, and he soon commenced to send articles to the Salem 'Gazette' and other papers, drawing the attention of political circles by a series of articles under the signature "ARISTIDES," with the view of removing the almost universal apathy on the subject of slavery. In 1824 he became editor of the 'Herald,' and some of Whittier's earliest poems were accepted by him, while their author was yet unknown to fame. In 1827 he became editor of the 'National Philanthropist,' the first American temperance journal, and afterward of a journal in support of the election of John Quincy Adams. With Mr. Lundy, a Quaker, he then started at Baltimore the paper called the 'Genius of Universal Emancipation' (1829). The vigorous expression of his anti-slavery views in this last paper led to his imprisonment for libel, from which he was released by Mr. Tappan, a New York merchant, who paid his fine. He now prepared a series of emancipation lectures, subsequently delivered in New York and other places. He returned to Boston, and in 1831 started 'The Liberator,' without capital or subscribers, a paper published weekly with the aid of one assistant and a negro boy, and with which his name is inseparably associated, and which he carried on for 35 years, until slavery was abolished in the United States. In 1832 appeared his 'Thoughts on African Colonization,' and in the same year he established the American Anti-Slavery Society. For several years the mail brought hundreds of letters to Garrison, threatening his assassination if he did not discontinue 'The Liberator'; the legislature of Georgia offered a reward of $5,000 to any one who should prosecute and bring him to conviction in accordance with the laws of that State; in 1835 he was severely handled by a Boston mob, and the mayor of that city was constantly appealed to from the South to suppress his paper. In spite of all, he successfully persevered. In 1833 he visited Great Britain, and again, in the furtherance of his anti-slavery opinions, in 1846 and 1848. The diverging views of the anti-slavery party, as to whether a political platform should be adopted, and as to the voting and speaking of women, rent the body for a time, but on 1 Jan. 1863 Lincoln's proclamation of freedom to the slaves as a military measure placed the civil struggle on an anti-slavery basis. In 1865, when Garrison's labors had been completely successful, and after the total abolition of slavery in the United States, his friends presented him with the sum of $30,000 as a memorial of his services.

A bronze statue has been erected to his memory in Boston. Some 'Sonnets and Other Poems' by him were published in 1847, and 'Selections from Writings and Speeches' in 1852. See Johnson, 'William Lloyd Garrison' (1882); 'William Lloyd Garrison: the Story of His Life,' by his children (1885–9); and poems to his memory by both Whittier and Lowell. The reformer's character, as revealed in the accounts of his life, shows his great humanitarian schemes to have been the inevitable outcome of a sensitive conscience, a humane spirit, and an overpowering sense of justice.

Garrote, ga-rŏt', a mode of punishment in Spain by strangulation, the victim being placed on a stool with a post or stake (Spanish, *garrote*) behind, to which is affixed an iron collar with a screw; this collar is made to clasp the neck of the criminal, and drawn tighter by means of the screw till life becomes extinct. This word, with the spelling *garrotte*, has of late years become naturalized in Great Britain and the United States as a term for a species of robbery effected by suddenly springing upon and throttling the victim, and stripping him of his property.

Garrupa, ga-roo'pa, the Spanish name, in the West Indian region adopted as generic, and also corrupted into "grouper" of the great black jewfish (*Garrupa nigrita*). See JEWFISH.

Garter King-of-Arms, the head of the heraldic establishment in England, consisting of three kings-of-arms — Garter, Clarencieux, and Norroy, and the herald of the military order of the Garter. The office of garter king-of-arms was instituted by Henry V. in 1417. The duties of the garter king-of-arms are principally to grant heraldic supporters, to arrange funerals, and to present the order of the Garter to foreign princes.

Garter, Order of the, the highest and most ancient order of knighthood in England. Two stories are told of its origin. The first is that Richard I. at the siege of Acre caused some of his officers to tie leather thongs around their legs as a distinction. The origin of the order is, however, generally attributed to Edward III., and the legend runs that the Countess of Salisbury having dropped her garter while dancing, the king restored it after putting it round his own leg, amid the jesting of courtiers, with the words, *Honi soit qui mal y pense* — "Shame be to him who thinks evil of it." The date of the foundation or restoration by Edward III. of the order is not exactly determined; 1344 is given by Froissart, while other authorities, founding on the statutes of the order, assign it to 1350. In the former year it appears that a festival was held, and a society or company instituted, called the Company of Saint George, with the design of furnishing soldiers of fortune to assist King Edward in asserting his claim to the crown of France, but it seems probable that the organization of the order as an order of chivalry was completed in 1350. The statutes of the order have been repeatedly revised. The order is said to have been founded in honor of the Holy Trinity, the Virgin Mary, St. Edward the Confessor, and St. George of Cappadocia, its special patron. Until the reign of Edward VI. its common title was the Order of St. George, which it still bears, besides that of the Garter. The original number of knights, 26, including the sovereign, its permanent head, is still retained, except that since 1786 princes of the blood are admitted as supernumerary members. The order is frequently conferred on foreign sovereigns. The vestures and insignia of the order are: The emblem of the order, the garter, a dark-blue ribbon edged with gold, bearing the motto, and with a buckle and pendant of gold richly chased; worn on the left leg below the knee; the mantle of blue velvet, the length of the train distinguishing the king; the surcoat and hood of crimson velvet, the hat of black velvet, with plume of white ostrich feathers, having in the centre a tuft of black heron's feathers, and fastened to the hat with a band of diamonds; the collar of gold consisting of 26 pieces, each in the form of a garter, with the badge of the order, called the George, pendent from it — a figure of St. George on horseback fighting the dragon — the lesser George being worn on a broad blue ribbon over the left shoulder. The star, formerly only a cross, is of silver, and consists of eight points, with the cross of St. George in the centre, encircled by the garter. A star is worn by the knights on the left side when not in the dress of the order. The officers of the order are the prelate, the Bishop of Winchester; the chancellor, the Bishop of Oxford; the registrar, Dean of Windsor; the garter king-of-arms, and the usher of the black rod. There are a dean and 12 canons, and each knight has a knight-pensioner.

Garter-snake, or Grass-snake. Names given in the United States to several small striped harmless serpents of the genus *Eutænia*, especially *E. sirtalis,* which abounds in all temperate parts of the continent from Guatemala to Canada, and is exceedingly variable. This species varies in color from light-green through olivaceous to black, marked by three stripes, but only the one along the spine is well defined, those on the sides being often obscure, broken, or altogether absent. The spaces between these may be spotted in double rows, or not at all; and the belly, usually light greenish-blue, may be darker, almost to blackness. Some varieties have a metallic lustre. The ordinary eastern specimens are olive-brown, with dull spots and stripes. It is everywhere abundant, frequenting grassy meadows, farm-fields, roadsides and gardens, where it searches for mice as the principal part of its food, but it eats insects, small toads and frogs, and the eggs and young of birds whose nests are on or near the ground, for it is not a bold climber. It is abroad by day as well as by night, and itself forms the prey of such larger snakes as the blacksnake and king-snake. In the West it eats all the young gophers and ground-squirrels it can get, and in these habits commends itself to the protection of agriculturists. These snakes are extremely active and swift, as they must be not only to capture their prey, but to avoid being caught by the larger blacksnakes, king-snakes, and the like which pursue them. They swim well and hide clearly in water, and in many habits, as in structure, resemble the water-snakes (*Natrix*); and like them they are pugnacious, and quick to bite when handled, but their teeth are minute and the bite, of course, quite harmless. Their abundance is due to these qualities, not only, but even more to their great fecundity, 25 to 40 young in a season not being an uncommon product for one mother, and an instance of 80 is recorded. These are born alive, in early warm weather, and are able to care for themselves from the start, but the mother remains near them and protects them vigorously for some time. When cold weather approaches, these serpents seek underground retreats, such as old gopher-holes, and there often gather in large numbers which hibernate entwined together in a mass; mating takes place at this season. The skin is usually shed in the spring, by creeping through some crevice and scraping off the old hide, which peels backward from the head.

Of the score or more of species the greater number are Mexican and Central American; and some are known by very few specimens. The beautiful slender ribbon-snake (*E. saurita*) of the southern States is chocolate in color with three narrow distinct stripes, and has highly aquatic habits. The common species of the plains region (*E. radix*) is peculiar in its fondness for fish, catching them constantly in the pools and seizing every dead one cast on shore. A similar fish-loving species is the subtropical *E. macrostemma,* which appears in the talons of the eagle in the coat of arms of Mexico. The common species of California is *E. elegans.* In the southern part of that State occurs a rare form (*E. infernalis*), sometimes wholly black, save a yellowish throat. For the identification of the various species of this wholly American group the reader should consult Cope's 'Crocodilians, Lizards, and Snakes of North America,' published by the Smithsonian Institution in 1900.

Gary, Elbert H., American financier: b. Wheaton, Ill., 8 Oct. 1846. He was graduated at the law school of Chicago University in 1867; admitted to the bar of the Illinois supreme court the same year, and to that of the United States Supreme Court in 1878. He early applied himself to the practice of corporation law, and became general counsel for a large number of railroad and industrial corporations. It was largely through his legal work that his talents as an organizer of large industries first came into recognition. He retired from law practice in 1898 to become president of the Federal Steel Company, which in 1901 was merged into the United States Steel Corporation, he then being chosen chairman of its finance committee.

Gary, James Albert, American statesman: b. Uncasville, Conn., 22 Oct. 1833. He was educated at Allegheny College, Meadville, Pa. In 1861 he became a member of the manufacturing firm of James S. Gary & Son, and in 1870 succeeded his father as head partner. He was defeated as Republican candidate for governor of Maryland in 1879; and was postmaster-general in 1897–8, when he resigned.

Gas. See Critical Point of Temperature; Gases, General Properties of; Gases, Kinetic Theory of; Gasometric Analysis.

Gas and Gas Making. Illuminating gas, generally speaking, is the aeriform product of the destructive distillation of a liquid or solid hydrocarbon, in some instances diluted by the admixture of other combustible gas or gases. Practically all the illuminating gas manufactured throughout the world is made from bituminous coal, or petroleum, or some of the products of the fractional distillation of petroleum. The gas made from petroleum or its products, and known as oil gas, has a very high illuminating value, and is generally mixed in the process of manufacture with hydrogen and carbonic oxide gases. The mixture is known as water gas. Upon the relative amount of hydrocarbon gas in the mixture will depend the candle-power of the final product. Gas made from bituminous coal is known as coal gas.

In the early days of the industry practically all the gas produced was from bituminous coal, but experiments were made with wood, rosin, and tar, all of them capable of producing illuminating gas, but not as satisfactorily or as economically as coal. The original works at Baltimore were constructed to make tar gas, but the attempt was a total failure, both in convenience to the consumer and profit to the manufacturer. In New York the first attempt was with oil gas, but as this was found too expensive, rosin was substituted, but subsequently abandoned, and coal used. In the Southern States pine wood and rosin have been used. When gas was first introduced its use was confined to shops and factories, a feeling being prevalent in the minds of owners of houses that it was dangerous, and productive of fires. Several delegations of citizens passed resolutions and signed memorials to various legislative bodies protesting against its use.

Water gas was first produced commercially by a Frenchman, Tessie du Motay, about the year 1865. About the same time an American, Prof. T. S. C. Lowe, who had won fame as an aeronaut during the Civil War, was experimenting in the manufacture of gas by the dissociation of steam in contact with incandescent carbon. The result of the operations of du Motay and Lowe was the development of the water gas systems which bear their names — the cupola-retort system of du Motay and the generator-superheater system of Lowe. These are the most important of all the inventions affecting the manufacture of gas up to this date. The experiments of du Motay as well as of Lowe were carried on in the United States, and the development of the water gas system is entirely American.

In all the processes of the du Motay type, the non-luminous gas is generated in cupolas, mixed with oil vapor, and passed through externally heated retorts, for the purpose of gasifying the oil vapor. The gases thereafter being condensed and purified, as are coal gas and water gas produced by other methods. The Lowe process, covered by patents dated 1872 and 1875, may be regarded as the basis of the modern water gas system. It covers, broadly, the use, in connection with a generator, in which non-luminous gas is made, of a superheater, or oil gasifying chamber, fired by internal combustion, the combustible being the carbonic oxide gas formed during the process of "blowing up" — that is, during and from the passage of air through the fuel in the generator. This air is blown through the fuel, hard coal or coke, at a high velocity, for the purpose of raising the fuel to a condition of incandescence fitting it to dissociate the steam admitted during the gas making period. The Lowe process further covers the introduction of oil, or other hydro-carbons, into the non-luminous gas, and the gasifying of this oil by passing through the previously heated superheater.

In the manufacture of gas from bituminous coal there are produced the so-called by-products, coke, tar and ammoniacal liquor, each of which finds a market, either in the raw state, or worked up into finer products for use in the various arts and manufactories. In the manufacture of so-called water gas, there is but one by-product, and that of minor importance, known as "Water Gas Tar." Its quantity and value depend in part in the kind of oil used in the manufacture of the gas, and, in part, on the care and intelligence with which the gas generating apparatus is operated. The tar contained in either coal gas or water gas exists in the form of a mist of small drops and vesicles, and is removed, in part by cooling and in part by rubbing against rough surfaces, or impinging against plates. This process is known as "condensation." The tar removed from 1,000 feet of coal gas is approximately one and one quarter gallons; the amount removed from a 1,000 feet of water gas varies between wide limits. It may be as much as one gallon. It is generally much less. The amount of ammonia that may be recovered from 1,000 feet of coal gas is approximately one half pound of ammonia gas.

Illuminating gas, whether made from coal or petroleum, contains certain impurities which must be removed before the gas is fit for consumption, or before it can yield the highest possible candle-power per foot of gas burned. These impurities are ammonia, which is present in coal gas, and sulphur compounds, which are present in both coal and water gas. Carbonic acid is also present in unpurified coal and water gas. It is of little importance, having no deleterious effect, beyond slightly reducing the illuminating value of the gas. It may be removed from the gas or its effect on the illuminating value compensated by the use of an enriching material, or it may be ignored. Ammonia is removed by bringing the gas into intimate contact with water, the water being applied either by a spray or a wetted surface of some so-called scrubbing material, which may be coke, brush, thin rough sawn boards or other material having a large surface per cubic foot of space occupied. The amount of water required per unit of ammonia removed depends upon the temperature of the water and the intimacy of the contact between the water and the gas.

Various forms of apparatus for the removal of the ammonia gas are in use, but all depend upon the principle that cold water absorbs many times its volume of ammonia gas. The process of removing the ammonia is called "scrubbing." In the process of purification from sulphur compounds, slaked lime may be used. It is placed on wooden grids in a closed box, the gas being permitted to enter from the bottom and pass upward through the lime. Through the affinity of slaked lime for sulphuretted hydrogen this impurity is removed, and the sulphide of lime so formed has power of combining with other of the sulphur compounds in the gas. The slaked lime also removes whatever carbonic acid may be in the gas. The more general practice is to remove sulphur compounds by the use of iron oxide mixed with small shavings, or planer chips, and exposed to the gas in the manner described above in referring to purification by lime. The active purifying agent in this mixture, which is called "iron sponge" or "iron mass," is hydrated ferric oxide of iron — Fe_2O_3, $3H_2O$. It possesses the property of combining with sulphuretted hydrogen, but has no affinity for other sulphur compounds. After it has been a time in use, however, it contains considerable free sulphur, which has the power of arresting some sulphur compounds other than sulphuretted hydrogen. An advantage in the use of "iron sponge" for purification is, that after it has removed from the gas all the sulphuretted hydrogen which it is capable of absorbing, it will, upon exposure to the atmosphere, absorb oxygen, giving up the sulphur, which remains in the mass as finely divided sulphur mixed through the iron sponge. The mass, having been thus thoroughly re-oxidized by this exposure, may be used again, and so repeatedly, until the amount of free sulphur in it is equal to from 40 to 50 per cent of the whole material. It is then of no further value for gas purification, but because of the large quantity of sulphur and because of its containing a considerable percentage of the ferro-cyanides, it finds a market with manufacturers of sulphuric-acid and other chemicals.

Lime, after use in purifying gas, is of no further value and must be removed from the works or used as filling. This process of removing sulphur compounds is called "purification." When gas has been purified as above, it is passed through a large meter known as the "station meter," and thence into a storage holder, and is ready for distribution.

The first step in the manufacture of coal gas is to subject the coal to a high temperature. The coal is placed (technically called "charging") in retorts which may be made of fire-clay or of iron, but are almost universally of fire-clay, and closed, except as to one outlet for the gas. From this outlet the gas passes through what are known as stand-pipes to what is known as a hydraulic main, where the gas from all the retorts mixes, passing thence to the condensing and purifying apparatus. The temperature to which the coal is subjected varies, but it is generally recognized that it is economical to have this temperature as high as is consistent with maintaining the integrity of the retorts and the enclosing furnaces. The retorts are supported by means of blocks of fire-clay in a structure technically called a "bench," and heated by means of a fire, ordinarily of coke, built in a furnace below the retorts. In modern practice the retorts are heated to what might be called a bright cherry red, and about four hours are required to drive the gas from the coal. When the gas has been driven from the coal, the remaining coke is drawn from the retorts on to the floor, or into some form of conveying machinery, collected, and removed to the yard for storage and sale, except that enough is drawn from the retorts directly into the furnaces to supply fuel for the distillation of the coal.

The construction of retorts and enclosing furnaces, with the pipe connections from the retorts to the hydraulic main, is shown, in elevation and in vertical section, in Figures 1 and 2.

Figure 1 is an elevation of what is technically known as a "bench of fives" — that is, a furnace containing five retorts. AA are the retorts, which are ordinarily D shape in vertical section, 9 feet in length and approximately 26 inches in width, and approximately 16 inches in height. Attached to the front end of each retort is a so-called "mouth-piece" which is closed gas-tight by a lid. It is cast iron.

Attached to the mouth-piece is a so-called "stand-pipe," B, which conducts the gas, as generated, from the retort into the "hydraulic main," C. This hydraulic main extends the entire length of the "stack," which is the name applied to a number of benches built adjacent to each other and within one brick structure.

The process of operation is as follows: A fire is kindled in the furnace D, Figure 2, and the products of combustion, arising from the fuel, pass around the retorts, heating them to a bright cherry red. When this temperature has been reached, coal is thrown into the retorts, the charge varying in weight with the size of the retort. A large retort may take a charge of 350 pounds. The coal having been thrown into the retort, the lid is closed. The heat destructively distills the coal and the gas so produced passes out through the mouth-piece and stand-pipe into the hydraulic main. It will be seen, from the arrangement of the hydraulic main, that the gas passing from the stand-pipe bubbles through the water in the hydraulic main, the presence of the water preventing the return of the gas when the lid is again opened to draw out the coke resulting from the distillation of the coal, and to throw in a new charge.

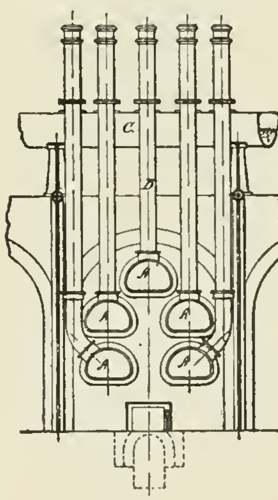

Fig. 1.

There are many forms of retort settings. In the more modern type the retorts are heated from what are known as regenerative furnaces, that is, furnaces which are worked at a comparatively low temperature and whose products of combustion contain a certain proportion of hydrogen and carbonic oxide, due to the introduction of steam below the fuel bed. These products, passing through ports to the chamber containing the retorts, meet there an incoming stream of air, which has been previously heated in flues, brought to a high temperature by the passage of the escaping chimney gases, through similar flues, parallel to and separated by a thin wall from the air flues. The furnace gases and the air combining in the retort chamber produce a very high temperature. The cuts illustrate the simpler form of retort setting and are given as being typical and easily understood, and not as showing modern practice.

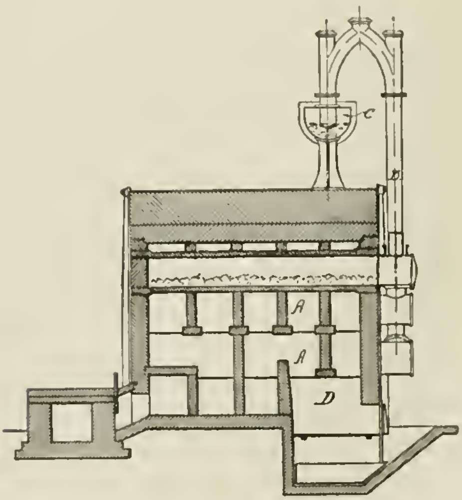

Fig. 2.

From the retort the gas passes to an exhauster, which is a form of gas pump, designed to draw the gas away from the retorts, and force it through the condensers, scrubbers and other apparatus and into the holder, thus reducing the gas pressure that would otherwise exist in the retorts. The operation of one type of exhauster will be readily understood from a reference to Figure 3, which is a cross-section of an exhauster. F is a cast-iron case, consisting of two half cylinders, of equal diameter, separated by a rectangular prism, and with flat ends. The moving parts consist of two impellers, C and D, keyed to the shafts, A and B, and so set in the case that the axes of the corresponding shaft, impeller and half cylinder, coincide. The impellers are so shaped that as they rotate each is always in contact, at some point, with the cylindrical portions of the case, and at the same time in contact with the other impeller, while the ends are practically in contact with the ends of the case. The shafts are supported by bearings on the case, and connected with each other at each end by two gear wheels, one on each shaft, of the same diameter and with an equal number of teeth, so that the relative position of the impellers is always the same at the same point in any revolution. The lower shaft is extended at one end and provided with a belt pulley, or connected direct to an engine on the same bedplate as the exhauster.

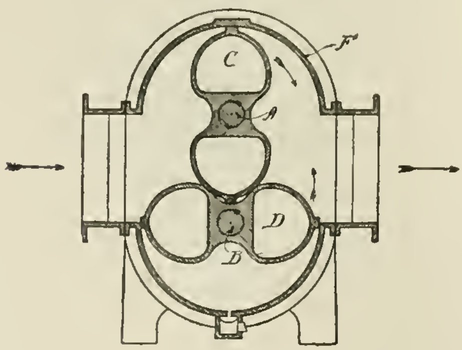

Fig. 3.

The action is as follows: Motion being imparted to shaft B, is transmitted through the gear wheels to shaft A, causing the two impellers to rotate, as shown by the arrows, and by the continual increase in volume of the space on the inlet side and decrease in volume of that on the outlet side, to draw the gas from the inlet and force it through the outlet, the contact between the impellers preventing the gas from passing back between them. From the exhauster the gas goes to the "condenser," a device designed for the cooling of the gas and the removal of the tar.

A simple form of condenser is shown in Figure 4. It consists of a nest of wrought-iron pipes enclosed in a cylinder, and so connected that gas passes around the tubes while water passes through the tubes. The gas passing around the tubes is cooled by contact with them, and partly by reason of this cooling and partly from the physical contact of the gas with the sides of the tubes, the tar vesicles are broken, and

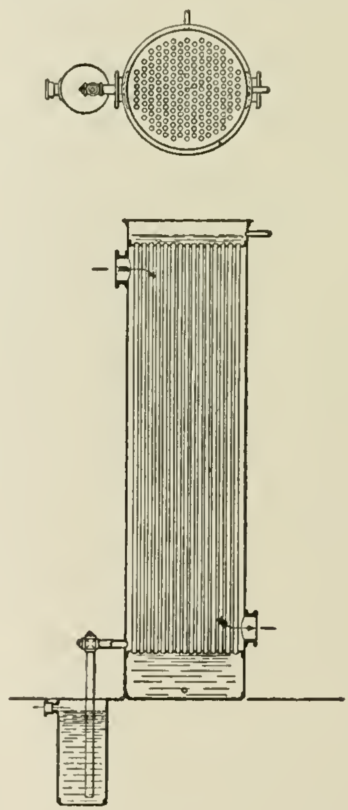

Fig. 4.

combining into drops, run down as drops of tar to the lower part of the cylinder, from which the tar is conducted, through an appropriate pipe, to the well or reservoir, as shown. The gas goes next to the "scrubber," which is designed for the removal of ammonia.

A simple type of scrubber consists of a wrought-iron cylinder, filled with wooden grids, coke or other porous material. Figure 5 shows

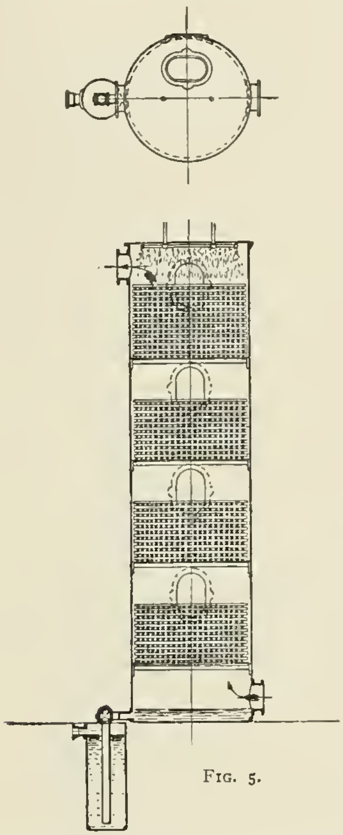

Fig. 5.

a scrubber with grids. The gas entering at the bottom passes up through the filling against a shower of water dripping over the filling. The intimate contact of the gas and water results in the absorption of the ammonia from the gas and also the removal of a certain part of the sulphur compounds and carbonic acid present in the gas, in combination with the ammonia — as sulphide of ammonia and carbonate of ammonia. The scrubber will also remove any traces of the tar that may have escaped from the condensing apparatus.

There are several forms of scrubbers. The above described is the simplest, and except that in some of them the scrubbing material is mechanically moved, so as to come alternately in contact with the water and the gas, the principle of all is substantially the same.

The gas passes from the scrubbers into the purifiers. These are rectangular boxes that are ordinarily built from 3 to 8 feet deep, and of a horizontal section depending upon the amount of gas that it is desired to purify in them. They are ordinarily built in sets of four or six, so connected by pipes and valves that the stream of gas may be made to flow through them in any order desired,— this because it is found economical to pass in sequence through the purifiers and to be able to vary this sequence as the material in the different boxes is more or less charged with sulphur compounds. A section and plan of a box are shown in Figure 6. A is the

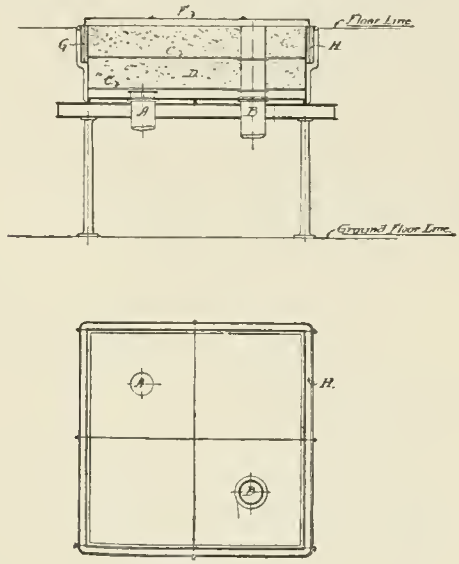

Fig. 6.

gas inlet at the bottom of the box. B is the gas outlet. C are the trays upon which the purifying material D, either lime or iron sponge is placed. F is the lid which is made gas-tight by the insertion of the lip G on its edges into the water-seal H, bolted to and encircling the box. When the lid is on the box the lip G, being in water, will prevent the flow of gas from the box into the atmosphere. When the purifying capacity of the material in the box has become exhausted, which is determined by appropriate tests, the gas is shut off from that box, the lid is raised, and the material is removed — to be carted away, if it is lime, or to be spread upon a brick or concrete floor, for re-oxidizing, if it is iron sponge.

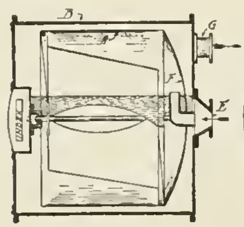

Fig. 7.

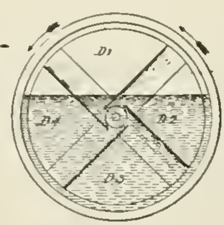

Fig. 8.

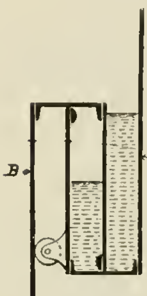
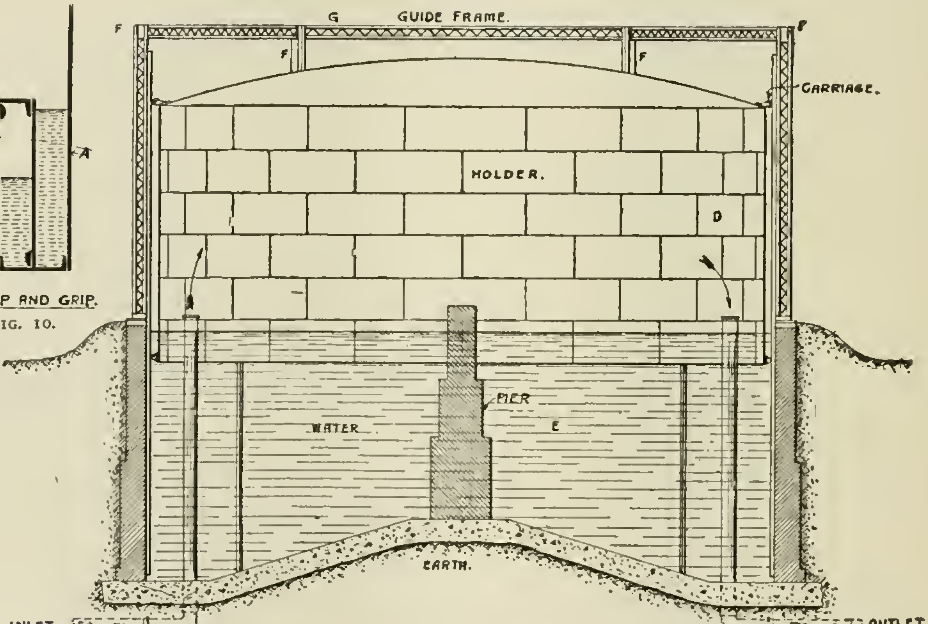
The gas having passed through the lime or iron sponge is completely purified and ready for measurement and storage, and for distribution to consumers in the territory supplied. It is measured by passing through what is technically known as a "station meter." The station meter of a gas works (see Figures 7 and 8) is a so-called "wet" meter of large dimensions. In principle it is the same as the small wet meters used for measuring gas as sold to individual consumers in those cities whose winter temperature is above the freezing point of water. Figures 7 and 8 show vertical sections of a station meter. It consists essentially of a drum or cylinder of metal, A, horizontally mounted in a metal case, B, so that it may revolve freely on its axis, and divided by wings or partitions into several compartments, D1 to D4, the shape and position of the wings being so designed that, as the drum revolves, each end of each of the compartments so formed, in turn opens above the surface of the water in which the drum revolves, and which fills the enclosing case to about three fifths of its diameter, no compartment having both its inlet and outlet ends above the surface of the water at the same moment. The gas to be measured is introduced through a pipe, E, entering one end of the meter case and compartments filled and emptied is the amount of gas that passes through the meter. This is registered on a dial connected to the drum through an appropriate series of gear wheels. The meter drum revolves because the gas entering is forced by the exhauster into the space between the outer surface and the inclined side of the compartment opening at the moment above the water.

The point of view of Figure 8 is the inlet end of the meter. The drum revolves in the direction of the arrows. Compartment D4, as shown, has its inlet submerged and its outlet open, and as the meter revolves the water enters this compartment, expelling the gas, which flows out of the drum and through the space between the drum and the case to the meter outlet, G. Compartment D1 is full of gas with both inlet and outlet submerged, the outlet being about to rise above the water. This will happen before D4 is entirely emptied of gas. D2 is filling with gas,



CUP AND GRIP.
Fig. 10.



SECTION.

Fig. 9.

rising to above the water line through a hood, F, covering the inlet end of the drum. Into this hood open the inlet ends of the compartments of the drum. As the drum revolves, the inlet end of each compartment in turn rises above the water and receives gas through the inlet pipe and hood. Because the other end of the compartment receiving gas is below the surface of the water, no gas passes through, but all that enters is retained in the compartment until its inlet end is again sealed by passing into the water. At that moment its outlet end rises above the surface, and the water, entering the inlet end as the revolving drum carries the inlet down, forces the gas through the outlet end of the compartment. As one compartment empties, another is filling, and the flow through the meter is continuous, though intermittent as to any compartment. The sum of the contents of the its inlet being above and its outlet below the surface. It is the force of the gas entering this compartment that is giving motion to the meter drum, and expelling the gas from the compartment D4. Compartment D3 is entirely filled with water. It will begin to receive gas before D2 is quite full and while D1 is emptying.

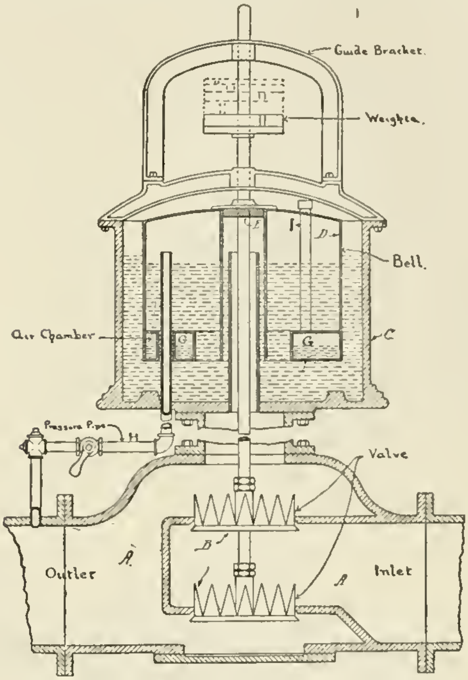
From the station meter the gas passes to the holder or holders, in which it is stored for use at such hours as the demand in the district supplied is in excess of the capacity of the manufacturing apparatus.

The construction and action of a gas holder, sometimes erroneously called a "gasometer," may be readily understood by reference to Figure 9.

A gas holder consists of a sheet iron cylindrical vessel, D, closed at the top, open at the bottom and floating in a tank, generally built of brick, as in the figure, or of iron, open at the top and filled with water. The holder is so guided in the tank and along columns FF, standing on the edge of the tank, and connected at the top by girders, that it will rise and fall freely as gas is forced into it or permitted to pass out. The columns and girders are called the "guide frame." To reduce to a minimum the friction produced by the rising and falling of the holder, rollers are attached to its upper and lower circumference. These rollers move on plates inserted into the tank for the purpose, and against the columns above referred to. Gas is admitted to the holder through what is known as the inlet pipe, A, rising above the water in the tank, and opening under the holder. As gas is forced through this pipe into the space between the water and the holder it forces the latter to rise. Gas passes from the holder to the street mains through the outlet pipe, B. As ordinarily used, gas flows continuously into and out of the holder, or set of holders, the excess of make of gas during the day filling them in preparation for the increased demand during the dark hours.

Large gas holders are often made of a so-called "telescopic" type. This expression means that there are within the tank several concentric cylindrical wrought iron sections, one of which only is closed at the top — this being the inner section. The columns in this case have a height equal to the sum of the heights of all the sections. The inner or covered section has as its lower edge a circular trough or "cup" A (Figure 10) which, as the section rises, engages with a similar but inverted trough B, called a "grip," on the upper circumference of the next section. The trough on the lower edge of the inner section being filled with water, a water seal is formed, which prevents the escape of gas. When the holder is down, the cups and grips are under water. Each section, in turn, as it fills with gas, and its lower edge rises to the surface of the water, engages the next lower section in a similar manner. When all the sections are full of gas the volume contained is approximately the capacity of a single section holder multiplied by the number of sections. The main advantage of the system is the small tank depth and ground area per unit of volume of holder capacity. As the gas flows out from the full holder, and the holder sinks into the tank, each section in turn rests on landing stones in the bottom of the tank. The inner section is not permitted to sink so far as to touch the landing stones, but is kept always afloat, except when necessary to make repairs.

The gas leaving the holder to enter the distributing system passes through a district governor, Figure 11. This is a device for establishing and maintaining, at the will of the operator, any desired pressure of gas at the point where the gas enters the street main system. It consists essentially of a valve box, A, inserted in the pipe leading from the holder to the street mains, and containing a valve, B; a cast iron tank, C, placed over the valve box; a sheet iron bell, D, working in the tank, and so fastened to the valve rod, E, that as it rises and falls the valve moves with it, and a connection, H, called the pressure pipe, from the outlet of the valve box to the interior of this bell. The shape of the valve is not important. It may be conical, parabolical or cylindrical, but it must always be so made and so arranged that the upward and downward pressures exerted upon it by the gas will be equal, and so balance each other. In the cut it will be seen that two surfaces of the valve are exposed to the inlet pres-



Non-Automatic Street Main Governor.

FIG. 11.

sure,— one a lower surface and the other an upper surface. Also that two surfaces of the valves are exposed to the outlet pressure,— one a lower surface and the other an upper surface. The pressure on the lower and upper surfaces, it will be seen, balance each other; therefore, they will have no effect on the position of the valve or the bell. There is an annular air chamber, G, on the bell, D, and located beneath the surface of the water in which the bell floats. It is designed to counterbalance the weight of the bell. The exact balance desired is established by pouring water into the air space through the pipe I, rising above the top of the bell. The interior of the bell is connected with the outlet of the governor, through the pressure pipe, H. When, because of an increased consumption of gas along the lines of mains, the pressure on the mains is reduced, the pressure on the interior of the bell is also reduced. This will cause the bell to drop until the opening in the valve connected to the bell is sufficient to pass enough gas to restore the pressure in the outlet, and, therefore, under the bell, which existed before the increased demand for gas occurred. In like manner, if the demand for gas upon the mains is reduced, the pressure in the mains will rise, which also raises the pressure on the interior of the bell — closing the valve until the opening is only sufficient to allow enough gas to pass to maintain the pressure previously existing in the outlet and under the bell. In order to increase the pressure in the outlet, which is important at hours of increased demand for gas, it is sufficient to place weights on the top of the bell, as shown in the cut. This addition of weight makes a higher pressure necessary at the outlet for any given position of the bell, and, therefore, for any given opening in the valve. To reduce the pressure at the outlet, weights are removed from the bell. It will be seen that it is thus a simple matter to regulate the pressure at the outlet of the governor, and therefore, in the inlet of the street main system, from hour to hour, as the demand for gas varies. It will be impossible with this device to increase the pressure at the outlet of the governor beyond the pressure at the inlet of the governor.

There are governors in use that automatically establish and maintain predetermined pressures in the main system. They are in principle as the governor described, except that by means of an ingenious device they automatically increase or diminish the weight on the bell as the pressure at the governor outlet diminishes or increases.

The sequence of the apparatus above described, and the part each takes in the preparation of coal gas for illuminating purposes, is graphically shown in Figure 12 which represents, in brief, the essential parts of a coal gas apparatus from the retort to the governor, and supposed to be in operation. All auxiliary apparatus, boilers, engines, pumps, conveyors, etc., are omitted from the sketch.

At A is the coal being distilled. At B the gas rising from the coal is bubbling through the water in the hydraulic main. At this point the gas contains all the tar and impurities with which it leaves the coal. It is a dark brown color and so dense as to be opaque. Its temperature is approximately 200° F. It consists of hydro-carbon gases, hydrogen, carbonic oxide, water vapor, ammonia, sulphuretted hydrogen and other sulphur compounds, carbonic acid, tar — as a mist of vesicles and small drops,— free carbon and traces of nitrogen and oxygen. At C is the exhauster pumping the gas from the retorts and forcing it through the subsequent apparatus into the holder. At D the gas entering the condenser is practically as it entered the hydraulic main, except that a proportion of the tar and water vapor and all the free carbon have been deposited, due to the cooling of the gas and friction. At E the gas entering the scrubber has parted with practically all of the tar and most of the water vapor it contained when leaving the retort, and with the water vapor there has been deposited a certain amount of ammonia, which the water vapor absorbed as it condensed to liquid. The ammonia absorbed by the water also carried out of the gas a certain part of the carbonic acid and sulphur compounds. At F, the outlet of the scrubber, the gas has practically lost all of its ammonia, water vapor and tar. It is now transparent, and contains of deleterious constituents only sulphur compounds. At G, the outlet of the purifiers, the sulphur compounds have been removed to an extent that renders the gas fit for consumption in closed rooms. The gas may now be used without fear of injury to person or fabrics. At H the gas is passing through the station meter. At I the gas is entering the holder, where it is stored, to be used as the demand of the town or district supplied may require. At J the gas is entering the governor. At this point the pressure will vary and have no relation whatever to the requirements of the district supplied. At K the gas is leaving the governor. At this point the pressure of the gas may be varied in accordance with the demands of the district supplied. If, owing to the approach of evening, or other causes, the consumption of the gas in the town or district increases, the governor, if automatic, will open, thus providing a passage for a larger supply of gas and increasing the pressure at the outlet of the governor. If the governor is not automatic in its action, the pressure may be varied by the addition or subtraction of weights as heretofore described.

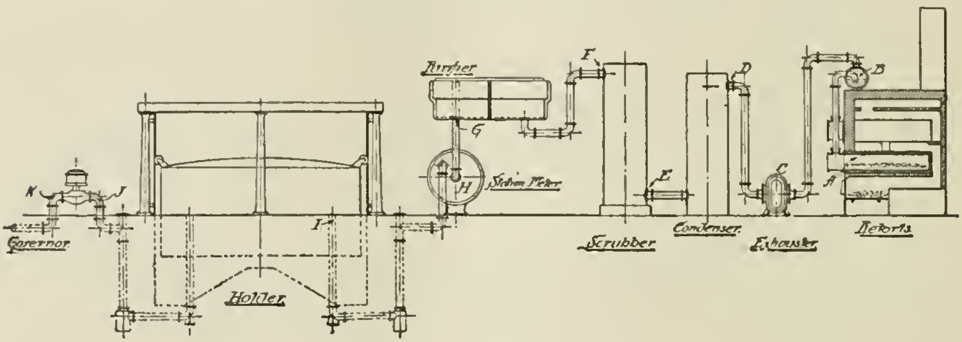


Fig. 12.

The generation and preparation of water gas differs radically from coal gas manufacture, up to the point of entrance to the purifiers; thereafter there is no material difference in the treatment of the two gases.

Figure 13 represents in brief the essential parts of a water gas apparatus, from the generator to the purifier. All auxiliary apparatus, boilers, engines, blowers, etc., are omitted from the sketch.

The Lowe Double Superheater Water Gas Apparatus, which is the modern type of apparatus for the generation of what is known as carburetted water gas, consists essentially of three wrought-iron cylinders connected in sequence, the top of the first cylinder or generator being connected to the top of the second cylinder, or carburetter, which is at its bottom, connected with the bottom of the third cylinder or superheater. The connections in practice are short and like the cylinders lined with fire-brick.

In Figure 13, A is the generator, B the carburetter, and C the superheater. A, B and C are connected with a main blast pipe H and so arranged that air may be introduced in desired quantity and proportion to beneath the grate in A, to the top of B, and to the bottom of C. At the top of C is a stack valve (7) for the exit of the waste furnace gases, and a take-off pipe (8) for the exit of the water gas. When the apparatus is in operation A is filled nearly to its outlet with coke or anthracite coal. B is filled to within a short distance of the connection with A with so-called "checker brick," or fire-brick placed on edge, and with openings between them of from one and one half to three inches. C is similarly filled with fire-brick to within a short distance of its outlet. The fire-brick in B and C are supported on fire tile arches a short distance above the connection from B to C.

The process of making gas in this apparatus may be conveniently divided into two periods, called, respectively, the "blow" and the "run." The blow is the period of introduction of air to gases still contain a small proportion of the unconsumed carbonic oxide and hydrogen, which burn in the air introduced at this point through valve (3) heating the checker work in C to the temperature desired. During the blow the "stack" valve (7) is open and the products pass out of the chimney and so into the open air. When the apparatus has been brought to the desired temperature, which is known from observation through sight cocks conveniently placed, the air is shut off from the three chambers A, B and C, and steam is admitted under the fuel bed A. Oil is then admitted into the top of the chamber, B, spraying down over the checker work in B, and mingling with the carbonic oxide and hydrogen gases formed by the passage of the steam through the fuel in A. The oil is vaporized immediately upon contact with the bricks in the hot chamber, B, and the vapor passing with the gases down through the hot checker brick of B, and up through the hot checker brick of C, is gasified, and the mixture of gases passes out through the outlet valve at the top of C, as carburetted water gas. The

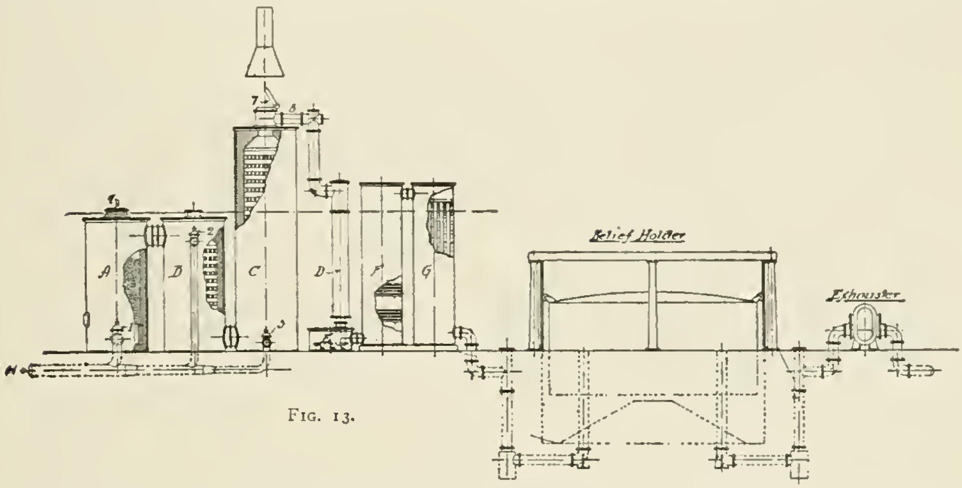

Fig. 13.

the apparatus in the process of heating it to a temperature at which it can economically treat the steam and oil used in the manufacture of the gas. The run is the period of the introduction of steam and oil, and therefore of the generation of gas. Necessarily the blow precedes the run. A power blower maintains a pressure of air on the blast pipe to which are connected the blast valves leading to the apparatus as above described. The valve (1) being opened, air flows into the generator A beneath the grate. Being under pressure this air rises through the fire bed, bringing it to a high state of incandescence. The products of combustion leaving the fuel bed are nitrogen and carbonic acid, with a relatively small proportion of carbonic oxide and hydrogen. Passing into the top of the carburetter B these gases meet an incoming stream of air, admitted through the valve 2, in which the carbonic oxide and hydrogen in part burn to carbonic acid and water vapor. This combustion raises the temperature of the gases and of the checker brick in B down through which the gases pass to the outlet of B and into the bottom of the superheater, C. At this point the stack valve (7) is closed at the moment that the carburetted gas appears, which marks the expulsion of all the blast gases previously contained in the apparatus. Upon the closing of the stack valve the carburetted water gas makes its exit through the outlet pipe D to the wash box E. At this point the gas is brown in color and opaque; it is composed of hydro-carbon gases, hydrogen, carbonic acid, carbonic oxide, sulphur compounds, tar, water vapor, free carbon, nitrogen and oxygen. In E, which has the function of the hydraulic main in coal gas generation, the gas deposits a considerable amount of the tar and free carbon, or lamp black, which it contained and which are due to the gasifying of the oil. From the wash box E the gas passes through the scrubber, F, which in design is similar to the scrubber described above in connection with coal gas manufacture. The scrubber F removes the lamp black and a large proportion of the tar from the gas. These are washed down through the trays in F by a spray of water admitted at the top. The gas passing through the condenser G is cooled to the temperature desired. The last traces of tar may here be removed.

The run is continued until the temperature of the apparatus falls to a point that makes it necessary to re-heat the brick work and the fuel bed. When this temperature has been reached, the oil and steam are shut off. The air valve (1) is opened. The blast rising through the fuel bed in A forces ahead of it the good gas contained in B and C until the judgment of the operator tells him that all the good gas has been forced out of the cylinders, at which moment he opens the stack valve (7).

It will be noted from the above description that the scrubber is before the condenser, which is the reverse of the order in coal gas manufacture. The reason of this is that in water gas manufacture there may be a certain amount of lamp black in the crude gas which must be washed out at the earliest possible moment, and also because there is no necessity of cooling water gas before scrubbing, because there is no ammonia to be removed. The gas leaving the condenser passes to a gas holder, known as a "relief holder," used to equalize the flow of gas to the purifiers, making it uniform from minute to minute, although the process of water gas generation is intermittent, as above described.

From the relief holder the gas is drawn by an exhauster located at the inlet to the purifiers, and from that point on its preparation for use is the same as described above in coal gas manufacture.

After purification, measurement, and storage, the gas, whether coal or water gas, enters the "distribution system," through the governor heretofore described.

The gas leaving the governor enters the street main system. The size of the pipes in this system and their distribution in the streets of the districts supplied depend upon the amount of gas to be delivered in the period of maximum demand, and upon the location, in the district supplied, of the areas of large and small consumption at the time of maximum delivery. The main pipes are ordinarily of 12-foot cast iron lengths, jointed with lead or cement. Wrought iron mains are in use to a considerable extent in some cities.

A "service" is the technical name applied to a pipe laid from the main to supply an individual consumer, the distinction between a main and service pipe being that the main pipe is laid for the general supply of a district or street,—a service pipe being used to connect this main with the premises of a consumer.

A certain amount of water vapor condenses in the mains and services of a gas distribution system, and it is necessary that these should be so laid as to drain to some central point or points, at which this water can be collected in so-called "drips," and the stoppage of mains and services by this accumulated condensation prevented. These drips are cast iron pots, and are connected to the mains at low points in the distribution system. The condensation is pumped from them through a small pipe rising from the bottom of the drip to the surface of the ground, where it is plugged and covered with an iron cap. Observation soon indicates how frequently it is necessary to pump any drip, and at such times a wagon, fitted with a tank, a pump and a hose connection, is sent to the spot and the water is pumped from the drip into the tank on the wagon.

Services are almost universally of wrought iron. It is common practice to provide on a service, at or near the curb line of the street, a cock which may be opened with a wrench inserted through a cast iron box having a lid at

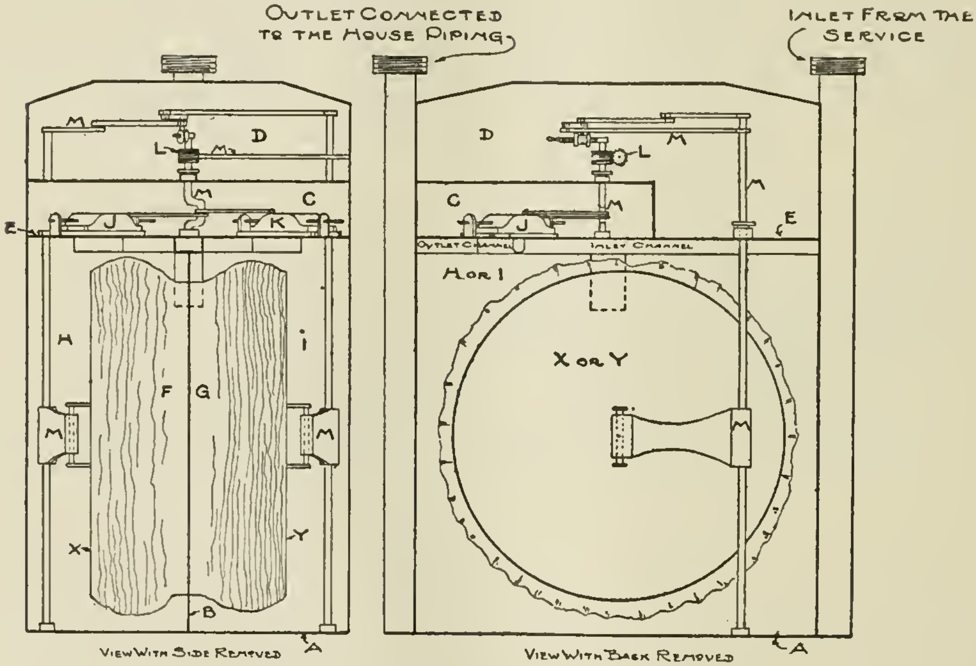

Fig. 14.

the surface of the sidewalk. The purpose of this is to enable the gas company to shut off the supply of gas from any premises in case of fire, or in case of the abandonment of the use of gas on the premises. The arguments for and against the practice of using so-called "service cocks" have persuaded some companies to adopt and some companies to reject them. The service pipe passes ordinarily through the cellar wall to a meter located in the cellar of the premises to be supplied.

The meter used in cold countries to measure the gas supplied to an individual consumer is almost universally of the "dry" type, which, as shown in Figure 14, consists of a tin box A divided into two measuring compartments by a vertical partition, B, these measuring compartments being separated from the superimposed valve and dial compartments, C and D, by a horizontal partition E. The measuring apparatus consists of two leather bellows, F and G, attached to the tin partition, B, and having light tin heads, X and Y, and located one in each of the measuring compartments H and I. The bellows are connected with the valves J and K and the dial gearing L through the rods and cranks M, M.

Gas is measured, as is any liquid commodity, by the alternate filling and emptying of enclosed spaces having a determinable and unvarying capacity. The capacity of the spaces multiplied by the sum of the fillings and emptyings is the volume measured. In the dry meter the gas is measured in the bellows F and G, and in the measuring spaces H and I, surrounding the bellows. Each bellows and each surrounding measuring space is alternately filled with gas, shut off for a moment from any connection with either the inlet or the outlet of the meter, and then opened to the outlet. This filling and emptying is so alternated that there is a continuous flow of gas through the meter, as long as there are any openings for the escape of gas in, or connected with, the house piping connected to the meter outlet. When no openings exist there is no place for the gas to escape and the meter will not move. To understand the action of the meter it is best to follow it through a complete cycle — see Figure 14. Assuming th burners to be all shut off and no leaks to exist in the house piping, the pressure on the outlet of the meter will be the same as on the inlet, no gas will pass, and as it is the passing of gas that moves the meter, it will, under the conditions assumed, be at rest.

In whatever position the bellows and connected valves of the meter may be, and whether the meter be in action or at rest, there is always an opening for the gas into one of the bellows or measuring spaces, and another opening from the other bellows or measuring space into the meter outlet and house piping. If now a burner cock be opened, the gas in the house pipes will begin to flow out through the burner, the pressure in these pipes and in the bellows, or measuring space, at the moment open to the house piping, will fall, and the gas in the service will tend to flow in to restore the pressure. To do this the gas must pass into the meter. Assume that the inlet of bellows F is open. The valves and connections are so arranged that when this condition exists the outlet of F and the inlet of space H will be closed, and the outlet of space H will be open. The gas from the service will then, by reason of the reduced pressure in the house piping and in the space H, force its way into the bellows F, expanding it into the space H, and forcing the gas from the space H through its outlet valve into the meter outlet and the house piping. When the bellows F has expanded to its full working length the rods and cranks connecting it to the valve J will have so far moved the latter that the inlet to the bellows F will close and its outlet open. This change also closes the outlet of space H and opens its inlet. Gas now flows into H, compressing the bellows F, and forcing the gas from it into the house piping. It is clear that at each filling of the bellows F there will be displaced from H and forced into the house piping as much gas as enters F; and that at each emptying of F an equal volume of gas enters H. Thus we have H and F alternately filling and emptying as long as the burner cock is open. It is evident that the gas does not flow through the bellows or through the measuring space. It flows into them alternately, is for a moment shut in, and then as the outlet valve opens flows out. There is, therefore, a definite measuring of each volume of gas that passes the meter. This volume is indicated on the dial by the movement of the rods, cranks and gearing.

In order to insure a continuous flow of gas to the burner, with an intermitting motion to the bellows, each meter is composed of at least two bellows and measuring spaces, so valved that there shall be no moment when there is not at least one inlet and one outlet open. When the burner cock is closed the pressure in the house piping rises in a moment to that in the service and the meter ceases to move. It is evident that when gas is passing the meter it is because the pressure in the service is enough in excess of the pressure in the house piping to overcome the inertia and friction of the moving parts of the meter; and, further, that the meter must cease to move the moment these pressures are equalized. As this difference cannot continue if there is no outlet for the gas, no gas can pass unless an opening exist in the house piping.

Meters are tested for accuracy by passing through them a volume of gas accurately measured in a small gas holder. The law commonly recognizes as accurate a meter that is not more than 1½ per cent "fast" or 2 per cent "slow."

Pure oil gas and acetylene gas are, to some extent, used for illumination.

Oil gas is extensively used for car lighting. It is ordinarily generated in retorts very similar to coal gas retorts — the oil being drippec into the retort from the end of a pipe. The gas, after purification, is compressed in cylinders, from which it is drawn into similar and smaller cylinders, located under the car to be lighted. Pure oil gas after compression has an illuminating power of approximately 50 candles.

Acetylene is one of the most interesting of illuminating gases. It is produced from carbide of calcium and water. Carbide of calcium, chemical formula — CaC_2, is produced by the fusion of carbon and quicklime in the heat of the electric arc. When water is poured upon this substance acetylene gas is liberated. The chemical reactions are as follows:

Calcic Carbide + water = Lime + Acetylene

$CaC_2 + H_2O = CaO + C_2H_2$.

When there is an excess of water present the following reaction also takes place:

$CaO + H_2O = Ca(HO)_2$

Quicklime + water = Slaked lime.

Acetylene has an illuminating power of approximately 240 candles. Coal gas has an illuminating power of 14 to 18 candles, and water gas as ordinarily supplied, has an illuminating power of 20 to 27 candles.

Gas produced by the distillation of coal for the production of coke, for industrial uses, has in recent years been conserved, and in some cases is being distributed by local gas companies. This gas is generated in large ovens, generally heated by the combustion of a part of the gas produced, and is treated in the same manner as coal gas generated in retorts, as heretofore described.

The "candle-power" of gas is the amount of light it yields, expressed in terms of standard sperm candles, made under rigid specifications and burning at the rate of 120 grains of sperm each per hour, the gas being consumed through a specified burner at the rate of 5 cubic feet per hour, and depending for its light on the incandescence of some of its component parts, and not, as in the case of the Welsbach burner, on the incandescence of some extraneous substance, subjected to the heat of the flame. Briefly, when it is said that certain water gas is of 25 candle-power, it means that when burned at the rate of 5 cubic feet per hour, through a suitable burner — it would yield 25 times as much light as would a standard sperm candle, made under specifications prepared by the Board of Trade of London, and burning at the rate of 120 grains of sperm per hour.

There are some gases, as for instance acetylene, which cannot be burned at as high a rate as 5 cubic feet per burner per hour without badly smoking. When it is said that acetylene gas is of 240 candle-power it means that when burned at an efficient rate it yields a candle-power that bears the same proportion to the rate at which it is burned as 240 bears to 5.

The calorific or heating value of a gas is the amount of heat generated by the combustion of one cubic foot of the gas, generally expressed in British thermal units. A British thermal unit is the amount of heat absorbed by one pound of water when raised 1° F. in temperature — the temperature being at or near the maximum density of water, or 39.1°. The heating power of gas varies. Acetylene gas has a calorific value of 1,477 heat units per cubic foot. That is to say, the combustion of one cubic foot of acetylene generates as much heat as it is necessary to add to 1,477 pounds of water to raise the temperature of the water from 39.1° to 40.1° F. Natural gas may have a value of approximately 1,000 heat units per cubic foot. Following are analyses of a water gas and a coal gas, giving the calorific value by calculation; that is, the theoretical heating value, as estimated from the heating value of the components of the gas. The value by calculation will be higher than the value developed in a test with the calorimeter, because of some slight losses in the use of the calorimeter.

Gas develops its highest illuminating effect when flowing from the burner at a low pressure. To accomplish this there is located in the burner, at some point below the tip, a so-called "check," having an opening of less area than the opening in the tip at the point of combustion. Obviously, the gas flowing through the burner at any rate per hour, will pass through the outlet and larger opening at less pressure than is required to force it through the smaller opening in the check.

Burners for illumination, excluding the Welsbach and other forms of incandescent burners, are of three general types, the batwing, the fishtail and the argand. (See GAS ILLUMINATION, HISTORY OF.)

Gas pressures are expressed in terms of height of water column. If we say the gas pressure is "one inch" we mean that it is equal to the pressure of a column of water one inch high. If we connect to a gas pipe one leg of a U-shaped glass tube, half full of water, the other leg being open to the atmosphere, the water will fall in one leg and rise in the other until the difference in the water levels in the two legs equal the pressure of gas in the connected pipe. If this difference is one inch we say the gas has a pressure of one inch.

The conception of a system of illumination comprehending a central source, and radiating lines of conduits; the measurement and recording of the service rendered as rendered, and the absolute and immediate control by the served of the time, period and measure of service, was as bold and startling as has occurred in the mind of man. Its fruit, the science and art of gas lighting, has amply justified the conception and has had a leading position among the activities of the wonderful 19th century. Wax and sperm oil were for 50 years its most potent competitors in the field of artificial illumination. Then came the discovery and the utilization of petroleum. Next, and so far last, came the wonderful and adaptable electric light.

WALTON CLARK,

Gen. Supt. the United Gas Improvement Co., Philadelphia.

Gas Engine. There are two classes of engine other than those driven by steam: (1) external combustion engines or hot air engines driven by the expansive energy of air or a mixture of air and gas heated from an external source through the walls of the containing vessel, as in the production of steam from water in a steam boiler; and (2) internal combustion engines driven by the expansive energy of air heated by the combustion of the fuel *within* the working cylinder itself.

The former, even in their highest form of development, were practical failures and are obsolete, but the latter have been developed within the last few years into an important class of highly efficient prime movers, represented by the various types of engine now commonly known as gas, gasoline, distillate, alcohol, and oil engines.

History.—The prototype of the modern internal combustion or gas engine was first conceived, in 1678, by the Abbé d'Hautefeuille, an eminent mineralogist and chemist of France. He proposed to drive a piston in a cylinder by the energy developed from explosions of gunpowder; but it does not appear that any machine was actually built by him, and besides the fact that, about two or three years later, small engines employing the same motive power were devised by Christian Huygens and Denis Papin, no further development of this class of engines occurred until 1791.

In this year, John Barber, an Englishman, patented an engine which was to be driven by the motive power derived from the explosions of a mixture of hydrocarbon gas and air. This engine was essentially a gas turbine. The gas used was generated from solid or liquid fuel, and after being mixed with a suitable quantity of air and water, was exploded in a vessel called the exploder, the energy thus developed being exerted against the vanes of a turbine.

A few years later, John Street, another Englishman, received a patent for an engine which he proposed to operate by the use of vapor derived from a liquid fuel and air, which was to be ignited and exploded in a suitable cylinder.

About the year 1799, Philip Tebon, a Frenchman, patented an engine designed to use coal gas for the fuel component of the explosive mixture or charge. He was soon followed by several inventors with similar engines of very ingenious construction, but none of them appear to have attained any practical success.

About the year 1860, Lenoir, a Frenchman, produced the first practical gas engine. It was of the double-acting type, and consisted of a cylinder three inches in diameter in which a piston worked with a stroke of five and one-half inches, and developed about one horsepower. The charge, consisting of an explosive mixture of coal gas and air, was drawn into the cylinder during the first half of the outward stroke of the piston and exploded by an electric spark from an induction coil at the beginning of the second half of the stroke. The products of combustion were exhausted during the return stroke at the same time that effective work was being done by the explosion on the other side of the piston. The igniter was placed in the cylinder wall at a point opposite the half length of the stroke, the platinum igniter points extending into the cylinder and exposing the electric spark, which constantly jumped through them, to the gas in each end of the cylinder alternately, according to the outward and inward movement of the piston. The cylinder was provided with a water jacket to prevent the overheating of its walls, and the engine worked so smoothly and regularly, that several manufacturers expected it would prove a successful substitute for the steam engine, and built it for commercial purposes in sizes up to 12 horsepower.

Many defects were soon discovered, however, especially the great fuel expense due to the consumption of over 100 feet of illuminating gas per brake horsepower under the most favorable load, and quickly led to the discontinuance of its manufacture.

It is interesting to note, however, that the Lenoir engine, although unsuccessful owing to a lack of fuel economy, yet possessed all the accessories of the successful modern gas engine, such as the electric igniter, the water jacket, etc. Its lack of success was directly due to the employment of a cycle of operations which did not include as one of its phases the compression of the charge prior to ignition.

Lenoir's effort, however, proved very important. The attention of inventors and scientists, long directed to the development of the steam engine, was re-directed to the gas engine, and led to the valuable experiments and works of Beau de Rochas, N. A. Otto, and Eugen Langen, during the period of 1861 to 1878.

It appears that about 1862, Rochas was granted a patent for the specifications of an engine in which the charge passed through four distinct phases in one cycle of operations as follows: It was drawn into the cylinder during the first outward stroke of the piston; compressed during the return stroke; ignited and exploded at the beginning of the second outward stroke or power stroke; and the products of combustion expelled from the cylinder during the second return stroke. Although this cycle gave only one power impulse for every two revolutions of the engine crankshaft, it included the feature of compression as one of its phases; and although Rochas stood on the very threshold of success, he failed to build an engine under his patent and it remained practically unnoticed for sixteen years.

About the same time, 1862, Otto, then a young German merchant, built an experimental engine on a somewhat similar principle, but abandoned it for lack of success.

Subsequently, in 1867, with the assistance of Eugen Langen, a skillful mechanical engineer, he produced a vertical engine in which a free piston was driven upward by the explosion of a charge of gas in the bottom of the cylinder and gave a power stroke only as it descended under the pressure of the atmosphere. This so-called "atmospheric engine," although very crude in mechanical construction, consumed only about one-half the amount of gas required by the Lenoir engine, and served to demonstrate the advantage of compression.

About the year 1873, Brayton of Philadelphia, produced the first successful gas engine built in the United States. It was of the vertical type and had two cylinders—a working or power cylinder and a charging cylinder, in which the charge was compressed prior to its introduction into the power cylinder. The charge used was an explosive mixture composed of one volume of gas to nine of air and was admitted into the power cylinder under a compression pressure of 74 pounds per square inch, during the earlier part of the downward stroke of the piston, and ignited after the piston had traversed one-fourth of its stroke, so that the force of the explosion pushed the piston to the completion of its stroke without any increase in pressure. Accidental ignition of the highly compressed mixture in the charging cylinder was prevented by placing a grating consisting of several layers of wire gauze in the port connecting the charging cylinder with the working cylinder. This engine showed a thermal efficiency about 33 per cent. higher than that of the Lenoir engine.

In the meantime Otto's labors had not ceased with the production of his atmospheric engine of 1867. At the Paris Exposition of 1878, he exhibited a new engine which worked on the Rochas cycle of operations. Its most ingenious feature was a slide valve which accomplished the double purpose of admitting the charge to the working cylinder, and then igniting it by means of a gas flame which passed from a jet in the valve cover, through the valve itself, into the combustion chamber. Its fuel economy was equal to that of his atmospheric engine. Its thermal efficiency was much higher than that of Brayton's. It worked noiselessly, smoothly, and regularly, and served to clearly establish the fact that the four-cycle principle was the most effective method for overcoming the many difficulties which up to that time had stood in the way of the successful operation of an internal combustion engine.

Since then, although many successful gas engines have been built which work under different or modified cycles, especially those of the two-cycle type, in which a power impulse is realized for every revolution of the crankshaft, the great majority of the standard types of internal combustion engine operate on the four-cycle principle. It is a fact, however, that the relative merits of these two principal types of engine have not as yet been satisfactorily decided by practical results.

Working Principles.—All heat engines operate through the medium of a working substance which absorbs heat, converts a portion of that heat into mechanical energy, and rejects the remainder still in the form of heat. The working substance may be a solid, a liquid, or a gas, and the action of the engine may be due to changes of either the form or the volume of its working substance.

In the case of an internal combustion engine, the actual working substance is atmospheric air, and the action of the engine is due to changes of the volume of this working substance under the influence of the heat evolved by the combustion of the fuel gas with which it is intimately mixed. The fact that the fuel gas or other vapor can be derived from coal burned in a gas producer, and from gasoline, oil, and alcohol transformed by means of carburetters and vaporizers, has created the various trade name such as producer gas engines, gasoline engines, oil engines, etc., but in all of them the actual working substance is atmospheric air, and they are all essentially gas engines, differing from each other only in the manner in which the working substance is heated.

Methods of Heating.—In all cases, the working substance is heated by the burning of the fuel gas or vapor within the working cylinder itself; this is the general gas engine method of heating, but the manner in which the heat is applied varies in the different types of engine, and permits of their being grouped into three well-defined classes:

1. Engines heating at constant temperature; with an increase of volume and a decrease of pressure of the working substance, and *vice versa.*

2. Engines heating at constant pressure; with an increase of temperature and an increase of volume.

3. Engines heating at constant volume; with an increase of temperature and an increase of pressure.

The first is represented by the Diesel engine, the second by the Brayton engine, and the third by the Otto, and by the great majority of internal combustion engines regardless of the peculiarities of their cycles of operation.

The effect of heating at constant volume is as follows: Imagine a cylinder of non-conducting material having an area of 10 square inches. Let 10 cubic inches of an inflammable gas at a temperature of 32° Fahr. (493° absolute) be placed in the bottom of the cylinder and under a piston having no weight except that due to the normal pressure of the atmosphere

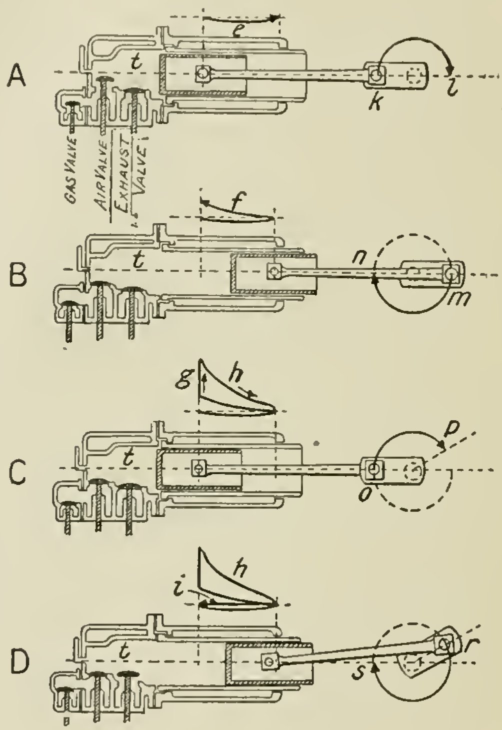

Fig. 1. Four-Cycle Engine.

(14.7 pounds per square inch). Let the gas be ignited, and assume that the resulting combustion raises its temperature to 1200° Fahr. (1661° absolute). According to Gay-Lussac's law, a gas increases in volume by 1-493 of itself for each degree of temperature above 32° Fahr., or, for convenience, the rate of expansion may be taken as equivalent to $\frac{1}{\text{Absolute temperature}}$. Therefore, 10 cubic inches of gas heated to a temperature of 1661° absolute will increase in volume to $1 \div 439 = .002035 \times 10 \times 1661° = 33.8$ cubic inches, or a little over three times its original volume, and raise the piston to a corresponding height. During this operation, the pressure (14.7 pounds per square inch) will remain unchanged.

Now, suppose that while the gas is kept at a constant temperature of 1661° absolute, the piston is forced down and the gas compressed to its original volume. The pressure will then rise from 14.7 pounds per square inch to $14.7 \times 3.38 = 49.6$ pounds per square inch, and represent the amount of energy expended by the gas in raising the piston to a height of 33.8 inches.

Again, suppose that after the gas had been ignited, the piston is held fast, thus preventing the gas from expanding. Then, while the volume is thus kept constant and the temperature raised to 1661° absolute, the pressure would rise to 49.6 pounds absolute, and represent the mechanical energy stored up in the gas and available as power for doing work.

This increasing of the pressure by raising the temperature while the volume is kept constant, exactly represents the action of the working substance of an engine heating at constant volume—the explosive mixture being ignited during the slow movement of the crank over its inner dead center so that the heat evolved by the explosion, often as high as 3000° absolute, increases the pressure behind the piston up to 250 or 300 pounds per square inch, before it can move outward and relieve the pressure by increasing the volume.

Cycles of Operation.—The practical working cycles in use at present are the Beau de Rochas or Otto cycle, already partially defined, and more commonly known as the four-part cycle and the two-part cycle—the former giving a power impulse for every two revolutions of the crank, and the latter one power impulse for every revolution of the crank.

Four-Cycle Engine.—The successive phases of the four-part cycle are shown by the diagrams A, B, C, D, of Fig. 1, in which the lines *e, f, g, h, i,* show the pressure conditions existing within the cylinder during the successive strokes of the piston required to complete the cycle. By referring to these diagrams and also to Fig 2, which shows the normal indicator diagram of an engine heating at constant volume, this cycle may be explained as follows:

Diagram A, represents the charging stroke. When the crank revolves from *k* to *l*, the gas and air valves open, and the suction caused by the outward motion of the piston fills the cylinder with the explosive mixture. During this operation, the pressure of the indrawn charge is slightly diminished by expansion in a partial vacuum, so that the admission line *e* falls below the atmospheric line.

Diagram B, represents the compression stroke. When the crank continues its revolution and passes from *m* to *n*, the gas and air valves close, and the inward movement of the piston on its first return stroke compresses the charge into the compression space *t*, raising both its temperature and pressure, the accession of temperature being exactly sufficient to bring the special mixture used to its point of ignition or inflammation, as shown by the line *f*.

Fig. 2. Indicator Diagram Four-Cycle Engine.

Diagram C, represents the power stroke. At the end of the compression stroke and while the crank is passing over its inner dead center *o*, the charge is ignited by contact with a hot tube, electric spark, or otherwise, and the heat caused by the resulting explosion causes a sudden increase of pressure which carries the explosion line *g*, upwards almost vertically, until the outward motion of the piston allows the heated air to expand with a consequent reduction in temperature and pressure as shown by the expansion line *h*. Usually, the exhaust valve opens when the crank reaches a point *p*, at about ⅛ the length of the piston stroke from its termination, and allows the pressure of the gas to drop to about that of the atmosphere.

Diagram D, represents the scavenging or exhaust stroke. The exhaust takes place during the revolution of the crank from *r* to *s*, the second inward movement of the piston expelling the products of combustion into the open air. The cycle then repeats itself.

Usually, the presence of a slight amount of back pressure causes the exhaust line *i*, to lie a little above the atmospheric line with which it would otherwise coincide. Back pressure is usually due either to a too early opening of the exhaust valve, or to a restricted valve area which results in the "wire-drawing" of the products of combustion during exhaust.

It is apparent that, in a single cylinder engine, the intermittent character of the power impulses requires the use of a heavy flywheel to equalize the motion of the crankshaft, by storing up enough energy from the working stroke to overcome the resistance and carry the piston through the other three strokes of the cycle. Therefore, it is evident that a high rotative speed is advantageous, and a high initial pressure and temperature at the instant of explosion are desirable, with a low terminal value for both at exhaust, so as obtain a high, mean effective pressure. Under these conditions the use of highly explosive gaseous mixtures and reliable methods of ignition become very important.

drives the piston downwards on its power stroke, and as it passes the exhaust port J, Fig. 4, the products of combustion are exhausted into the open air, and the fresh charge drawn into the crank chamber is compressed and permitted to pass through the port D, and the by-pass E, into the combustion space G. The momentum of the flywheel then carries the piston upwards on another compression stroke proper, and the cycle of operations is repeated, giving a power impulse for every revolution of the engine crankshaft.

Lubrication.—In the successful operation of an internal combustion engine, the proper lubrication of the working parts requires the most careful consideration. The provision of a water jacket around the cylinder and other water cooling arrangements in connection with the valve chambers and pistons, serves a two-fold purpose: (1) to keep the cylinder walls from becoming so hot that they will cause premature explosions by igniting the fresh charges while they are being drawn into the cylinder, or before final compression; and (2) to keep the temperature of not only the cylinder walls, but also those of the valve chambers, and in the case of large engines, the walls of the pistons, down to a point low enough to prevent the burning of the lubricating oil.

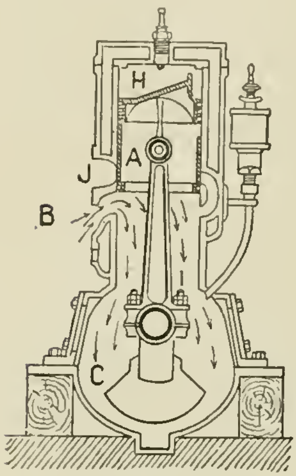

Fig 3.

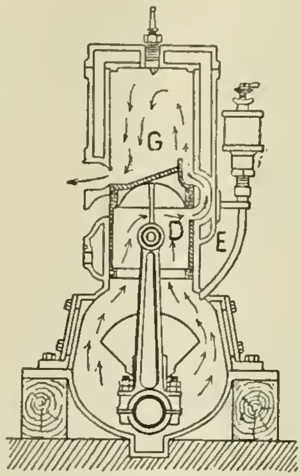

Fig. 4.

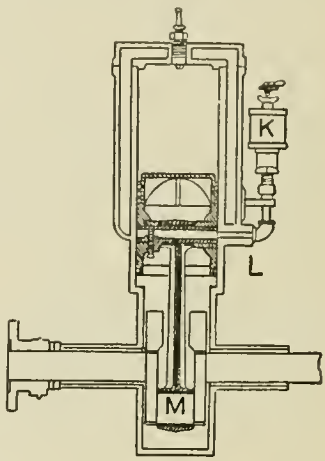

Fig. 5.

Two-Cycle Engine.

Two-Cycle Engine.—The principle of operation of a two-cycle engine heating at constant volume may be briefly explained as follows: Figs. 3 and 4, show vertical cross-sections through the cylinder and crank case of a two-cycle engine; and Fig. 5, a longitudinal section through the crank shaft.

The suction due to the up stroke of the piston A, draws a charge of vaporized gasoline and air through the vaporizer inlet B, into the interior of the crank case or crank chamber C, Fig. 3.

The following down stroke of the piston compresses the charge thus introduced into the crank chamber, and as the piston reaches the lower limit of its stroke, it brings the admission port D, opening into the hollow of the piston, opposite the by-pass E, Fig. 4, communicating with the crank chamber, and permits the compressed charge to pass into the combustion space G, of the cylinder. The next up stroke of the piston compresses the charge into the compression or clearance space at the top of the cylinder, where it is ignited by a spark from the igniter terminals at the lower end of the spark plug H, Fig. 3. The resulting explosion

Fig. 5, illustrates the method of lubricating an engine of the vertical two-cycle type. In the first place, the oil used should invariably be a mineral oil of high fire test, from 450° to 600° Fahr.

For the wrist pin, piston, and cylinder, it is carried directly from the sight feed cylinder lubricator K, through the passage L, in the hollow of the piston pin. In the case of the crank pin M, the revolving crank pin connection takes up the oil fed into the crank chamber through the pipe leading from a separate sight feed lubricator placed on the crank chamber.

In order to permit of the effective lubrication and economical operation of a gas engine, the cooling water circulating through the water jacket should not be allowed to issue at a temperature higher than 150° Fahr. nor lower than 100°.

Double-Piston, Two-Cycle Engine. — The chief motive for the development of the two-cycle types of engine is the desire to attain the ideal condition—an impulse at every revolution of the crankshaft. In the types already developed, the chief cause for whatever lack of success there may be, lies partly in the conditions attending the transference of the gases from one part of the cylinder to the other, and partly in the insufficient scavenging permissible.

In order to obviate these difficulties, many attempts have been made to produce a double-piston engine, but although many patents have been granted for very ingenious machines of this type, all of them appear to be more or less impracticable or uneconomical.

The Atkinson Differential Engine appears to be the pioneer of this type. It was exhibited at the British Inventions Exhibition in 1885, and consisted of a single cylinder with two trunk

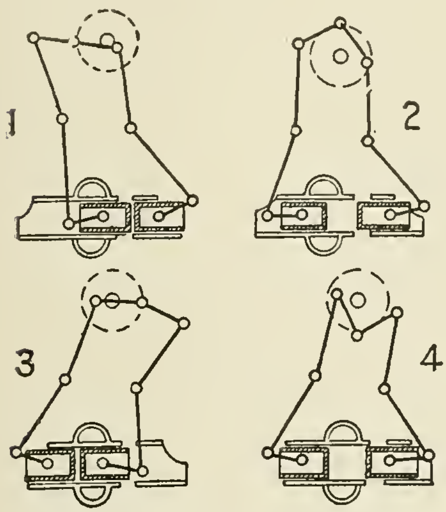

Fig. 6. Double Piston, Two-Cycle Engine.

pistons working in the opposite ends thereof. These pistons were connected to the engine crankshaft by an ingenious system of levers and connecting rods which transmitted the motion of the pistons to the crankshaft.

The four diagrams of Fig. 6, show the positions of the pistons at different points of the cycle. In the first, the pistons are at one extreme of their stroke and are just beginning to separate. The charge is now admitted between them through an automatic lift valve. In the second, the admission of the charge has been completed and the further movement of the pistons is about to close the ports leading to the admission and exhaust valve. In the third, the charge is compressed and ignited, the resulting explosion causing the pistons to rapidly separate. In the fourth, the exhaust port is uncovered, and the products of combustion discharged into the atmosphere. By this method, the several operations of admission, ignition, expansion, and discharge are performed in a single cylinder during one revolution of the crank. This engine was never manufactured for commercial purposes.

Six-Cycle Engine.—The so-called six-cycle or scavenging engine has never proved of much importance, and is here mentioned solely for the purpose of covering the principal points in the general development of the various gas engine cycles. A six-cycle engine is essentially of the four-cycle type, but in addition to the operations taking place in the latter, a third revolution of the crank or two additional piston strokes, serve the purpose of admitting and expelling a charge of pure air into and from the cylinder immediately after the products of combustion have been expelled therefrom by the exhaust stroke proper. By thoroughly scavenging the cylinder in this manner, the designers expected to lessen the dilution of the fresh charges by the inert gases forming the products of combustion, and thus obtain a higher economy of fuel consumption. These expectations were not fully realized, however, and the construction of this type of engines has been entirely abandoned in recent years.

Types of Gas Engine.—As already stated, the various types of internal combustion engine may be grouped into several well-defined classes according to the method of heating their working substances or according to their cycles of operation. They may also be grouped according to their structural characteristics, their action, and the method of governing employed.

When classified according to their structural characteristics, the usual definitions are based on the position and number of cylinders comprising an engine unit, with the addition of the terms four-cycle or two-cycle to indicate their mode of operation. This method of grouping is the one generally employed for trade purposes.

Thus, both the four-cycle and the two-cycle engines may belong, either to the horizontal or to the vertical, single, twin, tandem, or multi-cylinder types, and may be either single-acting or double-acting.

The designations "hit-or-miss" and "throttling" engines, very popular among writers and tradesmen a few years ago, are rarely used at the present time. In the hit-or-miss engines, the governing mechanism operates to reduce the speed by entirely cutting out a charge or a number of charges whenever necessary. In the throttling engines the governing is effected by increasing or reducing the area of the admission valve opening according to the variations of the load on the engine. It is obvious that any gas engine can be governed by either method, regardless of its cycle of action, or of its structural characteristics.

Governing.—The principal if not the only point to be considered in the matter of governing is the efficiency of a particular method to maintain uniform speed under varying loads, and different conditions of service. Some engines are equipped with very sensitive hit-or-miss governing mechanisms, but at their very best, they are not satisfactory for use on engines employed to drive direct connected dynamos for electric lighting and other purposes requiring a steady current. In this connection the throttling method is much more effective, and with reliable igniters and proper ignition control, is giving eminent satisfaction in all standard engines. Its application is also practically essential in the case of a marine engine, where the rocking of the vessel tends to operate against the action of a hit-or-miss governor.

Ignition.—In the matter of ignition, the most important conditions are safety and reliability. The use of the naked flame is obsolete, and that of the hot tube or hot head nearly so, the latter being still satisfactorily used in some types of oil engine.

The method almost universally employed at present is that of the electric spark. The necessary current is derived either from chemical or storage batteries, or from small dynamos or magnetos driven by the engine itself, and passed through an inductive resistance or spark coil. The efficiency and reliability of the igniter devices now on the market leave very little to be further desired in this connection.

Oil Engines.—As already stated, gasoline, oil, and alcohol engines are essentially gas engines having the additional accessories such as carburetters and vaporizers for converting the liquid fuel into vapor prior to its admixture with the air, and its introduction into the working cylinder. All of them are of either the four-cycle or two-cycle type, and ignite their charges either by hot head or by electric spark. There is, however, one important exception to this general rule, and that is the Diesel engine.

The Diesel engine was originally designed to operate on solid, liquid, or gaseous fuel and to ignite its charge by the heat of compression, thus doing away with all ignited arrangements, and establishing a truly ideal system of power generation. It is of the vertical type, works on the four-cycle principle, and has been chiefly developed as an oil engine.

Its cycle of operations is as follows: During the charging stroke, air only is admitted to the cylinder at atmospheric pressure and temperature. On the return stroke, this air is compressed to a pressure of about 500 pounds to the square inch, and its temperature thus raised to about 1000° Fahr. Then, at the instant of the beginning of the power stroke, the fuel oil is sprayed into the heated air in the compression space and instantly ignited. The admission of fuel is continued for about a tenth of the stroke, and the combustion maintained during the whole or a portion of this period according to the action of the governor. After the fuel supply is cut off, the working substance expands adiabatically during the remainder of the stroke to a terminal pressure but slightly above that of the atmosphere. The return stroke of the piston exhausts the products of combustion in the usual manner.

The unusually massive type of construction required to apply the high compression pressures, and to successfully withstand the severe shocks of the resulting powerful explosions, unfits it for service where a minimum of weight is essential, but for heavy work, and especially for driving electrical and pumping machinery, it is equal to any of the standard types of engine on the market.

Alcohol Engines.—Any gas or gasoline engine may be operated with alcohol by the use of a suitable carburetter. This accessory is the principal element which limits the use of alcohol as a fuel, requiring to be kept at a much higher temperature with alcohol than with gasoline. On this account, it is very usual to start the engine and run it with gasoline until the burner is well heated, when the gasoline is shut off and the alcohol turned on. For this purpose, two types of carburetters are employed—the duplex carburetters of the constant level or float feed type, and the atomizing carburetters.

The alcohol engine has been developed to a greater extent in France and Germany than in the United States. This is due to the fact, that while the policy of the French and German governments has always been favorable to the production of alcohol by distillation, a high revenue tax has been the feature of American practice up to April 1906, when Congress passed the bill removing the tax on denatured alcohol, thus placing it upon the list of available fuels for internal combustion engines. Under these conditions, and the effort to produce it cheaply in large quantities, great progress in the development of alcohol engines, especially for marine purposes, may be confidently expected in the immediate future.

American practice appears to favor the use of methyl alcohol, regardless of its disagreeable odor, on account of its cheapness, while in France, ethyl alcohol or spirits of wine is more commonly used on account of the prevalence of the vineyard.

A satisfactory mixture, quite extensively used, consists of

Ethyl 90 per cent.	100	volumes
Methyl 90 per cent.	10	"
Hydrocarbon	0.50	"

This mixture added to an equal volume of benzole forms the denatured or non-potable alcohol commonly known by the trade name of "electrine." It has a calorific value of 13,150 B.T.U.'s, and contains a hydrocarbon having a boiling point about 400° Fahr.

Horsepower of Gas Engines.—Up to within the last few years, a gas engine of 100 brake horsepower was considered to be a very large power generating unit of its class. The recent discovery, however, of the suitability of blast furnace gas, and other lean gases such as the different kinds of natural gas, and producer gas, for use in gas engines, has led to the development of large engine units developing as high as 7000 horsepower.

Up to the present time, the efforts of the English and German manufacturers have been the most active and successful in this direction. The Crossley, Cockerill, Nurnberg, Oechelhauser, and Deutz engines represent some of the standard types. Some of these—the American-Crossley, Nurnberg, and the Cockerill—are also built in this country under United States patents. They range in size from 500 to 7000 horsepower per engine unit, and are especially designed to burn blast furnace, natural, and producer gas.

Large engines of distinctively American construction are, however, being gradually developed to a state of high efficiency by several of the more prominent American concerns. The Westinghouse tandem engines of the single or double crank type, are being built in units ranging from 500 to 6000 horsepower, while those of the Standard Gasoline Engine Co., consisting of six-cylinder units of the marine type, range from 500 to 1000 horsepower.

Use and Economy of Gas Engines.—With a full appreciation of all their shortcomings, it is safe to assert that the gas engine is the most efficient and economical power generator of the day. It is more portable than any other type of prime mover, as exhibited by its application to automobiles, roading machines, farming machinery, etc., and its cleanliness and adaptability are making it the choice in many other kinds of service heretofore performed by steam engines.

Its use for marine purposes, even as a gasoline motor, indicates its ability to compete in economy with the triple expansion steam engines which are well known to be the most economical of their class. In this connection, it is interesting to note that both in this country and in Europe gasoline engines are being extensively used on torpedo boats, destroyers, and other forms of naval craft, and points to the strong probability of producer gas engine installations on the larger naval vessels in the near future.

For stationary service, the producer gas engine has fully demonstrated its economical superiority over steam-engine plants of equal power. The reasons for this superiority are now very clearly understood. The steam engine is an economical motor only when made in large power units. In units of 100 to 500 horsepower, operating under actual working conditions, the coal consumption per brake horsepower hour ranges from 2.4 to 4 pounds. With smaller powers, present practice requires 5 or 6 pounds, and the average for an ordinary working district using a large number of small engines ranges from 10 to 12 pounds of coal per brake horsepower hour.

With producer gas engines, one brake horsepower hour has been attained on one pound of coal, and judging from present developments such performance or better may be confidently expected as that of daily practice in the near future. See GAS PRODUCERS in this Encyclopædia.

The advantages of its use in connection with electric power plants have been also satisfactorily demonstrated. One of the highest authorities (Schoemburg) gives a comparative estimate of the cost of equipping a mill with an electric power plant for supplying direct current to lamps and motors, the power furnished during the day being 900 kilowatts, and that furnished during the night 250 kilowatts.

The power systems compared are as follows: dynamos driven by steam engines; dynamos driven by steam turbines; and dynamos driven by suction producer gas engines. The following figures give the first cost per kilowatt, and the cost of operation per kilowatt, of each system.

	First Cost per Kw.	Cost of Operation per Kw. Hour
Steam engines	$135.00	1.44 cents
Steam turbines	104.50	1.30 "
Gas engines	112.75	1.15 "

It will be understood, of course, that estimates of this nature necessarily depend on local conditions, and on the various assumptions made, and that, as a general rule, the question as to which system is best must be solved for each particular case.

The chief limitations of the gas engine are irregularity of torque and consequent variation of angular velocity, and lesser capability of adapting itself to varying loads, and especially to extreme over-loads, than either the steam engine or the steam turbine. The adoption of multicylinder types of construction and the use of large fly-wheels reduce the magnitude of these defects to a minimum, however, so that in the opinion of the best engineering foresight, the internal combustion engine, in some one or more of its various forms, is more likely to be the prime mover of the future than any of its present competitors.

Consulting Civil and Mechanical Engineer, New York.

Gas Holder. See GASOMETER.

Gas Illumination, History of. The development of gas lighting can properly be placed to the credit of the 19th century. "Spirit of Coal," produced by the distillation of coal, was known as far back as 1739, and the attention of Robert Boyle was called to this substance by Dr. Clayton, bishop of Cork. Its properties were studied and its inflammability and many of its general characteristics were known at this time, although an inflammable gas rising from the surfaces of certain stagnant pools had been noted as far back as 1659.

The first practical application of gas for illuminating purposes was made in 1792. William Murdock, an English engineer, produced gas by the destructive distillation of coal in iron retorts and conducted it for a distance of 70 feet through iron pipes and lighted and heated his house in Redruth, Cornwall. Lebon in 1801 illuminated his house and garden in Paris by gas produced from the destructive distillation of wood. This method of illumination proved a failure on account of the poor illuminating power of the gas. In 1802 Mr. Murdock installed a plant for illuminating the foundry of Watts & Bolton, near Birmingham, and a similar installation was introduced in Manchester shortly after this time.

Street lighting was introduced by F. A. Winzer (afterward changed to Winsor) in 1807 in Pall Mall. Mr. Winsor promoted a company for general gas lighting in 1809, and was granted a charter by Parliament in 1810 for the establishment of the London Gas Light and Coke Company, generally known as the Chartered Gas Company.

In America David Mellville, of Newport, R. I., was attracted by the developments made along the lines of gas lighting in England, and installed in his house, and in the streets in front of his house, the first gas lights used in the United States. This installation was made in 1806, his apparatus, with improvements, was patented in 1813; and a general installation made in several cotton mills and lighthouses.

Baltimore was the first city in the United States to install gas lighting, in the year 1817.

and since that time the growth of the gas lighting industry has proceeded uninterruptedly, for its convenience and economy have been impressed upon the public.

The original promoters of gas lighting encountered many difficulties. At the time of the installation of gas pipes in the House of Parliament, it was stipulated by this body that no pipes should be placed nearer than six inches to any wood-work. Numerous explosions and fatal asphyxiations caused by lack of experience in handling the new substance are recorded. The disagreeable and often injurious odor of the products of combustion of the gas greatly retarded its favor with the public. With the increasing experience of gas engineers, the dangers of explosions and accidental asphyxiations were eliminated. Considerable inventive genius was brought to bear to remove from the room the products of combustion, or to purify the gas for the removal of those constituents which gave the disagreeable products on burning. Several means were proposed for accomplishing these purposes. The most original improvement, and one in use at the present time, was the invention of Clegg, who introduced the use of slaked lime for removing the sulphurous constituents of the gas before it entered the holders. A later development was that of Lanning, who used ferrous oxide mixed with sawdust or wood pulp to make it porous for the absorption of the sulphur constituents. These methods are to-day in general use. Many other methods, of more or less value, have been proposed.

The illuminating power of a flame is derived from the heating of solid particles to incandescence, and the practice of gas illumination can therefore be divided into two general principles.

1. Where the solid incandescent material is supplied by the decomposition of the gas in the process of combustion.

2. Where the complete combustion of the gas is produced by the Bunsen burner, and a permanent incandescing material is supplied as a part of the apparatus.

The latter method is what is generally known as the Incandescent Gas Lighting system. The original developments in gas lighting were made on the first of these principles. The batswing or fishtail flame was produced by releasing the gas through a narrow slit, and its illumination was produced by the incandescence of the solid particles of carbon derived from the decomposing gas in the flame. The Argand gas burner is a modification of the old Argand oil burner, and consists of a ring of small openings arranged near enough together so that the gas flame is in the form of a continuous cylinder, admitting air to the inside and outside of the cylinder.

The Siemens-Lungren system, known as the Regenerative system, consisted in applying to the burner, gas and air which has been preheated.

Prof. Bunsen, professor of chemistry in Heidelberg, designed a burner to produce a non-luminous flame with complete combustion, and to give the maximum heating effect of the gas. This was accomplished by so constructing a burner that it will carry in and mix with the gas a limited amount of air before it reaches the point of combustion. The additional air necessary to produce complete combustion is drawn from the atmosphere surrounding the flame. This type is known as the Bunsen burner.

The experiments of Henry Drummond in 1826, in which he placed a solid stick of lime in the oxy-hydrogen flame, was the first systematic attempt at the development of what is now known as the Incandescent Gas Lighting system. The Drummond, or lime-light, was until recently in general use for the production of very high power lights, especially in theatres and for stereopticon practice, etc. This system, however, was not applicable to the ordinary conditions of gas lighting. A modification of the Drummond light was made by Tessie du Motay, in which he substituted coal gas for the hydrogen in the ordinary Drummond oxy-hydrogen flame. A burner exhibited at the Crystal Palace Electric and Gas Exposition in 1883, by Lewis, was constructed with a platinum mantle suspended over the flame, and designed to produce a high incandescence. This mantle, however, was unsuccesful, owing to the fact that it rapidly deteriorated by the reducing action of the gas. This burner was designed to operate with compressed air.

Clamond about the same time introduced a burner similar to the Bunsen type, in which he placed a mantle made of threads of magnesia. He also introduced an inverted pattern of burner in which a basket or mantle was made of magnesia threads held in a platinum basket. This burner, like the Lewis burner, was operated by compressed air, and was claimed to produce 4½ candles per foot of gas consumed, with a life of from 50 to 60 hours. Mantles in modification of the Clamond type were produced by C. B. Harris, in which he moulded a refractory material into sheets, pressed into the proper shape and perforated in any desired pattern. Attempts have also been made to make a mantle of asbestos or similar non-combustible material, and saturate this with a substance giving high incandescence.

The first commercially successful results accomplished in the field of Incandescent Gas Lighting were made by Dr. Carl Auer von Welsbach, of Vienna. Welsbach's work in this field began in 1880, in Bunsen's laboratory in Heidelberg, where he was studying the rare earths from a standpoint of pure chemistry. His attention was centred on the oxide of erbium. To produce a continuous light for spectroscopic study he saturated a cotton fabric with a solution of erbium, and after burning out the cotton suspended the residual ash in the flame. This produced an intense green light. The idea occurred to Welsbach to utilize this particular method for producing an ash fabric of incandescing material in the ordinary Bunsen gas flame. When this plan was communicated to Bunsen, he replied: "It appears most improbable that the oxides could be made to adhere." Welsbach, however, continued his experiments, choosing not erbium oxide, but oxides which would give a high white incandescence when heated. His researches led him through the entire field of the elements having stable oxides, and certain oxides of the so-called rare earths were found to give the most promising results.

The oxide of lanthanum made a perfect mantle in appearance and produced an intense glow in the colorless flame of a Bunsen burner, but the mantle was found to crumble to a powder within a short time.

Dr. Auer then began experiments with a view of mixing something with the lanthanum which would produce a non-slaking body. In 1887 what is known as the lanthanum-zirconium mantle was introduced. This mantle was made by saturating a closely knit cotton fabric with the proper mixture of zirconium and lanthanum nitrates, burning out the cotton and leaving a network of ash composed of the oxides of zirconium and lanthanum. These mantles gave 12 candle-power per cubic foot of gas consumed, and lasted several hundred hours. To quote Dr. Auer: "The sum of all these results appeared encouraging, and I was audacious enough to pronounce the endeavors of the gas engineers to increase the illuminating power of the open flame, as useless and vain; for it was evident that it was much more economical to renounce the lighting power of the open flame and to transform it into a Bunsen flame, and to get those substances to incandesce in the very hot part of that Bunsen flame, by which method two or three times the amount of light of an open flame could be attained."

The invention was now called to the attention of the public, and Welsbach delivered numerous lectures before the press representatives. The invention was named the Incandescent Gas Light by Mr. Sceps, editor of the *Neue Wiener Tageblätter*. The announcement of the Welsbach mantle was received with various comment, and many prominent engineers refused to take the matter seriously. Welsbach's confidence, however, was not shaken, and companies were formed for the development of the industry and the manufacture of the lighting fluid from the rare earths. The services of Dr. Ludwig Haitinger, an able chemical engineer, were added to those of Dr. Auer in the development of this work.

The increased efficiency of this method of lighting, however, was not what had been expected, and the public refused to take it up. The mantle rapidly deteriorated and required to be rejuvenated. At that time it must also be understood that these mantles were very fragile and in the early stages of the work they were delivered in the city of Vienna by a boy carrying one in each hand, as they would not bear the ordinary handling in transportation. The usual skepticism of the public in regard to new inventions prevailed, and the commercial failure of this enterprise seemed imminent. The Vienna factory was closed and the plant and laboratory sold. The American factory, under the direction of Waldron Shapleigh, was still producing with some success the lanthanum-zirconium mantle.

Welsbach, however, was not discouraged by these drawbacks, and devoted his entire attention to the development and improvement of the mantle. In the early 90's he went before the public with an entirely new mantle, which was composed of 99 per cent thorium oxide and 1 per cent cerium oxide. This mantle gave 24 candles per cubic foot of gas consumed. The present system of manufacture of mantles is entirely in accordance with this last invention of Welsbach's, which consists in saturating cotton fabric with the proper mixture of the nitrates of thorium and cerium, burning out the cotton fabric and tempering the mantle. It is then coated with collodion and packed for the market.

The development of the invention of Welsbach can be said to consist of three distinct stages:

1. The idea of saturating a cotton fabric with a lighting fluid, afterward burning out the cotton and tempering the ash.
2. The formation of the lanthanum-zirconium mantle which gave about 12 candles per cubic foot of gas consumed.
3. The thorium-cerium mantle, which gave 24 candles per cubic foot of gas consumed.

Various improvements have been made in the Bunsen burner and a large number of designs are now on the market; but the general Bunsen principle is strictly adhered to and the present Incandescent Gas Light is invariably produced by applying the incandescing material to the colorless Bunsen burner flame.

To show the wonderful development of the Incandescent Gas Lighting System attention might be called to the fact that the American Welsbach Company manufactured in 1903 20,000,000 mantles; the English Welsbach Company 10,000,000, and the combined Continental companies 60,000,000 to 70,000,000.

The wonderful ability of Welsbach as a chemist and inventor should also be noted, from the fact that the chemicals used in the production of the mantles were very rare and almost unknown, and that he was called upon to find the raw material for the production of these chemicals, and to invent processes for their extraction in a sufficiently pure state for use. All of this work was accomplished successfully after years of patient, painstaking endeavor.

Within the past decade the decorative side of gas-lighting has been all-appealing. The primary idea of gas lighting was illumination, but with a desire for greater comforts and more luxuries in the everyday life has come the desire for decorative effects. Globes, shades and domes are now made in many varieties. Color schemes of beauty are evolved, and artist and artisan combine to lend decorative worth to shape, color and treatment of the globe or shade which is destined to add to the bare illumination of the gas jet or the incandescent mantle.

Table showing efficiency of various systems of gas lighting in use at the present time:

System	Candles per Cubit Foot of Gas Consumed
Welsbach incandescent thorium-cerium mantle	22 to 24
Welsbach incandescent lanthanum-zirconium mantle	11 to 12
Siemens-Lungren burner	5 to 6
Argand flame	3 to 4
Bray burner	3 to 4
Fish-tail flame	1½ to 3

SIDNEY MASON,
President Welsbach Company.

Gas, Liquefied. The use of compressed ammonia gas has reached large proportions since 1890, and has proven a valuable aid in the preservation of food, the refrigeration of malt liquors, and the manufacture of ice. The introduction of the use of anhydrous ammonia has given great impetus to the manufacture of special machinery adapted to its employment in the departments named. Taken as a whole, its manufacture may be classed as a distinct industry. Although Prof. A. C. Twining, of New Haven, Conn., had in 1850 received a patent for an ice machine using ethyl ether, or other compressed gas, and had in 1855 a machine of one ton capacity in operation in Cleveland, Ohio, and although in 1867, and probably earlier, the ammonia ice machines of Ferdinand Carré were in active operation, this seems to have been the first allusion in the census reports to compressed gases, and no data are there given for them. At the census of 1900 returns were made not only for compressed or liquefied ammonia (known technically as anhydrous ammonia), but also for sulphur dioxide, carbon dioxide, nitrogen monoxide (known technically as nitrous oxide), oxygen, and liquid air, the manufacture being carried on during the census year in 30 different establishments regularly devoted to this business. In addition there were six establishments reported in which liquefied gases were produced as a subordinate part of the product, the major part of the product being in some instances other than chemicals. Besides, one idle establishment was reported. Taking the returns together, it is found that there were 37 establishments devoted to this manufacture, producing $1,220,297 of products and giving employment to 251 wage-earners and $2,185,535 of capital.

Of these establishments 19, employing 181 wage-earners and $1,650,094 of capital, were engaged in producing liquefied carbon dioxide, and the output for the census year amounted to 12,196,061 pounds, of a value of $708,864. In addition, 1 establishment using carbon dioxide in manufacture reported having produced and consumed 165,000,000 pounds of this gas during the year; but, though it was compressed, it was not liquefied for use. There was employed in the manufacture of the liquefied carbon dioxide reported above, 7,027 tons of magnesite, 2,011 tons of limestone, 774 tons of coke, and 4,771 tons of sulphuric acid, and among other products there were obtained 3,095,000 pounds of Epsom salts, 3,278 tons of calcined magnesite, and 5,000 bushels of lime. About 3,500,000 pounds of the carbon dioxide reported came from fermentation or from effervescent springs.

Ten establishments employing 52 wage-earners and $453,328 in capital were engaged during the census year in producing anhydrous ammonia, and the output for the year amounted to 2,443,729 pounds, having a value of $448,157, and there were consumed in this manufacture 2,148 tons of ammonium sulphate, 4,199,708 pounds of aqua ammonia, and 83,402 bushels of lime.

Carbon Dioxide (carbonic acid gas, CO_2).—Carbon dioxide was liquefied by Faraday in glass tubes as early as 1823, through the pressure resulting from the gas being set free from combustion. In 1834 Thilorier operated this method on a much larger scale by the use of wrought-iron cylinders in place of the glass tubes. He discovered that by allowing the liquid to rapidly evaporate the reduction in temperature was so great that a portion of the CO_2 became solid. By moistening this solid CO_2 with ethyl ether he obtained a temperature of —100° C. In 1837 Dr. John Torrey, of New York, liquefied this compound in tubes and applied the liquid to guns as a propellent. In 1844 Natterer invented a pump by which very high pressures were obtained, and through which the liquefaction of carbon dioxide could be better accomplished than by the self-compression method previously used. In all these case when liquefying carbon dioxide, the gas was not only subjected to pressure, but it was also cooled. In 1869 Prof. W. N. Hill, at the United States naval torpedo station, Newport, R. I., proposed the use of liquefied CO_2 in torpedoes. In June-August, 1873, he made more than 500 pounds of the material, and the manufacture was continued at the station at intervals for some years.

In a private communication, from John B. Stobaeus, of Charles Cooper & Co., Newark, N. J., it appears that he began the liquefaction of carbon dioxide on a commercial scale in the United States in July 1884, and put the product on the market. The gas was generated from magnesite imported from Greece, by reaction with sulphuric acid, and the by-product was Epsom salts. The material was sent to the trade in steel tubes weighing about 27 pounds each, and these tubes were fitted with a valve, having a conical seat, which was invented by Mr. Stobaeus. The books of this firm show that 1,188 cylinders, containing 14,256 pounds of CO_2, were produced in 1885, and 10,704 cylinders, containing 128,448 pounds of CO_2, in 1891. The manufacture has since been taken up by others, and in addition to the method used by Mr. Stobaeus the carbon dioxide is now obtained by burning magnesite, by which magnesia is obtained as the by-product; or dolomite, by which a cement is obtained as the by-product; or marble or limestone, by which quicklime is obtained as the by-product; by treating marl with sulphuric acid; and by burning coke. The carbon dioxide issuing from effervescent mineral springs, and that produced in the fermenting tubs during the brewing of beer, is also collected and liquefied. In all of these processes the gas is washed and otherwise purified before compression.

From the data given by Mr. Stobaeus it appears that the cylinders supplied by his firm held 12 pounds of CO_2 each. The American Carbonate Company, of New York, advertise to supply cylinders in two sizes, containing 10 and 20 pounds of CO_2, respectively, representing 600 and 1,200 gallons of gas, the net weight of the cylinders being 27 and 70 pounds. Several of the companies announce that the cylinders are tested for a pressure of 3,700 pounds per square inch.

Compressed carbon dioxide is used in charging soda water, mineral water, cider, beer, and other effervescent drinks. By attaching a charged cylinder of the gas, governed by a proper regulating valve, to a barrel of beer or other beverage the liquid is not only continuously charged with the gas, but by the gas pressure the liquid is forced to the point where it is desired to serve it. By its use the old art of "krausen," which consisted in adding to stored beer, as it was being casked or bottled, some beer in the first stages of fermentation, has been displaced. Carbon dioxide is used in the manufacture of salicylic acid and of many carbonates. It is proposed for use as a medicinal agent by inhalation and in baths; for raising dough in the manufacture of aerated bread; as a refrigerating medium; as a buoyant material in raising wrecks or preventing disabled ships from sinking; and for extinguishing fires, R. Ogden Doremus having found that but 20 per cent of CO_2 in the air of the locality where fire exists is sufficient to arrest the progress of the flames. It has been used by the government as a motive power for automobile torpedoes.

Anhydrous Ammonia.— This material is the chemical substance ammonia (NH_3) in a pure and dry condition and in a compressed and liquefied state, and it is manufactured by the distillation of the ordinary 26° ammonia of commerce in a suitable apparatus. This apparatus, which should be of sufficient strength to stand a pressure of 65 pounds to the square inch, comprises a still, a condenser, three separators, and a drier or dehydrator. The still is heated by a suitable steam coil to a temperature of about 212° F., when the ammoniacal gas, together with a certain amount of water, passes off into the first separator, which latter is usually situated on the top, and forms an upward extension of, the still. In this first separator the greater portion of the watery particles carried over are eliminated by a series of perforated plates, through the perforations of which the gas had to pass, and are returned to the still through a dip pipe. From this first separator the partly dried gas passes through a water-cooled worm in the condenser, and then successively through the two other separators to the drier or dehydrator, where it is passed through a set of similarly perforated plates to those in the first separator, but having small-sized lumps of freshly burnt lime placed upon them, by which any moisture that may still remain in the gas is removed, and the completely anhydrous product can then be passed into the ammonia pump or compressor. It is found advisable to work the still at a pressure above 30 pounds to the square inch, so as to admit of the liquid being raised to a slightly higher temperature than the boiling point of water at atmospheric pressure, without causing the water to boil, the result of this being that the whole, or practically the whole, of the ammonia will be set free, while at the same time the least possible amount of the water will be vaporized and passed over with the ammonia gas.

Or it may be obtained from ammonium salts by heating them with lime and treating the gas as above described. The salt usually employed is ammonium sulphate. Aqua ammonia, or ammonia water, is of different strengths, according to the amount of NH_3 dissolved in it, but the standard strength has a specific gravity of 26° Baumé, and it contains 38.5 per cent by volume, or 26.6 per cent by weight of anhydrous ammonia. Thus 3.76 pounds of 26° ammonia will be required to make 1 pound of anhydrous ammonia. An excellent table of yields of anhydrous ammonia from 26° ammonia is given by Iltyd I. Redwood. The ammonium sulphate or sulphate of ammonia of commerce is reckoned as containing 25 per cent of anhydrous ammonia.

It is believed that some at least of the owners of ice machines produce the anhydrous ammonia that they employ, either in originally charging their machines, or in making good any loss which may take place, but there are no returns on this point. It appears also that there is some anhydrous ammonia imported, the report on «The Foreign Commerce and Navigation of the United States» from the Treasury Department placing this at 14,210 pounds, having a value of $5,870 for the year 1891, but the data for such importations as may have occurred in other years of the past decade do not appear separately.

Although Fourcroy and Vauquelin and, at about the same time, Guyton de Morveau, announced that they had accomplished the liquefaction of ammonia gas, it is believed that, as they had no suitable means for drying the gas, they failed to obtain the anhydrous ammonia. It was first certainly liquefied by Faraday in 1823, and it was not long before it was being produced in considerable quantities. Larkin and Scheffer began the commercial manufacture in St. Louis, Mo., in 1879.

Anhydrous ammonia appears, as stated above, to have first been used for refrigeration by Ferdinand Carré in his absorption machine, but it was not long before it was employed in compression machines of the type invented by Perkins and Twining, based on the refrigerating principle, which was demonstrated by Doctor Cullen in 1755; and although it has had to compete with ethyl ether, carbon dioxide, sulphur dioxide, and air, it is to-day the material which is most largely used in ice machines, and this is the principal use for this substance, though recent researches indicate that other uses will soon be found for it in chemical manufacture and in other arts.

Sulphur Dioxide (sulphurous acid gas, SO_2).— This substance is produced by burning sulphur in air or oxygen, 1 pound of sulphur giving 2 pounds of sulphur dioxide. It was liquefied by Monge and Clouet about the beginning of the 19th century. The liquefied sulphur dioxide is now a regular article of commerce, and is sent into the trade in glass «siphons» and in iron flasks, as being a convenient means of transportation and storage of the substance for use in chemical laboratories and in manufacture. The liquid has found some use in ice machines. The substance is used as a reducing agent, as a bleaching agent, and as a disinfectant. Hardin states that at present (1899) «about 4,000,000 kilogrammes of this liquid are being prepared annually.»

Nitrogen Monoxide (hyponitrous oxide, nitrous oxide, laughing gas, N_2O).— This body is prepared by heating ammonium nitrate to a temperature not exceeding 258° C., when the gas is evolved. It is carefully purified, well washed, and then compressed in steel cylinders. This gas was first liquefied by Faraday in 1823. The Lennox Chemical Company began the liquefaction of the gas for the trade at Cleveland, Ohio, in 1883. The exhilarating properties of the gas were discovered by Sir Humphry Davy, who was the first to inhale it, in 1809, and it then received the name of laughing gas. It is now used as an anæsthetic agent in minor surgical operations, especially in dentistry, its use for this purpose having been suggested by Dr. Horace Wells, and it was first applied by him in the extraction of a tooth at Hartford, Conn., 11 Dec. 1844.

Oxygen.— This gas, as commercially supplied in the compressed condition, is produced by heating potassium chlorate mixed with black oxide of manganese. It is sold in the market for use in medicine by inhalation, when it is usually mixed with nitrous oxide, essential oils, and other bodies which are believed to possess therapeutic qualities. Liquid oxygen is not known to be produced commercially except as referred to under liquid air, but it was the first of the so-called permanent gases to be liquefied, this having been independently effected by Pictet and Cailletet in 1877.

Liquid Air.— Atmospheric air is a mixture of approximately 21 per cent of oxygen and 78 per cent of nitrogen by volume, with ninety-four one-hundredths of 1 per cent of argon, about four one-hundredths of 1 per cent of carbon dioxide, and variable quantities of water vapor, ammonia, and other bodies, according to locality and conditions. After 1823, when Perkins erroneously believed that he had liquefied air, numerous unsuccessful attempts were made to accomplish this result, but in 1877 Raoul Pictet and Louis Cailletet, working independently in Switzerland and in France, achieved the result on a small laboratory scale, and it was later repeated by Wroblewski, Olszewski, and Dewar, who improved the methods so as to notably increase the yields, and in 1893 Dewar froze air into a clear, transparent solid. The liquefaction of air on an industrial scale began about this time with the invention of the machines of Linde, Hampson, and Tripler, and later those of Ostergren and Burger, Dewar, Kuhn, Chase, Code, O'Doherty, Johnson, and others.

The methods may be classified as the cascade method of Pictet, Cailletet, Wroblewski, and Onnes; the self-intensive motor method of Siemens, Kuhn, and Johnson; the countercurrent free-expansion system of Linde, Hampson, Tripler, Ostergren, and Burger; and the self-intensive work method of the American Liquid Air Company, known as the Ala system. Emmens states that the principal features of the method to effect the liquefaction of air on a commercial scale were clearly described in the specifications of British patent No. 2064, granted to Charles William Siemens in 1857.

Owing to the complex composition of air, several different products are obtained by its liquefaction, notably liquid oxygen and nitrogen and solid carbon dioxide. Pictet has invented a separator by which these bodies may be rapidly separated for use, and there is thus drawn off at —70° F., solid carbon dioxide; at —290° F., commercial oxygen gas of 50 per cent purity; at —296° F., oxygen gas of 99 per cent purity; at —300° F., liquid oxygen and nitrogen gas of 95 per cent purity; at —310° F., nitrogen gas of 99 per cent purity; at —312° F., liquid air; and at —316° F., liquid nitrogen.

While many commercial uses for liquid air have been proposed, it is not known to be so used at present. It may, however, be now looked upon as a source of oxygen which promotes combustion and enables man to obtain high temperatures and high illuminating power, but it is not yet proved that this method of heating and lighting can compete economically with electricity. Liquid air does enable man to readily obtain low temperatures, which can be usefully employed in chemical operations, and a continually extending use may be looked for in this direction. Elihu Thomson has pointed out that it may find a useful application in increasing the efficiency of conductors of electricity.

Chlorine.— This gas, which may be produced by the action of muriatic acid on black oxide of manganese or by the electrolysis of common salt, is produced commercially abroad in the liquid state, but no returns are made of it in this country. It is used in chemical manufactures and for bleaching and disinfection. It is sent out to the trade in iron cylinders.

Gas, Manufactured, in America. To relate the entire history of the industry of gas-lighting it is necessary to go back no further than the beginning of the 19th century. Moreover, this statement is just as true concerning other countries as it is in relation to the United States, for while William Murdock, of England, and Philippe Lebon, of France, began to investigate the possibilities of manufacturing and distributing illuminating gas distilled from bituminous coal late in the 18th century, it was practically the dawn of the 19th century before these experiments has resulted so successfully as to establish the practicability of the project. As the question as to whether the credit for the discovery of gas properly belongs to Murdock or to Lebon is still unsettled in the minds of scientists it is useless to attempt to discuss it in such a brief review of the gas industry as this must be.

So far as we have any record the first use of illuminating gas in the United States was in 1806, when David Melville, of Newport, R. I., lighted his house and the street in front of his residence with gas made by him upon his premises. This was fully one year before the first public gas-lighting experiments were given in England, although Murdock claimed to have lighted his place in Old Cumnock with gas manufactured by himself, a little less than nine years prior to the Newport experiment. In Melville's case, however, the question of prior invention was scarcely considered. Encouraged by his success in a project that was purely original with him, he continued to improve upon his process until, in 1813, when his apparatus was so nearly perfect that he decided to patent it. A year or two later he undertook his first big contract, which was to light the cotton mill at Watertown, Mass. This being successful he applied his gas invention to the lighting of another mill at Providence, R. I., and, in 1817, he introduced his system in the illumination of lighthouses.

It was from these small beginnings that the present great industry of gas manufacture in America has grown. It was a slow growth at first, but, gradually, as the apparatus for its manufacture improved, and man's knowledge of the physical laws involved became more accurate, it began to show a more rapid increase. The first company regularly established to manufacture gas was chartered in Baltimore, Md., in 1816. In 1822, Boston adopted the gas system of lighting. In 1823, a lighting company was organized in New York, and during the next three years gas was introduced in New York city, Brooklyn, and Bristol, R.I. In 1835, the New Orleans Gas-Light Company was chartered to manufacture the new illuminant, and these were the pioneer companies in the United States. From 1835, however, the organization of such corporations continued with great rapidity, until almost every progressive city in the country was provided with a gas-lighting plant. In 1859, according to the statistical tables prepared by the "American Gas-Light Journal," there were 297 companies in the United States, working with a capital of $42,861,174, supplying a population of 4,857,000, through 227,665 private meters, while the extent of the growth of the industry from

1860 to 1900, which, while they fall below those given in the «Directory of American Gas Companies," have been pretty generally accepted by persons looking for a conservative estimate. According to the census statistics, therefore, there were in the United States, in 1900, no less than 877 gas establishments; their capital invested was in excess of $567,000,000; the value of their products aggregated $75,716,693, of which amount $69,432,582 was received directly from the sale of gas. The figures of the 12th census show an increase of nearly 84 per cent. in the amount of gas sold during the last decade of the 19th century, and while it is impossible to give anything like an authoritative statement of the number of premises at present supplied in all parts of the United States, there is little reason to believe that the estimate which places the aggregate at more than 2,000,000 is an excessive one. Several years prior to the census year it was reported that there were 134,447 premises supplied with gas in the State of Massachusetts, and more than 153,500 premises in the city of Philadelphia alone.

As the Philadelphia gas-works is operated by the city it has records which are open to the inspection of the historian. Moreover, as its history is typical of that of other early plants established to supply gas to the consumer, its story is an excellent illustration of the development of the gas corporations of that day. The first attempt to manufacture gas in Philadelphia was made in 1815. At this time it was proposed to use wood, but the experiments failed. From that day, therefore, the matter was dropped until the winter of 1826-7, when several influential citizens appeared as advocates of a project to erect gas-works and light the city with gas made from coal. Although favorably regarded in many quarters the proposition was defeated owing to the strong opposition of other Philadelphians of high standing, all of whom claimed that the introduction of gas would be dangerous to the life, limb, and health of the people. Unable to overcome such a tide of popular disapproval of the scheme, the project was dropped until 1835, when an ordinance providing for the construction and maintenance of gas-works and the distribution of gas was finally passed. According to the provisions of this ordinance, stock was issued to the amount of $100,000, and it was estimated at the time that the lighting of the entire city would require the operation of some 20,000 burners, each capable of consuming an average of four feet per hour. The plant was so fully completed as to be put into operation in 1836, and, in 1837, 17,000,000 cubic feet of gas was distributed, 6,816 private burners, and 301 public lamps being supplied. Compare this record of the first year's operations with that of the census year, when the sales in Philadelphia aggregated 7,055,559,210 cubic feet, at an average of $.0761 per 1,000.

The story of the development of the New Orleans Gas Company shows a similar growth. In 1830, the company had an output of 7,300,000 cubic feet, at $7 per 1,000; in 1840, the product had increased to 20,075,000 cubic feet, but the price was unchanged; in 1850, the output was 53,562,000 cubic feet, at $5 per 1,000; in 1860, 132,418,000, at $4.50 per 1,000; in 1870, 236,468,000, at $4. The effect of the panic of 1873 was to cause such serious depression in every line of business in New Orleans that gas sales were naturally reduced, so that, in 1880, they amounted to only 230,296,000, at $2.70 per 1,000. The period between 1880 and 1890 saw a change in the candle-power, the gas which had previously been about 16.5 being raised to 33. Thus while the record of sales for 1890 shows a consumption of only 181,497,000 cubic feet, the increase in the candle-power made the total illuminating value of the gas sold in 1890 equal to fully 363,000,000 cubic feet of the gas sold in 1880.

It was in 1837 that seven of the prominent citizens of Cincinnati procured a charter for the purpose of making and selling gas in that city. In 1843, the capital of the company was nominally $100,000, although it is scarcely probable that even so much as half that sum had been expended in building the works and the six miles of mains through which they operated. In the beginning, $3.50 per 1,000 was the price charged for gas in Cincinnati; in 1846, it was reduced to $3; in 1854, to $2.50, and since that time it has enjoyed periodical reductions until the present day, when it is sold at the price of 75 cents per 1,000 cubic feet. On 1 Jan. 1847, the company had 546 meters and 192 public lamps in use, these being supplied through 32,487 feet of main pipe, ranging from two to eight inches in diameter. In New York, the story is a similar one, for while the first company was started with small facilities, to furnish a few thousand meters and a comparatively small number of public lamps, the system had been extended to meet new requirements, until, in 1900, the annual sale of gas in New York aggregated 18,180,821,125 cubic feet, or 27.1 per cent. of the total sale of the entire country. The rate in New York during this census year was $0.905.

In the early days in the history of gas manufacture in America, soft or bituminous coal was practically the only material used. In some sections of the South gas was manufactured from rosin and pine-wood, and, during the War times, when the existence of the blockade made it almost impossible to obtain coal, nearly all the towns were glad to employ these materials in the making of gas. Compared to the old-fashioned whale-oil lamps and the tallow dips, even the wood-made gas seemed like a brilliant illuminant, whereas the best gas of that day — that which was manufactured from the soft coal — bore only a remote comparison to that which is sold at the present time, the soft coal gas having an illuminating value which was approximately not more than from 15 to 17 candle-power.

It was about this time that M. Tessie du Motay, a Frenchman, and Professor T. S. C. Lowe, the famous American æronaut, began their independent experiments in the manufacture of gas by the dissociation of steam in contact with incandescent carbon. The result of these two series of experiments, both of which were conducted in the United States, was the discovery of Du Motay's cupola-retort system, and the development of the generator-superheater system of Prof. Lowe, the latter being the most important of all inventions that had yet affected the manufacturer of gas thus, as may be seen, it was to America that the world owes the discovery and development of the water-gas system of lighting.

The introduction of the two new systems of gas manufacture was an event of vital importance to the industry. The Municipal Company of New York was the first to construct a large plant under the Du Motay system. By this process non-luminous water-gas was generated in cupolas, carburetted with oil vapor, and passed through retorts externally heated, the gas thereafter being condensed and purified by processes very similar to those of coal-gas and other water-gas systems. Important as this improvement was, it was the Lowe process — covered by patents dated 1872 and 1875 — that was actually the basis of the modern water-gas system. It covers, broadly, the use, in connection with a generator in which non-luminous gas is made, of a super-heater, or fixing-chamber, fired by internal combustion, the combustible being the gases which are formed during the process of "blowing up;" that is, during and from the passage of air through the fuel in the generator. The fuel used in this generator is hard coal, or coke. The air is blown through it at a high velocity, which raises the fuel to a condition of incandescence, which fits it to dissociate the steam that has been admitted during the gas-making period. Lowe's process also covered the introduction of oil, or other enriching substances, into the non-luminous gas, and the fixing of this oil by passage through the superheater. The first attempt to introduce the Lowe system was made at Phenixville, Pa., in 1873. A few months later, the inventor himself erected his apparatus at Conshohocken, Pa., and at Columbia, Pa.

The method which is now used in the making of water-gas is the double superheater, or improved Lowe apparatus, which was developed by the United Gas Improvement Company, the owners of the now-lapsed Lowe patents for the greater part of the country. Of course, many modifications of the two water-gas systems have been made and patented during the past quarter of a century, but none of them have been of so much importance as to deserve special attention, and while the first years of the fight for the introduction of water-gas was waged against the most bitter antagonism on the part of the coal gas interests, the product of the later inventions was so much superior in every way to the old-time coal-gas, that its growth, after it had once obtained a foothold, was very rapid. In 1880 there were less than 90 water-gas plants in the United States — about 75 of the Lowe type and 12 of the Tessie du Motay type, to be as exact as possible — but in 1890 the number had extended to such an extent that there were no less than 260 of the Lowe plants and fully 30 of the Du Motay plants in operation. By that time every city in the United States that could boast of a population of more than 400,000 had introduced water-gas, wholly or in part, while all but six of the cities with more than 50,000 inhabitants had gas made by one of these processes. Since 1890 the ratio of water-gas as compared to coal-gas has further increased until the former now represents fully 75 per cent of the total product of the country. The largest water-gas plants in the United States are the Tessie du Motay plants in New York and Baltimore, and the Lowe plants in Chicago, Boston, Providence, and the 25th Ward Works, in Philadelphia.

The victory of the water-gas interests was due to perfectly logical causes for each of the many arguments which finally obtained for the system such widespread adoption was based upon a demonstrative point of advantage. Its influence upon the mind of the consumer, however, was largely due to its advantage in the matter of candle-power. Whereas the coal-gas averaged about 15 candle-power, the water-gas that is sold is of candle-power varying from 22, which is probably the minimum, to its 25 candles in Pensacola, 33 in New Orleans, and 30 in New York, and with a probable average throughout the country of from 25 to 27 candles. Compare this, from a luminating point of view, with the conditions existing in England, where here are some companies that are chartered to furnish gas of 14 candle-power, and where not over 5 per cent of all the gas manufactured is in excess of 17 candle-power. In its ratio of purity the American water-gas is equally fortunate. The English law, for example, permits 20 grains of sulphur in forms other than sulphuretted hydrogen, and three grains of ammonia for every hundred cubic feet of gas, whereas the average of sulphur per 100 cubic feet of gas sold in the United States is seldom as great as 12 grains, while of ammonia there is only the merest trace. In one long series of analyses, which extended over a period of fully 10 years, it has been shown that the gas manufactured by this particular city contained less than 10 grains of sulphur per 100 cubic feet, and practically no ammonia.

If it had not been for the development of the water-gas process the industry of gas manufacture in American would not improbably have been doomed. The invention of this new system came at a day when the gas manufacturers were already trying to devise means of competing against cheaper oil and the improved oil lamps. A few years later the electrician appeared, and his coming had a most disastrous effect upon gas-making companies and the value of their shares. The introduction of the water-gas system, however, and the development of the improvements which followed its introduction, have been the factors which have enabled the gasman to hold his own. Although in some respects electricity furnishes a more desirable light, the high candle-power of water-gas makes it a cheaper illuminant, unit for unit, than the cheapest incandescent electric lamp. Thus, while the introduction of electric lighting systems has made some inroads into the use of gas for street lighting, and, to some extent, has reduced the sale of gas to the private consumer, practically all of the losses that may be traced to such sources have been offset by the fact that so many other uses have been found for gas besides that of illumination. The gas stove for heating and cooking purposes, the gas-engine, and the many other mechanical devices for the utilization of gaseous fuel are developments of this idea, and this branch of the business has grown so rapidly that fully 60 per cent of all the gas produced in this country is now used for fuel purposes. Then came the Welsbach lamp, the invention of Auer von Welsbach of Vienna, which made the illuminating power of the best burners from five to seven times greater than before, and this so cheapened gas that it once more placed the gasman in a position where he could compete with the purveyor of electric illumination.

As the American gas business stands to-day it is in every sense of the word a home industry, being one of the domestic industries which is entirely independent of foreign countries for the material which it uses. When the New York Gas Company was incorporated in 1823 it made its first gas from oil; later rosin was used, and, by 1860, it was distilling English coals. During that period most of the companies imported the material from which their gas was made. Most of it came from England. Finally, however, they began to use the product of the American mines and it was soon found that none of the soft coals that could be used for gas-making purposes was superior to the bituminous coals mined in this country. The making of watergas called for no further importations. In view of the substances from which it is made — anthracite and petroleum — there is no country in the world that can produce better materials than the United States, and while, up to a few years ago, cannel-coal was imported from Scotland and Australia for the enrichment of coal gas, beds of such coal, equal to any in the world, have since been found in the United States. So, too, as to the meters and clay retorts, which were once imported from Europe. Years ago they were supplanted by American-made goods and the gas concerns never had any that gave better satisfaction. During the early years of the gas lighting business — in fact, up to 1870 — lime was the purifying agent used by American manufacturers to the almost complete exclusion of other materials. About 1880, however, the use of oxide of iron was introduced. To-day more than three-quarters of the gas made in the United States is purified by this agent.

To tell the story of the birth and development of the gas industry in America without reference to the municipal ownership and management of gas proprieties would he impossible. Because of the dissatisfaction which was certain to exist in view of the monopolistic privileges enjoyed by some of the companies under their old charters, such things as legislative investigations and judicial injunctions were inevitable. In some places relief has been sought in the adoption of municipal ownership. Of course, it may be admitted that the charters granted during the early days were extremely favorable to the companies. It must be remembered, however, that gas-making was then an untried field and that some inducements were necessary to tempt capital to enter such an uncertain industry. As the result important concessions were offered in the form of exclusive franchises, etc., but since it has been shown that the business is a safe and profitable one legislation has been far more exacting.

Gas, Natural. *Early History.*— Natural gas is chiefly a natural combination of carbon and hydrogen, which is only about 60 per cent as heavy as air, and is highly inflammable. Its existence has been known since the earliest records of the human race as a curiosity. Perhaps the earliest historical record of the use of natural gas is that of the Apollo Oracle at Delphi in Greece, about one thousand years before the Christian Era. The Chinese are credited with the practical application of this fuel to the evaporation of salt brine for centuries.

The fire worshippers on the shores and islands of the Caspian Sea, Russia, and those of Punjab, India, have preserved a continuous flame in their temples, caused by a steady flow of natural gas for centuries. In after years it caused the deadly explosions in the deep coal mines in Europe and America, being known to the miner as fire damp. Its existence in the United States has been known since the first white men crossed the divide and explored the Ohio River watershed, as the Indians invariably conducted them to these natural vents, and, setting fire to them, viewed the effect with a semi-religious veneration. The discovery of vast reservoirs, sealed up in the porous rocks of the United States and Canada, is of recent years. The artesian driller, searching for salt brine, knew of its presence since the first wells were drilled on the western flank of the Appalachian uplift; afterward the driller in search of petroleum encountered it, but by both of these early prospectors it was considered a source of danger and annoyance. It frequently caught fire, causing loss of life and destruction of the drilling outfit by a sudden outburst.

The earliest economic use of natural gas known in the United States occurred in 1821, when it was used for the illumination of the village of Fredonia, N. Y. A well one and one half inches in diameter was drilled to a depth of 27 feet near a noted gas spring and for many years supplied the village with 30 street lights.

In 1838 a water well dug at Findlay, Ohio, encountered such quantities of a foul smelling gas that it was abandoned for the original object. It was subsequently covered up and conveyed to a house near by and utilized for domestic fuel and lights for nearly 50 years.

About the year 1841, natural gas was found in a well near Charleston, W. Va., which also supplied salt brine, from which it was separated and for many years used as a fuel for making salt.

More or less natural gas was developed in the rush to find petroleum in the valley of Oil Creek in the winter of 1859 and the year following.

One of the first attempts to employ natural gas for fuel purposes was at a well drilled at Erie, Pa., in 1868, which was soon followed by many others; these wells were only 600 feet in depth and supplied from one to three families each. Titusville, Pa., enjoys the distinction of installing the first modern equipped natural gas plant, as well as the first well drilled for petroleum. This plant was constructed during 1872, 13 years after the first oil well was drilled by Col. Drake.

During 1873 natural gas was introduced into many of the villages of Butler and Venango counties for light and fuel, being supplied from wells drilled not far distant in prospecting for petroleum. In the year 1875 the first long line (17 miles in length) was built; the pipe used was 6¼ inches in diameter, supplying the natural gas produced from the Harvey well at Larden Mills, in Butler County, Pa., to a large manufacturing plant known as the Etna Iron Company on the Allegheny River, a few miles above Pittsburg. In the 10 years that followed slow progress was made in the actual use of the known gas wells; many were utterly ruined by pulling the casing and allowing the inflow of water, which gradually sealed up the rock and prevented the flow; this was after a struggle for years. Others were allowed to escape into the air for years. There seemed to be an uncertainty in the minds of all, as to the lasting properties of this natural product.

In the year 1876 the large Haymaker well was drilled in at Murraysville, Pa., and was not utilized until the year 1883, when its product was piped to Pittsburg. By the close of 1883 a number of pipe lines were supplying Pittsburg and the Beaver Valley with natural gas from a number of good gas wells drilled in Washington, Beaver and Butler counties. During May 1885, the first natural gas well from the deep Speechly sand was drilled, seven miles south of Oil City, Pa. During the same year the remarkable deposit of natural gas in the Grapeville pool, near Greensburg, Pa., was also found.

These numerous natural reservoirs at this period with their initial pressure seemed to convey the impression that it could be found in almost any locality and that the supply was practically inexhaustible.

In 1885 the large natural gas fields near Findlay, Ohio, became prominent and the year following large wells were also found in Indiana. These latter developments seemed to give additional assurance of its unlimited supply.

In Pennsylvania, Ohio, and Indiana immense quantities of gas were consumed in the most wasteful manner and in the extravagant display, which in numerous instances turned night into day. The effect upon witnessing mile after square mile illuminated by the burning of escaping wells and torches produced an impression long to be remembered. This extravagance and waste were not realized until many of the then known fields began to show a serious decline in the rock pressure and, knowing the original pressure, it was a simple calculation to show that a large percentage of the quantity of natural gas originally contained in the natural reservoirs had been withdrawn and that something must be done to stop the waste. Even then the reforms were slow and gradual and many companies became bankrupt. It was not until the general introduction of the gas meter in 1890 and 1891 that economy in its use by the consumer was inaugurated. Formerly the natural gas was sold by the size of the orifice through which it was delivered without regard to the manner of its combustion and use. The metre made it to the interest of the consumer to use this convenient fuel in an economical manner. It is estimated that under the metre system a saving of fully one half the gas required to accomplish the same results was made. Another economical improvement introduced consists of shutting in the wells when their flow is not required; their closing or opening being regulated by telephone from a central office. The wells are also more carefully watched and the salt water removed by pumps, instead of by blowing out as formerly. The pipe lines were thoroughly overhauled for leaks and the new pipe afterward used was heavier and of larger diameter, being supplied with heavier thimbles or improved rubber-packed joints. In the cities and towns larger distributing mains are used and a greater number of regulators secured — thereby maintaining a more even pressure — throughout all the changes in consumption, due to changes in temperature.

Production of Natural Gas in the United States.— No other country enjoys the luxury of natural gas to the extent of the people of the United States. It is used in Canada and in a very limited way in England, Germany, Rumania, Galicia, Russia, Persia, India, China, and Japan, but all these countries combined use only 2 per cent of the known world's production of this efficient and convenient fuel, leaving 98 per cent to be consumed by the people of the United States. The total value of the natural gas produced and sold since its introduction, commercially, in the United States, in 1872, up to the close of 1904, was $395,298,090. The following table is compiled from the reports of the United States Geological Survey and shows the value of the production of natural gas in the United States from 1872 to the close of 1904:

YEAR	Value	YEAR	Value
1872 to 1884.	$ 9,100,000	1895..........	$ 13,006,650
1885..........	4,857,200	1896..........	13,002,512
1886..........	10,012,000	1897..........	13,826,422
1887..........	15,817,500	1898..........	15,296,813
1888..........	22,629,875	1899..........	20,074,873
1889..........	21,107,099	1900..........	23,698,674
1890..........	18,792,725	1901..........	27,066,077
1891..........	15,500,084	1902..........	30,867,863

1894..........	13,954,400		
		Total......	$395,298,090

*Estimated

Assuming that 8 cents per 1,000 cubic feet was the average price for this period, this value should represent 4,941,226,100,000 cubic feet in amount. If it were possible to confine this immense quantity in a tank whose end was one square mile in area it would require to be 336 miles in length. Its heating value would equal 247,561,000 tons of coal. Large as this quantity seems, it is quite probable that it does not represent one half of the actual quantity taken from the earth's rocky reservoirs since the discovery of petroleum. The early (and in some cases the more recent practice) in developing petroleum fields, was to allow large quantities of natural gas to escape unconsumed. It is often found in the strata above that containing the petroleum and at thousands of oil wells it has been permitted to exhaust itself into the air.

Value of Natural Gas and Petroleum and Their Combined Value, by States, in 1903.— The combined value of natural gas and petroleum produced by 20 States and Territories amounted, in 1903, to $130,509,410, which is greater by $28,462,637 than $102,046,773, the combined value in 1902. Of the combined value for 1903, 27.4 per cent is the proportion furnished by sales of natural gas and 72.6 per cent is the proportion furnished by the sales of petroleum. The value of all the coal produced in the United States in 1903 was $503,724,381. In

1902 the proportion of the value of the natural gas to the petroleum produced was as 30.2 per cent to 69.8 per cent, a comparative decrease in 1903 of 2.8 per cent. These two products are so intimately connected in the strata and methods of development, that their separate and combined value by States for 1903 is appropriate and interesting.

shut in and the gas held in the rock when not in use.

The reservoirs in which natural gas is usually found stored when pierced by the drill, are composed of porous sandstone or limestone. In some cases a limited quantity of the gas has been found in shales, but this gas may be regarded as having gradually accumulated from

State	Value of Natural Gas	Value of Crude Petroleum	Value of Natural Gas and Crude Petroleum
Pennsylvania	$16,182,834	$18,170,881	$34,353,715
Ohio	4,479,040	26,234,521	30,713,561

Illinois	3,310	....	3,310
Total	$35,815,360	$94,694,050	$130,509,410

The States that produce large quantities of natural gas, as Pennsylvania and West Virginia, distribute it to the adjoining States by a system of pipe lines, so that in some instances the natural gas consumed in a town or city is produced over 200 miles from where it is consumed. Ohio is conspicuous in the table because it consumed much more than it produced, while West Virginia produced much more than it consumed.

Natural Gas Wells and Structural Conditions of Strata.— There is a great variation in the depth of natural gas wells, owing to the diversity of the strata in which the product exists and the changing position of the underlying rocks with reference to the general surface. Some natural vents have produced natural gas in considerable quantities and have proved the incentive for drilling down to the original reservoirs, from which the gaseous fluid was escaping. Other gas wells have been discovered in drilling wells for oil or salt brine. Some of the most important gas fields have been located by expert geologists, who have traced out the summits of the anticlinals, or rock waves, for many miles from surface exposures of the strata.

The depth of wells varies from 250 to 3,000 feet, while their diameter varies from 2 inches up to 8 inches; their output, or open flow, varies from 500 cubic feet per day to 35,000,000 cubic feet per day; their shut in, or rock pressure, varies from 1 to 1,500 pounds to the square inch in extreme cases, while 300 to 400 pounds to the square inch and a volume of 1,000,000 cubic feet per day is considered a very fair well. In many of the deeper wells, two or more reservoirs of natural gas are often found. The cost varies from a few hundred dollars in the shallow shale districts to $10,000 in the deep wells in West Virginia. All large wells are usually tubed and a packer set just above the gas sand; the top of the tubing is held by clamps attached to bolts that are anchored and a heavy gate valve attached, so that the well can be

the underlying rock formation. Almost invariably the large reservoirs have been developed in the strata on or near the crests of the anticlinal or rock waves, while petroleum has been generally collected on the lower horizon; and frequently salt water is found at a still lower level. Sometimes, however, the gas fields are entirely isolated from the petroleum producing areas. There are three leading requisites necessary for the accumulation of natural gas in merchantable quantity. These are as follows:

1. An open or porous strata capable of storing the gas under pressure, generally sandstone or limestone.

2. A slate or shale covering of this porous strata to seal in the upper surface and the fractures of the strata saturated with natural gas.

3. A sufficient flexure or relief of the strata to enable the separation of the salt water and the petroleum from the natural gas, which is almost invariably found in the higher portion of the strata.

These gas reservoirs have been accumulating for ages the gas they contain, gradually reaching the maximum pressure.

Original Pressure.— The original pressure of natural gas reservoirs has been found in many cases equal to the hydrostatic balance, or, in other words, to the weight of a column of water equal to the vertical distance between the reservoir and the surface of the ground. Allowing 2.3 feet for each pound, or about 43 pounds to the hundred feet, a reservoir at a depth of 1,000 feet should show 430 pounds rock pressure per square inch. This hydrostatic pressure has been equalized to a certain extent by a large number of minute vents that have permitted the escape of the lighter hydrocarbons to the surface. These vents are of common occurrence throughout the Appalachian gas field from northwestern central New York to central Tennessee and along the great Cincinnati uplift from central Kentucky to northern Ontario.

These vents have during past ages allowed the gas to escape in immense quantities, amounting to unnumbered millions of cubic feet, so that the supplies from which we are now drawing are presumably but a small fraction of what has been produced in the earth.

Record of Natural Gas Wells.— There were 15,689 wells producing gas at the beginning of 1904. The total number of wells drilled for natural gas in 1904 was 3,095 and of this number 566 were unproductive, amounting to 18.3 per cent.

In the following table will be found the number of wells producing natural gas at the close of 1903, together with the number of unproductive or dry holes completed in the latter year, by States. The number of feet and miles of pipe lines from 2 inches up to 36 inches diameter in use at the close of 1903 is also given by States, as reported by the United States Geological Survey.

out increasing the size of the main lines, many of the large companies have erected powerful compressing plants in convenient localities. Many of these plants are models of mechanical engineering skill. The compressors are, in many cases, operated by large internal combustion engines of from 500 to 1,500 horse-power each. About 9 cubic feet only of natural gas is required to develop one horse-power and 1,000 cubic feet of natural gas at a pressure of 0 compressed to 270 pounds, by consuming 33⅓ cubic feet, or 3⅓ per cent, where very close to double this quantity is required if the natural gas be consumed under boilers and the steam used in condensing engines. There are very few known fields outside of Kansas, Indian and Oklahoma Territories, that have not been more or less depleted. The deep sand reservoirs in southwestern and central Pennsylvania and those of West Virginia should keep up a fair

State	Wells		Total Pipe Laid to Dec. 31, 1903

Exhaustion of Natural Gas Reservoirs.— Many of the original natural gas fields have been practically exhausted and a large number of the producing companies have had to seek new localities, where a fresh supply could be secured. This has been often accomplished by drilling deeper wells in more remote regions. The original gas fields adjacent to Pittsburg have been practically exhausted; most of the supply now comes from the deep natural gas sands of southwestern Pennsylvania and West Virginia, distant from 80 to 100 miles. The gas pressure in the original pool in northwestern Ohio is practically exhausted. That of central Indiana has only about 15 per cent of the original pressure and volume remaining. The newly developed field in eastern central Ohio has recently supplied a large and increasing quantity to the inhabitants of that State. West Virginia has, for the past ten and more, especially in the last four years, supplied a yearly increasing quantity of natural gas to Ohio and Pennsylvania. New York and Ohio have also been supplied by Pennsylvania. In all the natural gas fields it requires a constant drilling of new wells and connecting them to the main lines to keep up the supply, which is constantly being depleted. Owing to the decrease in pressure at the wells and the desire to deliver large quantities of natural gas to distant consumers, with-

supply for many years to come. As there are no virgin fields now known to exist it will be impossible to continue the present enormous supply for a long period of years in the future. What may result from the deeper drilling of wells in localities where structural conditions are favorable, is a problem for future determination.

Occurrence, Geological Horizons, etc.— In the United States the principal sources of natural gas are located on the west slope of the great Appalachian uplift, extending from New York through Pennsylvania and West Virginia to southern central Kentucky, with a considerable portion of southeastern Ohio, also along the northern portion of the great Cincinnati uplift in northwestern Ohio and central Indiana and southeastern Kansas. There has been recently developed an important natural gas field in eastern central Ohio. These areas, briefly described, produced in 1903 99.5 per cent of the value of the entire output of the United States.

In California, Texas, Louisiana, Colorado, South Dakota, and Alaska gas is found in geologically more recent rocks, but no attempt is here made to correlate the rocks of one field with those of another. In the Mississippi valley to the eastward natural gas occurs almost universally in rocks of Palæozoic age, extending from the highest Carboniferous down at least as far as the Trenton limestone, a distance of over 9,000 feet. The rocks vary greatly in thickness from place to place, so that no one section can be regarded as typical of all parts of the region. The 50 gas-bearing horizons known are composed of very different material, ranging from the coarser sandstones of the Upper Carboniferous and Catskill period to the finer sands of the Middle and Lower Devonian, the limy sands of the Silurian period, the crystalline limestones of the Ordovician, and the crystalline sands of the Cambrian period.

Uses.—Natural gas is used principally as a source of heat and light in the domestic service. It is employed extensively in industrial establishments for many purposes, notably in the generation of steam, in the manufacture of glass, puddling of iron, in roasting ores, in heating furnaces, in the manufacture of steel and pottery; it is also utilized as a source of power in the gas engine, used in drilling and operating oil and gas wells, and in pumping oil, and as a general source of power for all purposes. The heat value stored in natural gas is greater than that caused by any artificial combination of carbon and hydrogen, and is a perfect fuel as it issues from its original rock-sealed reservoirs. No preparation is necessary for its combustion and no residue is left. It is not affected by ordinary temperature and it is easily distributed by pipes to points of consumption. It is a most economical source of light and power, and an ideal household fuel. Lampblack is the only commercial article that is made directly from natural gas.

Illuminating Properties.—The illuminating properties of natural gas vary in different localities, because of the difference in the percentage of the heavier hydrocarbon, ethane (C_2H_6). All the natural gas found adjacent to petroleum fields has a larger proportion of ethane than the gas farther removed, and therefore the candlepower is considerably greater. Ordinary natural gas, if consumed with a common tip at the rate of 7 or 8 cubic feet per hour, will yield about 6 or 7 candlepower. In an ordinary Argand burner with chimney, it will give about 12 candlepower in consuming 5 to 6 cubic feet per hour. When natural gas is consumed in contact with a mantle of alkaline earth (thoria, etc.), the result is the cheapest and best illuminant known. When the price of natural gas is 25 cents per 1,000 cubic feet, and 50 candlepower is obtained from a consumption of 2½ cubic feet per hour, the cost per candlepower per hour is only 0.00125 of a cent.

Domestic Consumption.—There were 630,000 domestic consumers of natural gas during 1903; and it is estimated that in the western portions of New York and Pennsylvania, in central and western West Virginia, and in Ohio, Indiana, and Kansas, not less than 4,500,000 persons received the benefit of natural gas used as a fuel and an illuminant. Over 8,000 manufacturing establishments were also supplied.

The introduction of natural gas into the household, for which it is eminently fitted, has been accomplished without personal inconvenience or loss of life, except in very rare cases. The risk from fire is less than when wood and coal are used. There have been some cases of asphyxiation when a stove has been burned in a room without a flue connection, as it has been found by experiment that combustion under these conditions is imperfect, especially so as the air in the room becomes more and more saturated with carbonic acid and the vapors of water, the result being the formation of poisonous carbonic oxide.

Calorific Value.— The calorific or heat value of natural gas varies slightly in different localities, as the amounts of carbon and hydrogen vary. Those natural gases which contain the highest percentage of carbon give the best results in evaporating water. The standard used in measuring the evaporation of water is called the British thermal unit, written B. T. U., and is the amount of heat necessary to raise 1 pound of pure water 1° F. at or near 39° F., which is the temperature of the maximum density of water. The quantity of air necessary for the perfect combustion of natural gas varies from 10.4 to 10.8 parts of air to 1 part of natural gas. A number of tests have fully demonstrated that when ordinary care is taken in burning natural gas under boilers in actual service, 1 cubic foot of natural gas will do the work equivalent to the evaporation of 1 pound of water from and at 212° F. Since 20 cubic feet of ordinary natural gas weigh 1 pound, 1 pound of natural gas will evaporate 20 pounds of water, while, under similar conditions, 1 pound of petroleum will evaporate only 16 pounds of water, and 1 pound of good coal will evaporate but 10 pounds of water; therefore 10 cubic feet of natural gas or one half a pound is equal to one pound of good coal. In fact in a number of tests with a Klein or a Kirkwood burner, .87 cubic foot of natural gas has evaporated 1 pound of water from and at 212° F., which will make 17,400 cubic feet equal to one ton of good coal. The actual heating effect of natural gas as a fuel approaches much nearer the theoretical result than when coal is used. The price paid by the domestic consumer for natural gas varies in localities, ranging from 13 to 27 cents per 1,000 cubic feet. The consumers near the supply pay less than those farther off. Manufacturers pay less, ranging from 6 to 18 cents per 1,000 cubic feet. About 20,000 cubic feet of natural gas will equal one ton of good bituminous or anthracite coal. If we assume the average price to be 22 cents per 1,000, then $4.40 worth of gas will produce the same heating effect of one ton of good coal delivered in the bins — to which must be added the expense of shoveling it into the furnace and the removal of the ashes, as well as the inconvenience of the necessary dust and dirt which invariably accompanies a coal fire.

The Natural Gas Engine.—Natural gas, as applied to the internal combustion engine, has caused a complete revolution in the methods of securing power throughout the gas belt. It has in nearly all instances superseded any other source of power in pumping petroleum wells. In some instances this has been done by substituting a gas cylinder for the steam cylinder, using the same engine bed. The economy in the use of natural gas and the dispensing with the costly and troublesome boiler, with its constant attendant, has brought it into great favor for all sources of power, from a 1 horse-power up to 1,500 horse-power engine.

The following table gives the equivalents of natural gas and coal for both the gas and steam engine per indicated horse-power per hour:

Type of Engine	Equivalent of gas and coal	
	Gas	Coal
	Cubic feet	*Pounds*
Large natural gas engine, highest type....	9	0.9
Ordinary natural-gas engine..............	13	1.3
Triple expansion condensing steam engine.	16	1.6
Double expansion condensing steam engine.	20	2.0
Single cylinder and cut-off steam engine...	40	4.0
Ordinary high pressure, without cut-off, steam engine	80	8.0
Ordinary oil well pumping steam engine...	130	13.0

Products of Combustion.— The products of combustion are water and carbonic acid, slightly over two cubic feet of the former in the form of water vapor and about one foot of carbonic acid gas for each cubic foot of natural gas consumed; both are invisible and nearly odorless. Somewhat more than 2 cubic feet of oxygen are necessary, but, owing to the air being composed of a larger percentage of nitrogen, a little over 10 cubic feet of air is required for thorough combustion.

It has been found that in a stove without a flue connection the combustion is imperfect, especially so if the air in the room becomes more or less saturated with carbonic acid and the vapor of water from lack of fresh air. Under these conditions there is a small percentage of carbonic monoxide (CO) produced, which is a deadly and insidious poison, and if breathed by a man or an animal will soon cause death, even when a comparatively small percentage is present.

When but a small stovepipe connecting with a flue is used, recent tests have demonstrated that no carbon monoxide (CO) is formed in the room thus provided, the greater portion of the products of combustion being carried outside as the fresh air is drawn in to supply their place. On the other hand, where there is no flue or other large opening a number of fatal results and narrow escapes from asphyxiation have occurred.

Carbon monoxide (CO) does not usually exist to such an extent in the natural gas produced in West Virginia or Pennsylvania as is found elsewhere. On the other hand, analysis shows its presence in the natural gas produced in the Lima-Indiana field to the average extent of about one half of 1 per cent, and to the average extent of 1 per cent in the natural gas produced in Kansas. Formaldehyde is in some cases formed upon putting the cold surface of a teapot in contact with the gas jet of a stove, or when the gas flame impinges on the cold sheets of a steam boiler. Its presence in small quantities is made known by its pungent and irritating effect upon the nostrils and throat. The effect is dangerous, yet there are no cases known in which death has resulted from this gas thus generated.

Composition.—Analysis of natural gases and manufactured gases, their weight and heating quality per 1,000 cubic feet; also their specific gravity compared:

Constituents	Average for Penna. and W. Virginia	Average for Ohio and Indiana	Average for Kansas	Average of Coal Gas	Average of Water Gas	Average of Producer Gas from Bit. Coal

Gas Poisoning, poisoning by the vapor of some substance taken into the body through the air-passages. Theoretically, a large number of substances used in the arts may cause gas poisoning; practically, there are only a few that need special attention.

In general, gaseous substances reach a certain grade of concentration before they become poisonous. This varies with each gas. Forms of gas poisoning comparatively common are numerous, particularly in Europe, where many dangerous industries are established that are here unknown. A partial list of these includes poisoning from muriatic acid gas (HCl), occurring in factories in which soda, glass, and colored wools are made or handled; from saltpetre gas (NO_3H, NO_2H), which is found in fireworks factories, and from sulphurous acid gas (SO_2), which causes trouble in wool-dyeing factories, in paper manufactories, in making sulphuric acid, in sugar-making, and in disinfection. Ammonia gas (NH_3) also frequently causes poisoning; and chlorine (Cl), bromine (Br), iodine (I), in gaseous form, may all cause fatal poisoning. Formaldehyde gas (CH_2O), which is being widely employed as a disinfectant, is a violent poison. Sulphuretted hydrogen (H_2S) is a severe poison, 6 per cent. in the air constituting a menace to health. Practically all of these gases possess distinctive odors sufficient to give warning of their presence. It is, however, a matter of immense moment to realize that there are gaseous poisons that are destitute of any odor whatever. The most important of these are carbon dioxide (CO_2) and carbon monoxide (CO), both of which are odorless gases in the degree of concentration sufficient to cause serious poisoning. Carbon-dioxide poisoning occurs in crowded halls, in theatres, in closed cars, in tunnels, etc., when the normal proportion of this gas is disturbed by oxygen consumption and carbon-dioxide production, the resulting poisoning being from a combination due to these two factors. (See CARBON DIOXIDE.)

Poisoning from carbon monoxide (CO) is not frequent in this country, except by the medium of illuminating gas, of which it is an important constituent, but where old-fashioned stoves without vents are used, and where there is insufficient air to convert the CO to CO_2, this form of poisoning is not uncommon.

Poisoning by illuminating gas is extremely common, occurring both by intent and accidentally. The character of the poisoning and its mode of treatment will vary with the composition of the particular variety of illuminating gas that may be inhaled. The so-called "water-gas" is particularly rich in CO. The leading symptoms of this form of poisoning are, in the beginning, headache, with sense of pressure in the temples, ringing in the ears, flashes before the eyes, beating of the temporal arteries, dizziness, and perhaps unconsciousness. If the breathing of the gas continues, dangerous symptoms develop. There is marked redness of the skin, with unconsciousness; the blood is bright-red—a marked contrast to the dark blood with blueness of the skin seen in carbon-dioxide poisoning. Occasionally there are cramp-like convulsions. The pulse is at first full and strong; later it is thin and small. The breathing is slowed, and becomes a kind of snoring. Vomiting is common, and occasionally the vomit is drawn into the lungs and causes the additional symptoms of suffocation. The patient may die in deep slumber. The diagnosis is not simple, but the chief signs are the reddish face, the snoring breathing, the absence of alcoholic breath, and perhaps the slight odor of gas in the room. The treatment should be energetic. The patient should be brought into fresh air at once, the clothing loosened, and hot bottles applied to the extremities. Active rubbing of the skin with coarse towels, mustard-water applications to the extremities, and artificial respiration should be instituted. The breathing of camphor vapor, or well-diluted ammonia gas may stimulate the breathing. So long as the heart beats there are hopes of reviving the patient. The injection into the rectum of large quantities (2 quarts) of hot salt solution (110°-118° F.), a teaspoonful of salt to a pint of water, is of great service. Small quantities of whiskey (½ ounce) may be added to this. The transfusion of salt solution into the veins is sometimes necessary, but should be performed only by the medical practitioner.

Gas Producer. The primary requirement in using any form of fuel is its conversion into a gas; but whether the gas thus obtained is combustible, *i.e.*, possesses heating value, or otherwise, depends upon the nature of the fuel from which it is derived, and upon the method of gasification employed.

In most fuels, the chief combustible elements are carbon (C) and hydrogen (H), which are present in a great variety of chemical combinations and physical characteristics. When these fuels are completely burned, the products of combustion contain only carbonic acid (CO_2) and water (H_2O), with nitrogen (N) and some of the oxygen (O) of the air supplied for combustion, all of which are incombustible. But when the fuel is incompletely or partially burned, the products of combustion will also contain varying quantities of carbon monoxide (CO), various forms of hydrocarbons (CHy), hydrogen, and sometimes tar and smoke as the products of distillation, all of which are combustible or have a heating value.

Fuels may be burned by either grate or direct firing, or after conversion into gaseous form. The ultimate object of direct firing is the attainment of complete combustion in close proximity to the fuel bed, by vaporizing, distilling, gasifying, and completely burning the fuel elements within the same chamber. It is well known, however, that the processes of vaporization and distillation absorb heat only, and, therefore, it is advantageous to separate them from the point at which the combustion of the gases takes place, and where high temperatures are developed by the heat evolved, as is accomplished by the use of a gas producer or generator.

Generation of Producer Gas.—In the gas producer, the processes of vaporization, distillation, and gasification, result in the generation of a combustible gas, which is led away to a separate combustion chamber in which it is subsequently burned under conditions more favorable to a full realization of the heat value of the fuel, and the attainment of high temperatures absolutely unattainable by any other method of firing.

It should be clearly understood, however, that the use of a gas producer does not enable the generation of a greater quantity of heat than may be obtained by direct firing. Even when the producer is closely connected to the furnace so as to utilize the sensible heat of the gas, a loss of energy of from 15 to 20 per cent. of the calorific value of the fuel is sustained; but notwithstanding this loss, practical experience has very satisfactorily demonstrated that the gas producer accomplishes, with much less fuel, results equal to those obtained by direct firing, and has made possible metallurgical operations impracticable by the latter method.

The advantages of gas firing over direct firing will be better understood by a general knowledge of the manner in which producer gas is generated.

As already stated, the products of the incomplete combustion of a fuel contain various combustible elements which are susceptible of with carbonized fuel; the H being derived from either the fuel, or the decomposition of the moisture in the air supply when it comes in contact with the glowing carbon, so that the theoretical form $CO_2 + C +$ heat $= 2CO$, becomes $H_2O + C +$ heat $= H_2 + CO$.

When uncarbonized fuels such as soft coals are used, the products of distillation of the raw fuel in the upper zone of combustion, consisting chiefly of hydrogen and the hydrocarbons—marsh gas (CH_4) and olefiant gas (C_2H_4), will become mixed with the products of gasification in the zone below, thus affecting the quality of the gas, so that in order to raise

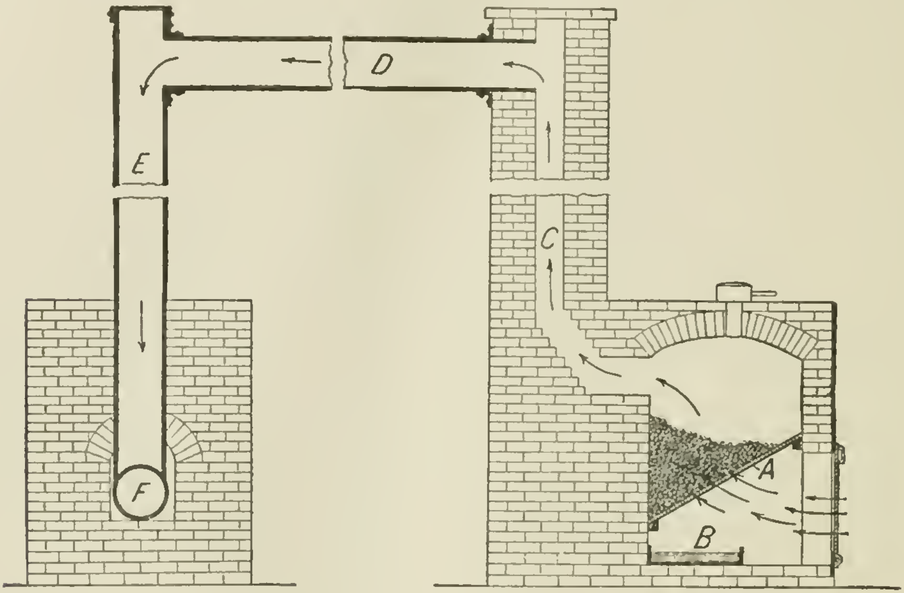

Fig. 1. Sectional Diagram, Siemens Gas Producer.

being burned at a higher temperature than that of the original combustion, and producer gas is simply the product of an incomplete combustion of a fuel in the generator.

The oxygen of the air admitted to the producer comes in contact with the incandescent carbon of the fuel and forms a certain amount of incombustible carbonic acid gas (CO_2). The heat evolved by this reaction is absorbed by the CO_2 thus formed and by the nitrogen of the air supplied. These gases ascend and yield their heat to the fuel above and bring it to the point of incandescence, so that the CO_2 first formed is brought in contact with this glowing carbon, and taking up an additional quantity of carbon is converted into combustible carbon monoxide (CO).

If this gas is generated with dry air in contact with fuel free from impurities, it will contain all the nitrogen of the air, and will be, approximately, composed of carbon monoxide (CO), 34.7 per cent.; nitrogen (NO), 65.3 per cent. by volume, and will possess a heating value of about 118 British Thermal Units per cubic foot.

In actual practice, however, it usually contains a certain amount of CO_2, a little hydrogen (H), and the nitrogen (N) of the air blast used the percentage of the combustible elements in the final product, it is necessary that as much as possible of the CO_2 first formed should be converted into carbon monoxide (CO).

Air when passed over incandescent carbon (C), gives minimum CO_2 at a temperature of about 1900° Fahr.; therefore, the higher the temperature of the producer, and the greater the surfaces of the fuel exposed to the contact of the ascending gases, the greater will be the proportion of CO_2 converted into CO. Furthermore, the formation of CO is greatly affected by the character of the fuel and the depth of the fuel bed, so that, the greater the depth of the fuel bed, and the more porous and finely divided the fuel, provided it does not offer too much resistance to the passage of the air or gases, the greater will be the percentage of CO formed.

Other things being equal, the higher the temperature of the producer, the greater will be the amount of fuel gasified per unit of time, but as this depends largely upon the air supply, an increased air supply signifies more rapid combustion, greater velocity of the gases through the fuel bed, briefer contact of the gases with the fuel, and, therefore, indicates that a greater depth of contact is required if it is desired to maintain a given quality of gas with a low percentage of CO_2.

It is important to note that wet coals retard the development of high temperature in a gas producer, on account of the great heat losses sustained through the high latent and specific heats of the vaporization of water, and also, that for like reasons, carbonized fuels work at a higher temperature than uncarbonized fuels.

Another condition which affects the percentage of combustibles in the gas is the presence of steam in the air supply. Blowing with air alone introduces a large amount of inert nitrogen which tends to dilute the gas and reduce its calorific value. On the other hand, the use of steam increases the percentage of combustibles by adding hydrogen and decreasing the amount of nitrogen, thus increasing the calorific value of the gas, reducing its exit temperature, and preventing clinkering.

The use of steam does not, however, result in the production of a greater amount of heat. The heat is simply transferred from the generator to the furnace by the more potential heat value of H, instead of the less efficient, though greater sensible, heat in the gas itself. Yet, an excessive amount has its disadvantages, as it tends to reduce the amount of CO and increase that of CO and H, thus reducing the percentage of combustibles in the gas and lowering its calorific value as shown in the accompanying table, which gives the analysis of different gases produced with excess of steam in moderate and large quantities.

Volume of Gas	Excess of Steam Moderate	Large
CO_2	5.30	8.90
CO	23.50	16.40
CH_4	3.30	2.55
H	13.14	18.60

Types of Gas Producer.—The various gas-producer arrangements are represented by two general types: (1) The Siemens gas producer, which operates without artificial blast, and is typical of the older producers; and (2) the Taylor producer, equipped with a rotative ash table and operating with a forced steam blast, and representing the later developments in this line.

Fig. 1 shows a vertical section through a Siemens gas producer and regenerator furnace. It consists of two essential parts—the gas producer proper in which the raw fuel is converted into a combustible gas, and the furnace with its regenerators or chambers for storing the waste heat of the flame, given up to the incoming air and gas. As the air is drawn into the producer through the firebars *A*, a certain quantity of the water contained in the trough *B* is vaporized by the heat of the fire above, and mixing with the air, is drawn with it into the fire. The necessary indraught of air, and the pressure required to cause the gas generated in the producer to flow into the furnace, is obtained by means of the vertical uptake *C*, usually built of brick; the horizontal iron tube *D*, of relatively large diameter; and the vertical tube *E*, leading to the gas flue *F* of the furnace. By this arrangement, as the hot gas rises from the producer and passes through the tubes, it is considerably reduced in temperature, thus rendering its density much greater at the furnace end than at the producer, and thereby causing a suction and an indraught of air at the latter.

Fig. 2 shows a vertical cross-section of a Taylor producer charged with anthracite coal. The incandescent fuel is supported by the bed of ash put upon the rotative ash table *A*, before firing, and kept there constantly as an essential feature in the successful operation of the producer. The rotative ash table has a greater diameter than the bosh *B*, and is placed at such a distance below the latter that upon being revolved, the descending ash forms its own slope at an angle of about 55°, and is discharged uniformly by gravity over the periphery of the ash table into the sealed ash pit *C*.

When operated regularly, the line between the ash and the fuel is kept always about six inches above the cap *D* of the central air pipe *E*,

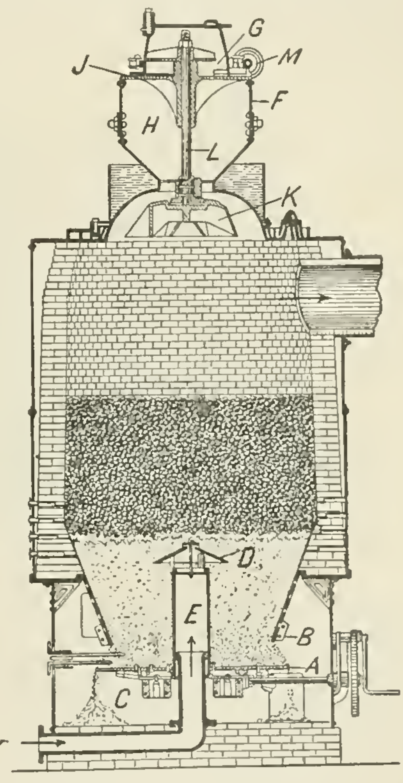

Fig. 2. Vertical Cross-Section, Taylor Gas Producer.

thus allowing the fire to come in contact only with the brick lining, so that all the iron work is protected from the heat. The height of the fire line is maintained by grinding or revolving the ash table once every six or twenty-four hours, according to the rate at which the producer is worked.

The air blast is furnished, usually, by a steam jet blower, but a fan blower may be used if more convenient, and a pipe from some auxiliary source of steam run into the vertical air pipe to supply the steam required for softening the clinkers and maintaining the proper temperature of the producer.

The producer as shown is equipped with a Bildt continuous automatic feed device *F*, consisting of a receiving hopper *G*, which surmounts the main storage magazine *H*, the communication between the two being regulated by a horizontal rotary register *J*, operated by a lever. The distributor plate *K* is suspended below the main magazine, and supported by a steel shaft *L*, which passes upward through the storage cylinder. Both the hood of the distributor plate and the inverted conical base of the magazine are water-cooled, the tendency of the cooling water and the location of the plate above the gaseous current, tending to facilitate the discharge when using strongly caking coals. The receiving hopper is rotated by means of a worm wheel and worm attached to the upper end of the shaft, and the distributo plate is rotated by means of the radial arms and hub of the receiving hopper, which are also keyed to the steel shaft. A hand-wheel nut upon the threaded end of the axis affords means for adjusting the distance between the distributor plate and the coal reservoir, and this adjustment together with the variable speed secured by means of the stepped cone pulley *M*, permits of a ready control of the rate of coal discharge. Experience shows that the use of feeders equipped with distributing plates not only tends to reduce the amount of furnace wear, labor, and repairs, but also results in a great reduction in the coal consumption.

The following table gives the average analyses by volume of the gas produced by the two types of producers:

Constituent	European Siemens Gas	American Anthracite Gas	American Bituminous Gas
Carbon monoxide (CO)..	23.7	27.0	27.0
Hydrogen (H)............	8.0	12.0	12.0
Marsh gas (CH_4..........	2.2	1.2	2.5
Carbonic acid (CO_2)......	4.1	2.5	2.0
Nitrogen..................	62.0	57.3	56.5
	100.0	100.0	100.0

Types of Gas Producer System.—The Taylor gas producer embodies in its structure and method of operation the principal features of the successful producers of the modern type, which are applicable to the production of gas from different fuels for various purposes, and when considered in connection with gas-engine work, form the principal parts of two general but well-defined systems of gas production—the pressure system and the suction system.

In the pressure system, the air required for combustion and for the generation of the gas is supplied to the gas producer under pressure, and the gas generated is delivered under pressure to the engine using it.

In the suction system, both the passage of the air through the producer, and the introduction of the producer gas into the cylinder of the engine, are effected by the suction or aspiration caused by the forward stroke of the piston.

Although the pressure system is composed, usually, of more cumbrous apparatus, and requires more space, it possesses greater elasticity than the suction system for meeting variations in the quality of fuel, and greater capability for utilizing different kinds and cheaper grades of fuel. It is also the better for use with large power-producing units, or where several gas engines receive gas from the same producer plant.

On the other hand, for isolated plants of small capacity, or where only a single gas engine is used intermittently, the application of the suction system not only simplifies the bulk and reduces the cost of the plant, but what is more important, it makes the demand of the engine for gas the controlling factor of its generation from solid fuel.

Pressure Gas Producer System.—Fig. 3 shows the general arrangement of a pressure gas producer system. Usually it consists of a small steam boiler *A*, for making steam, or producing the necessity air pressure; a gas producer *B*, with a continuous-feed arrangement; an economizer *C*, with superheater and wash-box; a scrubber *D*; a purifier *E*; a gas holder *F*, consisting of a steel tank; and suitable drips and connections.

The details of the several organs may be modified to adapt them to varying conditions. For example, the boiler may be omitted where steam can be obtained from some other convenient source of supply, and in some cases a

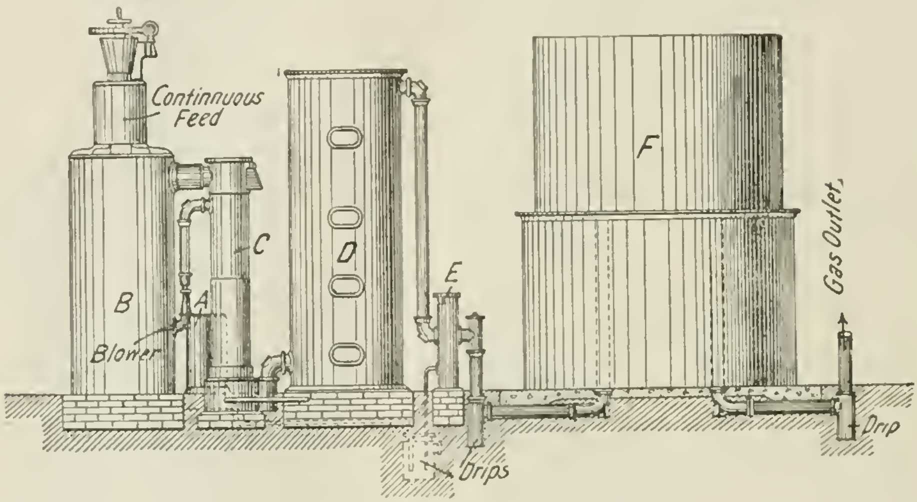

Fig. 3. Pressure Gas Producer System.

separate steam generator is not absolutely necessary.

For smaller equipments, or those employed for operating engines up to 500 horsepower, single producers are generally considered sufficient, but the larger equipments require two or more producers, which may be varied in design and arrangement.

In the operation of a plant of this type, the gases generated in the producer enter the superheater and economizer. In the latter, the air blast of the producer travels in a direction opposite to that of the blower, and the gas passing through the wash-box deposits a large portion of its extraneous matter. The economizer also contains the seal arrangement against the gases stored in the holder and present in the other organs of the plant. From the wash-box, the gas passes into the scrubber, the compartments of which are filled with coke. Here the gas is showered by water sprays, and still further purified by the removal of any tar, sulphur, or ammonia that may be present prior to its introduction into the purifier where the final purifying operations are performed. From the purifier the gas passes into the holder, which stores a supply sufficient to start and run the plant for several minutes, but the main function of the holder is to regulate the pressure, and care for variations in the consumption and mixture of the gases.

The drip pots and drainage pipes are very essential parts of the plant and are suitably placed as shown, while the hot water issuing from the top of the producer is carried by suitable pipes to the holder.

In the pressure systems all of the following named or similar materials may be used for fuel: Anthracite and bituminous coals, lignites, coke, charcoal, wood, peat, and tanbark. Good anthracite coal is the best when convenience of operation is the primary consideration. When bituminous coals are used, preference should be given to those of the semi-bituminous class. According to general experience, soft-coal plants appear to be more expensive than those operated with hard coal, and when the price of anthracite does not exceed that of soft coal more than $1.00 per ton, it is advisable to employ a hard-coal plant. When coke is used, it should be in small pieces of about one cubic inch; as the tendency of large-size coke is to give a weak gas. When coke is used instead of anthracite, one-third more, by weight, of the former should be taken as the fuel consumption.

Suction Gas Producer System.—Fig. 4 shows the general arrangement of the several organs of a suction plant: *A*, represents the producer; *B*, the evaporator; *C*, the scrubber; and *D*, the receiver. The plant operates as follows:

The gases generated in the producer pass through the evaporator, which is simply a small multitubular boiler, and serves to utilize the sensible heat of the gases for evaporating the water. The vapor thus obtained is conducted through the pipe *E*, to the ash-pit of the producer, by the suction caused therein by the action of the engine piston, while at the same time, the gases pass from the evaporator to the scrubber filled with coke. As these gases rise through the interstices of the coke, they come in contact with the descending washing water, which not only takes up and thus removes the dust brought over from the producer, but also purifies the gases of ammonia and any other impurities which the water will absorb. From the scrubber, the purified gas passes into the receiver. The diameter of the receiver is relatively large as compared with that of the suction pipe of the engine, and thus prevents the pulsations which would otherwise be caused by the strokes of the engine piston, between the receiver and the producer.

Usually, in the smaller plants, the producer is provided with a charging hopper of sufficient capacity for holding enough fuel for several hours' operation, and permits the admission of coal to the combustion chamber without allowing air to enter it, during the charging operation.

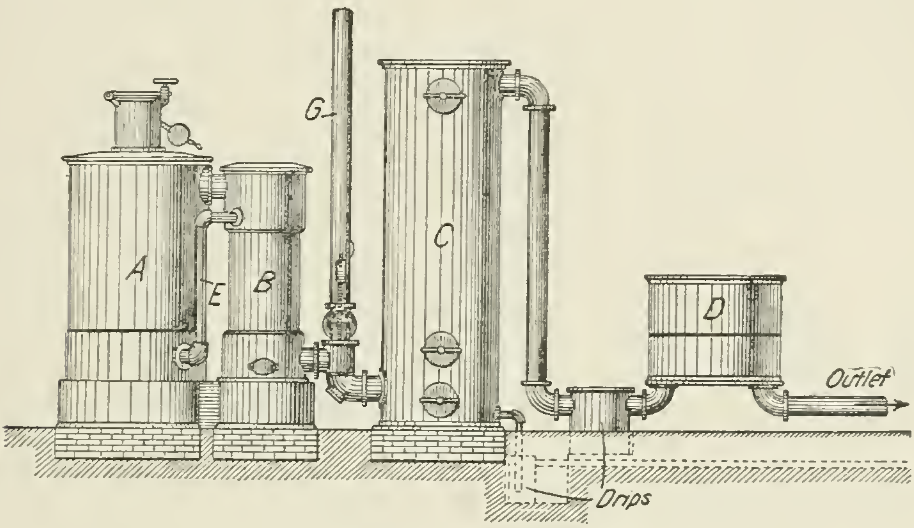

Fig. 4. Suction Gas Producer System.

To operate the plant, a fire is first kindled upon the grate of the producer; the fuel bed then built thereon, and the air necessary for starting combustion is supplied by means of a hand- or belt-driven fan. At first, the poor or lean gases produced at starting are allowed to escape into the open air through the vent-pipe *G*, until the test-cock shows that good gas of the desired quality is being generated. Then, the vent-pipe is closed and the scrubber and receiver brought into the gas circuit. The engine is now brought into operation, and as the suction caused by the strokes of its piston thereafter performs the function of the fan, the latter is stopped.

In the suction systems, only anthracite coal, and the so-called carbonized fuels such as gas-house coke and charcoal, have been used up to the present time. When anthracite is used it should not be less than "pea" size, clean, and of good quality. It is evident that the finer the size of the fuel and the greater its tendency to clinkering, the greater will be the amount of work required of the engine to draw the air current through the fuel bed. Therefore, if continuous action and easy operation are desired, the use of anthracite of the ordinary "nut" size will give the most satisfactory results.

The following table shows average analyses of the gases produced by the two systems.

Element	Per cent. Pressure Plant	Per cent. Suction Plant
Carbonic acid (CO_2)	8.2	8.0
Oxygen (O)	.7	
Carbon monoxide (CO)	19.5	26.3
Hydrogen (H)	16.5	18.2
Marsh gas (CH_4)	2.[illegible]	0.5
Nitrogen (N)	52.2	47.0
	100.0	100.0

In either case, the gas produced is of good quality, when good fuel is used, the pressure-producer gas averaging about 125 B.T.U.'s per cubic foot, and the suction-producer gas about 145 B.T.U.'s per cubic foot, with variations according to the method of operation, and the proportion of hydrogen and carbon monoxide present.

In power-plant operation, the fuel consumption will average $1\frac{1}{2}$ pounds of coal per brake horsepower hour for small powers, and decrease in amount with the increase in the size of the engine until a rate of 1 pound per brake horsepower hour is attained, thus giving a higher efficiency than that of the best marine steam engine or the largest steam pumping engine in the world.

Quality of Gas for Power Plants.—In considering the quality of a gas suitable for the production of power or for use in gas engines, it is necessary to inquire into the amount and quality of gas obtainable from various kinds of fuels.

The following table gives an approximate index to the difference of yield of gas for the different materials available for this purpose.

Material	Yield per pound in cubic feet
Coke or Charcoal	1[illegible]4
Bituminous Coals	75
Brown Coals	55
Turf	45
Wood	35

The actual yield of gas varies, however, within wide limits, according to the composition of the fuel, its general character, and the method of gasification, and in the case of coal, as already stated, according to the proportion of steam used in the producing operations. It may be assumed, however, that on the average, 1 ton of anthracite buckwheat coal will yield about 170,000 cubic feet of gas, having a calorific value of 138,000 B.T.U.'s per 1,000 cubic feet; with an average composition as follows:

Element	Per cent.
Carbon monoxide (CO)	22.0 to 3[illegible]
Hydrogen (H)	15.0 " [illegible]7.[illegible]
Marsh gas (CH_4)	3.0 " 1.5
Carbonic acid (CO_2)	6.0 " 1.5
Nitrogen (N)	54.0 " 60.0

The analysis of gas derived from bituminous coal gives very nearly the same results, with the exception that the values of CH and H are somewhat higher.

Advantage of Using Producer Gas.—The advantage to be derived from the use of producer gas may be briefly stated as follows:

The combined efficiency attainable in the best steam engines and boilers, operating under the most favorable conditions, is about 12 per cent. of the intrinsic heat energy of the fuel used. On the other hand, the modern gas engine, even in small powers, will give an efficiency much higher, but if it be supplied with illuminating gas for fuel, a large amount of the economy due to the higher efficiency is lost in the cost of the gas. Heat energy in the form of coal gas at a dollar per thousand feet, costs thirteen times as much as an equivalent amount of energy in the form of coal at three dollars per ton; therefore, in order to utilize a gas engine to its full advantage, the gas used must be produced as economically as possible. This is exactly the function of the gas producer, and by its use a good gas engine with a theoretical thermal efficiency of 75 or 80 per cent., or a practical thermal efficiency of 25 or 30 per cent., will readily convert into actual work, or available power, 25 per cent. of the heat energy of the gas delivered to it. The gas producer of such a plant will transfer to the gas about 80 per cent. of the intrinsic energy of the coal, so that a gas-producer engine operating on an inferior grade of coal will show an efficiency of 20 per cent., as against the 12 per cent. of a steam engine and boiler plant using the best steaming coal.

William Morey, Jr., C. E.,
Consulting Civil and Mechanical Engineer, New York.

Gas Tar. See Coal Tar.

Gases, General Properties of. The word "gas" was coined by the Belgian chemist Van Helmont, in the first half of the 17th century. It was possibly suggested to him by the Dutch word "geest," signifying a ghost or spirit, the allusion being to the apparently imponderable nature of gaseous bodies. It is known, however, that all gases possess both weight and inertia, and that they differ from other kinds of matter, in these respects, solely by reason of their lesser densities. Any object that is submersed in a gas is buoyed up by an amount equal to the weight of the gas that it displaces, in accordance with the same principle that holds true of solids that are submersed in liquids; and in making refined determinations of the weight of an object proper allowance must be made for the difference in the buoyant effect of the air upon the object weighed, and upon the weights against which it is balanced. It will be seen that it follows, by reason of the principle of buoyancy, that no gas has any apparent weight, when it is weighed in an atmosphere identical with itself in density. If a sphere or other vessel of convenient form is weighed, both when filled with a given gas and when completely exhausted by means of an efficient air-pump, the difference in the two observations gives the weight of the gas, because the buoyant effect of the air upon the containing vessel is the same, whether it is full or empty. In this way the weights of many of the better known gases have been determined with considerable precision. Following are the densities of some of the more familiar gases, as expressed in grams per cubic centimetre at the freezing point of water, and under a barometric pressure of 76 centimetres of mercury at Paris:

Gas	Density
Dry air	0.001293
Oxygen	0.001430
Nitrogen	0.001256
Hydrogen	0.0000896
Carbon dioxid	0.001978
Carbon monoxid	0.001234
Chlorine	0.003133
Ammonia gas (NH_3)	0.000770

The fact that gases have weight and inertia, and that they are also compressible, renders the mathematical study of their internal motions especially difficult. Aerostatics and aerodynamics, which treat, respectively, of the conditions of mechanical stability of gaseous masses, and of the motions of which such masses are capable, are therefore more intricate and difficult than hydrostatics and hydrodynamics, which treat, respectively, of the equilibrium and of the motions of incompressible fluids.

A gas which is mechanically at rest exerts, against the vessel that contains it, a pressure that is everywhere perpendicular to the surface upon which it acts, and which has everywhere the same intensity, save for the slight variation due to the action of gravity,— a variation which is so slight that it can be neglected in all but the most refined physical investigations. When the gas is in motion, the case is different, and the pressure phenomena are complicated, hard to compute, and quite difficult to measure with any considerable approach to precision. In general, the internal pressure of a gas is least in those regions in which the gas is moving fastest. In a mixture of gases, each constituent contributes to the total pressure by an amount equal to the pressure that it would exert if it occupied the given space alone. Like the other gaseous laws, this one (which is known as "Dalton's law") is a close approximation to the actual fact when the density of the gas to which it is applied is not too great. At high pressures, or exceedingly low temperatures, it gives results that are measurably different from the actual facts of observation.

When a gas is subjected to a continuously increasing pressure, its behavior depends upon its temperature. If the temperature is greater than a certain critical value peculiar to each gas, it will never liquefy, no matter how great the pressure to which it is subjected; but if the temperature is lower than this critical value, the gas will ultimately condense into a liquid. (See CRITICAL POINT; GASES, LIQUEFACTION OF.) There is no essential distinction between a gas and a vapor, a "vapor" being merely a gas that is in such a condition that it may be condensed into the liquid form by a comparatively small change of temperature or pressure. The so-called "permanent gases," such as hydrogen and nitrogen, were formerly thought to be incapable of liquefaction; but it is now known that all gases can be liquefied, provided their temperatures are sufficiently reduced, and the phrase "permanent gas" is rarely used at the present day.

When the pressure of a given mass of gas is varied while the temperature remains constant, it is found that the volume is very nearly inversely proportional to the pressure. Thus if a mass of air is enclosed in a cylinder that is provided with a tightly-fitting piston, and the pressure upon it is increased so as to be five times as great as at first, the volume of the air becomes reduced to one fifth of the initial value, provided the compression is performed so slowly that the heat that is set free by it can escape by conduction and radiation. This principle, which was first discovered by the English physicist Robert Boyle, is known as "Boyle's law" in England and the United States. In continental Europe, however, it is known by the name of Mariotte, a French physicist, who discovered it independently of Boyle, but subsequently to him.

When a gas is heated under a constant pressure, its volume increases in a marked manner. All substances exhibit a change of volume under these circumstances, but in gases the change is far greater than for any other bodies, with the exception of certain liquids that are very near to their critical points. The increase in volume of a gas per degree of rise of temperature, when expressed as a fraction of the volume that the gas occupies when it is exposed (at the same constant pressure) to a temperature of 32° F., is called its "coefficient of expansion." The coefficients of expansion of the more familiar gases, such as oxygen, hydrogen, nitrogen, and carbon dioxid, are all very nearly equal; and they have, moreover, substantially the same value, whatever the constant pressure may be at which the experiment is performed. These two facts were discovered independently by Dalton, and by Gay-Lussac, and the first of the two was also discovered, previously, by the French physicist Charles, by whose name it is commonly known. Neither of these is exact, for delicate measurements have shown that the coefficient of expansion of a gas at constant pressure depends to a slight extent both upon the nature of the gas, and upon the intensity of the constant pressure at which the experiment is made. The coefficient of expansion (at constant pressure) of air, oxygen, hydrogen, nitrogen, and carbon monoxid may be taken as 0.00204 on the Fahrenheit scale, or 0.00367 on the Centigrade scale, for ordinary purposes, when the constant pressure at which the expansion takes place is not far from the ordinary atmospheric pressure. The corresponding coefficient for carbon dioxid is slightly larger than this, and may be taken as 0.00206 for the Fahrenheit scale, and 0.00371 for the Centigrade.

The increase in the pressure of a gas, when the gas is heated while its volume is kept rigorously constant, and the increase expressed as a fraction of the pressure that the same gas has when it is exposed (at the same constant volume) to a temperature of 32° F., is known as the gas's "coefficient of expansion at constant volume," although, as a matter of fact, there is really no "expansion" at all in such a case. The coefficients of expansion of gases are very nearly identical, whether the expansion takes place at constant pressure, or at constant volume. For more precise data with respect to the expansion-coefficients of gases, see THERMOMETER; THERMOMETRY.

When a gas is allowed to expand so as to do work (by pushing a piston before it, or in any other way), the temperature of the gas falls, unless it is maintained by the addition of heat from without; the fall of temperature being due to the fact that a portion of the energy that the gas contains is used up in performing the external work. See ENERGY.

When there is absolutely no addition of energy from without, and the gas performs all the work that it is capable of performing in expanding from one of the two given pressures down to the other one, the expansion is said to be "adiabatic." If, on the other hand, a mass of gas that is confined at a definite pressure and temperature is allowed to expand into a vacuum, it does no external work, since the vacuum opposes no resistance to it. In this case the gas is said to undergo "free expansion." The earlier experiments of Joule upon the free expansion of air indicated that it is not attended by any change of temperature whatever. Subsequent more refined experiments executed by Joule and Kelvin, and by Natanson, upon various gases, show that in all cases free expansion is attended by a slight change of temperature. Our experimental knowledge of these slight changes is still exceedingly imperfect, which is greatly to be regretted, since a thorough understanding of the phenomena of free expansion is essential to the numerical evaluation of the absolute thermodynamical scale of temperature. See TEMPERATURE; THERMODYNAMICS.

If P_0 represents the ordinary atmospheric pressure, and V is the volume, at T° and under a pressure of P atmospheres, of a definite mass of gas whose volume is known to be V_0 at the pressure P_0 and at the freezing point of water (T being the temperature as reckoned from this freezing point), then by combining the laws of Boyle, and of Charles and Gay-Lussac, we may easily show that the pressure, temperature and volume of a gas must fulfil the simple relation $PV = P_0V_0(1 + kT)$, where k is the coefficient of expansion of the gas. Since the laws which are thus combined into one expression are only approximately true, the mathematical expression just given is also only approximate. It is very convenient for purposes of calculation, however, when it is not essential that the results which are sought should be known with the utmost accuracy. A mathematical relation of this sort, expressing the relation that must subsist between the pressure, volume and temperature of a gas, is called the "elastic equation," or the "characteristic equation," of the gas.

A rigorously exact equation of this sort undoubtedly exists for every gas; but its precise form is not known in any case. The equation here given is a good first approximation to it, when the gas is sufficiently removed from its critical state; but in the immediate vicinity of the critical state the foregoing equation fails utterly. A better form of characteristic equation was proposed by the Dutch physicist, Van der Waals, as follows: $P = \frac{R(1+kT)}{V-a} - \frac{b}{V^2}$ where P, V, T and k have the same significance as before, and the remaining letters represent constants peculiar to the gas considered. Van der Waals' form of the characteristic equation includes the preceding simpler one as a special case, and it represents the general nature of the phenomena in the vicinity of the critical point quite faithfully.

It has already been said that no actual gas conforms rigorously to the laws of Boyle and Charles and Gay-Lussac, and also that the change of temperature is never rigorously zero, when a gas undergoes free expansion. It is often convenient, however, especially in illustrating the principles that underlie the action of heat engines, to conceive of an ideal gas which would fulfil all these conditions absolutely. An imaginary gas of this kind is commonly called a "perfect gas." This name is unfortunate in some respects, however. A departure from the approximate laws mentioned does not imply any actual imperfection in the gas, and it would be better to follow the lead of those writers who call the imaginary gas an "ideal gas."

Although the coefficient of expansion of a gas is very nearly the same, whether the pressure is kept constant, or the volume, the case is very different with respect to the specific heat; for the specific heat of any gas (that is, the quantity of heat required to raise the temperature of a unit mass of the gas by one degree), is always greater when the pressure of the gas is constant, than when its volume is constant. The heat absorbed by a gas when its temperature rises is expended partly in increasing the internal energy of the gas, and partly in performing the external work that the gas does when it expands. When the volume of the gas is kept constant, no external work is done by the gas; and hence the heat absorbed is less in this case than it is when the gas is allowed to expand while being heated, so as to keep its pressure constant. The quantity of heat required to raise the temperature of a pound of water by one degree being taken as the unit, the quantity required to raise the temperature of a pound of gas by the same amount, while its pressure is kept constant, is given, for several of the more familiar gases, in the accompanying table:

GAS	Specific Heat (Constant Pressure)
Air	0.238
Oxygen	0.217
Nitrogen	0.244
Hydrogen	3.409
Chlorine	0.121
Carbon monoxid	0.244
Carbon dioxid	0.20

The specific heat of carbon dioxid has been given to only two places of decimals, because it varies considerably with the temperature.

The specific heat of a gas at constant volume is hard to measure, and hence it is usually inferred from the observed specific heat at constant pressure, together with the ratio of the two specific heats, as obtained by experiments of a different kind. In the mathematical theory of sound, for example, it is shown that the velocity with which sound will travel through a gas depends upon the ratio of the two specific heats of the gas. It is therefore possible to determine, by calculation, the ratio in question, when the actual speed of sound through a given gas has been found by experiment. The values obtained for the several gases in this way, by different observers, are not as accordant as might be desired. The ratio of the specific heat at constant pressure to that at constant volume appears to have approximately the following values: Oxygen, 1.40; hydrogen, 1.41; nitrogen, 1.41; carbon monoxid, 1.42; carbon dioxid, 1.26.

One of the best-known phenomena of gases is diffusion. Thus when two bottles containing different gases are brought together, mouth to mouth, with the lighter gas in the upper bottle, it is found that the two become perfectly mixed after a time, the lighter gas traveling downward, and the heavier one upward. This phenomenon is believed to be due to the fact that gases consist of a multitude of little particles, or molecules, which are flying about among one another with considerable speed. Many of the molecules in each bottle will in time wander into the other one, so that a sensibly homogeneous mixture eventually results.

Liquids absorb gases, or dissolve them, and sometimes in considerable amounts. Carbon dioxid, for example, is quite soluble in cold water, especially under pressure; and it is upon this fact that the possibility of preparing effervescent mineral waters and wines depends. Porous solids, like freshly prepared charcoal, will also absorb gases in considerable quantity, the gases being retained, apparently, in the form of very thin films, covering the walls of pores of the absorbent substance. (See ABSORPTION.)

When two gases combine with each other chemically, simple volumetric laws are observed, which indicate («Avogadro's law») that the number of molecules per unit of volume is the same in any two gases that have the same temperature and pressure. Two volumes of hydrogen, for example, combine with one volume of oxygen, to produce water; one volume of hydrogen combines with one volume of chlorine, to produce hydrochloric acid gas; one volume of nitrogen combines with three volumes of hydrogen, to produce ammonia gas; and so on.

(See GASES, KINETIC THEORY OF; HEAT; THERMODYNAMICS.) Consult, also: Kimball, 'Physical Properties of Gases'; 'The Laws of Gases' (miscellaneous memoirs, edited by Carl Barus); 'The Expansion of Gases by Heat' (miscellaneous memoirs, edited by W. W. Randall); Preston, 'The Theory of Heat.'

Gases, Kinetic Theory of, the theory which regards gases as aggregates of discrete particles (or «molecules») of matter that are incessantly flying about and colliding with one another, the space in which they are moving being presumably absolutely vacuous, save for the omnipresent luminiferous ether. (See ETHER.) According to this theory, the molecules which are in the outer parts of a given mass of gas must beat incessantly upon the walls of the containing vessel, flying back again from these walls in the same way that they fly away from one another after collisions among themselves. This being the case, it is plain that the walls of the containing vessel are in the same condition as a target against which a furious storm of bullets is striking perpetually. Such a storm of bullets would tend to force the target in the direction in which the bullets were moving before collision; and if the impacts were frequent enough, they would have an effect upon the target which could not be distinguished from a continuous pressure. And if we pass, in thought, from target to retaining vessel, and from bullets to molecules, we shall have a good conception of the kinetic theory of gaseous pressure. Before the behavior of molecular aggregates can be studied by mathematical methods, it is necessary to make certain assumptions with regard to the nature of the molecules. Some of the received assumptions have been made on account of their apparent necessity, and others have been made for no reason whatever, except that they simplify the mathematical treatment of the problems that arise. Thus molecules are assumed to be perfectly elastic, because it has been held to be evident that if they were not so, their incessant collisions must result in a gradual loss of velocity, which would not cease until they were all at rest. The assumption of perfect elasticity is therefore commonly regarded as a logical necessity, since we do not observe any tendency toward rest among the molecules of gases; that is, we do not perceive any tendency toward a fall of pressure, in a gas that is isolated, thermally and otherwise, from its environment. In the earlier mathematical investigations of the properties of gases, from the standpoint of the kinetic theory, the molecules were assumed, furthermore, to be exceedingly small (practically mere physical points), and they were considered to be hard, smooth, and spherical, and to exert no influence upon one another when not in actual contact; these assumptions being made, not because it was considered to be in the least degree likely that molecules have such properties, but merely in order to lessen the mathematical difficulties involved in the subsequent analysis,— difficulties that are serious enough, even when the problem is made as simple as possible. For example, they were assumed to be hard, in order that collisions might be considered as having no sensible duration. They were assumed to be exceedingly small, in proportion to the space in which they move, in order that the probability of a collision in which three or more molecules should come together at once might become vanishingly small in comparison with the probability of a collision in which the molecules come together in pairs, the discussion of the more complex collisions being thereby avoided. They were assumed to be spherical, because spheres can collide with each other in only one way; whereas other bodies (cubes, for example) can come together in the greatest variety of ways, according to their relative orientation at the moment of collision. They were assumed to be smooth, in order to avoid the necessity of taking account of the rotations that are produced when rough spheres glance against one another obliquely. The assumptions stated above were adopted in what may be called the Maxwellian period of the development of the kinetic theory, and Maxwell and other mathematicians made elaborate investigations of the behavior of a practically infinite number of molecules having these properties, when once set in motion in a finite space.

Following are a few of the results obtained by the mathematical study of such molecules as are defined above. It is evident, in the first place, that the velocities of the various molecules are not all equal; for even if such equality existed at any given instant, it would be quickly destroyed by the inter-molecular collisions. Maxwell investigated the distribution of velocities that must subsist in a gas composed of such molecules, and gave a formula by which it is possible to calculate, at any given instant, the number of molecules that have velocities equal to, or less than, any assigned velocity. Thus if the total number of molecules present be taken as unity, the number having a velocity less than the average velocity is 0.533; the number having a velocity less than one half the average velocity is 0.112; the number having a velocity less than twice the average velocity is 0.9820; and the number having a velocity greater than four times the average velocity is 0.0000000074. It appears, therefore, that although any velocity whatever is theoretically possible (so far as Maxwell's formula is concerned), the incessant collisions bring about a sort of averaging which is effective enough to ensure that an almost vanishingly small proportion of the whole number will be actually moving with a speed as great as four times the average. The number having higher velocities falls off with still more remarkable rapidity: for example, the formula shows that less than one molecule in 10^{53} will be moving with a speed as great as 10 times the average. When two or more different kinds of molecules are simultaneously present, the molecules in each set being exactly alike and very numerous, and every molecule being hard, smooth, small, spherical, and perfectly elastic. Maxwell found that the different sets will mix with one another uniformly, and that the velocities in each set will be distributed precisely as though the other sets were not present. The average velocity in each set will be different, however, from the average velocity in every other set, the set in which the molecules are heaviest having the smallest average velocity. In fact, the velocities, in such a case, will be such that the average kinetic energy of a molecule of one set will be precisely equal to the average kinetic energy of a molecule of any other set.

Some of the mathematical difficulties that appeared almost insuperable to Maxwell have been partially overcome by other mathematicians, and, largely owing to the labors of Boltzmann, we now have a far more general form of the kinetic theory of gases. Before stating the nature of the generalizations that Boltzmann effected, it is necessary to offer a short explanation of the expression "degrees of freedom." A mathematical point is completely defined when its three co-ordinates are given; it can move by the variation of any one of these three co-ordinates, while the other two remain constant. Such a point is therefore said to possess three "degrees of freedom." A rigid body in space similarly has six degrees of freedom. Three co-ordinates must be given in order to fix the position of some one of its points,— say its centre of gravity; and it may also have three independent rotations about three independent axes passing through the point so fixed. If the rigid body is not free to rotate, or if (as in the case of the smooth spherical molecules imagined by Maxwell) there is no force acting which tends to produce rotation, the number of degrees of freedom may be considered as reduced to three, the three co-ordinates of the centre of gravity being then sufficient to define the state of the body completely. In particular, a molecule shaped like a dumb-bell may be considered to have but five degrees of freedom, if it is so smooth that collisions cannot set it in rotation about its axis of symmetry. The number of degrees of freedom of a rigid body is six, in the most general case; but if two or more rigid bodies be joined together by hinges, or any other analogous mode of connection that will allow of relative motion between the components, the number of degrees of freedom of the system so formed becomes greater than six. Thus a sytem composed of N straight rods, connected together by flexible joints at their ends, has $(2N+3)$ degrees of freedom.

Boltzmann's form of the kinetic theory may now be stated as follows: Let there be a gas composed of any number of sets of molecules, such that the molecules belonging to each set are exactly like one another, though a molecule belonging to one set may be totally unlike a molecule belonging to another set. Let these molecules have any number of degrees of freedom (which number of degrees may be different in the different sets), and let them be acted upon by parallel forces (such as gravity), or by forces tending toward fixed centres, or by internal forces (that is, forces acting within the individual molecules, between their parts). Let all the bodies be very small in comparison with the total space they occupy, so that the chance of their colliding three or more at a time is practically nothing. Moreover, let them be very numerous, and let them be perfectly elastic, and let them be smooth, so that when they collide the only force tending to make them rotate is that due to normal impact. Let them be set in motion among one another with any distribution of velocities; and let them be hard, but not infinitely so, the force called into play during collision being very great, but not necessarily infinite (as it would be if the hardness were infinite); and let the duration of a collision be exceedingly short, yet not necessarily zero. Then Boltzmann reaches the following conclusions: (1) After a short time, the law of distribution of positions and velocities in each set of the molecules will be precisely the same as it would be if all the other sets were absent; so that each set behaves as a vacuum to all the rest, so far as the distribution of velocities, and the density of aggregation of the molecules in any given region, are concerned. (2) The law of distribution of the velocities in each set is the same as that deduced by Maxwell for spherical molecules. (3) The average kinetic energy *of translation* of the molecules of any one set is equal to the average kinetic energy *of translation* of any other set. (4) The *total* kinetic energy of each set of molecules (including that due to translation, rotation, etc.,) is divided up equally among the different degrees of freedom of that set. This last proposition is undoubtedly one of the most remarkable ever enunciated with regard to molecules, and it appears not to have met with unqualified acceptance among mathematicians, though there are many experimental facts which tend to show that it is at all events a good approximation to the truth.

Although Maxwell and Boltzmann agree that the percentage of molecules that have velocities much larger than the average velocity is very small, it must be remembered that according to either form of the kinetic theory there is always a certain number of molecules that have velocities of any assigned magnitude whatever; and Stoney has pointed out that if this conclusion is really sound, one consequence of it is, that the earth must be continually losing molecules of its atmosphere by their flight from the upper layers of the atmosphere, into space. A molecule of air escaping into space with a vertical velocity greater than about seven miles per second would possess sufficient momentum to carry it beyond the range of the earth's attraction forever. The loss of air that takes place in this manner is probably very gradual, but it is doubtless real, and in the course of ages it may result in the entire dissipation of the earth's atmosphere into the depths of space. It has been suggested that the absence of an atmosphere about the moon, and the apparent rarity of the atmosphere of Mars, may be due to this cause; the action having been more rapid in the cases of these two bodies, because their attractive power is smaller, and hence a larger proportion of atmospheric molecules would have the critical speed necessary to enable them to pass off into space.

It has been stated, above, that Boltzmann found that in a gaseous mixture each set of molecules would assume the same distribution that it would have if it existed in the given space alone. This corresponds to the known experimental fact that gases of different kinds will diffuse into one another, so as to eventually form a homogeneous mixture. When a bottle of some strong-smelling gas, like ammonia, is opened in a room containing still air, we cannot perceive the odor at any considerable distance until quite a time has elapsed. The molecules of the ammonia vapor are indeed moving with high velocities, but they continually strike against air molecules, rebounding from them in such a manner that in any given region there are almost as many of them returning toward the bottle as there are going away from it. They are forced to describe zigzag lines which are so very crooked that by the time an ammonia molecule has reached a point actually 10 feet distant from the bottle, it has in all probability traveled many miles. But eventually the ammonia molecules and the air molecules become thoroughly mixed, just as the kinetic theory predicts. Boltzmann's theory also teaches that in a gaseous mixture the distribution of velocities is the same in each set of molecules as it would be if that set existed in the same space alone. If the explanation of gaseous pressure suggested at the beginning of this article is correct, it follows that each constituent of the gaseous mixture will contribute to the total pressure that the gas exerts against the vessel containing it, by an amount equal to the pressure that this constituent would exert if it existed in the same space by itself. This corresponds to the known law of Dalton with regard to gaseous mixtures,—the law which states that in a gaseous mixture the total pressure is equal to the sum of the partial pressures due to the several constituents separately.

It may be shown that the average kinetic energy of translation of the molecules of a given mass of gas is sensibly proportional to the absolute temperature of the gas. This being admitted, it is easy to understand the reason for Boyle's law. (See GASES, GENERAL PROPERTIES OF.) For so long as the temperature of the gas remains constant, the average velocity of translation of the molecules also remains constant, and therefore the average effect of the blow that a molecule strikes against the walls of the containing vessel is also constant. But the pressure, in this case, will vary in direct proportion to the number of blows that the molecules strike against a unit area of the walls in a given time, and this will also vary in direct proportion to the number of molecules that a cubic inch of the gas contains. We see, therefore, that if the temperature of a gas remains constant, the pressure that the gas exerts will vary directly with the density of the gas; or, to state the same fact in another way, the pressure will be inversely proportional to the volume of the gas, which is Boyle's law.

Avogadro's law may be derived in a somewhat similar manner. Thus let P be the pressure that a gas exerts against a unit area of the containing vessel, let N be the number of molecules that it contains, per unit of volume, and let K be the average kinetic energy of translation of its molecules. Then the kinetic theory shows that the pressure of the gas can be expressed in the following manner: $P = \frac{2}{3}NK$. If two different kinds of gas are to be compared, we may conveniently distinguish the values of P, N and K that relate to the separate gases by using the subscripts 1 and 2. Then for one gas we shall have $P_1 = \frac{2}{3}N_1K_1$, and for the other $P_2 = \frac{2}{3}N_2K_2$. If the pressure is the same in both gases, we have $P_1 = P_2$, and it is easily seen that this involves the equation $N_1K_1 = N_2K_2$. Now, if the temperatures of the two gases are also equal, the average kinetic energy of translation is likewise the same in both gases; that is, $K_1 = K_2$. Taking this into account, we see that it follows that $N_1 = N_2$: or, in other words, when two gases have the same temperature and the same pressure, they also contain the same number of molecules per unit of volume; and this is Avogadro's law.

Knowing the mass of a given volume of a gas, and the pressure that the gas exerts against the boundaries that confine it, we may calculate the average speed that the constituent molecules of the gas must have, in order to produce the observed pressure. The formula by which the calculation is effected need not be given here, but some of the results are of interest. Thus it is found that at 32° F. the molecules of the more familiar gases have the following average velocities, in feet per second: Hydrogen, 5,571; oxygen, 1,394; nitrogen, 1,488; carbon dioxid.

1,491; carbon monoxid, 1,189. At higher temperatures, the velocities are greater, being proportional, for any one gas, to the square root of the absolute temperature.

A very important application of the kinetic theory of gases, which has recently been especially emphasized in connection with the determination of the atomic weight of argon (q.v.), relates to the ratio of the specific heats of a gas. Boltzmann's theory shows that if the specific heat of a gas at constant pressure be divided by its specific heat at constant volume, then the quotient can be expressed in the form $1+\frac{2}{n}$, provided the effects of such forces as may exist between the different molecules of the gas are negligible, n being the number of degrees of freedom of the molecules of gas under consideration. This equation, it will be seen, affords a means of ascertaining the number of degrees of freedom of the molecule of a gas, by setting the foregoing expression equal to the observed value of the ratio of the specific heats, and then solving the equation for n. By this method, it has been inferred that the molecules of hydrogen, nitrogen, oxygen, and carbon monoxid have each five degree of freedom; for the ratio of the specific heats of these gases approximates closely to 1.4, which is the value of the foregoing expression for $n=5$. If the molecules of a gas were really smooth spheres,— so smooth that they could not be set in rotation by their collisions,— then we should have $n=3$, and hence the ratio of the specific heats would be 1.667, a value which is actually observed in the cases of argon, helium, mercury vapor, cadmium vapor, and perhaps a few other substances. Hence it is inferred that argon and helium really are elementary bodies; because it is difficult to conceive of a compound body behaving, so far as collisions are concerned, as though its molecules were smooth spheres; and if they had any other shape, it would be necessary to admit that they have at least five degrees of freedom (since it is impossible for any body in free space to have four degrees of freedom), and this would reduce the calculated value of the ratio of the specific heats to 1.400, a value which it is apparently impossible to reconcile with the results of direct observation.

Most of the results of the kinetic theory, as given above, involve the assumption that the effects of the mutual attractions that may exist between the individual molecules of a gas are small, on the whole. The forces, when they exist, may be great; but we assume that under ordinary circumstances the radius of sensible action of these forces is small in comparison with the length of the average distance that the molecules travel, between successive collisions. When, by reason of the gas being greatly compressed, this assumption becomes of doubtful validity, the foregoing conclusions become correspondingly weakened. The average distance that a molecule travels, between successive collisions, is known as its "free path"; and numerical estimates of the length of the free path have been obtained, by methods which cannot be given in the present article. Thus the free paths of some of the more familiar gases are as follows (expressed in ten millionths of an inch), the gases being supposed to be at 32° F., and under ordinary atmospheric pressure: Oxygen, 38; nitrogen, 36; hydrogen, 67; carbon monoxid, 36; carbon dioxid, 25. When the density of a gas is diminished, the average free path of the molecules increases in direct proportion to the decrease in density. Thus in the high vacua that prevail in Crooke's tubes, the mean free path may be measured in inches; the free path for hydrogen, for example, being about 6.7 inches, when the density of the gas has been reduced to the millionth of the normal density at 32° F. and atmospheric pressure.

The whole kinetic theory of gases is likely to be profoundly modified in the near future, when physicists have learned more about the "electron" (q.v.), which is now commonly regarded as the foundation unit in molecular architecture. For further details concerning the subjects touched in this article, consult Meyer, 'Kinetic Theory of Gases'; Risteen, 'Molecules and the Molecular Theory of Matter.' See also CRITICAL POINT; GASES, GENERAL PROPERTIES OF; MATTER, PROPERTIES OF; MOLECULAR THEORY; THERMODYNAMICS.

A. D. RISTEEN.

Gases, Laws of. Since 1877, when Cailletet and Pictet liquefied hydrogen and other gases, the laws of permanent gases are assumed to apply to a gas which can be liquefied only with difficulty, either by the use of a very low temperature, an extremely high pressure, or by the combined effect of both.

These laws may be stated as follows:

Boyle's or Mariotte's Law.—About the year 1626, Robert Boyle, an Englishman, discovered that, at constant temperature, the volume of a given weight or mass of gas varied inversely as the pressure.

The same law was announced about 14 years later (1640) by Edme Mariotte of France, and is, therefore, often called Mariotte's law.

According to this law, if V_1 represents the initial volume of a given weight of gas expressed in any unit of cubical measure such as cubic feet or cubic inches, and P_1 the initial pressure, expressed in any unit of pressure on a unit of area such as pounds per square inch, then, for any variations of pressure and volume, at a constant temperature, the volume multiplied by the pressure gives a constant result regardless of variations in them, or

$$P_1V_1 = \text{Constant},$$

and for any other volume V_2 and pressure P_2,

$$V_1 : V_2 :: P_1 : P_2,$$

$$\text{and } \frac{V_1P_1}{V_2}=P_2, \quad \text{also } \frac{V_1P_1}{P_2}=V_2.$$

Furthermore, the density of a given weight of gas will vary inversely as the volume, and, therefore, the pressure will vary directly as the densities, and will be directly proportional to them at the same temperature, or—

$$P_1 : P_2 :: D_1 : D_2;$$

or

$$\frac{P_2}{D_2}=\frac{P_1}{D_1}=\text{Constant}.$$

For example: If the initial volume of a given weight of gas is 20 cubic inches, and its initial pressure is 14.7 pounds per square inch, at a temperature of 32° Fahr., and if it be compressed to 10 cubic inches, while its temperature is kept constant, its final pressure will be—

$$\frac{20 \times 14.7}{10} = 29.4 \text{ pounds per square inch,}$$

or two times the initial pressure.

Under the same law, if the initial volume of the gas be expanded to a final volume of 40 cubic inches, while its temperature is kept constant, the final pressure will be

$$\frac{20 \times 14.7}{40} = 7.35 \text{ pounds per square inch.}$$

or one-half the initial pressure.

Isothermal Expansion and Compression.—According to Boyle's law, if a given weight of gas be placed in a cylinder having a tight-fitting piston working therein, and the volume and pressure of the gas made to vary by moving the piston back and forth so as to alternately compress and expand the gas, the action of the gas will be isothermal: *i.e.*, during expansion it will take in an amount of heat equal to the energy expended by it in increasing its volume, and during compression it will reject an amount of heat equal to the energy spent upon it.

In order to perform actual work, however, the pressure exerted against the piston ought to be due to the expansion of the gas under the influence of heat, and under such a condition, its action will conform to the law enunciated by Gas-Lussac, which establishes the mutual relations of the temperature, volume, and pressure of a gas acting under an increase or decrease of temperature.

Gay-Lussac's Law.—This law was recognized by M. Charles, professor of natural philosophy at Paris, some time previous to its announcement by Gay-Lussac, and is, therefore, sometimes called Charles' law, but the credit of establishing it as one of the fundamental bases of modern chemistry belongs to the latter, who announced, in 1802, that different gases expanded in the same proportion when heated from 0° to 80° Réaumur, or that at constant pressure, equal volumes of different gases increase equally for the same increment of temperature; also, that equal increments of volume correspond very nearly to equal intervals of temperature on the scale of a mercurial thermometer.

Absolute Temperature.—According to Gay-Lussac's law, equal volumes of hydrogen, oxygen, air, etc., at a temperature of 32° Fahr., kept at a constant pressure (not necessarily the same for all) and increased in temperature 1° Fahr., will expand, in each case, 1-493 of itself. Therefore, if the original volume of any gas at 32° Fahr. is 493 cubic inches, it will be 494 cubic inches at 33° Fahr., 495 cubic inches at 34° Fahr., etc. Under the same law, if the temperature be reduced, the original volume of the gas will contract by 1-493 of itself for each degree below 32° Fahr. Therefore, at 0° Fahr., the volume will be 493 — 32 = 461 cubic inches; and at 461° below 0° Fahr., the volume will be 0: or in other words, if a perfect gas be cooled to a temperature of — 461° Fahr., it will be in a condition of perfect stability, having neither volume nor pressure, and will afford an ideal point from which all temperature can be counted as zero.

This point is, therefore, called the absolute zero of temperature, and the absolute temperature of a gas according to the scale of a Fahrenheit thermometer is, for example, 32° Fahr. + 461° = 493° absolute; or 64° Fahr. + 461° = 525° absolute.

In the Centigrade thermometer, the zero point of which corresponds to 32° Fahr., the melting point of ice, and each degree of which is equal to 1.8 Fahr., degrees, the absolute zero of temperature is 493 ÷ 1.8 = 273° absolute, or — 273° C., and absolute Centigrade temperatures will be, for example, 0° C. + 273° = 273° absolute; or 100° C. + 273° = 373° absolute, etc.

The temperature of interstellar space corresponds to the absolute zero of temperature defined by this law.

Use of Absolute Temperatures.—By using absolute temperature values in computations and formulæ, all temperature readings are made positive throughout the range of experience and practice, thus eliminating negative readings which result from the arbitrary location of the zero points in the scales of ordinary thermometers relatively to the freezing point of water. Furthermore, as the volume of a gas at absolute zero is 0, the use of absolute temperature value results in expressions which include both the increment of temperature and the increment of volume in the same expression.

Absolute Pressure.—Although the pressure and volume of a gas become 0 at the absolute zero of temperature, that condition is not in any manner connected, as it might be inferred, with the matter of absolute pressures involved in steam or gas engine practice.

Gay-Lussac's Law Applied.—Referring to Boyle's law and the formulæ deduced therefrom, in which V_1 represents the initial volume; V_2 the final volume; P_1 the initial pressure, and P_2 the final pressure; it is clear that $V_1 \; P_1 = V_2 \; P_2$; but according to Gay-Lussac's law, the volume of a gas varies with its temperature; therefore, at constant pressure, the volume of a gas will vary directly as its absolute temperature; and at constant volume, the pressure will vary as the absolute temperature, or the pressure or volume of a gas is directly proportional to its absolute temperature, and if V_1 be the volume of a gas at absolute temperature T_1, and V_2 the volume at absolute temperature T_2, then

$$V_1 : V_2 :: T_1 : T_2;$$

and

$$\frac{V_1 T_2}{T_1} = V_2;$$

or if P_1 be the pressure for absolute temperature T_1, and P_2 the pressure for absolute temperature T_2, then

$$P_1 : P_2 :: T_1 : T_2;$$

and

$$\frac{P_1 T_2}{T_1} = P_2.$$

These ratios indicate the mutual relations of the initial and final volumes, pressures, and temperatures of a gas acting within the cylinder of a heat engine.

For example: If 20 cubic inches of gas at a temperature of 525° absolute be placed in a cylinder and raised to a temperature of 2811° absolute, its volume will increase to

$$\frac{20 \times 2811}{525} = 107 \text{ cubic inches};$$

while its pressure will remain unchanged.

On the other hand, if the initial pressure of the gas is 14.7 pounds per square inch, and it is not allowed to expand when its temperature is raised, its pressure will increase to

$$\frac{14.7 \times 2811}{525} = 78.7 \text{ pounds per square inch},$$

and represent the amount of static energy in the gas available for doing work.

Specific Heat of Gases.—The foregoing laws define the capacity of a gas for doing work as depending on, first, its mass or the amount of matter present; and second, upon the amount of heat it contains as represented by its absolute temperature.

Another important factor, however, is its capacity for absorbing heat or the amount of heat required to raise the temperature of a unit weight of the gas by one degree as measured by a thermometric scale.

This heat-absorbing capacity of the gas stated in units of weight, is called the specific heat of the gas, and if the weight of the gas be multiplied by its specific heat and by its absolute temperature, the product will express the intrinsic energy of the gas under those particular conditions and without an artificial increase of that energy. So that, if W represents the weight of a given quantity of gas, C the specific heat of the gas, and T its temperature, then

$$W \times C \times T = \text{the intrinsic energy of the gas.}$$

It has been shown, however, that the temperature of a gas may be increased either at constant pressure or at constant volume. Therefore, gases must have two specific heats.

The Specific Heat at Constant Pressure is the amount of heat absorbed by the gas when its temperature is increased by one degree on a thermometric scale, with the pressure remaining constant, but the volume increasing.

The Specific Heat at Constant Volume is the amount of heat absorbed by the gas when its temperature is increased by one degree on a thermometric scale, with its volume remaining constant, but its pressure increasing.

Regnault's Law.—According to this law, the specific heat of constant pressure is constant for any gas.

Therefore, if Cp represents the specific heat of a gas at constant pressure, and Cv the specific heat at constant volume, and the temperature of a unit weight of the gas at a constant pressure P be raised from absolute temperature T_1 to absolute temperature T_2, then

$$Cp\,(T_2 - T_1) = \text{Heat absorbed by the gas.}$$

Now, if V_1 be the volume of the gas at T_1, and V_2 the volume at T_2, then

$$P\,(V_2 - V_1) = d\,(T_2 - T_1) = \text{Work done by the gas};$$

in which, d is a constant depending on the specific density of the gas and on the units in which P and V are stated, and the difference between the quantities represented by these two expressions, or $(Cp - d)\ (T_2 - T_1)$ is the increase in the amount of the internal energy of the gas when its temperature is raised from T_1 to T_2.

It can be shown, however, that this increase of internal energy would be the same if the gas be heated in any other manner from T_1 to T_2, and since a gas when heated at constant pressure expands and does work on the external air, the specific heat at constant pressure must necessarily be greater than the specific heat at constant volume by the amount of heat expended in doing that work.

Joule's Law.—But according to Joule, when a gas expands without doing external work, its temperature does not change. In other words, changes of pressure and volume not connected with changes of temperature, do not affect the internal energy of a gas. Therefore, in any change of temperature, the change of internal energy is independent of the relation of pressure to volume, and when two states of a gas are compared, the internal energy is represented by their difference of temperature and not by the difference of pressure or volume.

It has been shown that $(Cp - d)\ (T_2 - T_1)$ represents the increase of internal energy when the temperature of the gas is raised from T_1 to T_2 at constant pressure, and that it also represents the increase of internal energy when the temperature of the gas is changed from T_1 to T_2 in any manner whatsoever.

Now, take the case of a unit weight of gas, the temperature of which is raised from T_1 to T_2 at constant volume.

$$Cv\,(T_2 - T_1) = \text{Heat absorbed by the gas.}$$

But the gas does not expand, therefore no external work is done, and all the heat absorbed represents increase of internal energy, so that

$$Cv\,(T_2 - T_1) = (Cp - d)\,(T_2 - T_1),$$

and

$$W \times Cv\,(T_2 - T_1).$$

represents the available internal energy of a given weight of gas when its temperature is raised from T_1 to T_2, and for any gas

$$Cp - d = Cv;$$

or as already stated, the specific heat at constant pressure is greater than that at constant volume by the amount of the external work done.

When the weight per cubic foot, and the coefficient of expansion by heat, are known, the value of d for any gas may be computed as follows:

Imagine a cylinder one square foot in area having a piston working within it against the normal pressure of the atmosphere.

The total pressure on the piston will be $14.7 \times 144 = 2{,}116.5$ pounds. Let one cubic foot of air at a temperature of 32° Fahr., be placed under the piston and expanded by heat until its volume is equal to two cubic feet. The work done by the cubic foot of air will be 2,116.5 foot pounds, and as a cubic foot of air under the assumed conditions of pressure and temperature weighs .080728 of a pound, the work done by one pound of air will be equal to $2{,}116.5 \div .080728 = 26{,}217.6$ foot-pounds.

According to Gay-Lussac's law, an addition of heat equal to 493° Fahr., or 273° Centigrade, is required to double the volume of a gas, therefore, the external work which will be done by the gas when its temperature is raised one degree will be 1-493 of that done when its temperature is raised 493°, and the external work required to be performed by air when its temperature is raised by one degree Fahrenheit will be $26{,}217.6 \div 493 = 53.3$ foot-pounds = d.

The accompanying table of properties of gases will be found useful in connection with calculations relating to the action of gases in heat engine practice.

PROPERTIES OF GASES.

	Specific Gravity	Pounds per Cubic Foot	Cubic Feet per Pound	Cp	Cv	Ratio $\frac{Cp}{Cv}$	d
Air..	1.0000	0.080728	12.387	0.2375	0.1689	1.406	53.3
Oxygen .	1.1051	0.08921	11.209	0.2175	0.155	1.403	48.2
Hydrogen..	0.0695	0.00561	178.23	3.409	2.406	1.417	768.
Nitrogen....	0.9714	0.07842	12.752	0.244	0.173	1.409	54.8
Carbon monoxide	0.9674	0.07810	12.804	0.245	0.173	1.416	55.7
Carbon dioxide	1.5290	0.12343	8.102	0.216	0.171	1.165	34.8
Marsh gas..	0.5560	0.04488	22.301	0.593	0.467	1.27	94.7
Ethylene....	0.9847	0.07949	12.580	0.404	0.332	1.144	54.2
Steam......	......	0.03794	26.42	0.480	0.369	1.302	85.6

Excepting steam, all the values given in the table are for gas at atmospheric pressure (14.7 pounds per square inch) at 32° Fahr. In the case of steam the temperature is that of boiling water (212° Fahr.).

Mutual Relations of Temperature, Volume, and Pressure.—In conformity with the foregoing laws, the mutual relations of the temperature, volume, and pressure of a gas vary with the conditions obtaining at heating: (1) At constant temperature, an increase of volume is accompanied by a decrease of pressure. (2) At constant volume, an increase of temperature results in an increase of pressure. (3) At constant pressure, an increase of temperature results in an increase of volume.

In doing work under these conditions, a gas acts by four well-defined modes of expansion or compression—isothermally, adiabatically, isometrically, and isopiestically.

Isothermal Expansion or Compression.—In this connection, it might be stated that the most natural conditions for the expansion or compression of a gas doing work, as in the case of one acting in the cylinder of a heat engine, are: (1) For expansion—that in which the pressure decreases as the volume increases, with a corresponding decrease in its temperature due to the external work done by the gas in moving the piston. (2) For compression—that in which the pressure increases as the volume decreases, with an increase in its temperature due to the work spent upon the gas by the piston in the act of compression.

If, however, during expansion the gas absorbs an amount of heat equal to that expended by it in moving the piston, and during compression it rejects an amount of heat equal to that which is spent upon it, thus maintaining a constant temperature, its action will be isothermal, or the heat will be equal at all points of the piston stroke, and the product of the volume and pressure at any point will be constant.

It is obvious, that in the case of a gas acting isothermally, the piston must be perfectly free from leakage, and its movement must be regulated to correspond exactly to the heat-absorbing capacity of the gas.

On the other hand, it is clear, that if the piston were moved in and out rapidly, thus unduly increasing or decreasing the temperature of the gas, the fundamental condition of constant temperature will not be satisfied, and the action of the gas will not be isothermal.

Adiabatic Expansion or Compression.—In order to utilize a gas acting isothermally, to do work, suitable means have to be provided for adding to the gas a sufficient amount of heat to replace the loss due to the external work done during expansion, and to withdraw the heat added to it during compression.

But, suppose that no such means are provided for maintaining a constant temperature, and that the gas acts within a cylinder which is a perfect non-conductor of heat. Then, during expansion the temperature of the gas will be diminished by an amount equal to the heat units expended by it in doing external work, and during compression its temperature will be increased by an amount equal to the number of heat units of work spent upon it.

In this case, the action of the gas will be adiabatic—the external work during expansion being done entirely at the expense of the intrinsic energy of the gas, and the work spent upon it during compression being an increase of that intrinsic energy by mechanical means.

It is obvious, that adiabatic action must be accompanied by change in the ratio of pressure to volume; therefore, at the end of the piston stroke the pressure will be less than it would be in the case of isothermal expansion by an amount corresponding to the amount of heat expended in doing external work.

Thermal Lines.—Since the work performed by the action of a gas in the cylinder of a piston engine is represented by the product of two factors—the pressure of the gas multiplied by its volume,—it is clear that if the pressure

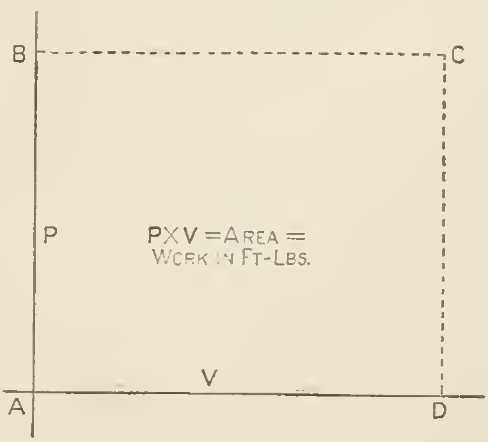

Diagram 1.

be stated in pounds, and the volume in feet corresponding to the length of the piston stroke, a diagram can be drawn which will represent in foot-pounds the work performed by the engine.

In diagram 1, let the line AB represent a pressure P of 300 pounds expended by a gas in increasing its volume and driving a piston from A to D, a distance V of two linear feet. Then, P × V represents the area of the rectangle ABCD, and $300 \times 2 = 600$ foot-pounds, represents the work performed.

In this case, the pressure is assumed as constant, and illustrates the simplest form of a pressure-volume diagram. Usually, however, the pressure is not constant, but diminishes as the volume increases, and *vice versa*, according to variations of temperature which cause corresponding variations of pressure and volume, so that the areas of the pressure-volume diagrams or indicator diagrams of heat engines will be bounded by either straight lines or curves representing the thermal lines of the action of gases under different modes of expansion or compression, as shown in diagram 2.

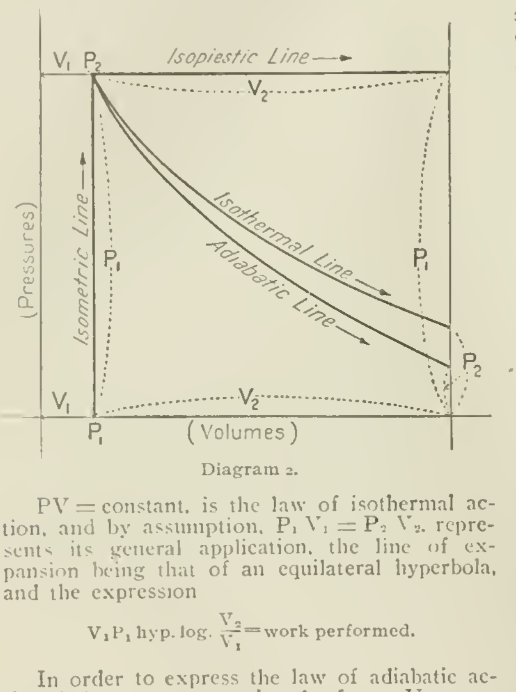

Diagram 2.

PV = constant, is the law of isothermal action, and by assumption, $P_1 V_1 = P_2 V_2$, represents its general application, the line of expansion being that of an equilateral hyperbola, and the expression

$$V_1 P_1 \text{ hyp. log. } \frac{V_2}{V_1} = \text{work performed.}$$

In order to express the law of adiabatic action, it is necessary to give the factor V an exponent n equal to the ratio—specific heat at constant pressure divided by the specific heat at constant volume, so that $PV^n =$ constant, and by assumption $P_1 V_1^n = P_2 V_2^n$, and

$$\frac{P_1 V_1 (1 - r^{1-n})}{n - 1} = \text{work performed.}$$

where r is the ratio $\frac{V_2}{V_1}$, or the ratio of expansion.

Isometric action is shown by thermal lines parallel to the line of pressures, the heating being at constant volume.

Isopiestic action is shown by thermal lines parallel to the line of volumes, the heating being at constant pressure.

Relative to the horizontal and vertical lines on a pressure-volume diagram, it will be observed, however, that in the case of isothermal expansion or compression, if the temperature and pressure remain constant, the line traced on the diagram will be a horizontal line, and if the temperature and volume remain constant, the line traced will be a vertical line, thus resembling isopiestic and isometric lines respectively, although actually representing an entirely different mode of action. It may be stated as a general rule, however, that horizontal and vertical lines indicate isothermal action in the case of a steam engine, and isopiestic or isometric action respectively, in the gas of an internal combustion engine.

Gases, Liquefaction of. It has also been long known that most solids can be transformed into liquids by the application of heat, and that many liquids can also be transformed into vapor by a further addition of heat. Conversely, it was known that certain aëriform substances, such as steam, can be converted into liquids by the mere abstraction of heat. It was believed, however, that an essential difference exists between gases and vapors, vapors being condensible to the liquid form, while gases were believed to be permanently aëriform, and not condensible by any experimental means at our disposal. In the early part of the 19th century the validity of this distinction came to be doubted, and Faraday, at the suggestion of Davy, undertook the systematic study of the question. He succeeded in reducing to the liquid form quite a number of gases that had previously resisted liquefaction. His general method consisted in generating the gas in large quantities in a limited space, so as to produce a very high pressure, under the influence of which (when the experiment was successful) the gas passed into the liquid state. The most convenient way of carrying out this experiment is to make use of an inverted U-shaped glass tube, one of whose legs contains a chemical preparation suitable for the generation of the gas in question, while the other end dips into a freezing mixture; the tube being hermetically sealed. If cyanide of mercury be heated in one of the legs of a tube of this kind, for example, cyanogen gas is generated in such quantities that the pressure causes a large part of it to condense in the chilled end of the tube. Chlorine was liquefied by Faraday in this manner in 1823. Shortly afterward Thilorier succeeded in solidifying carbon dioxid by the combined application of intense cold and great pressure, and Cagniard de la Tour, Regnault, Natterer, and many other experimenters, improved the methods in use with the result that many of the gases that had been previously regarded as non-condensible were reduced to the liquid form. Oxygen, hydrogen, nitrogen, and some few other gases still resisted all attempts at liquefaction, however, and these were still called "permanent gases," although the conviction had forced itself upon physicists that all gases could be conquered, if the necessary conditions of success could be discovered. The subject was in this state when Andrews undertook his classical study of the phenomena of liquefaction of carbon dioxid. In 1863 he made the following announcement: "On partially liquefying carbonic acid by pressure alone, and gradually raising at the same time the temperature to 88° F (31° C.), the surface of demarcation between the liquid and gas became fainter, lost its curvature, and at last disappeared. The space was then occupied by a homogeneous fluid, which exhibited, when the pressure was suddenly diminished or the temperature slightly lowered, a peculiar appearance of moving or flickering striæ throughout its entire mass. At temperatures above 88° F. no apparent liquefaction of carbonic acid, or separation into two distinct forms of matter, could be effected, even when a pressure of 300 or 400 atmospheres was applied." It appeared, therefore, that a certain temperature exists, above which carbon dioxid cannot be liquefied by any pressure whatever; and this discovery was soon verified in the case of other gases. The temperature in question is known as the "critical temperature" of the gas under experiment. (For its numerical values in the cases of the more important gases, see CRITICAL POINT.) The reason that oxygen, nitrogen and hydrogen resisted previous attempts at liquefaction, even when the pressure was pushed to 3,000 atmospheres, was that the critical points of these gases are very low indeed,— far below any temperature at which the attempt at liquefaction had been made. The problem of liquefying the so-called "permanent gases" was, therefore, resolved into the production of exceedingly low temperatures. One means for the production of such temperatures was given by Thilorier, who showed that by mixing solid carbon dioxid with ordinary ether, a temperature as low as 165° F. below zero may be attained. The cold produced by the expansion of the gases themselves has also been utilized for the production of the necessary degree of cold, and in the best modern forms of apparatus the gas, after being cooled by its own expansion, is furthermore caused to circulate about the pipes that are conducting fresh supplies of gas to the point at which the expansion takes place. In all cases, every care is taken to make use of any process or device which will lower the temperature of the gas; and by the strictest attention to this general principle, it has been found possible to liquefy every known gas except helium and possibly one or two of the other rare gaseous elements recently discovered in the atmosphere. It is highly probable that these will also succumb, when they can be obtained in sufficient quantity to be treated by the same methods that have yielded success in the case of so obdurate a gas as hydrogen. Hydrogen was first liquefied, in quantity, by Dewar, in 1898. Consult: Hardin, 'Rise and Development of the Liquefaction of Gases.'

Gas'kell, Elizabeth Cleghorn Stevenson, English novelist: b. Chelsea 29 Sept. 1810; d. Alton, Hampshire, 12 Nov. 1865. She was brought up by an aunt at Knutsford in Cheshire, where she spent the greater part of her early life. This town is said to be the original of the village in her story of 'Cranford,' described as inhabited exclusively by maiden ladies and widows of limited means. She married in 1832 the Rev. William Gaskell (q.v.), a Unitarian clergyman then recently appointed minister of Cross Street Chapel, Manchester. Her first work, 'Mary Barton,' appeared in 1848. The 'Athenæum' says it raised the Lancashire dialect almost to the level of the broad Doric used by Scott in his northern novels. In this, as in most of her works, Mrs. Gaskell appears as a social reformer. Her moral and economical theories may be questioned, but as a writer of fiction she wields artistic and dramatic powers of a high order. 'Mary Barton' represents the struggles formerly so rife in Lancashire, and which have since passed in new phases and into other quarters, between workmen and employers. 'The Moorland Cottage' appeared in 1850; and in 1853, her next novel, 'Ruth,' which aims a distinct blow at the common moral judgments of society. The tale is powerfully told, but will hardly satisfy a dispassionate reader of the soundness of Mrs. Gaskell's moral theories. Her later works include: 'Cranford' (1853), an English classic, the popularity of which is constantly increasing; 'North and South' (1855); 'Sylvia's Lovers' (1860); 'Cousin Phillis' (1865); 'Wives and Daughters' (1866). In 1857 appeared a 'Life of Charlotte Bronte,' of which the 'Athenæum' observed "As a work of art we do not recollect a life of a woman by a woman so well executed."

Gaskell, William, English Unitarian clergyman: b. Latchford, near Warrington, Lancaster, 24 July 1805; d. Manchester 11 June 1884. He was graduated from the University of Glasgow in 1824; studied theology at Manchester College, York, in 1825–8; was junior minister of Cross Street Chapel, Manchester, from 1828, and senior minister from 1854. In 1840–6 he was secretary to Manchester New College, and in 1846–53 professor there of English history and literature. He also taught logic and English literature in Owens College. He was an editor of the 'Unitarian Herald' 1861–75; made a favorite rendering of Luther's 'Ein feste Burg'; wrote many original hymns, of which some appear in James Martineau's 'Hymns of Praise and Prayer' (1874); and published numerous tracts and sermons, besides 'Two Lectures on the Lancashire Dialect' (1844), appended to the 5th edition (1854) of the 'Mary Barton' of his wife, Elizabeth Cleghorn Gaskell (q.v.).

Gasoline. A colorless, inflammable fluid, the first and highest distillant of crude petroleum; an arbitrary name first given to certain gravities of naphtha used for making illuminating gas in house-plants. Specifically all gasoline is naphtha in the manufacturing laboratory. The specific gravity ranges from .58 to .90, compared with the unit 1 assumed for water, at 60° F. For every 20° F. the specific varies .01. Measured on the Baumé scale, higher specific gravities are denoted by lower numbers, and lower specific gravities by higher numbers without definite graduations. For example, a change of 6° on the Baumé scale, from 74° to 68°, means a difference in specific gravity of .017, the increase being from .690 to .707; in the other direction a change from 74° to 80° Baumé shows a difference of .022, or a change in specific gravity from .690 to .668. Gravities from .50 to .65 are used in varnishes, paints, oilcloth manufacture, etc., as driers; gravities .65 to .68 are generally known as "stove" gasoline; .68 to .76 are used in burners for steam automobiles and in carburetters of gasoline (hydrocarbon) automobiles; higher gravities are used in cleansing establishments, and to raise the specific gravities of lower grades which contain more or less grease from lower distillation. Crude petroleum yields about 15 per cent gasoline (naphtha) for all gravities and about 4 per cent only for gravities above .76. Gasoline, like all other products of crude petroleum, was for a long time disposed of as waste in the effort to make kerosene; it was there and had to come out. In the latter sixties it was exported to Europe in small quantities. Representing the lightest portion of crude oil, gasoline is extracted by distillation, just as whiskey is produced, and in much the same sort of apparatus. The stills or retorts may be of any shape and size; both are immaterial, and practice has differed. They may be cylinders placed horizontally and in banks, or cylindrical or conical, standing perpendicular and having curved domes. Rectification is effected by a copper coil, many feet in length inside the retort and passing through the crude petroleum, carrying steam at a high pressure, assisted by a gentle direct fire varying from 122° to 257° F. Each retort has an inlet pipe for the crude petroleum and an outlet pipe for the distillant. The outlet pipe passes over the side and down to a cooling coil or worm immersed in cold running water. This worm acts as a condenser that changes back to liquid form the vapors driven off the petroleum by the heat. A smaller pipe leads from the condenser to a receiver having glass sides through which the "still-man" can watch the flow of distilled oil. From the bottom of the receiver a number of pipes lead to different storage tanks, each pipe having a cut-off valve to regulate the flow of the varying gravities to their proper tanks, each cut-off being known as a "sweeping." The first product from the retort is a gas formed by the mingling of the fumes of the petroleum with the small volume of air left in the reservoir; this is sometimes conveyed to the fire-box and used as fuel. When the first flow of the distillant reaches the receiver, the still-man tests it with a Baumé hydrometer for its specific gravity. Usually this first flow is found to be about .90 specific gravity. It is of a highly volatile nature, so nearly a gas that when exposed to air it rises in an invisible vapor and will quickly evaporate. It cannot be confined for any length of time in barrels, even if they have been successively coated inside with wax and repeatedly painted outside to make them air-tight. Even in the coldest weather it will pass through the wood. For these reasons this gravity is not put out commercially, but is used to bring up the gravity of a mass made up of lower gravities; that is to say, if .88 is being tanked the still-man lets all the .90, .89, .88 and enough of the .87 gravity oil flow into the receiver to make an average mixture of the density wanted. The oil is repeatedly tested with the hydrometer until the right gravity has been produced in the receiver, when it is let off to the proper storage tank. If .82 is the next grade wanted, all the gravities from .86 down to perhaps .78 are commingled in the receiver until a uniform fluid of the required gravity is obtained to let off into its tank. This process is called "fractioning," and is continued through gasoline into kerosene, the next distillant, down about .42 specific gravity. Gasoline is known in England as "petrol," in France as "essence." The English term is a copyrighted name first given some years ago by a refining firm called upon for high gravity naphtha by an experimenter in hydrocarbon mixtures. See PETROLEUM.

ERNEST L. FERGUSON,
Writer on Gasoline Engines and Components.

Gasom'eter, or **Gas Holder**, an inverted cylindrical vessel of sheet iron, placed in a tank of cast iron, stone, or brick containing water. A pipe ascends from the bottom of the tank through the water, to admit the gas to the space between the surface of the water and the crown of the gas holder. Sometimes a second pipe descends through the water and the bottom of the tank, for the issue of the gas to the main pipe. Frequently only one pipe is used for the inlet and outlet alternately. The water is for the purpose of retaining the gas within the vessel. The pressure of the gas raises the gas holder; and the weight of the gas holder, or such part of it as is not taken off by balance weights, impels the gas through the pipes. When balance weights are necessary, they are attached to the edge of the crown of the gas holder by long chains, which pass over pulleys on the top of columns which serve also to guide the motion of the vessel in rising and falling. Gas holders are constructed of various sizes, some exceeding 200 feet in diameter and having nearly 6,000,000 cubic feet capacity.

Gasometric Analysis. In chemistry, the art of separating, and of estimating, quantitatively, the several constituents of a gaseous mixture. The methods employed may be divided into three general classes: (1) Those based on diffusion; (2) those based upon the absorption of certain constituents by substances over or through which the mixed gases are passed; and (3) those in which the given mixture is oxidized, and its original composition inferred from an examination of the products of the oxidation. In the application of diffusion methods, the mixture is caused to pass through a porous septum of graphite, gypsum, or baked clay. The lighter constituents pass through faster than the heavier ones, so that a partial separation is effected. By causing the mixture to pass through a succession of such porous partitions, the concentration effects may be correspondingly increased. This method has been employed in many chemical researches, especially for effecting the concentration of gaseous substances that are present in a mixture in very small quantity. Its value as an experimental method was well demonstrated in connection with the study of the rare gases of the atmosphere, in effecting the separation of helium from argon. In general, the rates of diffusion of two gases are proportional to the square roots of their densities; and the density of argon being 10 times that of helium, it follows that helium will diffuse through a porous septum about 3.2 times as fast as argon.

In the analysis of gases by the absorption of certain of their constituents by means of chemical substances, use is made of the following facts (among others): Water absorbs HCl, HBr, and HI, very readily; solid caustic potash, when moist, absorbs all acid gases, such as CO_2, SO_2, H_2S, HCl, etc.; dilute sulphuric acid absorbs all alkaline gases, such as ammonia; concentrated sulphuric acid also absorbs water, alcohol, ether, methyl oxid, and (more slowly) propylene and its homologues; alkaline solutions of pyrogallic acid absorb oxygen very readily; cuprous chlorid in solution in hydrochloric acid absorbs oxygen and carbon monoxid; and solutions of CrO_3 and of $KMnO_4$ absorb H_2S and SO_2. In the study of special problems, certain unusual absorbents also suggest themselves. Thus in the isolation of the rare gases of the atmosphere, great use was made of the fact that red-hot metallic magnesium absorbs nitrogen gas, while it is without effect upon argon, helium, and the other gases of that group.

The combustion methods are particularly applicable to those cases in which the mixture to be analyzed is capable of being burned so that the final products are water, carbon dioxid, and free nitrogen, together with excess of such gas as may have been added in order to effect the combustion. The combustion is effected in an instrument called a «eudiometer,» which commonly consists of a graduated glass tube that is closed at the upper end, and which is provided with a pair of platinum electrodes fused through the glass near the closed end. A sample of the gas to be analyzed is introduced into the tube (the lower end of which dips into a mercury bath), and its volume is determined by reference to the graduation marks; readings being simultaneously taken of the thermometer and barometer, so that the observed volume of the gas can be reduced, in the subsequent calculations, to standard conditions of temperature and pressure. A known quantity of such gas as may be required to effect the combustion is next added; pure oxygen being used if the gas under examination is rich in carbon and hydrogen, and pure hydrogen being used if it is highly oxygenated or chlorinated. It is usual, also, to add a known quantity of «fulminating gas,» which is prepared by the electrolysis of water, and consists of pure oxygen and hydrogen, in the proportion in which they combine to form water. The mixture is then exploded by passing an electric spark between the electrodes that are sealed into the eudiometer near its closed end, and after the heat developed by the explosive combustion has been lost by radiation, the volume of the mixture is again determined. The several constituents that remain in the eudiometer tube are then removed, one by one, by the temporary introduction, into the tube, of suitable absorbent substances. The volume of the gaseous contents of the eudiometer tube are observed after each partial absorption, and from the data so obtained the quantities of carbon, oxygen, hydrogen and nitrogen that were present in the original sample may be calculated. Consult: Hempel, 'Methods of Gas Analysis'; Sutton, 'A Systematic Handbook of Volumetric Analysis.' See also, in this encyclopedia, Chemical Analysis; Spectroscope.

Gasparin, Agénor Etienne, ä-zhä-nôr ā-tē-ĕn gäs-pä-răn, Comte de, French author: b. Orange, France, 12 July 1810; d. near Geneva, Switzerland, 4 May 1871. Elected to the Chamber in 1846, he attracted attention by his advocacy of religious liberty, prison reform, abolition of slavery, and social purity. At the outbreak of the American Civil War he published two books maintaining the justice of the Federal cause entitled, 'The Uprising of a Great People' (1861), and 'America Before Europe' (1862). Other important works were: 'Slavery' (1838); 'Christianity and Paganism' (1850); 'Liberal Christianity' (1869); 'Innocent III.,' published posthumously.

Gasparin, Valérie Boissier, vä-lā-rē bwä-sē-ā, Comtesse de, French author: wife of A. E. de Gasparin (q.v.): b. Geneva, Switzerland, 13 Sept. 1813; d. near Geneva 1894. Two of her works obtained the Montyon prize at the Academie Française: 'Marriage from the Christian Point of View,' and 'There are Poor in Paris and Elsewhere.' Among her other publications are: 'Journey in the South by an Ignoramus'; 'Let's Go Make a Fortune in Paris'; 'A Book for Wives'; 'Read and Judge' (strictures on the Salvation Army), and 'The Near and the Heavenly Horizons.' Several of her books were translated into English, the last named being read very widely in America in its English form.

Gaspé, gäs-pā, **Philip Aubert de**, Canadian author: b. Quebec 30 Oct. 1786; d. there 29 Jan. 1871. A lawyer, afterward sheriff, he became involved in debt for which he was imprisoned four years; and when released, secluded himself on his estate of St. Jean Port-Joli. His 'Old-Time Canadians' (1862), and his 'Memoirs' (1866), treat of Canadian traditions and folklore, and were written in French. The former was perhaps the most popular book ever published in Canada. An English translation was made by Mrs. Pennie.

Gaspé, Canada, a district in the province of Quebec, forming the northern part of the peninsula that lies between the Bay of Chaleur and the Gulf of St. Lawrence. Area, 7,500 square miles. Pop. (1901) 52,200. The name is sometimes extended to the whole peninsula. Cape Gaspé is a bold headland of the Schikshock or Notre Dame mountains, terminating the peninsula and forming the north shore of Gaspé Bay. The inhabitants are chiefly engaged in important fisheries, which with the export of lumber, form the staple industries. Gaspé, a village and port of entry in Gaspé Bay where Cartier landed in 1534, is the capital and commercial centre of the district. Pop. (1901) 454.

Gaspee, The, British revenue vessel, burned 1772. She was an armed schooner of eight guns, stationed at the entrance of Narragansett Bay to prevent that evasion of the British navigation laws which had largely built up the prosperity of the Atlantic coast and was almost the entire subsistence of Rhode Island. Its authorities connived at the traffic, and at a regular price furnished false flags, which for years passed muster, but Lieut. Dudingston of the Gaspee adopted the method of searching thoroughly every trading vessel which entered or left the bay, without regard to her flag or papers, and sending the contraband goods to

Boston for adjudication. This meant ruin to Rhode Island; the executive wrote demanding Dudingston's authority, and the chief justice sent a sheriff on board; both held that his proceedings were illegal, as he should have a commission from the governor and be sworn in. They were referred to the admiral, and then to the British secretary of state. On 9 June 1772, the regular packet left Newport for Providence without notifying Dudingston, who gave chase but ran the Gaspee aground at Namquit Point, seven miles below Providence, at low tide. That night the leading men of that city, with a company of assistants, set out in eight large boats, boarded and captured the vessel, badly wounding the commander, set the crew on shore, and burnt the schooner. The Rhode Island authorities opened an investigation with great zeal, and offered rewards for the apprehension of the guilty parties, but could discover none. The home government was greatly incensed, and appointed colonial commissioners, who sat at Newport 4-22 Jan. 1773, to make inquiry, and ordered Gov. Wanton to arrest the offenders and send them to England for trial. The governor and the chief justice applied to the assembly for instructions, which body referred it to the discretion of the chief justice, who refused to allow any arrests for transportation to be made.

Gasquet, gās'kĕt, **Francis Aidan**, English Roman Catholic ecclesiastic: b. London 5 Oct. 1846. He was educated at Downside College, Bath, and was superior of the Benedictine Monastery, and college of Saint Gregory, Downside 1878-84. He is the presiding abbot of the English Benedictines and has published: 'Henry VIII. and the English Monasteries' (1888-9); 'Edward VI. and the Book of Common Prayer' (1890); 'The Great Pestilence' (1893); 'The Last Abbot of Glastonbury' (1895); 'A Sketch of Monastic Constitutional History' (1896); 'The Old English Bible, and Other Essays' (1897); 'The Eve of the Reformation' (1900).

Gassendi (properly **Gassend**), **Pierre**, pē-ār gä-säṅ-dē, French philosopher and mathematician: b. Champtercier, near Digne, Provence, 22 Jan. 1592; d. Paris 24 Oct. 1655. At 19 he was appointed to fill the chair of philosophy at Aix, and although the authority of Aristotle was still warmly maintained, he ventured publicly to expose the defects of his system. His lectures on this subject, 'Exercitationes Paradoxicæ adversus Aristotelem' (1624), gave great offense to the votaries of the Aristotelian philosophy, but obtained him no small reputation with others, through whose interest, after taking orders, he was made doctor of divinity. A second book of 'Exercitationes' excited so much enmity that he ceased all direct attacks on Aristotle, although he still maintained his preference for the doctrines of Epicurus, which he defended with great learning and ability. He strenuously maintained the atomic theory, in opposition to the views of the Cartesians, and, in particular, asserted the doctrine of a vacuum. On the subject of morals he explained the doctrines of Epicurus in a sense the most favorable to morality. He was appointed lecturer on mathematics in the Collége-Royal at Paris in 1645. He is ranked by Barrow among the most eminent mathematicians of the age, and mentioned with Galileo, Gilbert, and Descartes. Gassendi was the first person who observed the transit of Mercury over the sun. His chief works are: 'De Vita Moribus et Doctrina Epicuri' (1647); 'Institutio Astronomica,' 'Syntagma Philosophiæ Epicuri' (1649); 'Tychonis Brahæi Copernici, Peurbachii et Regiomontani Vitæ' (1654).

Gasterop'oda, the largest and most typical and familiar of the four classes of mollusks (phylum *Mollusca*). The name refers to the most prominent tribal characteristics, namely, that the inferior surface of the body forms a flattened sole or disk, by the contractions of which the animal advances. In all these animals the primitive symmetry of the body is obscured by the unequal development of parts, whence results the spiral disposition of the majority. The simplest gasteropods, however, such as the chiton, are symmetrical, not lop-sided like the higher forms. They have the mouth at one end of the long axis of the body, the anus at the other; the gills, kidneys, genital ducts, and circulatory organs are paired; there are two pairs (pedal and visceral) of nerve cords running parallel to one another along the body, and the ganglia are slightly developed. Of all mollusks these simplest gasteropods are probably nearest the hypothetical worm-like ancestor. When a shell is present it consists of only one piece, whence the name "univalve," formerly applied to the class; or if of more than one piece the separate portions are placed one behind the other in the axis of the body (*Amphineura*, chitons). The gasteropods agree with the cephalopods in possessing a distinct head, containing a feeding instrument or "tongue" in the form of a lingual ribbon, but are separated from that class by the mode of formation of the shell, and by the absence of arms around the head. The lingual strap or odontophore consists of a central portion (*rachis*) and lateral pieces (*pleuræ*). On all three of these, on the central, or only on the lateral regions, are placed silicious denticles, whose number, form, and arrangement have been made the basis of classification of genera.

Mode of Life.— Though the number of terrestrial gasteropods, breathing the air directly by means of a pulmonary chamber, is very large — over 6,000 living species — those living in water are greatly in the majority, including over 10,000 forms, mostly marine. Of these, some 9,000 or so belong to the prosobranchs or *Streptoneura*, a relatively small minority being opisthobranchs and nudibranchs. The heteropods and some opisthobranchs enjoy a free-swimming pelagic life, but most marine forms frequent the coasts either on the shores or along the bottom. Deep-sea gasteropods are comparatively few. The locomotion effected by the contractions of the muscular "foot" is in almost all cases very leisurely, and the average tendency is toward sluggishness. As to diet, the greatest variety obtains; most prosobranchs with a respiratory siphon and a corresponding notch in the shell are carnivorous, and so are the active heteropods; most of the rest are vegetarian in diet. Numerous genera, both marine and terrestrial, are very indiscriminate in their feeding; others, are as markedly specialists, keeping almost exclusively to some one vegetable or animal diet. Some marine snails partial to echinoderms have got over the digestive difficulty presented by the calcareous character of the skins of their victims by a secretion of free sulphuric acid from the mouth. This acid changes the carbonate of lime into sulphate, which is brittle and readily pulverized by the rasping tongue. A few are parasitic — for example, eulima, stylifer, and the very degenerate *Entoconcha mirabilis,* all occurring in or on holothurians.

Life-history.— The eggs of gasteropods are usually small, and are surrounded with albumen, the surface of which becomes firm, while in the common snail (*Helix*) and some others there is an egg-shell of lime. The eggs not unfrequently develop into embryos within the parent, but in most cases they are laid, either singly or in masses, and often with cocoons. Few objects are more familiar on the seashore than the clustered egg-cases of the whelk, which together form a ball often about the size of an orange. Inside each of the numerous egg-cases are many embryos, but only a few reach maturity, the others serving as food material, an infantile cannibalism or struggle for existence not uncommon in the class. As to development it may be noted that the ovum divides more or less unequally, according to the amount of yolk, that a gastrula-stage occurs as usual, and that this is succeeded in typical cases, first by a «trochophore» and afterward by a «veliger» larva (see MOLLUSCA).

General Interest.— As voracious animals, furnished with powerful rasping organs, many gasteropods play an important part in the struggle for existence among marine organisms, while other terrestrial forms are most destructive devastators of vegetable and flowering plants. The manner in which numerous plants are saved from the ravages of snails, by their chemical and physical characters, is an interesting subject of investigation recently worked out by Prof. E. Stahl. From very early times, various gasteropods, such as whelks, have been utilized for human consumption and also as bait, while yet more frequently the shells, often so beautiful in form and color, have been used for the decoration of the person and the dwelling, for the basis of cameos, as domestic utensils, or even as weapons, and in many other ways. From the mucous glands of the roof of the gill-cavity in the genera *Purpura* and *Murex*, there exudes the famous secretion, at first colorless, but afterward becoming purple or violet, which furnished the ancient Tyrian dye.

Geological History.— A few gasteropods occur in strata as far back as the Cambrian, from which remote period they have continued with a steady increase. Almost all the Palæozoic genera are now extinct, and during these ages the siphon-possessing forms seem to have been almost, if not altogether, unrepresented. A host of new gasteropods appeared in the Jurassic period, and many of the modern families have their origin in Cretaceous times. Numerous as the fossil forms are, the number of types wholly extinct is comparatively small; both as regards persistence of types and increase of numbers, the gasteropods are a peculiarly successful class.

Classification.— The grouping of forms within the class is as follows, according to the latest conclusions of naturalists, as summarized by Cooke in the third volume of the Cambridge Natural History' (1894):

Class GASTEROPODA; order *Amphineura;* sub-orders, *Polyplacophora, Aplacophora;* order, *Prosobranchiata;* sub-orders, *Diotocardia, Monotocardia;* order, *Opisthobranchiata;* sub-orders, *Tectibranchiata, Ascoglossa, Nudibranchiata, Pteropoda;* order, *Pulmonata;* sub-orders, *Basommatophora, Stylommatophora.*

(For the characters of the orders see *Classification* in the article ANATOMY.) The sub-divisions are based upon different anatomical categories in each order. Thus the first sub-order of *Amphineura* embraces all the ordinary chitons having a foot and plated shell, both of which are absent in the degraded *Aplacophora.* Among the *Prozobranchiata* (which embrace the ordinary marine shells) two auricles in the heart characterize the *Diotocardia,* a single auricle the *Monotocardia,* of which the strange pelagic *Heteropoda* are now regarded as only a subordinate group. The *Opisthobranchs* are classified according to gill-features; and the *Pulmonata,* according to relative position of the eyes.

See MOLLUSCA, and consult the works cited thereunder, especially Cooke, 'Shells' (New York 1896), in which will be found many instructive references to other authorities.

Gaston, William, American jurist: b. Newbern, N. C., 19 Sept. 1778; d. Raleigh, N. C., 23 Jan. 1844. He was graduated at Princeton 1796; was admitted to the bar 1798; elected to the State Senate 1799; and congressman 1813–17, voting with the Federalists and opposing the «Loan Bill.» Returning to the practice of the law he obtained great reputation as an orator, and was frequently a member of the State legislature. He drew up the act creating the supreme court of North Carolina and served as judge of that court 1834-44. During his later years he was a Whig, opposing nullification.

Gastor'nis, a genus of fossil birds of the epyornis family, whose remains, indicating several species, have been found in the Eocene rocks of both England and France. They were birds of the size of an ostrich, with long legs, weak wings, and little if any power of flight.

Gastræa, găs-trē'a, a hypothetical primitive animal consisting simply of a sac or stomach, with an ectodermal and endodermal layer of cells. This simple organism, to which the embryonic gastrula-stage (see EMBRYOLOGY) is the nearest modern approach, and was regarded by Hæckel as recapitulative of the primitive gastræa, Hæckel assumes to have been the first animal generated on the earth, and the germ from which the whole animal kingdom with its infinite diversities was gradually evolved. His hypothesis, called the Gastræa theory, asserted that there must have been many species, families, etc., of these primitive organisms, whence all the *Metazoa* have been evolved. These generalizations were announced by Hæckel in 'Die Gastræa-theorie, die Phylogenetische Classification des Thierreichs und die Homologie der Keimblätter,' published at Jena in 1874, and have since been extensively considered in all works on embryology.

Gastrec'tomy, the removal of a part or the whole of the stomach-wall. It is performed for the cure or relief of deep ulcerations, cancerous growths, or contractions of the wall that cause serious obstruction.

Gastric Juice, the secretion of the stomach, is in man a clear almost colorless fluid of acid reaction, containing one half of 1 per cent solids. The amount secreted varies with the demand, but approximates 1,000 cubic centimetres in 24 hours. In health secretion takes place only under the stimulus of food. Hydrochloric acid, the chief constituent, is present in one or two parts per thousand. During the first stage of digestion it is all combined with the food, but later it is found free. The other important ingredients of this secretion are pepsin, a ferment that has the power of converting albuminous foods into forms that can be absorbed and assimilated; and rennin, a ferment that causes coagulation of milk by converting the casein, one of the milk proteids. Inorganic salts, the alkaline chlorides and phosphates, and phosphates of calcium, magnesium, and iron constitute most of the solids.

Gastritis, găs-trī'tĭs, a general term that includes all strictly inflammatory diseases of the stomach. Phlegmonous gastritis is a very acute, fatal, but rare disease that starts in the deeper layers of the stomach-wall and results in an abscess. Acute gastritis or acute gastric catarrh is an acute inflammation of the lining mucous membrane. The membrane becomes swollen, is covered by a coating of tenacious mucus, and tends to bleed at minute points. Errors in diet, either by over-indulgence or the ingestion of improper food, is the most frequent cause of the malady. Certain chemicals and drugs, very hot food or liquid, foreign bodies, and unripe fruits may cause the irritation. The symptoms depend on the severity of the inflammation, the milder forms being spoken of as sub-acute. Frequently premonitory symptoms, such as a feeling of fulness or tenderness, or the eructation of gases, may be noticed, and may be soon followed, in the more severe cases, by nausea, vomiting, and a rise of temperature, accompanied by painful thirst. If the retching or vomiting of mucus continues, there is apt to be great weakness and prostration. The duration of the disease under proper treatment is seldom over three or four days. The stomach should be given absolute rest for 24 hours, or even longer if nausea or retching continue. The intense thirst may be relieved by small pieces of ice, but not even the drinking of water is permitted. Rest in bed may be indicated in the more severe cases and, if so, hot poultices applied to the stomach region relieve some of the distressing symptoms. Drugs are of little value except to quiet excessive vomiting. Toxic gastritis is that form caused by the ingestion of corrosive and irritating drugs and chemicals. It is a severe form of acute catarrh, with the added effect of the particular poison taken. Strong acids and corrosives cause death of the deeper tissues, with ulceration and even perforation of the wall. The treatment depends upon the poison taken, but dilution by the imbibing of demulcent drinks is usually of value if sufficiently early. Chronic gastritis or chronic gastric catarrh is a chronic inflammatory change in the mucous membrane of the stomach. It is the most wide-spread of maladies, affecting all classes and ages. Not uncommonly successive attacks of acute gastritis, even in early life, start those progressive changes that sooner or later make themselves known as chronic catarrh. The most common cause is the repetition of insult to the stomach in food, both as to quantity and quality, and in drink irritating from high temperature or presence of alcohol. Other causes may operate, such as venous congestion from disease of the heart, liver, and spleen, changes in the blood-elements, and the constant poisoning of infectious diseases.

For an understanding of the symptoms of this affection it must be appreciated that three mechanisms make up gastric digestion — the nervous, the muscular, and the secretory. Deviation from the normal in any one of these is almost certain to act on the others, and when, in addition to these mechanisms, the close relation of the stomach and other digestive organs is considered, a marvelous complex is apparent. The symptoms of a chronic catarrh may be unnoticed, may be merely evidenced by changes due to poor gastric digestion, or interwoven with resulting derangement of all the digestive apparatus. In the early stages the mucous membrane is swelled, the gastric juice still has its normal ingredients and, in addition, the membrane secretes a mucus owing to degeneration of the cells. From this stage to a complete absence of acid, and then of ferments, the change is gradual, the final stage being known as atrophic gastritis. No symptom or group of symptoms is characteristic of the disease, the diagnosis being made with accuracy only by examination of the gastric contents. At one time or another one or more of the following symptoms are noticed. Absence of appetite, bad taste in the mouth, coated tongue, nausea and, occasionally, vomiting, eructation of gases and some liquid, heartburn, and a feeling of fulness or bloating after meals. The presence of inflammation, and the stage, are determined by chemical and microscopical analysis of the contents of the stomach after a test-meal has been eaten. In all except the atrophic stage there is always more or less mucus found mixed with the food. This is the distinguishing feature.

Of itself the disease is not fatal, but severe disorders of nutrition may result that render the sufferer more liable to other diseases.

The treatment consists in correction of the causes as much as possible, particularly in a dietetic regimen free of irritation and of ready digestibility. Lavage or washing of the stomach is of supreme importance where it can be borne. Drugs are of little use except for the relief of distressing symptoms. Where great diminution or absence of acid is found, it may be supplied, but the large amount necessary usually makes the procedure impracticable. Electricity, massage, and hydrotherapy may be beneficial.

Gastros'tomy, the operation of making a more or less permanent opening between the interior of the stomach and the overlying surface, the lining membrane of the stomach being joined to the skin entirely around the margin of the opening. This procedure is undertaken when for any reason the entrance of food into the stomach by natural passage is prevented.

Gastrot'omy, a simple incision of the wall of the stomach, usually undertaken for the exploration of the interior or for the removal of foreign bodies.

Gas'trula. See EMBRYOLOGY; GASTRÆA.

Gatacre, SIR **William Forbes**, English soldier: b. 1843; d. 6 March 1906. He joined the English army in 1862; was instructor of surveying in the Royal Military College in 1875–9;

deputy-adjutant and quartermaster-general in the Hazara Expedition in 1888, and in the Burma, Tonhon Expedition in 1889. He led the British forces in the Sudan in 1898, during the first advance against Atbara, and later commanded a British division in that region during the movement against Khartum and Omdurman. When the war in South Africa broke out he was ordered there and given an important command. He was repulsed at Stormberg with heavy loss. In April 1900 he was recalled to England.

Gatchina, gä'chē-nä. See GATSCHINA.

Gate City, The, a name given to Keokuk, Iowa (q.v.), and to Atlanta, Ga. (q.v.).

Gate of Tears, or **Gate of Mourning**, the Straits of Bab-el-Mandeb, Arabia; the term is an exact translation of the words Bab-el-Mandeb, which have reference to the many shipwrecks which anciently occurred thereabouts.

Gates, Elmer, American psychologist and inventor: b. Dayton, Ohio, 1859. He has done much original work in electric meteorology and has made several electrical mining inventions. He is the author of a system of mind-building and experimental psychology, having four laboratories for experimental research in these fields. Among his works are: 'Psychurgy or the Art of Using the Mind'; 'Art of Mind-Building.'

Gates, Horatio, American military officer: b. Maldon, Essex, England, 1728; d. New York 10 April 1806. He joined the British army early in life; in 1755 was assigned to duty at Halifax, N. S., and later served with Braddock's expedition. In July 1775 Congress appointed him adjutant-general; in 1776 he was given a command in the Northern army, and 2 Aug. 1777 assumed command of the Northern department. He defeated Burgoyne at Saratoga, 7 Oct. 1777, the British general surrounding his army on the 17th. (See SARATOGA, BATTLE OF.) In November of the same year he was appointed president of the new board of war and ordnance; and in 1778, while holding that post, sought with the aid of his friends in Congress to supersede Washington as commander-in-chief. This action soon brought him into discredit, and he resigned from active service. In June 1780 he again entered the army, becoming commander of the troops in North Carolina. On 16 August of that year, his army was defeated near Camden, S. C. He was soon afterward suspended from duty, but reinstated in his command in 1782 after the capture of Cornwallis.

Gates, Lewis Edwards, American educator and critic: b. Warsaw, N. Y., 23 March 1860. He is a brother of M. E. Gates (q.v.). He was graduated at Harvard 1884, instructor in forensics there 1884–7, instructor in English 1890–6, then becoming assistant professor of English. He is a frequent contributor of critical articles to the magazines. He has published: 'Selections from Jeffrey' (1894); 'Selections from Newman' (1895); 'Selections from Matthew Arnold' (1898); 'Three Studies in Literature' (1899); 'Studies and Appreciations' (1900).

Gates, Merrill Edward, American educator: b. Warsaw, N. Y., 6 April 1848. He was graduated at the University of Rochester 1870, was principal of the Albany Academy 1870–82, president of Rutgers College 1882–90, and president of Amherst College 1890–9. He has been very active in promoting Civil Service measures, and ballot reform. He was made chairman of the United States Board of Indian Commissioners 1884, and was president of the American Missionary Association 1893–8. He has published: 'Athens and the Greeks of To-day'; 'Sidney Lanier, Poet and Artist'; 'The Debt the School Owes the State'; 'Land and Law as Agents in Educating the Indians'; 'International Arbitration'; etc.

Gates, SIR Thomas, English colonial governor of Virginia: d. after 1621. He sailed from England in May 1609, in charge of a colony of 500 emigrants to the New World, but his vessel, the Sea Venture, was stranded on the rocks of Bermuda. Here the passengers built two new ships and finally reached Virginia in May 1610. Gates went to England in the meantime and returned in 1611 with 300 more emigrants. He was made governor the same year and held that office till 1614, when he returned to England.

Gatesville, Texas, city and county-seat of Coryell County, on the St. Louis S. R.R., 80 miles north of Austin. It is situated in the fertile valley of the Leon River, and has considerable agricultural, stock-raising, and produce-shipping interests. Pop. (1900) 1,865.

Gath. See TOWNSEND, GEORGE ALFRED.

Gath (Heb. «wine-press»), one of the five cities of the Philistines which were presided over by so many princes or lords from the time of Joshua to a comparatively late period. It was situated on the borders of Judah, and was in consequence a place of much importance in the wars of the Jews and the Philistines. It is stated in Joshua that Gath was one of the cities in which, at the time of the conquest, there still remained some of the ancient Anakims or giants, and they appear to have perpetuated the race here till much later times, for it was from Gath that the renowned Goliath issued. The exact site of the ancient city cannot be determined with any degree of certainty, but some identify it with the eminence Tell-es-Sâfieh, about midway between Ekron and Ashdod.

Gath'mann Gun. See ORDNANCE.

Gatineau, gä-tē-nō, a river of Canada, in the province of Quebec, rising in a large lake of the same name, from which it flows south, and falls into the Ottawa opposite the town of Ottawa. Its total length is 450 miles.

Gatling, Richard Jordan, American inventor: b. Hertford County, N. C., 12 Sept. 1818; d. New York 1903. While a boy he assisted his father in perfecting a machine for sowing cotton seed, and another for thinning out cotton plants. Subsequently he invented a machine for sowing rice. Removing to St. Louis in 1844, he adapted this invention to sowing wheat in drills. For several winters he attended medical lectures in Cincinnati, and in 1849 removed to Indianapolis, where he engaged in railroad enterprises and real estate speculations. In 1850 he invented a double-acting hemp brake, and in 1857 a steam plow, which, however, he did not bring to any practical result. In 1861 he conceived the idea of the revolving battery gun which bears his name. Of these he constructed six at Cincinnati, which were destroyed by the burning of his factory. Afterward he had 12 manufactured elsewhere, which were used by Gen. Butler on the James River. In 1865 he improved his invention, and in the year following, after satisfactory trial, it was adopted into the United States service. It has also been adopted by several European governments. At the time of his death he was perfecting a few business formalities prior to placing his new motor plow on the market. Although best known as the inventor of a terrible death-dealing weapon, he was the gentlest and kindliest of men. The sight of returning wounded soldiers early in the Civil War led him to consider how war's horrors might be alleviated. By making war more terrible, it seemed to him nations would be less willing to resort to arms, and he accordingly devoted himself to the study of ordnance and ballistics, with this end in view.

Gatling Gun. See ORDNANCE.

Gatschet, Albert Samuel, American linguist: b. Berne, Switzerland, 3 Oct. 1832; d. Washington, D. C., 16 March 1907. He was educated at the universities of Berne and Berlin, and removing to New York in 1868 made a special study of the languages of the American Indians. In 1879 he became connected with the Bureau of American Ethnology. He wrote: 'The Klamath Indians of Southwestern Oregon'; 'A Greek Migration Legend'; etc.

Gatty, Margaret Scott, English writer for young people: b. Burnham, Essex, England, 3 June 1809; d. Ecclesfield, Yorkshire, 3 Oct. 1873. She was married to Rev. Alfred Gatty in 1839. Her career in letters was begun with 'The Fairy Godmother and Other Tales' (1851); but 'Parables from Nature' (1855–71) was the most popular and still holds its place in public favor. She edited 'Aunt Judy's Magazine' (1866–73).

Gauchos, gow'chōz, hybrid inhabitants of South America, mostly cattle-raisers of nomadic habits. They are natives of the pampas, and descendants of Spaniards and Indians. The white strain has largely faded out from them, and a modified Indian type has been developed which has an ethnological interest. As a distinct people, however, they may be said to be disappearing. They are now mainly confined to the Chaco region. Many of them possess figures and bearing which show a proud descent. They wear a costume picturesque in fashion and color, and their skill as horsemen and in using the lasso and bolas is remarkable. They subsist almost wholly on meat, and are noted for their hardiness, bravery, and free mode of existence.

Gauden, gâ'dĕn, **John,** English bishop: b. Mayland, Essex, 1605; d. 20 Sept. 1664. In the early part of his life he belonged to the popular party. After the outbreak of the civil war, he hesitatingly submitted to the Presbyterian discipline, omitted the liturgy from the Church service, and even subscribed to the covenant, although he secretly wrote a treatise against it. After the Restoration he was appointed chaplain to Charles II., and successively created bishop of Exeter and of Worcester. He claimed the authorship of the 'Eikon Basilike,' or the 'Portraiture of his Sacred Majesty in his Solitudes and Sufferings,' a work which was once almost universally attributed to Charles himself, and which in one year went through 50 editions. Hallam and Sir James Mackintosh pronounce his claim valid. Other works of his are: 'Cromwell's Bloody Slaughter House' (1660); 'Tears of the Church' (1659). See EIKON BASILIKE.

Gauge, gāj, the name of many different instruments and appliances used for measuring various dimensions, forces, etc. The various kinds of gauge are distinguished by means of special names indicating the use to which they are applied. Among the most important contrivances of this nature are the instruments fixed to engine boilers for registering the force of the steam and the level of the water. In one of its simplest forms the pressure or steam gauge consists of a bent siphon-tube, with two unequal legs, partly filled with mercury. The top of the shorter limb is connected to a short pipe, which enters that part of the boiler which contains the steam; the other end is open to the atmosphere. A stop-cock is generally placed between the gauge and the boiler, so that it may be put in communication with the boiler at pleasure. When the stop-cock is open, the steam, acting on the mercury in one leg of the gauge, presses it down, and the mercury in the other leg rises. The difference between the two columns is the height of mercury which corresponds to the excess of the pressure of the steam in the boiler above the pressure of the atmosphere. For high pressure engines, however, the steam-gauge usually works in the manner of an aneroid barometer, a pointer moving on a circular scale under the influence of the motion of a corrugated diaphragm; or, as in the Bourdon gauge, the tendency of a bent tube to straighten itself under the influence of the steam pressure communicates movement in a similar manner to a pointer or index hand. The water-gauge is a vertical glass tube called a gauge-glass, communicating above and below with the boiler. The gauge-glass is not fixed directly to the boiler, but to a brass column known as the gauge-column, communicating with the boiler by two copper tubes of considerable length, the upper leading to the steam space and the lower to the water space. These tubes are fitted with cocks or valves. Two gauge-glasses of different lengths are sometimes fitted to the one column. Gauge-cocks are used as checks on the water-gauges. There are usually three of them on the front of the boiler, one at the normal level of the water, one above, and one below. As applied to railroad gauge signifies the clear distance between the rails. The usual distance in the ordinary or narrow gauge is 4 feet 8½ inches. The broad gauge of the Great Western Railway of England was formerly 7 feet; the Irish, Indian, and Spanish gauge is 5 feet 6 inches. Special narrow gauges have been adopted for certain lines, especially for mountain and mineral lines, such as the 3 feet 6 inch Norwegian gauge. Gauge is also the name applied to various contrivances for measuring any special dimension, such as the wire-gauge, an oblong plate of steel, with notches of different widths cut on the edge, and numbered, the size of the wire being determined by trying it in the different notches till one is found which it exactly fits. The thickness of sheet-metal is tried by a similar gauge.

Gau'gengigl, Ignaz Marcel, American painter: b. Passau, Bavaria, 1856. He was a pupil of Diez and Raab at Munich, and set up a studio in Boston, Mass., in 1879. He paints preferably interiors, introducing numerous small figures. Among his picture titles are: 'My Studio,' 'The Duel,' and 'The First Hearing.'

Gaul, gâl, **Alfred Robert**, English composer and organist: b. Norwich, England, 1837. He was chorister and assistant organist of Norwich Cathedral 1846–59 and subsequently organist of St. Augustine's Church, Edgbaston, Birmingham. He has composed an oratorio, 'Hezekiah'; the cantatas 'Ruth' (1881), 'First Psalm,' 'Ninety-sixth Psalm,' 'Holy City' (1882), a widely popular work; 'Passion Music'; 'The Ten Virgins' (1890), dedicated to the choirs of America; 'Song of Life'; 'Una'; etc.

Gaul, Gilbert William, American artist: b. Jersey City, N. J., 31 March 1855. He was a pupil of J. G. Brown, and studied at the National Academy of Design, exhibiting first there in 1872. He was elected associate in 1880 and National Academician 1882. He is a scene painter often choosing battle subjects, and has won several medals, including two at the World's Columbian Exposition 1893. Among his works are: 'Indian Girl'; 'Coquette' (1880); 'Old Beau' (1881); 'Charging the Battery'; 'News from Home' (1882); 'On the Outpost' (1883); 'On the Lookout'; 'Guerrillas' (1885).

Gaul, Gallia, the country of the Gauls which extended in the times of the Romans, from the Pyrenees to the Rhine, and on the side of Italy, beyond the Alps to the Adriatic. It was divided into Gaul on this side (the Italian side) of the Alps (Gallia Cisalpina), and Gaul beyond the Alps (Gallia Transalpina).

Gallia Cisalpina extended from the Alps to the Adriatic Sea, and consequently comprised all Upper Italy as far as the Rubicon and Macra, on account of its adoption of the Roman toga was called *Gallia Togata*. It was divided into Liguria; Gallia Transpadana; Gallia Cispadana. Liguria was inhabited by the Ligurians, Gallia Transpadana principally by the Taurinians, Insubrians, and Cenomani; Gallia Cispadana by the Boii, Senones, and Lingones, all of them nations of Gallic descent.

Transalpine Gaul was also called *Gallia Comata* in distinction from *Gallia Togata*, because the inhabitants wore their hair (*coma*) long, or *Gallia Braccata*, because, particularly in the southern parts, they wore a peculiar kind of breeches (*braccoc*). Caesar, who conquered Transalpine Gaul at a later period, found it divided into three parts: Aquitania, extending from the Pyrenees to the Garonne, chiefly occupied by Iberian tribes; Gallia Celtica, from the Garonne to the Seine and Marne; Gallia Belgica, in the north, extending to the Rhine.

The Gauls were the chief branch of the great original stock of Celts. On the whole, a great resemblance appears to have existed among all the Celts; and although they were divided into numerous tribes, there were but few branches that were perceptibly different from each other. It is probable that coming from the east, they took their way along the south side of the Danube, having the numerous nation of the Thracians in their rear and the Germans on their side; but the period of this event is so remote that we cannot even venture a conjecture in regard to it.

A too great population (which is not uncommon in half savage and partly nomadic nations whose means of supplying their wants are very imperfect, and who require a great extent of country), and the pressure of German and Thracian tribes, caused general migrations among the Gauls about 397 B.C. Colonies from many tribes took their course over the Alps into Italy, and eastwards along the Danube. This passage of the Celtic Gauls over the Alps first brings that nation into the region of history.

Our accounts of the course of the eastern Gauls along the banks of the Danube are very imperfect; this, however, is evident, that their movements occasioned the migrations of the whole nations. One hundred years after the burning of Rome, the eastern Gauls, from 280–278 B.C., made three destructive irruptions into Macedonia and Greece, which had already been depopulated by former wars. Ptolemy Ceraunus, king of Macedonia, and Sosthenes, the commander of the army, fell in battle, and Greece trembled. But in an attack on the temple of Apollo at Delphi (which contained immense treasures, but was protected by its situation) the terrors of religion and the assaults of the elements (tempest and hail-storms) came over them; they were defeated, and hunger, cold, and the sword of the Greeks completed their destruction. Several tribes pursued their course into Asia Minor, where, under the name of Galatians, they long retained their national peculiarities, and preserved their language even to the latest period of the empire. The reaction of these migrations upon Gaul itself appears to have been considerable. The Gauls along the banks of the Danube and in the south of Germany disappear from that time. Tribes of German origin occupy the whole country as far as the Rhine, and even beyond that river. The Belgæ, who were partly German, occupied the northern part of Gaul, from the Seine and Marne to the British Channel and the Rhine, from whence colonists passed over into Britain, and settled on the coast districts. The Celtæ in Gaul, attained a higher degree of cultivation, to which probably their intercourse with the Greeks in Massilia (Marseilles), whose letters they used in writing their own language, and with the Carthaginians, in whose armies they frequently served as mercenaries, contributed in a great measure. But they were then hardly able to resist the Germans who lived on the other bank of the Rhine. Their kinsmen, the Britons, who painted their bodies, fought from chariots, and practised polygamy, were more fierce than the Gauls.

Meanwhile the Gauls of Cisalpine Gaul had taken up their residence in the fertile plains of Upper Italy. Rome trembled at the irruption of these barbarians into Italy; but Caius Marius saved the republic. In two bloody battles, at Aix (Aquæ Sextiæ) in 102, and at Vercelli in 101 B.C., he destroyed these nations. Only that portion of them which had remained in Gaul to await the issue of the expedition escaped the general ruin. Forty-three years after this event Caius Julius Cæsar received the proconsulship over the countries bordering on Gaul.

He resolved to subject all Gaul, and executed his purpose in less than nine years (58-50 B.C.), in eight bloody campaigns.

The religion of the Druids, being suppressed in Gaul by Tiberius and Claudius, gradually retreated into Britain, where, particularly on the small islands near the British coasts, the priests established their mysterious rites, of which in ancient times strange and dreadful accounts were current. The Britons also were soon conquered by the Romans. After the extinction of the family of the Cæsars, the Gauls once more made an attempt to recover their liberty by the aid of the Germans, but in vain. After this last effort they gradually became Roman citizens, and so entirely Romanized that even their ancient language, the Celtic, was supplanted by a corrupt Latin dialect, retaining, however, a considerable number of Celtic words, especially as roots, which, intermingled with Franco-Germanic words, formed the modern language. About the year 486 the Franks subdued the greater part of Gaul, and put a period to the dominion of the Romans in that country.

Gauley Bridge, W. Va., an important strategical point at the head of Kanawha Valley, and one of the three passes of the Alleghanies. It was the objective point of Gen. Cox in his campaign from the Ohio in July 1861, and was occupied by him and strongly fortified after he had driven Gen. Wise from the valley and eastward to Lewisburg. After the battle of Carnifax Ferry (q.v.) Rosecrans advanced to Sewell Mountain, confronted Gen. Lee, who had assumed command of the Confederate forces, for several days, and then fell back to Gauley Bridge disposing the greater part of his army from 5 to 12 miles in front of it, along the Lewisburg road. With Lee's assent Gen. Floyd, with about 5,000 men, crossed New River and moved down its south side to Cotton Hill, a bold height in the angle formed by the junction of the New and Gauley rivers. He got artillery in position commanding Gauley Bridge, the ferry across the Gauley, and the road leading to Rosecrans' camps. On the morning of 1 November the artillery opened fire, sunk the ferryboat and, with sharpshooters beyond New River, stopped the passage of Rosecrans' supply-trains. The contest on both sides, with artillery and musketry, across the narrow river was severe, and ended only by darkness. The next day it was resumed and continued for ten days, the trains moving only by night. Meanwhile Rosecrans was preparing to capture Floyd by moving a force on his left and rear, a movement in which Cox, who was in command at Gauley Bridge, was to co-operate. On the 10th Cox crossed his brigade in boats over New River, at and near its mouth, and drove Floyd from Cotton Hill, after a sharp fight of two days. The co-operative movement on Floyd's left and rear failed. Floyd became aware of it, and on the 12th retreated as rapidly as possible, abandoning wagons and supplies, and pursued as far as Fayetteville. He continued his retreat to Dublin, on the Virginia and Tennessee Railroad.

E. A. CARMAN.

Gauley Mountains, W. Va., a range in Kanawha and Fayette counties, extending eastward for about thirty miles, from the Kanawha River near Charleston, and divided near the middle into two ridges between which flows the Gauley River.

Gauley River, W. Va., an affluent of the Great Kanawha River. It rises in the Black Mountains in Pocahontas County, and after a course of 75 miles, first westward between the Gauley Mountains (q.v.), then southward, joins New River which, from the point of junction at Gauley Bridge, is called the Great Kanawha.

Gault, gâlt (originally a local name in Cambridgeshire, England, for clay), one of the subdivisions of the Cretaceous system (q.v.). The gault is a stiff, bluish-gray clay, which here and there contains indurated nodules and septaria. Now and again it becomes somewhat calcareous, or sandy and micaceous. In some parts of Sussex a band of phosphatic nodules occurs at its base. The deposit is of variable thickness — reaching in some places over 300 feet, while occasionally it hardly attains a greater thickness than 50 feet, and forms a well-marked geological horizon — forming the bottom member of the Upper Cretaceous rocks. It is abundantly fossiliferous, the remains being almost exclusively marine, only a few drifted land-plants having been met with. The gault is extensively employed in the manufacture of bricks and tiles; it forms a retentive and rather unproductive soil.

Gaulthe'ria, (named for Dr. Gaultier of Quebec), a large genus of evergreen shrubs, or under-shrubs, with small, axillary, nodding flowers, white, pink or red, having a corolla and calyx with five divisions, the former urn-shaped or companulate; and a berry-like fruit, red or blackish, consisting of a fleshy calyx enclosing a capsule. There are about 100 species, found mostly in the Andes, a few being Asiatic and North American. Of the latter, the best known is *G. procumbens*, the familiar aromatic or creeping wintergreen, known in different localities as checkerberry (a name sometimes applied to *Mitchella repens*), boxberry, spice-berry, ground-berry, mountain tea, and partridge-berry (q.v.). This plant is found in cool, damp woods, chiefly under the shade of evergreens, in Canada and the United States, extending southward along the Alleghanies. The leaves are mostly clustered at the top of branches rising from creeping stems; the flowers are white, the berries red and spicy, with a flavor (also characterizing the leaves) resembling sweet birch. The leaves of *G. procumbens* and *G. hispidula* contain an aromatic oil which has a greater density than any other essential oil. It contains about 10 per cent of a terpene called gaultherilene and about 90 per cent of methyl salicylate. Oil of wintergreen is colorless when fresh, but later becomes yellowish, and is used for flavoring candy and for disguising the taste of unpleasant medicines. This oil may be extracted from a few other plants, particularly sweet birch (*Betula lenta*). See WINTERGREEN.

Gaur, gowr, a very large, fierce, and untamable ox (*Bos gaurus*) found in the forests of India and Burma, called «bison» by Anglo-Indian sportsmen, and distinguished by the Malays into two varieties called «sladang» and «sapio.» Old bulls are sometimes six feet high at the shoulders, making them the largest of wild oxen. The horns spread laterally and curve

GAUR, GENET, ETC.

1. Gopher (Geomys bursarius).
2. Genet (Viverra genetta).
3. Gayal (Bos frontalis).
4. Galago (Otolicnus galago).
5. Gaur (Bos gaurus).
6. White-tailed Gnu (Connochætes gnu).

upward to the length ordinarily of 20 to 30 inches, and are large and flattened, while the ridge of the forehead between them leans forward decidedly and is covered with a mop of gray hair. The general color is smooth, shining, blackish brown, with the feet white. This magnificent animal, which is semi-domesticated to some extent in northern India and never in the south, wanders about the jungles in small shy herds under the leadership of a powerful bull, as is the habit of forest oxen generally. It is one of the foremost objects of rifle sport in India, and the best accounts of its habits are to be found in the books of sportsmen-writers, such as Baker, Kinloch, Shakspear, Hornaday, etc. The animal must be followed on foot, in which the aid of good trackers is essential; and when it has been overtaken it is usually hidden in some dense cover, whence it is likely to charge without warning. Its flesh is excellent. See GAYAL.

Gauss, Karl Friedrich, kärl frēd'rĭн gows, German mathematician: b. Brunswick 30 April, 1777; d. Göttingen 23 Feb. 1855. At 18, while a student at Göttingen, he solved a problem (that of the division of the circle into 17 equal parts) which had occupied geometers from the time of Euclid. In 1801 was published his 'Disquisitiones Arithmeticæ,' treating of indeterminate analysis or transcendental arithmetic, and containing, in addition to many new and curious theorems, a demonstration of the famous theorem of Fermat, concerning triangular numbers. He calculated, by a new method, the orbit of the newly discovered planet Ceres, and afterward that of Pallas, for which he received from the French Institute in 1810 the medal founded by Lalande. In 1807 he became professor of mathematics and director of the observatory at Göttingen, a position which he held till his death. In 1821, being charged by the government of Hanover with the triangulation of that country and the measurement of an arc of the meridian, he rendered the most distant stations visible by means of the heliotrope, an instrument of his invention for reflecting solar light; and in connection with Weber made valuable investigations concerning terrestrial magnetism. He was pronounced by Laplace to be the greatest mathematician in Europe. Among the more celebrated of his works are 'Theoria Motus Corporum Cœlestium' (1809); 'Intensitas Vis Magneticæ Terrestris' (1833); 'Dioptrische Untersuchungen' (1841); and 'Untersuchungen über Gegenstände der höheren Geodesie' (1844).

Gautama, gow'ta-ma, **or Gotama,** the patronymic of several celebrities connected with Hindu Vedaism, and of Siddartha Gautama, the founder of Buddhism. See BUDDHA.

Gautier, Emile Théodore Léon, ā-mēl tā-ō-dōr lā-ôn gō-tē-ā, French scholar and critic: b. Havre 8 Aug. 1832. He held official positions connected with the schools and libraries of his native place till his growing eminence as a writer brought him to Paris. His works, which place him among the very foremost authorities on mediæval European literature, include: 'Definition Catholique de l'Histoire' (1860); 'Benoit II.' (1863); 'Etudes litteraires pour la defense de l'Eglise' (1864); 'Epopées françaises' (1866–7); 'Vingt nouveaux portraits' (1878); 'La Chevalerie' (1884); 'Histoire de la poésie religieuse dans les cloitres des IXe et XIe siècles' (1888); 'Etudes et tableaux historiques' (1890).

Gautier, Judith, zhü-dēth, French novelist, daughter of Théophile Gautier (q.v.) and Carlotta Grisi, the famous Italian singer: b. Paris, France, 1850. She married Catulle Mendès, but was divorced. Her first work, under the name "JUDITH WALTHER," was 'The Book of Jade' (1867), a collection of prose and verse translated from the Chinese; it was followed by 'The Imperial Dragon' (1869), a Chinese romance, signed "JUDITH MENDÈS"; 'The Usurper,' a Japanese romance, crowned by the French Academy in 1875; 'Lucienne' (1877); 'The Cruelties of Love' (1878); 'Isoline' (1881); 'Poems of the Dragon Fly' (1884), adapted from the Japanese; 'Potiphar's Wife' (1884), a Persian romance; 'The Merchant of Smiles' (1888), a drama adapted from the Chinese; 'The Marriage of Fingal' (1888), a lyric poem.

Gautier, Théophile, tā-ō-fēl, French poet and prose writer: b. Tarbes, France, 31 Aug. 1811; d. Paris, 23 Oct. 1872. He was educated at the grammar school of his native town, and afterward at the College Charlemagne in Paris. He applied himself at first, but without much success, to painting; and then turned to literature. In verse he published: 'Albertus' (1830); 'Comedy of Death' (1832); 'Enamels and Cameos' (1856); his best poetry; etc. His novels and short stories include: 'Young France' (1833); 'Mademoiselle de Maupin' (1835); 'Fortunio' (1838); 'A Tear of the Devil' (1839); 'Militona' (1847); 'The Tiger's Skin' (1852); 'Jettatura' (1857); 'Captain Fracasse' (1863); 'Handsome Jenny' (1865); 'Spirite' (1866); etc. He was drawn early to feuilleton writing, and for more than 30 years contributed to the Paris newspapers criticisms on the theatre and the salon. He also wrote: 'Journey in Spain' (1843); 'Zigzags' (1845); 'Constantinople' (1854); 'Journey in Russia' (1866); etc., which rank among the most delightful books of modern travel. Still other works were an enlarged edition of 'Enamels and Cameos' (1872); 'The Grotesques' (1844); 'History of Dramatic Art in France' (1859); 'Balzac' (1858); 'Private Menagerie' (1869), biographical; 'History of Romanticism' (1872); 'Literary Portraits and Souvenirs' (1875); 'The East' (1877), the last two being posthumous. Gautier's whole philosophy is a philosophy of paradox, his ideal of life hardly more than a picturesque viciousness. His besetting sin was a desire to say something clever and wicked to shock the Philistines. See lives by Feydeu (1874); Bergerat (1878); Richet (1893); Brunetière, 'Evolution de la poésie lyrique' (1894).

Gauze, a light, transparent silk stuff, or sometimes a fabric of silk and cotton or silk and hemp, or of other material. In weaving gauze, at every third cast of the shuttle the warp-threads are turned or twisted after receiving the woof from right to left, and the reverse, alternately, between each throw of the shuttle, so that the weft-threads are separated from each other, the slight texture being thus produced. Gauzes are either plain or figured. The latter are worked with flowers of silver or gold, on a silk ground, and are chiefly made in China. For antiseptic purposes, etc., cotton gauze is specially made for the use of surgeons. Special fabrics to which the name is given are also manufactured to be made into light underwear. The term has further been extended to any slight open material, as bolting-cloth and wire-cloth for various purposes. A wide-meshed, unsized cheese-cloth, which is called gauze, is considered by surgeons to be the cheapest and most convenient material for dressing wounds, being comfortable and absorbing fluid without disagreeable matting.

Gavarnie, Cascade de, France, a waterfall in the Cirque de Gavarnie, Pyrenees. It is the second highest in Europe, being 1,385 feet in height.

Gavarnie, Cirque de, France, a natural amphitheatre in the Pyrenees. It is 2¼ miles in width and 5,380 feet in height.

Gavazzi, gä-vät'sē, **Alessandro,** Italian reformer: b. Bologna, Italy, 21 March 1809; d. Rome, 9 Jan. 1889. At 16 he became a monk of the Barnabite order, and subsequently was appointed professor of rhetoric at Naples, where he speedily acquired a reputation as an orator. On the ascension of Pius IX. to the papal chair, he devoted himself to the diffusion of political enlightenment and patriotic aspirations among the masses of the Roman population. Later he forsook the papal ranks and to Gavazzi's fervid and patriotic oratory may be attributed, in no slight degree, the universal spirit of self-sacrifice evoked throughout Italy during this period of her history. He was called Peter the Hermit of the national crusade. On the establishment of the republic at Rome he was appointed almoner-in-chief to the national army. Rome having fallen, Gavazzi went to England, where he delivered numerous addresses and lectures illustrative of the political and religious aims of his country. He twice visited the United States. He was the founder of the Free Christian Church of Italy in 1870, and author of 'Recollections of the Last Four Popes' (1859); 'No Union with Rome' (1871), etc.

Gaveston, găv'ĕs-tŏn (Fr. gä-vĕs-tôn), **Piers,** favorite of Edward II., king of England: d. 19 June 1312. He was a Gascon by birth, and on account of his father's services to Edward I. was chosen companion to the Prince of Wales, over whom he acquired a complete and very mischievous ascendency, wasting his resources, and breeding dissension between him and his father. Edward I. banished him in 1307, but died the same year, and Edward II. at once recalled him, made him Earl of Cornwall, and gave him in marriage his niece, Margaret de Clare. Intoxicated with his elevation and honors Gaveston became intolerably insolent and exasperated the nobles. He was again banished, again recalled, and, the barons having declared war, was captured, and executed near Warwick.

Gavial, gā'vĭ-al, or **Ghavial,** the common crocodile of northern India (*Gavialis gangeticus*), characterized by its greatly prolonged and slender snout, a peculiarity which increases with age and varies according to sex. In the male the nose is very much swollen, and can be inflated like a bag when the nostrils (at the extremity) are closed. The teeth are very numerous,— usually more than 100. The cranial structures accompanying these peculiarities indicate a separate family (*Gavialidæ*), which first appears in the Upper Cretaceous, and has had many fossil genera and species, among them an Asiatic monster (*Rhamphosuchus crassidens*) of the Pliocene which was 50 feet in length. The gavial inhabits chiefly the basins of the Ganges, Indus and Brahmaputra, and reaches a length of 20 to 25 feet. In the Ganges it of a deep sea-green color above, with numerous irregular brown spots, smallest and thickest about the jaws, and below pale yellowish white. It feeds on fish and is harmless, in spite of its huge size. Its habits are little known; and still less is known of a closely related but smaller gavial (*Tomistoma schlegeli*) of Borneo, and Sumatra.

Gavotte, ga-vŏt, or **Gavot,** originally a dance of the Gavots or people of the Gap, department of the Upper Alps in France. It was a peasant dance, not unlike a minuet, and happily uniting liveliness with dignity. It was popular from the 16th to the 18th century, and at one period was in favor at court. After undergoing modifications it fell into disuse. The name is also given to a kind of music at first intended for such a dance. It came into great favor and was a frequent movement in suites, sonatas, etc., having been used by Bach and other great composers. In our time it has again become popular.

Gay, Delphine. See Girardin, Madame de.

Gay, Edward, American painter: b. Dublin, Ireland, 1838. He came to the United States in 1848, studied art in Albany, N. Y., and as a pupil of Schirmer and Lessing at Carlsruhe; established a studio in New York; and was elected an associate of the National Academy of Design in 1868. In 1887 he obtained the Metropolitan prize for his picture 'Broad Acres,' now in the Metropolitan Museum, New York. His works have been prominent in exhibitions of the Water Color Society and the National Academy, and include: 'Washed by the Sea'; 'The Suburbs'; 'Where Sea and Meadow Meet' (Executive Mansion, Albany); 'The Waving Grain,' etc.

Gay, John, English poet: b. Barnstaple, Devonshire, England, baptized 16 Sept. 1685; d. London 4 Dec. 1732. In 1713 he published his 'Rural Sports,' which he dedicated to Pope. This compliment introduced them to each other, and proved the foundation of a friendship which lasted for life. In 1714 his caricature of Ambrose Philips' pastoral poetry was published under the title of 'The Shepherd's Week.' His pleasant mock-heroic poem, entitled 'Trivia, or the Art of Walking the Streets of London,' was published in 1715, and in that year also was acted his burlesque drama of 'What d'ye Call It?' followed by a farce, in conjunction with Pope and Arbuthnot, called 'Three Hours after Marriage.' The production of this play altogether failed. In 1720 he published his poems by subscription, in 1723 his tragedy, 'The Captives,' and in 1726 his well-known 'Fables.' His 'Beggar's Opera' was first acted in 1727 at Lincoln's Inn Fields, where it ran for 63 nights, but the lord-chamberlain refused to license for performance a second part entitled 'Polly.' The latter part of his life was spent in the house of the Duke of Queensberry, where he wrote his sonata 'Acis and Galatea' and the opera 'Achilles.' He was interred in Westminster

Abbey, where his monument bears a flippant epitaph taken from one of his letters to Pope. Among his smaller pieces, his two ballads of 'Black-eyed Susan' and ''Twas when the Seas were Roaring,' are much admired.

Gay, Sidney Howard, American journalist and author: b. Hingham, Mass., 22 May 1814; d. New Brighton, Staten Island, N. Y., 25 June 1888. Unwilling to take the oath to support the Constitution of the United States, which fostered and protected slavery, he gave up a legal career and devoted himself to anti-slavery journalism and lecturing. He became, in 1842, editor of 'The Antislavery Standard,' a position he retained till he joined, in 1857, the editorial staff of the New York *Tribune*, of which he was managing editor 1862–6. From 1867 to 1871 he occupied the same position on the Chicago *Tribune*, and for another two years was managing editor of the *Evening Post*. He was the author of Bryant & Gay's 'Popular History of the United States,' and in 1884 wrote the life of James Madison in the 'American Statesmen' series.

Gay, Walter, American artist: b. Hingham, Mass., 22 Jan. 1856. He is a nephew of S. H. Gay (q.v.), and W. A. Gay (q.v.). At 20 he went to Paris, where he studied art under Bonnat, and he has been a frequent exhibitor at the salon. Among his paintings, which have won many medals, are 'Benedicite,' now in the Museum of Amiens, France, 'Las Cigarreras' ('The Cigarette Sellers') in the Luxembourg, Paris; and canvases in the Metropolitan of Fine Arts, New York, the Museum of Fine Arts, Boston, and several noted collections in Europe.

Gay, Winckworth Allan, American artist: b. Hingham, Mass., 18 Aug. 1821. At an early age he became a pupil of Weir, professor of drawing at West Point, subsequently went to Europe, and passed five years there in study, a part of the time under Troyon in Paris. He paints exclusively in landscape. 'A Scene in the White Mountains,' a picture painted for the Boston Athenæum, is a good specimen of his method of treatment of mountain scenery. Some of his best works depict that region. But he has also painted views of Nantasket beach and rocks, which have attracted much attention, and some critics have pronounced coast scenery to be his proper specialty.

Gay-Lussac, Joseph Louis, zho-zĕf loo-ē gā-lü-säk, French physicist: b. St. Leonard, Haute-Vienne, France, 6 Dec. 1778; d. Paris 9 May 1850. In 1804 he was the first to make balloon ascensions for purposes of scientific investigation: became a member of the society of Arcueil, and was introduced to Humboldt, with whom he prosecuted an investigation of the polarization of light and other subjects. He also devoted much of his time to the study of chemistry, and to him we are indebted for the discovery of the hydro-sulphuric and oxy-chloride acids. In 1830 he became a member of the Chamber of Deputies, and in 1839 was created a peer of France. He enjoyed several official appointments, and was professor of chemistry at the Jardin du Roi.

Gay Head, a promontory and lighthouse on the western extremity of Martha's Vineyard, Mass. Lat. 41° 21′, lon. 70° 50′ W.

Gay-Lussite, gā'lŭ-sīt, a native hydrous carbonate of calcium and sodium, $CaCO_3.Na_2CO_3 + 5H_2O$. It was described by Boussingault from crystals found in a bed of clay in the bottom of a lake near Maracaibo, Venezuela. These are vitreous, white, monoclinic prisms, having a hardness of 2 to 3 and a specific gravity of about 1.94. It also occurs in the waters of a lake near Ragtown, Nevada. It was named after the French chemist, Gay-Lussac. The name "natrocalcite" has been applied to pseudomorphs of calcite, which were supposed to be after gaylussite, but which now seem proven to be after celestite.

Gaya, gī'ä, India, chief town of a district of the same name in Bengal. It is a place of the greatest sanctity, from its associations with the founder of Buddhism, and is annually visited by about 100,000 Hindu pilgrims, who pray for the souls of their ancestors at the 45 sacred shrines within and without the walls. In Gaya proper the Brahmans reside; adjoining is Sahibganj, the trading and official quarter. Six miles south is the village of Buddha-Gaya, the home of Buddha. (See BUDDHISM.) Pop. (1901) 80,383 for the district; city 15,000.

Gayal, gī'al, or **Mithan,** a tame ox (*Bos frontalis*) of northwestern India and the hilly regions of Indo-China, known principally in the herds of the semi-civilized hill-tribes, but which also exists wild in Tenasserim. These cattle are kept for the sake of their beef, gayals never being put to any sort of work, as are humped cattle. This ox is somewhat smaller than the gaur (q.v.), has proportionately shorter legs, rounder and shorter horns, a flatter forehead and greater dewlap. It will interbreed with the gaur and various other bovine species.

Gayarré, gā-ä-rā', **Charles Etienne Arthur,** American lawyer and historian: b. New Orleans, La., 9 Jan. 1805; d. 11 Feb. 1895. He was admitted to the bar in 1829; was several times a member of the Louisiana legislature; deputy State attorney-general (1831); secretary of state of Louisiana (1846–53). Among his works, which deal largely with the history of his native State, are: 'History of Louisiana,' in French (1830); 'Louisiana, its History as a French Colony' (1851); 'Philip II. of Spain' (1866); 'Fernando de Lemos,' a novel (1872).

Gay'ler, Charles, American playwright: b. New York 1 April 1820; d. Brooklyn 28 May 1892. He removed to the West, was a law pupil of Abraham Lincoln, was admitted to practice, in 1848 edited the Cincinnati *Evening Dispatch*, and in 1850 became connected with the New York press, to which he contributed for many years. He wrote for English and American production a large number of plays, according to some statements nearly 400. These include: 'The Heir of Glen Avon,' his earliest attempt, produced in 1839; 'Taking the Chances'; 'Olympiana'; 'The American Cousin at Home' (for E. A. Sothern); 'Night and Morning'; 'With the Tide'; 'Brom Bones'; 'The Connie Soogah'; 'Bull Run'; 'Inflation'; 'Lord Tatters, Irish'; and 'Fritz, our Cousin German,' his most successful work, written for J. K. Emmet and first produced at Buffalo, N. Y., in 1869

Gayley, Charles Mills, American educator: b. Shanghai, China, 22 Feb. 1858. He was graduated at the University of Michigan in 1878, and became professor of the English language and literature in the University of California in 1889. His publications include: 'Songs of Yellow and Blue'; 'Guide to Literature of Æsthetics'; 'English in Secondary Schools'; 'Classic Myths in English Literature'; etc.

Gaynor, William Jay, American jurist: b. Whitestown, Oneida County, N. Y., 1851. He was for a time a journalist, studied law and in 1875 was admitted to the bar, wrote on legal subjects, and was identified with many cases of importance. In 1893 he was elected a judge of the State supreme court. He became best known through securing the conviction of John Y. McKane of Gravesend for election frauds.

Gayoso, José Brunetti, hō-sā' broo-nĕt'tē gī-yō'sō, Duke of Arcos, Spanish diplomat: b. Madrid, 6 Feb. 1839. He was educated at the University of Madrid, was admitted to the bar, entered the diplomatic service in 1864, and was secretary of legation at various capitals. He became minister plenipotentiary to Bolivia in 1881, to Uruguay in 1889, Chile in 1893, and Mexico in 1898. In 1899 he was appointed Spanish envoy extraordinary and minister plenipotentiary to the United States.

Gaza, gä'zä, **Theodorus,** Greek scholar: b. Thessalonica, Macedonia, about 1400; d. Italy 1478. He fled about 1444 before the Turks to Italy, where he became teacher of Greek at Ferrara, next of philosophy at Rome. Gaza has been warmly praised by subsequent scholars, such as Politian, Erasmus, Scaliger, and Melanchthon. His principal work was a Greek grammar in four books, first published by Aldus Manutius at Venice in 1495. He translated into Latin portions of Aristotle, Theophrastus, St. Chrysostom, Hippocrates, and other Greek writers.

Gaza, gā'za, Syria, an ancient town, capital of the district of the same name, about 3 miles from the mouth of the river Gaza, 50 miles from Jerusalem, on the high road between Egypt and Damascus. The bazaar and markets are of considerable importance. Gaza is a depot for barley, and has many potteries. The district of Gaza occupies the southwest corner of Syria, having the Mediterranean on the west, the valley of the Jordan and of the Dead Sea on the east, and Arabia Petræa on the south. Pop. (1900) 34,500.

Gazelle, a small antelope of the genus *Gazella*, or some related genus, exemplified by the "ariel" or "dorcas" of the Saharan and Syrian deserts, famous in poetic literature. The group contains some 25 species scattered throughout all Africa and southern Asia; and as a whole is characterized by small or moderate size, a sheep-like dentition, sandy coloration with white belly, and the usual presence of dark and light stripes on the face and flanks. The horns are of fair length, ringed, lyrate and usually present in both sexes. The gazelle (*G. dorcas*), stands about 24 inches tall at the shoulders, and has horns about 13 inches long. It is of delicate build, and extreme swiftness, leaping high as it runs, so that at full speed it seems to skim the ground like a flying bird. Its color is a light fawn upon the back, deepening into dark-brown in a wide band which edges the flanks and separates the yellow-brown of the upper portions of the body from the pure white of the abdomen. The face is marked with two stripes of contrasting colors, and the hindquarters are white. The eye of any gazelle is large, soft, and lustrous, and has been long employed by eastern poets as the most flattering comparison to that of a woman. Gazelles feed generally at dawn and at evening, and approach water only once in 24 hours. They are hunted in various ways, and their flesh is excellent. This species is becoming rare, but may still be found throughout the Sahara, and in the stony deserts of Syria. Many local names have been applied to it in books of travel and reference, most of which belong elsewhere. Such are the "korin" or "corinne" of Senegal (*G. rufifrons*); the West African "mohr" (*G. mohr*), the largest (32 inches high) and tallest of the race; the "aoul" (*G. sœmmerringi*) of Abyssinia and Somaliland, the "dama" (*G. dama*) of the Sudan, and others formerly confused with *G. dorcas*. Still other species range the plains of Central and South Africa, where some, as the springbok (q.v.), formerly assembled in vast herds, as described under Antelope. Another group is formed by three similar Asiatic gazelles, — one common in Persia (*G. gutturosa*), and the others eastward, where the "goa" dwells on the high Tibetan plateau. Lastly in the Indian gazelle (*G. bennetti*), the "ravine-deer" of Indian sportsmen, we have a species with almost straight horns, which is about 26 inches tall, light chestnut in color with a blackish tail, and dwells in small bands in the dry plains along both sides of the Indus.

Gazette. *Gazzetta* was the name of a small coin once in use at Venice, and also of a kind of primitive newspaper, published there and sold for that sum. *Gazzetta*, Spanish *Gazeta*, French *Gazette*, are still used for a newspaper, but the term in England is confined to that paper of news published by authority of the government. The first 'Gazette' in England was published at Oxford 7 Nov. 1665. From that period the 'Gazette' has appeared regularly twice a week, and besides the notifications published by court and government, contains those required by law in private transactions. See Newspapers.

Gazetteer, a geographical dictionary. The first work of this kind with which we are acquainted is that of Stephen of Byzantium, who lived in the beginning of the 6th century. We have only an abridgment of it. The first modern work of the kind is the 'Dictionarium Historico-Geographicum' (Geneva 1565), by Charles Stephens, with additions by N. Lloyd (Oxford 1670, and London 1686). The works of Ferrari ('Lexicon Geographicum,' 1627) and Baudrand ('Geographia Ordine Literarum Disposita,' 1682) are full of the strangest errors. Those of Maty (1701), Thomas Corneille (1708), and Savonarola (1713) were based on the former, with additions and corrections. The 'Dictionnaire Géographique, Historique et Critique,' of La Martinière (1726), superseded all that had gone before it, though it retained many errors. The 'Geographisch-Statistisches Handwörterbuch' of the eminent German geographer Hassel (1817) was the result of laborious and judicious investigations. The 'Universal Gazetteer,' by Cruttwell (London 1808) and the 'Edinburgh Gazetteer'

(1817–22), once the principal works of the kind in English, were in course of years superseded by several others, among them Macculloch's 'Geographical Dictionary,' Blackie's 'Imperial Gazetteer' (Glasgow 1850), Lippincott's 'Pronouncing Gazetteer of the World' (Philadelphia 1855, with new editions and revisions), and Longmans' 'Gazetteer of the World.' The most valuable among European gazetteers further include the French 'Dictionnaire Géographique Universel,' Saint-Martin's 'Nouveau Dictionnaire de Géographie Universelle,' and Ritter's 'Geographisch-Statistisches Lexikon.' There are also gazetteers confined to individual States of the Union, and others to particular countries of the world.

Gears. See WHEEL GEARING.

Geary, John White, American military officer and politician: b. Mount Pleasant, Westmoreland County, Pa., 30 Dec. 1819; d. Harrisburg, Pa., 8 Feb. 1873. He was a lieutenant-colonel in the Mexican war; went to California and was appointed postmaster at San Francisco in 1849, being the first to hold that position in the city. In 1850 he was elected the first mayor of San Francisco, and in 1856 was made territorial governor of Kansas. When the Civil War broke out he enlisted in the Union army and became brigadier-general of volunteers 25 April 1862. He was in the battle of Cedar Mountain 9 Aug. 1862, and commanded a division at Chancellorsville, Gettysburg and Lookout Mountain. He also participated in Sherman's march to the sea. He was governor of Pennsylvania from 1867 till shortly before his death.

Gebhardt, Eduard von, ed'oo-ärd fōn gāb'-härt, German painter: b. St. Johannes, Esthonia, 13 June 1838. He studied at the St. Petersburg Academy in 1854–7, and later with Wilhelm Sohn at Düsseldorf, where he established his studio and attracted much attention by his religious works, in which he treated biblical scenes after the manner of the Dutch and Germans of the 15th and 16th centuries, imitating their introduction of costumes and other features contemporary to them. He also painted many scenes from the period of the Reformation. In 1873 he was appointed professor in the Düsseldorf Academy. His subjects include: 'Christ's Entry into Jerusalem'; 'The Rich Man and the Beggar Lazarus'; 'The Last Supper,' his chief work (National Gallery, Berlin); 'The Ascension,' one of his best canvases; 'Religious Conversation'; and 'The Reformer at Work.'

Geckos, gek'ōz, the small lizards of the family *Geckonidæ*, distinguished from other lizards by structural peculiarities which indicate that the group is a very ancient and distinct one. Externally their robust forms, short heads and thick, but fragile tails; the skin, in most soft and pebbled with minute bony concretions (osteoderms); the lack of eyelids, the ball of the eye being studded by a transparent watch-glass-like scale; and adhesive feet are so highly characteristic that a gecko is usually recognizable at a glance. The group consists of about 50 genera, comprising some 270 species, and they are scattered all over the warmer part of the globe, occurring even in New Zealand and many oceanic islands. Most of the species are small, the largest not much exceeding a foot. They dwell mainly in the woods, and among rocks, hiding by day, or basking quietly in the sun, and becoming active at night. They are carnivorous, the smaller eating insects, and the larger bigger insects and whatever else they can catch. They are well fitted for scrambling about tree-trunks and cliffs, as is seen in the agility of the common "tarentola," "osga" and other geckos of southern Europe, and the almost domestic "cheecha" (*Hemidactylus*) of Ceylon and India, which are numerous both outside and inside of farm and village houses, snapping up flies. They will climb a smooth wall or even a window pane without difficulty, and even run back downward along the smooth whitewashed ceiling. This is possible for them by the fact that the soles of the cushions of the toes are furnished with transverse lamellæ beset with tiny hair-like excrescences, between each two of which a vacuum is formed by the pressure of the foot on every step. Upon the differences in the arrangement of the pads and lamellæ are based generic distinctions. In addition to this facility of movement, one species (*Ptychozoön homalocephalum*), the flying or fringed gecko of the Malayan region, has a lateral parachute-like membrane assisting it to make long leaps from tree to tree.

Geckos are entirely harmless and could not inflict a painful bite if they tried; yet the peasants of Spain and Italy fear as poisonous even those which they see daily in their houses, and the Egyptians accuse them of leprosy. When encouraged they become tame and friendly and show considerable intelligence. Their voices produce a feeble clicking sound, often repeated, from which comes the term "Gecko" and such local names as "toco-toco" and the like. They reproduce by hiding among rotten wood two or three globular hard-shelled eggs, from which the young hatch, and are ready at once to begin to care for themselves. Consult Gadow, 'Amphibia and Reptiles' (1901); Gosse, 'A Naturalist's Sojourn in Jamaica' (London 1851).

Ged, William, Scottish goldsmith, inventor of stereotyping, b. Edinburgh 1690; d. there 19 Oct. 1749. In 1725 he took out a patent for his method of stereotyping, which was for long the only one in use. He met with such opposition in Edinburgh that he went to London, but there also failed to get his invention adopted. In 1731 he obtained a contract to print Bibles and prayer-books for the University of Cambridge, but only two prayer-books had been executed when the lease was surrendered. He stereotyped an edition of Sallust in 1744. Consult 'Memoir,' by Nichols (1781).

Geddes, gĕd'ĕs, **James,** American scholar: b. Boston, Mass., 29 July 1858. He was graduated from Harvard in 1880, was instructor in Romance languages at Boston University in 1887–90, assistant professor in 1890–92, and in 1892 was appointed professor. His writings include various monographs and articles for periodicals, and student's editions of Spanish and Italian classics.

Geddes, James Lorraine, American soldier: b. Edinburgh, Scotland, 1827; d. 1887. After residence in Canada, he studied in the British military academy of Calcutta, India, distinguished himself in the Punjab, and settled at Vinton, Iowa, in 1857. In the Civil War he served from 1861 to 1865, and attained the brevet rank of brigadier-general of volunteers. He wrote: 'The Stars and Stripes,' 'The Soldier's Battle Prayer,' and other war verse.

Geefs, Gillaume, gē-yōm gāfs, Belgian sculptor: b. Antwerp 10 Sept. 1806; d. Brussels 24 Jan. 1883. He became professor at the Academy of Antwerp in 1834. Among his most important works are the monument to the victims of the Revolution of 1830 at Brussels; a statue of Rubens in front of Antwerp Cathedral; statues of King Leopold, etc.

Geefs, Joseph, Belgian sculptor: b. Anwerp 25 Dec. 1808; d. there 10 Oct. 1885. He was a brother of Gillaume Geefs (q.v.). In 1841 he was appointed professor of sculpture in the Antwerp Academy, and in 1846 became a member of the Belgian Academy. Among his principal works are: A statue of Vesalius, at Brussels; one of Martens, the first Belgian printer, at Aelst; an equestrian statue of Leopold I., at Antwerp; and 'The Fallen Angel,' in the Brussels Palace of Fine Arts.

Geelong, gē-lŏng', Australia, a city of Victoria, on Corio Bay, 45 miles south of Melbourne. The gold discoveries in 1851 added to its prosperity. Limestone and a kind of marble are found in the neighborhood. The industries are the manufacture of woolen cloths and paper, meat preserving, tanning, rope making, fishing, etc. The city is lighted with gas, and has two parks, botanical garden, government buildings, a town hall, hospital, chamber of commerce, mechanics' institute, etc. Corio Bay is a favorite bathing resort. Pop., including suburbs (1901), 23,440.

Geelvink (gāl'vĭnk) **Bay**, an arm of the Pacific in New Guinea. Its entrance, about 155 miles wide, is protected by several islands.

Geertz, gārts, **Julius**, German painter: b. Hamburg 21 April 1837. He was a pupil of Günther and Martin Gensler at Hamburg, of Descoudres at Carlsruhe, and of Jordan at Düsseldorf, located his studio at Düsseldorf, and established his reputation by his skilful genre scenes, of which the 'Criminal after Condemnation' was the first to win prominent notice. His works, characterized in general by excellence of design and color, fidelity of interpretation, and a capital sense of humor, include: 'The Fly-catcher'; 'Die Wacht am Rhein'; 'A Prisoner of War'; 'The Village Hero'; 'Alms.' During a visit to the United States he painted portraits of Oswald Ottendorfer, Carl Schurz, and other German-Americans.

Geese, a large group of water-birds allied to the ducks and swans, and forming with them the family *Anatidæ*. It is not possible to separate geese and ducks into two well-defined groups. Generally speaking, however, geese are distinguished by their larger size; short, heavy bill, with reduced lamellæ; longer legs, placed nearer the centre of the body; and the absence of enlargements of the bronchial tubes. Some thirty species of true geese exist, and about a dozen others are usually known by that name. Males are called "ganders," and young birds "goslings." The most typical geese are those of the genus *Anser*, represented in Europe by the gray lag (*A. cinereus*), bean-goose (*A. segetum*) and white-fronted goose (*A. albifrons*). A variety of the last occurs also in North America. The gray-lag goose is the original of the domestic races of geese. In its wild state it ranges over nearly the whole of Europe and northern Asia, and was formerly an abundant breeder on the British Isles.

The best known wild geese in America are the Canada goose (*Branta canadensis*), the brant (*B. bernicla*) and the snow-goose (*Chen hyperboreus*). The former presents several varieties differing mainly in size, the Hutchin's and cackling goose of the West being not larger than big ducks. One form or another occurs all across the continent, breeding mainly north of the United States, migrating southward in the autumn, and wintering on the coasts and inland waters, where they are regularly hunted by sportsmen. In early spring the northward flight of these geese in their customary V-shaped rank is heralded as an indication that winter is over. The brent goose or brant is a smaller darker bird, breeding far northward and occurring along our coasts often in immense numbers during the winter, and also on the coasts of Europe, being everywhere a salt-water bird. The black brant of our western coast, and the bernacle goose (q.v.) of the north of Europe, are allied species. Several species of snow-geese or laughing geese, are found in America, most plentifully in the interior. Most of them are pure white in the adult state, more or less gray during the first year; but the blue goose (*Chen cærulescens*) is always bluish gray, with the head white in the adult.

In Patagonia and the adjacent islands are several peculiar geese in which the sexes differ totally in coloration, the males being white and the females brown; some of them are strictly upland birds. The largest known goose is the Chinese swan-goose (*Cygnopsis cygnoides*), which is supposed to be the parent stock of the domestic geese of some eastern countries. The peculiar Cape Barren goose of Australia (*Cereopsis novæ-hollandiæ*), an upland goose which has lost the power of flight, has the webbing of the toes greatly reduced and the bill very short and rounded. Another curious species is the spur-winged goose of Africa (*Plectropterus rueppelli*) which possesses hornlike weapons on the bend of the wing. This is a beautiful bird bred in captivity by fanciers for ornamental service.

Domestic Geese.— The breeding of geese is followed on a large scale in some countries and was formerly extensively carried on in parts of England, where the flocks were regularly tended by a gooseherd and driven daily to pasture and water. Geese are valuable not only for their flesh and eggs, but for the plumage, and where kept for the latter purpose are plucked four or five times a year. The feathers are used chiefly for stuffing pillows, etc.; but as a result of public sentiment against the use of the plumage of wild birds in millinery, the manufacture of artificial plumes and feather-ornaments for hats is becoming an important industry, and goose-feathers form the basis of most of these fabrications. Geese are often specially fattened for the table. The liver of a fat goose is often larger than all the other viscera. The celebrated *pâtés de foie gras* of Strasburg are made of goose-livers, which are brought to a state of abnormal enlargement by keeping the birds in an apartment with a high temperature and cramming them with food. The oily fat and preserved breasts of geese are German delicacies. Six standard varieties of domestic geese are kept in the United States, for practical purposes, as follows:

Gray Toulouse.— Derived from the neighborhood of Toulouse, France; compact in form; gray, with brown wing-quills, hazel eyes, and bills and feet deep orange; full weight, 20 pounds. They are late in maturing, and hence are often called Christmas geese; their flesh is not of the best, but they are good egg-layers. They are bred largely by farmers.

White Embden.— Large, tall, snow-white geese derived from Westphalia, weighing 18 to 20 pounds when adult; eyes blue, bills flesh-color; feet deep orange. They are highly regarded by farmers as practical birds.

Gray African.— Tall, with long necks and large heads, a large knob on the base of the bill and a heavy dewlap: general color gray, darkest on the back; eyes hazel; bill black; feet dark orange; weight, 18 to 20 pounds. These are by many raisers considered the most profitable of all geese to keep. They grow the heaviest in the shortest space of time, are ready for market in 10 weeks, and as compared with other geese give the most satisfactory returns for the least labor and time spent in growing them. They are first-class layers and their flesh is fine and nicely flavored.

Chinese Geese.— Small graceful geese in two varieties, brown and white, weighing as adults 12 to 14 pounds. In colors and the shape of the head and knobbed bill they resemble the African breed; the white variety is pure white throughout, with the bill orange instead of black. They are the most prolific layers of all the breeds, averaging 50 to 60 eggs a year; and are otherwise commendable, especially for the table.

Wild Geese.— Descendants of the American wild goose: weight 14 to 16 pounds. They are very generally bred throughout the country, and exhibit many good qualities.

Consult Weir, 'The Poultry Book' (New York, 1903).

Geezeh. See GIZEH.

Geffrard, zhĕ-frär, **Fabre,** Haitian president: b. L'Anse-à-Beau 19 Sept. 1806; d. Kingston, Jamaica 11 Feb. 1879. In 1843 he joined Gen. Hérard's insurrection against President Boyer, and as commander of Hérard's advance guard, annihilated Boyer's force at Numéro Deux. In the wars with Santo Domingo (1849, 1856) he fought with distinction, later led a successful insurrection against President Soulouque, and was president from 1859–67, when a conspiracy of Salnave, an army officer, obliged him to escape to Jamaica.

Gefle, yāf'lā, Sweden, a seaport town and capital of Gefleborg, and at the mouth of a river of same name in the Gulf of Bothnia. It stands on both sides of the river and two islands formed by it, consists of spacious and well-paved streets, and houses partly of wood and partly of stone; and has an old castle, ship-building yards, and an excellent harbor. Pop. (1900) 29,522.

The district of Gefleborg has an area of 7,614 square miles; a coast deeply indented by bays, and an interior partly mountainous and covered with pine forests, and containing a large number of lakes, which, with the streams between them, form a kind of continuous network. The rearing of cattle is the chief employment. The most valuable mineral is iron. Pop. (1900) 228,862.

Gefleborg. See GEFLE.

Gehenna, gē-hĕn'ạ. See HELL.

Gehennam, gē-hĕn'ạm. See TOPHET.

Gehlenite, gā'lĕn-īt (named by Fuchs after his colleague Gehlen), a grayish-green or brown tetragonal mineral; hardness 5.5 to 6; specific gravity 2.9 to 3.1; lustre resinous or vitreous; fracture uneven to splintery. It is composed of a silicate of calcium and aluminum, $Ca_3Al_2Si_4O_{10}$. This mineral has feeble double refraction. It is found in the Tyrol and in Banat, and occasionally occurs among the scoriæ of furnaces.

Geijer, gī'ĕr, **Eric Gustaf,** Swedish historian: b. Ransäter, Wermland, 12 Jan. 1783; d. Stockholm 23 April 1847. Beginning to lecture at Upsala in 1810, he was elected in 1815 assistant professor, and in 1817 professor of history at Upsala. Geijer exercised a marked influence on the poetic no less than on the historical literature of Sweden. Great as is the value of Geijer's historical works, he unfortunately did not complete any one of the vast undertakings which he planned. Thus, of the 'Svea Rikes Häfder,' or Records of Sweden (1825), which were to have embraced the history of his native country from mythical ages to the present time, he finished only the introductory volume. This, however, is a thoroughly good critical inquiry into the sources of legendary Swedish history. His next great work, 'Svenska Folkets Historia' (1832–6), was not carried beyond the death of Queen Christina. Of his other historical and political works may be mentioned 'The Condition of Sweden from the Death of Charles XII. to the Accession of Gustavus III.' (1838), and 'Feudalism and Republicanism' (1844). During the last 10 years of his life Geijer took an active part in politics; but, although his political writings possess great merit, the very versatility of his powers diverted him from applying them methodically to the complete elaboration of any one special subject. He was also known to his countrymen as a musician and composer of no mean order. His collected works were published by his son, with a biographical sketch (13 vols. 1849–56).

Geikie, gē'kĭ, SIR **Archibald,** Scottish geologist and scientific writer: b. Edinburgh 28 Dec. 1835. He entered the geological survey in 1855 and has since had a brilliant career of discovery and experiment, and held many important honorary positions. Among his publications are: 'The Story of a Boulder' (1858); 'Elementary Lessons in Physical Geography' (4th ed. 1884); 'Scenery of Scotland Viewed in Connection with its Physical Geology' (2d ed. 1887); 'Outlines of Field Geology' (4th ed. 1881); and 'Text-Book of Geology' (3d ed. 1893); 'The Ancient Volcanoes of Britain' (1897).

Geikie, James, Scottish geologist, brother of Archibald Geikie (q.v.): b. Edinburgh 23 Aug. 1839. He was educated at Edinburgh University in which he held the chair of geology in 1882. He is the author of: 'The Great Ice Age' (1874); 'Prehistoric Europe' (1882); 'Outlines of Geology' (1884); 'Fragments of Earth Lore' (1892); 'Earth Sculpture' (1898).

Geikie, John Cunningham, English Anglican clergyman: b. Edinburgh 26 Oct. 1824. He was educated at the University of Edinburgh, was pastor of Presbyterian churches in Halifax and Toronto, was ordained priest of the Established Church in 1876, and was successively curate of St. Peter's, Dulwich, 1876–9; rector of Christ's Church, Neuilly, Paris, 1879–81; vicar of St. Mary's, Barnstaple, 1883–5; and vicar of St. Martin-at-Palace, Norwich, in 1885–90. His publications include: 'The Life and Words of Christ' (1876); 'Old Testament Characters' (1880); 'The English Reformation' (1884); 'Landmarks of Old Testament History' (1895); 'A New Short Life of Christ' (1898); 'The Vicar and His Friends' (1901).

Geisha, gā'sha, a Chino-Japanese word, meaning "one with pleasing accomplishments." applied to Japanese singing and dancing girls who furnish entertainment in tea-houses and at social gatherings.

Geissler, Heinrich, hīn'rĭh gīs'lĕr, German mechanician: b. Igelshieb, Germany, 26 May 1814; d. Bonn, Prussia, 24 Jan. 1879. He became known as a maker of physical and chemical apparatus and principally as the inventor of Geissler's tubes (q.v.), an apparatus for producing light by an electric discharge in vacuo.

Geissler's Tubes, tubes made of very hard glass, and containing highly rarified gases. Each end of the tube has a platinum wire sealed into it to serve as electrodes. When a discharge of electricity is caused to take place in these tubes by connecting the electrodes to the terminals of a Ruhmkorff's coil or a Holtz's machine, very brilliant effects may be produced. The invention was named after Heinrich Geissler (q.v.).

Gela, jē'la, Sicily, a city of ancient Greece, situated on the island between Agrigentum and Camarina; founded in 690 B.C. by the Cretans and Rhodians. The colony was remarkably prosperous, and in 528 B.C. sent out a portion of its inhabitants, who founded Agrigentum. In 280 Phintias, the tyrant of Agrigentum, utterly destroyed Gela.

Gelada, gĕl'a-da, a kind of baboon (q.v.).

Gelasius (jē-lā'sĭ-ŭs) **I., Saint**, Pope: d. 19 Nov. 496. He succeeded Felix III. on 1 March 492. At the Council of Rome in 496 he distinguished the canonical books from the apocryphal of Scripture. He also regulated the canon of the Mass. He was succeeded by Anastasius II.

Gelasius II. (Giovanni di Gaeta, jō-vän'nē dē ga-ā'ta), Pope: d. Cluny, France, 29 Jan. 1119. He was cardinal and chancellor under Urban II. and Paschal II., and on the death of the latter was chosen pope by the party hostile to the Emperor Henry V. The imperial party at Rome under the Frangipani seized his person, but were forced to set him free by the menacing attitude of the mob. The new pope fled before the advancing imperial troops to Gaeta, where he first received his consecration, and whence he excommunicated Henry V. and Gregory VIII., the antipope Henry had set up. Soon after he was able to return to Rome, but ere long had to betake himself for protection to France, where he died in the monastery of Cluny.

Gelatine, jĕl'a-ten, or **Gelatin** (Latin, *gelatus*, "frozen," so named from the tendency which the substance has to congeal and become to a certain extent solid), in chemistry $C_{76}H_{124}N_{24}O_{29}$ (?). Animal glutin, obtained by treating bones with dilute hydrochloric acid, which dissolves the mineral constituents of the bone, consisting of phosphates and carbonates of calcium, magnesium, etc., and leaves the bone cartilage. This, when boiled for a long time with water, dissolves, and forms gelatine, which can be purified by dissolving in hot water and precipitating by alcohol. A pure variety is obtained from the swimming bladder of the sturgeon. Impure gelatine glue is prepared by boiling down pieces of hide, horn, hoof, cartilage, etc., with water under pressure. Pure gelatine is amorphous, transparent in thin plates, of a yellowish-white color; it has neither taste nor smell, and is neutral to vegetable colors; it is insoluble in alcohol and in ether. In contact with cold water it swells up, and is soluble in hot water. It is not precipitated by acids, except by tannic acid, which gives a flaky precipitate insoluble in water, alcohol, and ether. The aqueous solution of gelatine turns the plane of polarization to the left. Gelatine subjected to dry distillation yields methylamine, cyanide of ammonium, pyrrhol, etc.; by oxidation with sulphuric acid and manganese dioxide, or with chromic acid mixture, it yields hydrocyanic acid, acids of the fatty series, benzoic aldehyde and benzoic acid, etc. Gelatine boiled with caustic potash yields glycocine and leucine. Gelatine contains about 50 per cent. of carbon, 6.6 of hydrogen, and 18.4 of nitrogen. Moist gelatine exposed to the air rapidly putrefies, the liquid becoming first acid, but afterward it gives off ammonia. Gelatine gives no precipitate with lead acetate, alum, or ferrocyanide of potassium. A mixture of gelatine with potassium dichromate becomes, when exposed to the action of light, insoluble in water. The nutritious value of gelatine has been much overestimated. Isinglass is prepared from the form derived from the sturgeon's bladder; and gelatine is also made use of in photography (q.v.).

Gelatine Process. See PHOTOGRAPHY AND PHOTO-ENGRAVING.

Gelderland, hĕl'dĕr-länt, or **Guelderland**, a province of Netherlands, with the Zuyder Zee on its northern boundary. Area, 1,965 square miles. The surface is level, the soil of the north sandy, the southern part low, marshy, but when cultivated, fertile. The principal rivers are the Rhine and the Meuse. The capital is Arnhem (q.v.). (For history see NETHERLANDS.) Pop. 567,489.

Gelée, zhé-lā, **Claude.** See CLAUDE LORRAINE.

Gelert, Johannes Sophus, American sculptor: b. Schleswig, Denmark, 10 Dec. 1852. He studied in the Royal Academy of Fine Arts at Copenhagen in 1870–5, removed to the United States in 1887, received a gold medal and honorable mention at the World's Columbian Exposition (1893), a gold medal at the Nashville Centennial Exposition (1897), and honorable mention and a gold medal at the Paris Exposition of 1900. His works include the monument to the policemen killed by the Chicago anarchists, Haymarket Square, Chicago; statues of Beethoven and Andersen in Lincoln Park, Chicago; a statue of Grant at Galena, Ill.

Gellius, jĕl'ĭ-ŭs, **Aulus,** Roman author: b. possibly about 130 A.D. He studied rhetoric at Rome and philosophy at Athens, and practised as a lawyer at Rome. He is the author of 'Noctes Atticæ,' full of interesting observations and quotations, from the best Latin and Greek authors, relating to language, literature, history, and antiquities. This work was partly compiled in the winter nights during his residence at Athens. It is now of great value, as the authors from which he drew his materials are in a great measure lost. Among the best editions is that of Hertz (1883–5).

Gelon, jē'lŏn, tyrant of Gela and afterward of Syracuse: d. about 478 B.C. He was a scion of a noble family of the former city, and succeeded its tyrant, Hippocrates, in 491 B.C. Six years later he made himself master of Syracuse also, which then became the seat of his government, and to which he transferred the majority of the inhabitants of Gela. Gelon refused to aid the Greeks against Xerxes, as they declined to comply with his demand that he should be appointed commander-in-chief. The clemency and wisdom of Gelon rendered him so generally beloved that when he appeared unarmed in an assembly of the people, and declared himself ready to resign his power, he was unanimously hailed as the deliverer and sovereign of Syracuse.

Gelose, jē'lōs, a pectic substance containing carbon, 42.77; hydrogen, 5.775; oxygen, 51.455, prepared by Payen from a commercial article entitled Chinese moss, which consists of long white threads made up into bundles, and from various seaweeds. It is used for food, and is said to be the juice of a lichen growing on trees in the south of China and in the Philippine Islands. The moss, when boiled in water, dissolves, with the exception of 2 or 3 per cent of nitrogenized corpuscles and traces of other matter, and on cooling forms a transparent colorless jelly, which when dried constitutes gelose. It is distinguished from other bodies by certain characteristic reactions.

Gelsemium, jĕl-sē'mĭ-ŭm, yellow jasmine, the dried rhizome and roots of *Gelsemium sempervirens;* a southern climbing-shrub with a large woody underground stem and dark-green leaves, and bright, yellow sweet-scented flowers. It grows from Virginia southward in woods, and mounts to the top of tall trees. The active constituents contained in the underground stem are two alkaloids, gelsemine and gelseminine, the latter of which is the more potent. Gelsemium is an acute poison, acting both on the sensory and motor end-organs, causing anæsthesia and motor weakness. The early symptoms of large doses are loss of power in the muscles of the eye, causing drooping of the lids, dizziness, drowsiness, and disturbance of vision. In poisonous doses there is marked diminution in the force of the pulse and respiration, with difficulty of speech, coldness of the body surface and general loss of skin sensations. Death results from asphyxiation. Its most important medicinal use is in neuralgias, in sick-headache, and as a general nerve tonic.

Gemini, jĕm'ĭ-nī, the Twins (♊), the third sign of the zodiac. The sun enters this sign on or about 21 May, and leaves it on or about 21 June. The name belongs also to a northern constellation, of which the two chief stars are Castor and Pollux. They are very nearly equal in brilliancy, which fact probably suggested the name. Pollux is slightly the brighter. It is a quadruple star. Castor is one of the finest of the double stars. See ASTRONOMY.

Gemistus, jĕ-mĭs'tŭs, **Georgius.** See PLETHO, GEORGIUS GEMISTUS.

Gemmi (gĕm'mē) **Die,** Switzerland, a narrow pass, nearly two miles long, which crosses the Alps at a height of 7,553 feet, and connects the Swiss cantons of Bern and Valois.

Gemmules, jĕm'ūlz. (1) In actual biology gemmules are aggregations of cells set apart in the body of sponges and polyzoans to serve as reproductive agents. This is one of the most primitive forms of reproduction. (2) In philosophical biology gemmules are hypothetical, self-reproducing particles in the reproductive protoplasm (a structure which is assumed) supposed to be bodily transmitted from parent to child, and to carry such qualities as are inherited by offspring.

Gems are precious stones of small size, such as may be used for setting in a ring, or for any similar purpose of ornament. Like everything else of great value, precious stones have been imitated, and the practice has been carried on from the earliest times. The art of glass-coloring was known to the ancient Egyptians, who produced excellent imitations of the most beautiful gems. Among the Romans in the time of Pliny the manufacture of false stones was far advanced as a branch of industry. There existed several treatises on the subject, and Pliny declared that it was a difficult task to distinguish the false gems from the true. The alchemists of the Middle Ages, according to Aquinas, successfully fabricated artificial jewels, and he instances the jacinth, sapphire, emerald, topaz, and ruby, as being skilfully counterfeited. About the middle of the 17th century, false stones were no longer manufactured according to methods differing for each stone, but according to a general formula much the same as that followed at the present day.

Artificial Gems.— The base of all modern artificial gems is a peculiar kind of glass of considerable hardness, brilliancy, and refractive power, called paste or strass, which is distinguished from ordinary glass by the presence of 50 per cent of oxide of lead among its constituents. When the strass is obtained very pure, it is melted and mixed with substances having a metallic base, generally oxides, which communicate to the mass the various desired colors. We give a few details showing how the principal gems may be imitated. The diamond being colorless, pure strass simply cut into brilliants and roses is used as a counterfeit. The ruby is imitated by mixing 1,000 parts of strass, 40 parts of glass of antimony, 1 part purple of Cassius (a preparation of gold and binoxide of tin), and 1 part in excess of gold. Sapphires are counterfeited by 1,000 parts strass, and 25 of oxide of cobalt. Topaz — the same formula as for ruby, without the excess of gold, and heated for a less time. Emerald, 1,000 parts of strass, 8 oxide of copper, and 0.2 oxide of chromium. Amethyst, 1,000 parts strass, 25 oxide of cobalt, and a little oxide of manganese. Garnet, 1,000 parts strass, and a variable quantity of purple of Cassius according to the shade to be obtained. In all these preparations success mainly depends upon a thorough pulverization and mixture of the ingredients; the fusion should be long continued at a graduated and uniform maximum temperature, and the mixture be annealed in cooling. These imitations, which are made in immense quantities in large factories in France and elsewhere, are chiefly used in the manufacture of cheap jewelry.

Attempts have, however, been made with a fair measure of success to manufacture true gems by artificial processes. Of these processes we need only mention that introduced by the French chemists Frémy and Verneuil. They succeeded in manufacturing excellent rubies, very like the natural ones in shape and composition, by raising carefully to a red heat a mixture of alumina, barium fluoride, and a very small quantity of bichromate of potash. The rubies are found in a friable matrix. If a little cobalt oxide be present in the mixture, sapphires are obtained instead of rubies. Many experiments with a view to producing diamonds artificially have been made within recent years. From hydrocarbons, subjected to a very intense heat and enormous pressure, minute crystals have been obtained which are as hard as the natural diamond, scratching all other minerals, and not affecting polarized light. The process is, however, expensive, tedious, and dangerous, and the diamonds produced are as yet so small that it requires more than 1,000 of them to make a carat; only ½ carat has been produced, at an expense of $2,000; hence they represent nothing beyond a scientific value. A diamond exists in the meteorite from Cañon Diablo, Arizona, in the Kunz collection at the American Museum of Natural History, New York. This is the first diamond identified in a meteorite,— by Dr. G. A. Koenig, in 1891.

We come now to genuine precious stones which will be taken up in the order of their rarity and value:

Diamonds.— The diamond, although not the rarest nor the most valuable of precious stones, is often called "the king of gems." It consists of pure carbon, crystallized in what is known as the isometric system, almost always occurring in the form of a regular octahedron or some modification thereof. It is the hardest of all known substances, ranking as ten (10) in the scale of hardness. It possesses a higher refractive and dispersive power on light than any other gem, whence arise the extreme brilliancy, and the varied flashes of color, or "fire," that give it such beauty. Being carbon, it is combustible,— the only gem that is so,— burning to carbonic acid in oxygen, or even in air under suitable treatment; this property was discovered as long ago as 1691, by Cosmo I., of Tuscany, who ignited a diamond with a burning-glass. Its density is about 3.5. In color it varies much, from white or colorless to yellow, also brown, rarely green, blue, pink, rose-red, occasionally even black. Some diamonds phosphoresce upon friction, and glow strongly under the influence of violet and ultra-violet light, and the emanations from the new and singular element known as radium, or rather from its compounds. They are absolutely transparent to the X-rays, of Roentgen. All these properties serve as ready means for distinguishing real diamonds from the best imitations. The value of a diamond depends on several conditions, chiefly size, color, and brilliancy. As to size, they are rated by the carat (or karat). This was the name of certain small seeds, which when dried, are quite constant in weight, and were used in India for weighing gems. It has now become a fixed standard for this purpose, used among all civilized nations, as the "international carat." In 1871, the syndicate of jewelers, goldsmiths, and gem-dealers of Paris proposed to fix its value at .205 of a gram; and this was generally adopted in 1877, and accepted by the principal dealers of Paris, London, and Amsterdam,— the centres of the world's diamond trade. The English carat is equal to 3.1683 grains Troy (usually reckoned as 3.17 grains); so that there are 151½ carats in an English Troy ounce. The jewelers' carat is divided into halves, quarters, eighths, sixteenths, thirty-seconds and sixty-fourths. A quarter-carat is sometimes called a grain, though it is less than a true grain; and pearls are generally sold by the grain, in this sense. As to color, the highest value belongs to perfectly white stones, or to those of fine bright tints, whether rose, green, or blue. These last are very rare and command fancy prices. Yellow diamonds are much more frequent, but when of rich color, are valuable. Any half-way tints, however, such as yellowish whites, are far less desired. Some possess a delicate steely-blue tinge, sometimes a delicate opalescence, and are called "blue-white"; these are particularly the Brazilian stones from Bagagem, and are also notable for their phosphorescent property. Perfectly colorless and flawless diamonds are spoken of as of "first water," a term which varies, however, according to the class of goods carried by the dealer using it. Many of the African stones are what is called "Cape white," that is, faintly yellowish; these are indistinguishable from pure white ones by artificial light, but command much lower prices. The finest diamonds are not found in the Kimberley mines, but in the Orange River Colony and the Transvaal. Diamonds vary also in brilliancy, some having higher lustre than others. New South Wales yields small stones that are harder than usual, and at the same time exceedingly brilliant. All these natural qualities, together with perfection of cutting, enter into the estimate of values, and may cause very great differences. Of two diamonds of ten carats each, both flawless, one may be worth $600 and the other $12,000. Exceptional stones often bring special prices. Diamonds are occasionally found in many parts of the globe, but in only a few regions are they at all frequent or large, so as to be mined for. They were first obtained in India, then somewhat in Borneo, then in Brazil; more recently they are coming from New South Wales, and lately British Guiana is yielding a number. But all other sources are insignificant compared with the wonderful diamond mines of South Africa, which furnish 95 per cent of the world's supply, and have yielded since their discovery some 30 years ago, more diamonds than all other sources together in all past time. A few are found in Siberia, and in California; also along a line east of the Blue Ridge from Virginia to Georgia, and along another line from Wisconsin to southern Ohio; but these are only occasional, and are more interesting than important. The diamond seems to have been unknown to the ancients, outside of India, until about the beginning of the Christian era. The words rendered "diamond" in the Bible, and in classical writings prior to that time, refer to other hard minerals.

Rubies and Sapphires.— The ruby and the sapphire, transparent varieties of corundum (q.v.), the first being carmine red, and the second bright blue. Other colors also occur, as yellow, green, and purple, called respectively, Oriental topaz, Oriental emerald, and Oriental amethyst. Corundum crystallizes in the hexagonal system, and consists of alumina nearly pure. In hardness it ranks next below the diamond, being rated as 9 on the scale. The finest rubies are found in Burma, in the Mogok Valley, northeast of Mandalay. They are also mined in Siam, of a darker red, and in Ceylon, of a lighter shade. The Burmese rubies have a peculiar tint, called "pigeon's blood." Sapphires come principally from Siam and Cashmere, the finest tints being known as the cornflower and the velvet blue. Rubies of large size are extremely rare, and when they are as much as three or four carats in weight, they are worth from five to ten times the price of diamonds of the same size. Sapphires are found in Montana at several points; the finest are mined at Yogo Gulch, in Fergus County; these are of fine rich blue. Other mines are at Rock Creek, Granite County, where there is a great variety of colors; also at Cottonwood Creek, and along the bars of the Missouri, not far from Helena. True rubies have been obtained lately in the Cowee Valley, Macon County, North Carolina, though not in large numbers.

Emeralds.— Emerald and beryl are in fact the same mineral, a silicate of alumina and glucina. Beryl varies from blue through light green to yellow, when it is called golden beryl, and forms a gem resembling topaz. If colored a deep rich green by a little oxide of chromium, it becomes the emerald, a stone which when flawless, ranks in value with the diamond. The chief source of fine emeralds has long been the mines at Muzo, near Bogota, in Colombia, where they occur in a limestone rock. The mine has been worked by Europeans for three centuries, and previously by the native peoples of South and Central America. The emeralds known to the ancients came principally from Upper Egypt, near the Red Sea. These mines have been long abandoned and unworked, but are now being somewhat reopened. In the United States some very fine and large crystals of emerald have been found in Alexander County, N. C., though they were hardly clear enough to cut into gems. Very fine pale-green beryls (aquamarines) have been obtained in Maine, North Carolina, and Colorado, and golden beryls in Maine, Connecticut, and Pennsylvania. All the beryls crystallize in the hexagonal system, as six-sided prisms.

Chrysoberyl, a very hard gem, is a compound of alumina and glucina. It is a rare mineral, of various shades of yellow, brown, and light green. One variety contains minute impurities distributed between the layers of the crystal, and these layers so arranged by what is called "twinning," that when the stone is cut across the layers, the light is reflected or condensed in a transverse bright line; such a gem is called chrysoberyl cat's-eye.

Topaz is a rather complicated silicate of alumina, occurring in rhombic prisms and possessing a hardness of 8. It is generally yellow, also pale blue, pale green, pale brown, and white (colorless). The favorite tint is a peculiar yellow known as sherry-color. The finest come from Brazil and from the Ural Mountains; but some very handsome ones have been found in Colorado and Utah.

Tourmaline, another complex silicate of alumina, occurring in prisms of six, nine, or twelve sides, is usually black, but also of transparent red, green, and other colors, often singularly mingled in the same crystal. These are found in Brazil and Siberia, and also of great elegance at Paris and Auburn, Maine, Haddam Neck, Conn., and especially in San Diego County, California.

Garnet is the name of a group of minerals closely related in form and properties, but presenting a number of varieties. They are all very complex alumino-silicates, in which various metallic oxides enter as ingredients. The principal gem varieties are: almandine, or precious garnet, containing considerable oxide of iron; its color is a deep rather purplish or brownish red; pyrope, or Bohemian garnet, containing much magnesia, is a fine dark crimson, almost ruby color. These two are the red garnets of jewelry; when cut *en cabochon,* that is, not faceted but rounded, they are called carbuncles. Manganese garnet, or spessartite, is sometimes of a very beautiful orange-brown color; elegant gems of this kind have been found at Amelia Court House, Virginia. Uvarovite, or chrome garnet, is a rare variety of brilliant green color, resembling emerald, but the crystals are very small. Another green garnet of somewhat different composition, and with very brilliant lustre, from the Ural mountains, is called demantoid, or Uralian emerald. Much fine garnet is found in the United States. North Carolina yields a beautiful variety that has been called rhodolite,— a brilliant light red garnet, between almandite and pyrope in composition; these are largely mined in the Cowee valley, in Macon County. New Mexico and Arizona yield fine pyropes, often miscalled Arizona rubies, and equaling those of any other known locality. They are found where centipedes have carried them out in making the galleries of their hills.

Among the finest gem collections in the United States are the Tiffany-Morgan collection and the Bement-Morgan collections at the American Museum of Natural History, New York; the Isaac Lea collection, at the United States National Museum, Washington, D. C.; the Tiffany collection, Field Columbian Museum, Chicago, Ill.; the Tiffany collection, Golden Gate Museum, San Francisco, Cal.; and the Kunz collection, at the State Museum, Albany, N. Y.

Gems, Engraving of, the glyptic art, or lithoglyptics; the art of representing designs on precious stones, either in raised work (cameos) or by figures cut into or below the surface (intaglios). The latter method was practised at a very early period, and probably had its origin with the Babylonians 4000 B.C., who worshipped the heavenly bodies, and were accustomed to wear figured talismans, which served as symbols of their influences. The Egyptians cut the hardest kind of stones for like purposes as early as 3000 B.C. The custom of wearing cut stones as seal-rings appears to have been general among the Greeks in the time of Solon. One of the earliest artists in this branch of whom mention is made is Mnesarchus, the father of the philosopher Pythagoras, consequently a contemporary of that Theodorus of Samos who engraved the ring of Polycrates, of which such wonderful stories are told by the ancients. These early works were probably intaglios; the artist made use of the lathe, the diamond-point, and by some it is thought, diamond-powder; but it is a question if the diamond was known before the 6th century A.D. Gem engraving flourished in Mycenæ, Smyrna, and ancient Greece, and from the time of Alexander the Great; but we can only judge of the works of Pyrgoteles, Apollonides, and Cronius from tradition, as there are no works of these masters extant. Pyrgoteles was distinguished for works in relief, and from his time the art may have risen gradually to that later degree of perfection of which we possess such rich specimens. The artists, some of whose names we learn from their works themselves, often took the masterpieces of sculpture for their subjects and models. Under the Roman emperors, in particular, this was very common. The chief early Greek engraver whose name is known from extant works of his is Dexamenos (late in the 5th century). The names of Dioscorides, Apollonides, Aulos, Hyllos, Cneius, Solon, remind us of the most perfect works in this branch of art, and many of the signed gems are forgeries or old gems with old names forged on them. But some of the greatest ancient works — the sardonyx of the Sainte Chapelle (Paris); the apotheosis of Augustus, at Vienna; the onyx at The Hague, representing the apotheosis of the Emperor Claudius; Achilles lamenting Patroclus; the head of Julius Cæsar — these, like the Brunswick vase and the Trivulcian and Neapolitan cups, bear no distinguished names. Pompey consecrated the dactyliotheca or collection of rings of Mithridates, as a votive offering in the Capitol, and Julius Cæsar, six tablets with six gems in the temple of Venus. At a later period the collections of Herodes Atticus, of Vespasian, etc., were celebrated; yet this general taste was not able to preserve the art from decline. Notwithstanding this decline, however, gems continued to be highly prized, even in the times of mediæval barbarism, and served to ornament the shrines of saints, and for royal badges, and ceremonial dresses, and thus passed safely through the ages of destruction and ignorance in which the finest statues were only valued as materials for mortar or for building, till ages arrived which could again appreciate their value. If we may judge from the remains which have come down to us, engraved gems seem to have been more common in the Byzantine empire than in the West.

The earliest gem-engraver of modern times is Vittore Pisanello, who lived in Florence about the year 1406. The first among the Germans was Daniel Engelhard, of Nuremberg, who died in 1512. The discovery of some fine specimens in Italy, particularly in Florence, and the display of gems by the Emperor Palæologus, at the Council of Florence in 1438, were perhaps the original cause of the taste of the Medici for engraved stones. The popes and that family were the first patrons of this art in modern times. A Florentine artist, generally called on account of his great skill, Giovanni delle Carniole ("of the Carnelians"), distinguished himself in this early modern period. There are few gems which can be ascribed to him with any confidence, except the famous carnelian in the Florentine Museum, with the portrait of Savonarola, bearing the inscription *Hieronymus Ferrariensis ordinis prædicatorum, propheta, vir et martyr.* This stone, which must have been engraved later than 1498, is given to Agincourt's work. Contemporaries and rivals of Giovanni were Nanni di Prospero delle Carniole, in Florence, whom Francesco Salviati directed in his works, and Domenico Compagnie (*dei camei*), a Milanese, whose portrait of Ludovico Sforza, called Moro, cut in a ruby, is still preserved in the Florentine Museum. After Bernardi (delle Carniole), Valerio Vicentino (under Leo X.) rendered himself famous as a gem-engraver. This art found patrons in all the Italian princes; the number of artists constantly increased, and the sphere of their work was extended. The names of these artists, however, are not generally known, because they are rarely put on the stones. Many gems, too, are still concealed in the cabinets of the wealthy or the treasuries of princes. Till these are accurately described, as those of the Ambrosian collection, it will be difficult to obtain a complete general view.

Subjects of antiquity were preferred by the artists of the 15th and 18th centuries, who treated them with such ability that it often requires the skill of the most accomplished connoisseur to distinguish them from genuine antiques. The dispute concerning the famous seal-ring of Michelangelo is well known. It is not improbable that this carnelian is the work of Pietro Maria da Pescia; as the figure of the fisherman in the exergue may indicate the artist who, with Michelino, belonged to the age of Leo X. In order to give the gems more completely the appearance of antiques, some artists engraved their names in Greek, but with so little knowledge of the language that they sometimes betrayed themselves by this artifice. To this time we must ascribe the gems with the name Pyrgoteles, which Fiorillo endeavors to prove werthe work of an Italian of Greek descent (Lascaris).

The art of engraving was also applied to glass and gold. The crystal box of Valerio Belli, the most skillful and industrious artist in this branch during the 16th century, deserves particular mention. It was intended by Clement VII. as a present to Francis I., when Catharine di Medici went to Marseilles in 1533. At present it is in Florence. The Milanese particularly distinguished themselves in gem-sculpture, as the wealth of the principal citizens of Milan enabled them to patronize this art. Jacopo da Trezza, the same artist who in 1564 executed for Philip II. the famous tabernacle of the Escurial, made the first attempts at engraving on the diamond in Milan. The greatest cameo work of modern times is the stone from the Florentine Museum, seven inches in breadth, on which Cosmo, Grand Duke of Tuscany, with his wife, Eleonore, and his seven children are represented. A Milanese, John Anthony de Rossi, who was a contemporary of the Saracchi family (about 1570), is the artist. The Saracchi were five brothers, and the crystal helmet of Albert of Bavaria is a proof of their skill.

Gem-engraving was popular in Germany in the 14th and 15th centuries, and in England, Natter, Pichler, and Marchant are considered the restorers of the art in later years in that country. The most eminent artist of more modern times is perhaps, Berini, a native of Rome, who, with Cervera and Giromelli at Rome, and Putinati, at Milan, produced very fine works. In our own times the demand for cameos and intaglios in the United States was greatest from 1870 to 1880. During that time more than 100 workmen found employment here,— many of them as portrait artists. Among these was Lebrethon, who had as a pupil our great sculptor Augustus Saint Gaudens; another, Zöllner, who engraved some fine and important cameos, took up brass working. Perhaps the greatest artist and the most active, L. Bonet, to-day has scarcely one sixth of his time occupied, whereas in the "Cameo age" he had the aid of nine assistants. In 1903 there appeared a slight revival of the wearing of antique and old-fashioned cameos of rather a pronounced form, and it is quite possible that the glyptic art is again on the way to favor.

A few of the gem collections are the famous Rev. C. W. King collection of antique gems, of the types used in his works; the Cesnola and other collections, at the Metropolitan Museum of Art; also a fine collection at the Boston Museum of Fine Arts; and the Maxwell Somerville collection, the types of his works, at the University of Pennsylvania, in Philadelphia, while the Walters collection, at Baltimore, Md., contains many of the finest gems in America.

Gem Expert, Tiffany & Co., New York.

Gems, Mythology of. The ancients believed that each month of the year was under the influence of a precious stone, and in modern tin s this superstition has found many devotees. It is quite the prevailing custom in many fashionable European capitals to wear birth-month stones, in preference to other jewels. The following list has been current for many years:

January	Garnet	Constancy
February	Amethyst	Sincerity
March	Bloodstone	Courage
April	Diamond	Innocence
May	Emerald	Success in love
June	Agate	Health and long life
July	Cornelian	Content
August	Sardonyx	Conjugal felicity
September	Chrysolite	Antidote to madness
October	Opal	Hope
November	Topaz	Fidelity
December	Turquoise	Prosperity

The seven gems which are supposed to be unde the influence of the seven chief planets are these:

Saturn	Onyx
Jupiter	Cornelian
Mars	Diamond
Sun	Sapphire
Venus	Emerald
Mercury	Loadstone or lodestone
Moon	Crystal

The legend of the diamond tells how Diamond was the name of a beautiful youth of the island of Crete, who was one of the attendants of the infant Jupiter in his cradle. Diamond, not to be subject to "the ills that flesh is heir to," was transformed into the hardest and most brilliant substance in nature. The diamond among the ancients had the virtue of bestowing victory and fortitude. It calmed anger and strengthened wedded love; hence it was called the stone of reconciliation. The diamond, too, among the Greeks was a symbol of severe and inexorable justice and of the impassibility of fate. Hence the judges of Hades were described as having hearts of adamant.

Gemsbok, gĕmz'bŏk, a large South African antelope (*Oryx gazella*), gray in general hue, but along the back, on the hindquarters, and along the flanks the color is deep black. It has a short erect mane, a long sweeping black tail, and long sharp-pointed heavy horns, nearly straight from base to tip, and obscurely ringed throughout the lower half. It is asserted that the gemsbok never drinks water, the moisture which it needs being obtained from the succulent bulbous plants on which it feeds. It is one of a group of large antelopes, including the oryx, beisa, addax, etc., which are sometimes called the gemsboks, and the numbers of all which are rapidly diminishing toward extinction. See ANTELOPE.

Gemünder, August, ow'goost gĕ'mün-dĕr, German-American violin-maker: b. Ingelfingen, Würtemberg, 1814; d. New York 1895. He studied the art of violin-making with Vuillaume at Paris; from 1846 to 1860 was at Springfield, Mass., where he won wide recognition for his violins; and in 1861 established his business in New York. His most important work was a copy of an Amati owned by Pablo Sarasate, the well-known Spanish violinist, who declared it equal to the original instrument.

Gemünder, George, German-American violin-maker: b. Germany 1816; d. New York

1899. He was a pupil of Baptiste Vuillaume of Paris, came to America in 1847, won the first prize with his violins at the Crystal Palace exhibition, London (1851), and in 1873 sent to the Vienna exhibition a copy of a Guarnerius declared by the jury of experts to be an original. It is said that his were the finest violins yet made in America. He published 'George Gemünder's Progress in Violin-Making' (1881). He was a brother of August Gemünder (q.v.).

Gendarmes, zhŏṅ-därm (Fr. "men-at-arms") were originally mounted lancers, armed at all points, and attended by five inferior soldiers, who were furnished by the holders of fiefs; these were replaced by Charles VII.'s *compagnies d'ordonnance*, which were dissolved in 1787, one company of gendarmerie being retained as the bodyguard of Louis XVI. Since the French Revolution, except for a short interval at the Restoration, the gendarmes have constituted a military police, which superseded the old *maréchaussée*, and comprises both cavalry and infantry; divided into legions and companies, and these latter into brigades, the organization of the force corresponds to the territorial divisions of the army. The men receive much higher pay than the rest of the army, of which, however, the corps is a part, its members being drafted from the line for this service. Germany also since 1808 has had its *gendarmen*. See POLICE.

Gender, in grammar, a difference in words to express distinction of sex. Strictly speaking there are but two genders, the *masculine* and *feminine;* words which did not belong to those classes were said to be *neutrius generis*, of neither gender; and from this phrase grammarians have, somewhat incorrectly, come to speak of this third class as being of "the neuter gender," and thus recognize three genders. That the distinction of sex is the origin of grammatical gender cannot be reasonably disputed, and as a consequence the principle must have been originally restricted to living beings, and practically to those in which the distinction of sex was readily perceived. In the lesser animals it would have been more difficult to ascertain the sex, and generally unnecessary to denote it. But correctness and utility are not the only ruling principles of language; they are often sacrificed to the love of imagery and personification. In the infancy of language, when everything that was seen to produce an effect was conceived as actuated by a conscious will, every prominent object was endowed with one or other sex, the choice depending on the association of ideas. Strength, freedom, magnitude and violence are the marked attributes of the male; weakness, subjection, timidity, and gentleness of the female. In Hebrew there is no neuter; in Sanskrit, Greek, and Latin, the majority of the names applied to inanimate objects are either masculine or feminine; and in the languages derived from the Latin — Italian, French, Spanish, and Portuguese — a neuter gender is not recognized. In German, as in the classical tongues, the names of inanimate objects are sometimes masculine and feminine as well as neuter. English, getting rid of the spurious distinction that encumbered the Anglo-Saxon, attributes sex only to living beings. In the highly inflected languages there are certain terminations distinctive of the different genders, the most characteristic in the Greek being *os*, masc.; *ē*, fem.; and *on*, neuter; and the Latin *us, a, um*. In English the distinction of gender is often marked by the termination, the most common being the affix *ess* derived from the French; or by a different word. In most other languages the adjectives, articles, and participles are inflected for gender; in English the gender of a noun only affects the pronoun substituted for it. See GRAMMAR; LANGUAGE.

Gender, a Javanese musical instrument. It consists of a row of parallel metallic plates supported horizontally by two strings passed through the respective nodal lines of the plates. Underneath each plate is an upright bamboo, containing a column of air of such a height as to reciproceate the sound of the plate above.

Gendron, Auguste, ō-güst zhŏṅ-drŏṅ, French painter: b. Paris 1818; d. there 12 July 1881. He was long a pupil of Delaroche, and several times visited Italy, where he painted his first important works. In addition to several canvases, including 'The Island of Cythera'; 'Tiberius at Capri'; 'Sunday in Florence — 15th Century'; he executed frescoes in the Louvre and the church of St. Gervais.

Genealog'ical Society, The New York, was incorporated in 1869, to procure and perpetuate whatever may relate to genealogy and biography. The 'New York Genealogical and Biographical Record,' now in its 28th volume, is published under its supervision. The society has published: 'Marriage from 1639 to 1801 in the Reformed Dutch Church, New York,' and other volumes. The society's building is at 23 West 44th Street.

Geneal'ogy (from the Greek *genos*, race, and *logos*, discourse), the systematical account of the origin, descent, and relations of families is an auxiliary of historical science. Genealogical knowledge becomes important in a personal or legal view, when family claims are to be established. Genealogy is founded on the idea of a lineage or family. Persons descended from a common father constitute a family. Under the idea of degree is denoted the nearness or remoteness of relationship in which one person stands with respect to another. A series of several persons, descended from a common progenitor, is called a line. A line is either direct or collateral. The direct line is divided into the ascending and descending. The ascendants are called, in general, *majores* (ancestors), and the descendants *posteri* (or posterity). The collateral lines comprehend the several lines which unite in a common progenitor. They are either equal or unequal, according as the number of the degrees in the lines is the same or different. The collateral relations on the father's side are termed *agnati*, on the mother's *cognati*. Children stand to each other in the relation either of the full blood or the half blood, according as they are descended from the same parents, or have only one parent in common.

For illustrating descent and relationship genealogical tables are constructed, the order of which depends on the end in view. In tables the object of which is to show all the individuals embraced in a family, it is usual to begin with the oldest progenitor, and to put all the persons of the male or female sex in descending, and then in collateral lines. Other tables exhibit the ancestors of a particular person in ascending lines, both on the father's and mother's side. In this way 4, 8, 16, etc., ancestors, are exhibited. The tables showing the succession of rulers contain merely the descent of the persons who have reigned in succession, or who have claims to the government. In connection with them stand the tables of disputed succession, which represent several lines of a family, or several collateral families, in order to deduce their rights of succession from their degree of relationship. Synchronical tables consist of the genealogies of several families placed together, in order to compare, with facility, relationships, marriages, divisions of inheritance, etc. Historical genealogical tables differ from mere genealogical tables, as they attach to the descent the biographies also of the members. The common form of genealogical tables places the common stock at the head, and shows the degree of each descendant by lines.

The earliest genealogical tables are perpetuated in the Biblical family records of succeeding generations, in graven stone memorials of ancient Egypt, Assyria, Persia, India, and other oriental countries. Genealogical knowledge was most important in the Middle Ages, when the nobility was distinct from the other classes. Ancestors were unblushingly and impudently fabricated, the absence of criticism and the desire to flatter important people causing the introduction of the most absurd fables into genealogy, especially after the 14th century. Few families, no matter however distinguished and noble, can trace their ancestry beyond or even as far as the middle of the 11th century. The advance of civilization and particularly the institution of corporations and guilds in the towns of the principal European nations, afforded a wider scope for genealogy, and in the 12th and 13th centuries, family names began to be more common. The oldest trace of family names according to Gatterer is in 1062 when a Henricus de Sinna is mentioned in Schannat's "Buchonia Veteri." After history in general had attained a more systematic character, the Germans in particular treated genealogy on a more scientific basis. Ruxner's "Turnierbuch" (1527), and Reusner and Hennings' genealogical tables which appeared about the end of the 16th century, are among the earliest published works, but are not conceived in an historical spirit. Duchesne, Saint Marthe, Hozier, Chifflet, Lancelot le Blond, etc., in France, and Dugdale in England, initiated a clearer and more accurate treatment of the subject. The first genealogists in Germany to base the science on documentary evidence were Rittershusius of Altdorf (d. 1670) and Spencer of Wittenberg (d. 1730). The lines laid down by them were followed and carried to higher perfection by König, Von Imhof, and especially by Hübner in his "Genealogische Tabellen" (4 vols. 1725–33; new ed. 1737–66), to which Lentz added "Erläuterungen" (Elucidations, 1756), and Sophia, Queen of Denmark, "Supplement-Tafeln" (1822–24). Gatterer founded the scientific treatment of the subject in his "Abriss der Genealogie" (1788), and was followed by Pütter in his "Tabulæ Genealgicæ" (1798), by Koch in his "Tables Généalogiques" (1808), Voigtel (1810), Hopf (1861), Von Behr (1870), Cohn (1871), and Oertel (1871), all in Germany.

The principal genealogical MSS. sources in Great Britain are the public records, heraldic registers, and the parish registers of births, marriages, and deaths. The chief printed collections of genealogical information are the well-known Burke, Debrett, and other like publications of "Peerages, Baronages, Baronetages, and County Histories."

In the United States, genealogy was generally neglected until the latter part of the 19th century, when the organization of patriotic, State and colonial societies, like the Society of the Cincinnati, the Holland Society of New York, the Southern Society, etc., aroused an interest in genealogy. Genealogical societies have been organized in several States and the subject has received more or less attention. New York society folks in 1901–2 began to take up genealogy as a special fad or hobby and numbers of persons adopted the study of family trees as a regular employment. The principal publications in the United States on genealogy are 'The New England Historical and Genealogical Register;' 'The New York Genealogical and Biographical Record;' 'The Heraldic Journal;' the various biographical dictionaries and cyclopedias; the printed transactions and archives of State and city historical societies; county, State, city, and town histories.

Genee, zhē-nā, **Rudolf,** German author: b. Berlin, Prussia, 12 Dec. 1824. He abandoned wood engraving for journalism, and then became an instructor in literature at Berlin. As a reader and interpreter of Shakespeare he attained distinction; but his plays — 'The Prodigy' (1854); 'A New Timon'; 'In Front of the Cannon'; 'The Hermitess"; and adaptations from Sheridan — gave him wider fame. His works in criticism, treating of German poetry, the drama, and kindred themes, are highly esteemed. 'Marienburg' is a successful historical novel by him.

Genelli, Bonaventura, bō″nä-vän-too'rä gā-nĕl'lē, German painter: b. Berlin 28 Sept. 1798; d. 13 Nov. 1868. He was the son of Janus Genelli (1771–1812), an engraver, with whom he early studied. His chief artistic training was obtained as a pupil of Johann Erdmann Hummel at Berlin and at Rome, where he resided in 1822–32, and executed numerous pencil and india-ink drawings which carried his name over much of the continent. From 1836 he was in Munich, often in poverty; for he received no public commissions and his work had as yet met its due recognition among but a few. In 1859 he was called by Grand-duke Charles Alexander to Weimar, where ample leisure was afforded him for his larger works in oil. He was a classicist like Carstens, whose methods he followed, and with him the chief thing was the rendering of line. Among his many works are the series of drawings for Dante's 'Divine Comedy,' and for Homer; other drawings in ink or water-colors, such as 'Hercules Playing the Lyre'; The 'Vision of Ezekiel,' and 'Æsop Telling His Fables,' and the pictures in oil: 'Abraham and the Angels'; 'The Battle of Lycurgus with Bacchus'; 'Bacchus among the Muses.' There is a biography of Genelli by Jordan (1869).

General, (1) A military rank and title. In the United States army, this rank, as distinguished from and superior to the major-general, was created for Washington by Congress, 3 March 1799. He died shortly after, the office remained vacant, and in 1802 it was abolished. It was revived in 1866 for Grant, and on his accession to the Presidency in 1869, was conferred on William T. Sherman. On his retirement, 1 Nov. 1883, the rank was allowed to lapse. In June 1888 it was revived for Philip H. Sheridan; but on his death in August it again became extinct. The highest army officer has now the title of chief of staff. See GENERAL STAFF, UNITED STATES ARMY.

(2) The name given to the general superior of religious orders and congregations of men in the Roman Catholic Church. The general is usually elected in general chapter, and holds office for three years. In the Society of Jesus the general is elected for life. The generals of regular orders have been granted by popes special privileges, as power of absolution in reserved cases in relation to their subjects. Several modern congregations of women have general superiors, but their canonical position is quite different from that of the generals of the orders of men.

General Assembly. See ASSEMBLY, GENERAL; PRESBYTERIANS.

General Confession, in the Roman Catholic Church, is a sacramental confession of all sins committed by the penitent since baptism, or since of an age to know what sin is, so far as he can remember. Such general confession is made by persons who have made no previous confession, who have wilfully concealed a mortal sin; or been wanting in true and supernatural sorrow for the sins confessed in a previous confession; or are desirous of reviewing their past life for the purpose of interior advancement in the spiritual life.

General Court, the official name of the legislature of Massachusetts. The old English name of the meeting of a body of managers or members of any corporation is "court"; as court of aldermen, court of directors, etc. So the meeting of corporators of the old Massachusetts Company was called a court; then the primary assembly of freemen under its charter was called the General Court; and the name was retained after it became a representative body. There was the further reason that it really was the supreme judicial as well as legislative body. See MASSACHUSETTS.

General Education Board founded in New York City, February, 1902, chartered by Congress 12 Jan. 1903, has for its objects: (1) The promotion of education within the United States of America, without distinction of race, sex or creed; (2) the development of the public school system, especially in rural districts; (3) the development of the principle of self-help by promoting increased local taxation, local contributions or other means for educational purposes; (4) the increased establishment of training schools for teachers, especially those designed to educate instructors of industrial and manual training; (5) co-operation with the organizations interested in educational work, so as to simplify and make effective the general work of education, avoiding unnecessary duplication; (6) the collection of full information and statistics in respect to educational matters in the districts covered by the operation of the board, which shall be kept at a general office; (7) to furnish the public with information, suggestions and counsel, and for this purpose to act somewhat as a clearing-house for educational statistics and data to be collated by the board; (8) to educate public opinion in all matters pertaining to the general cause of education by publication of reports through the daily press and by other means.

The organization received the cordial support and gifts of several philanthropists, including John D. Rockefeller, Sr., and among the members of the board are John D. Rockefeller, Jr., Daniel Coit Gilman, Morris K. Jesup, William R. Harper, Frederick T. Gates, Walter H. Page, Albert Shaw, Hugh H. Hanna, E. Benjamin Andrews, Starr J. Murphy, secretary and executive officer for the states of the north and west; Wallace Buttrick, secretary and executive officer for the states south of the Potomac and Ohio rivers, and Arkansas, Louisiana and Texas; George Foster Peabody, treasurer; Robert C. Ogden, president.

When the charter with its broad provisions was signed by President Roosevelt, John D. Rockefeller made a special gift of $1,000,000 for exclusive distribution in educational work among the southern states, where the operations of the board were mainly confined at first. The intelligence, fidelity and efficiency with which this trust was discharged led Mr. Rockefeller, 30 June 1905, to announce a further contribution to the General Education Board of a sum of $10,000,000 to be paid October 1 of that year, in cash, or at his option in income-producing securities, at their market value, the principal to be held in perpetuity as a foundation for education, the income, above expenses and administration, to be distributed to or used for the benefit of such institutions of learning, or employed in such other ways as the board may deem best adapted to promote a comprehensive system of higher education in the United States. On 6 Feb. 1907 he gifted securities to the market-value of $32,000,000, one-third of the income to be applied to the endowment fund, the balance as Mr. Rockefeller or his son may direct.

While the endowment is designed especially for colleges as distinguished from universities, there is no prohibition against making contributions to universities. The funds may be employed for approved non-sectarian as well as denominational schools, but in the case of the latter cannot be applied for specific theological instruction. In distributing the funds the board aims especially at favoring those institutions which are well located and which have a local constituency sufficiently strong and able to insure permanence and power. No attempt will be made to resuscitate moribund schools or to assist institutions which are so located that they cannot promise to be permanently useful.

Within these limits there are no restrictions as to the use of the income. It may be utilized for endowment, for buildings, for current expenses, for debts, for apparatus or for any other purpose which may be found most serviceable, thus providing for a great work in a practical way.

General Issue, in English law, is that plea which denies at once the whole declaration or indictment, without offering any special matter by which to evade it. It is called the general issue, because, by importing an absolute and general denial of what is alleged in the declaration, it amounts at once to an issue, or fact affirmed on one side, and denied on the other. This is the ordinary plea upon which most causes are tried, and is now almost invariably used in all criminal cases, when the prisoner at the bar pleads "not guilty"; to money counts the plea is "never indebted"; or to actions on simple contract *nunquam assumpsit* ("never undertaken"). This plea puts everything in issue, that is, denies everything, and requires the party to prove all that he has stated. It is a frequent question, What can be given in evidence by the defendant upon this plea? and the difficulty is, to know when the matter of defense may be urged upon the general issue, or must be specially pleaded upon the record. See PLEA; PLEADING.

General Par'esis (known also as general paralysis, softening of the brain, paralytic dementia, paralysis of the insane, etc.), a disease of the nervous system that usually begins in early adult life, progresses steadily with increasing mental enfeeblement, and leads to ultimate motor paralysis, decay of all of the mental faculties, and death within a period averaging from three to five years. From the type indicated in this brief general definition there are numberless variations. It is a disease which, when well advanced, is recognized with great ease, but in its early stages it may be extremely difficult to know. From the standpoint of the patient's family and friends it is important to be able to recognize the disease; for it is in this initial period that the patient often ruins his business, his friends, his family, and brings shame and discomfort to all those connected with him. Much of this might be averted if the layman were better informed of this early period of one of the worst scourges of modern times. The disease has probably existed for many centuries, but it is only within comparatively recent times that its true character has been recognized, and in its present extreme forms it seems to be a product of the modern complex social system. It has been aptly termed a disease of civilization and *syphilization*, an alliteration that contains much truth. General paresis may develop in almost any one, but there are certain necessary antecedents and numerous contributory factors. It is believed by most students of mental diseases that syphilis is one of the most important antecedents. Accurate statistics on this point are extremely difficult to obtain, but most alienists believe that from 60 to 90 per cent of patients who have developed paresis have had syphilis. This as a purely statistical argument is of course no proof that syphilis is the cause of paresis; for probably 99 per cent of paretics have had measles, or whooping-cough; yet the changes that are found in the blood vessels of the brain in paretics are very closely allied to changes in the blood vessels known to result from the poison of syphilis. The theory of the syphilis etiology is, therefore, probably true for most cases, but not necessarily so. Another extremely important item is a characteristic mental type. In an extremely large number of paretics the mental character has been that of great emotional activity. People who use their brains very hard, and who can key them up to a high pitch, seem to succumb to this disease more than those of evener temperamental tone. It is this type, as seen in actors, in salesmen, in active business men, who become infected with syphilis, that is peculiarly liable to the disease. It is also this temperamental type that indulges in excesses of various kinds — excesses of work, of play, of excitement, of worry, of alcohol, of venery — and thus are undermined the foundations of healthy nerve-tissue, leading to its premature decay.

General paresis is commoner in men than in women, the proportion among different peoples and races, and times, varying from 25–1 to 3–1. Although it is a disease usually beginning in the thirties or forties, juvenile forms are known, and sometimes the old man is a victim. It seems to be more prevalent in crowded communities, for there the stress of excitement and depression, of gaiety and sadness, of extravagance and destitution, is more pronounced, for both extremes of the mental pendulum must be considered in the estimation of the causes of paresis. The brilliant financier, or the actress who succumbs to this disease may be more in the public eye, and moralists may adorn a tale concerning their supposed profligacy, but the poor harassed workman, diseased through lack of knowledge, and drink-sodden to escape the reproofs of his conscience, may also be the victim.

The initial symptoms are usually very insidious, although occasionally the disease appears in full-blown vigor. The previously healthy, neat, and careful workman begins to forget things. There is a period of disturbed mentality. Noises affect him unpleasantly. Undue irritability is evidenced by unwonted explosions of anger. This state may be weeks or months in its evolution, and may be confounded with a condition of overwork or overworry. In fact, such a condition is present in many tired people who never develop paresis. Added to this there are vague apprehensions in the patient's own mind of his gradually declining power; headaches, neuralgias, and vague pains may also be present; and poor sleep may be another symptom of the early stage. All of these symptoms are common to many people who have overworked, and should not occasion alarm. But when, little by little, one shows increasing carelessness in his personal habits, such as neglecting to button his trousers, or permitting his food to spill on his clothing, when he shows signs of mental exaltation and dreams of wonderful things, then the true disease begins to show itself. From this point on there are countless variations, but in general the typical paretic behavior that leads the person into economic danger, if not disaster, is characterized by an expansive and exaggerated conduct. Buoyancy and elation, with great projects and sanguine hopes, mark the initial stages of the paretic's mental decay. He becomes restlessly busy, is continually entering into new schemes, is incessantly talking about his affairs with effusive geniality, not only to his friends, but to utter strangers, and he even communicates to others his closest domestic concerns. There is a gradual breaking down of the finest sensibilities and, closely following this, slight evidences of the loss of the most delicate motor adjustments become manifest. It is in this stage that the symptoms become unmistakable. The partial impairment of the motor functions shows itself in an increased lack of control of the finer motions of the tongue, the lips, and the hands. There is a fine tremor in the tongue when it is protruded; on showing the teeth, the angles of the mouth betray a fine tremor; and the handwriting is seen to be less firm and even, approaching that of the formative period of the man's youth. The mild grade of inflammation in the brain causes certain changes in the reflexes of the body. Thus, the pupils of the eyes are not apt to act as rapidly as in health; they may be unequal in size; they are sometimes very small and do not open wide in the dark as is usual. With these symptoms the diagnosis becomes moderately certain, and from this time on the mental degeneration becomes marked. The carelessness becomes slovenliness; the memory goes rapidly; the loss of the finer sensibilities deepens to obscenity, to faithlessness, to utter loss of the moral faculties; the buoyancy becomes foolishness, and big projects are often launched, resulting in financial ruin. Grandiose ideas usually enlarge, and the afflicted one dreams of millions of money, of being a king, or president, or Christ, or a god. His personal strength is like that of Samson, his beauty comparable to Apollo's; his voice, his oratory, his writing, his poetry, his acting are superb — in short, his whole personality is puffed up with an amazing exaltation of the ego. Exulting self-confidence dominates all his designs, and a restless, busy, subdued delirium actuates his every thought and movement. From this stage, usually termed the grandiose stage, and which may persist for from six months to a year or more, the mental deterioration commences to show itself in a gradually progressive dementia. Mental dilapidation becomes mental decay. The motor restlessness goes on to loss of power and a gradual paralysis of the motor functions begins, passing through the stages of progressively increasing inco-ordination to complete powerlessness. Tottering, shambling, stumbling incompetence finally advances to absolute motor impotence. This affects all of the muscles of the body, but is appreciated in the speech more readily and earlier than in other motor acts. The loss of ability to repeat the r's and l's, as in "truly rural," "artillery," etc., is an early sign of this speech-defect. Finally the only answer that can be obtained from the patient is that he is "all right." The lack of motor power further manifests itself in the increasingly diminished control of handwriting. The paretic is unable to keep to a line. His writing goes up and down, letters and words are omitted, the up strokes are very wavy, and the letters become unequal in size.

Thus the course of the disease progresses until, in from two to three years, on the average, the paretic is a bedridden dement, who dies of exhaustion or an apoplectic or epileptiform convulsion. Occasionally remissions of the disease occur. These are particularly trying to most of the paretic's friends, for hopes of recovery receive a sudden stimulus only to be destroyed after a period of from six months to a year or so. Occasionally the remissions last a number of years, but at the present time it is believed that general paresis is a necessarily fatal disease. Alienists have a habit of calling the recovered cases pseudoparesis, a justifiable procedure in view of the many uncertainties attending the diagnosis of mental disorders.

The main features of a central type of the disease are here given, but there are countless variations. Acute maniacal states sometimes occur, and the patient dies in a galloping frenzy in from three to six months. Occasionally a paretic is melancholic or stuporous throughout. A small proportion, one half per cent of the cases, show this type. Occasionally — and many modern alienists believe this to be more common at present — a gradually progressive dementia without grandiose ideas marks the entire course of the disease. Most cases of paresis have apoplectiform or epileptiform attacks at some period of the disease. A few begin in this manner. There are countless numbers of mixed forms, the details of which may be consulted in text-books on insanity. Here also the subdivision of the disease into stages may be found.

Of the treatment little may be added. The most essential step in relation to this disease is its early recognition. To be able to know what is the matter before the patient has ruined his business, or his family and friends, is the most important feature for the layman to grasp. The paretic himself is doomed, but it is not necessary for those dependent on him to suffer irretrievable loss because of his disease. The proper course to pursue is to place the patient in a sanatorium or asylum at the earliest possible moment, the place selected depending largely on the means of his friends or relatives. Consult: Maudsley, 'Pathology of Mind' (1895); Chase, 'General Paresis' (1902); Krafft-Ebing, 'Die progressive allgemeine Paralyse' (1894); Starr, 'Organic Nervous Diseases' (1903); Ziehen, 'Psychiatrie' (2d ed. 1902); Kraepelin, 'Psychiatrie' (1900); 'Journal of Nervous and Mental Disease,' for bibliography and recent studies. See DEMENTIA; INSANITY.

SMITH ELY JELLIFFE, M. D.,
Editor 'Journal of Nervous and Mental Disease.'

General Service and Staff College, United States army, a training school for young officers of the United States army, located at Fort Leavenworth, Kan. Graduates from West Point are sent here for a further study of the profession of arms, and a more practical and theoretical training from the standpoint of the officer. Upon completing the course of study an officer returns to duty with his regiment. The course of study (1903) is one year, but, after the graduation of the class for 1904, will be extended to two years. At graduation the student class is divided into two classes, the "distinguished" class and the "proficient" class, the former becoming available for detail at the War College at Washington. The books to be used during the school year of 1903–4 are as follows: 'Horses,' 'Saddles and Bridles,' 'International Law,' 'Manual of Military Field Engineering,' 'Military Hygiene,' 'Military Law,' 'Military Topography and Sketching,' 'Organization and Tactics,' and 'Service of Security and Information.' See ARMY OF THE UNITED STATES; ARMY WAR COLLEGE.

General Sessions, Court of. See COURT.

General Staff of the Army, in the United States. History evinces that most competent and courageous commanders have at times charged failure of their operations to lack of preparation for which they were not responsible, or to ill-considered interference by those in high public office. Each successive war has developed accusations of shortcomings which though often indefinite, pointed in the main to defective organization and administration at the War Department. No two nations seem to favor identically the same methods of military administration, yet all have the same objects in view — correct organization, modern equipment, preparedness to strike the first blow with an assured and continuous supply of men, money, and war stores, during hostilities. During the early years of the United States the army was insignificant in proportions, but the business of the War Department gradually grew in volume until it was necessary to adopt some measures to save the secretary of war from being crushed by the burden of current routine work. In groping for some method which would relieve the secretary, the bureau system with numerous semi-independent chiefs was introduced. These bureaus were few in number at the beginning but gradually grew until at the commencement of war with Spain there were 10 chiefs of bureaus directly connected with the administration and supply of the army, each working along his own lines without of necessity having any knowledge of the character and extent of allied work going on in other bureaus. The army is absolutely dependent upon these administrative and supply bureaus and success depends upon the co-ordinated total of all their efforts. During a long course of years a system of laws and regulations had grown up for the governance of these bureaus. These bureaus have been controlled by many talented officers through whose honest and laborious efforts success has been made possible in the wars of the century just closed. It has gradually come to be the conviction of a large and increasing number of thoughtful and discerning officers and public men that success has been wrought in spite of the system and not altogether because of it. Chiefs of bureaus found themselves constantly hampered by reason of lack of information. Not by law but as a matter of expediency all looked to the adjutant general for information, but chiefs of bureaus claimed that the secretary of war alone was competent to give them orders or instructions.

Nations which depend upon volunteer armies are apt to ignore the lessons of war and to consider that all that goes wrong is chargeable to unusual conditions and not to lack of previous preparation. This lethargy would have supervened at the close of the brief war with Spain had not the insurrection in the Philippines and the occupation of Cuba commanded further attention to military matters. In all armies there are many important duties which by common usage have become designated as general staff duties. Much of the employment of general staff officers is in the nature of co-ordinating the action of others, but a large part is original work of the highest type. It was the lack of a corps of this kind which was always keenly felt in American army administration. It should be understood that general staff duties were not wholly neglected but their performance was spasmodic, uncertain and without fixed responsibility because executed by officers of other corps or of the line, detailed individually or as members of temporary boards.

After a patient and exhaustive study of the situation the secretary of war concluded that the more important duties of a general staff could be performed by a war college and its governing board. In furtherance of this idea a board of officers was convened to consider and recommend regulations for the establishment of an army war college. After mature study of the situation the board formulated a memorandum of an order for the execution of the project but unanimously recommended that a general staff be established by appropriate legislation which would free it from the uncertain tenure adhering to the war college which exists only by executive authority.

A continuing study of the manifold questions arising in the course of army administration brought prominently into view the never ending controversy as to the proper place of the "Commanding General of the Army" in the new scheme. The commanding general had long complained of loss of prerogatives believed to appertain to his office, while the generals commanding the geographical departments rebelled at being deprived of all initiative and being practically under the control of bureau chiefs, each naturally interested in enhancing the usefulness and dignity of his own bureau. The only solution which suggested itself as a practical and possible adjustment was the abolition of the office of "Commanding General of the Army" and the substitution of the office of "Chief of Staff," with the introduction of a new corps composed of trained officers to assist him. Out of these studies and efforts have come the law known as the General Staff Bill, which passed the Congress and was approved by the President 16 Feb. 1903.

Under this law the chief of staff, regardless of his relative rank, is the adviser and representative of the secretary of war, occupying a position between that official and the staff bureaus as well as the line of the army. Instead of 10 chiefs of bureaus and their numerous assistants having frequent interviews with the secretary concerning military affairs, the chief of staff has authority to adjust professional matters in the secretary's name. Conflicting elements of the larger administrative questions are thus brought together and harmonized without taking up the valuable time of the civilian secretary, who must of necessity acquaint himself concerning numerous technical details before undertaking to decide matters at issue. This is a decided improvement over the methods in vogue during the existence of the office of "Commanding General of the Army," for notwithstanding the title and high rank of the distinguished officers who have occupied that position, their influence and power over the army as a whole was so restricted as to be entirely incompatible with the title of their office.

It was not presumed in making so radical a change in the American military system that the general staff corps will be a panacea for all the misfortunes which may overtake a nation in war. History teaches that previous preparation and planning such as will be undertaken by the general staff will tend to render success more certain, abbreviate the period of actual hostilities and thereby effect an enormous saving of life and treasure. Commercial interests of all modern communities have become so enormous and widespread that a long-continued war means national paralysis to the defeated nation. Through the agency of the general staff, military and political policies may be harmonized as becomes a republican form of government. With the war policy determined, the general staff will be responsible that each part of the army line and staff is promptly acquainted with its duty and that it does its full duty in the premises. The preparation of armies and their equipment rests with the chief of staff and the various staff corps and departments. The responsibility for manœuvring the armies and for success in battle rests with the various generals assigned to command them. In past wars it has been the custom to depend upon Congress at the last moment to enact legislation for armies and grant appropriations at a time when, by reason of popular excitement, members are least able to give to the grave questions involved the consideration necessary.

The duties of the general staff consist, in peace, to a great extent, of bureau work — including the collection of information, preparation of maps, drawing up schemes for the organization and concentration of troops, formulation of plans for the national defense and a study of the higher military science to keep pace with modern progress. Bureaus organized and prepared to handle any particular class of army business will continue to initiate action and control its affairs subject to the supervision of the chief of staff. It is in the many important matters where the work of several bureaus must be harmonized and brought into the same channel, that the general staff will find its greatest field of usefulness. The general staff will be acquainted with contemplated changes in the organization and stations of troops and by preparing timely schemes will ensure arrangements being made for transportation and supply in the most expeditious and economical manner. The arrangement of all these interlocking details is necessary to successful campaigns of any duration. Armies are constantly called upon to endure all kinds of hardships, to which they submit cheerfully so long as there is no suspicion that any one is at fault. It is expected that the American general staff will plan to minimize the chances of failure due generally to lack of previous knowledge and preparation. The statute contemplates that the general staff corps shall be composed of officers detailed for periods of four years, and it is necessary that a sufficient number be maintained on duty to furnish details with troops as well as for bureau work. This ensures a body of officers in touch and sympathy with the fighting portion of the army. The general staff corps has been so recently organized that it will require some time to develop methods of operation, but as the soldierly spirit, informed by experience derived from actual service with troops, will be the guiding impulse of this corps, the expectation that the country will be better prepared for campaigning at the outbreak of the next war than it has ever been in the past, is fully justified. See ARMY OF THE UNITED STATES.

W. H. CARTER,
Brigadier-General, Assistant Chief of Staff.

General Theological Seminary, a seminary of the Protestant Episcopal Church in the United States, established in 1817. Instruction was begun in New York city in 1819, but in 1820 the seminary was removed to New Haven. It was again re-established in New York in 1822. The gifts of Dean Hoffman to the school amounted to over $1,000,000, while in 1902 the total resources of the school were over $4,000,000. The theological course of the school extends over a period of three years, and there is a post-graduate course. The degrees of D.D. and B.D. are conferred. The control of the seminary is vested in a board of trustees composed of the bishops of the Church, 25 members elected by the general convention and certain other members elected by various dioceses. There are about 150 students in regular attendance.

Genera'tion, popularly used as a measure of time, and usually represents about 30 years, the period which man requires to attain maturity, and the age at which, as a general rule, fruitful marriages are contracted. This secondary sense of the term is thus indirectly derived from the primitive meaning, which has reference to the origin of living things. In the higher animals and plants the offspring is due to the congress of distinct individuals or elements. (See REPRODUCTION.) Alongside of this process, sometimes even concurrently with it, new forms may arise by fission, or by budding; by a process akin to the latter, as in the parthenogenesis of bees, etc.; or by a combination of the sexual and asexual processes, alternate generation.

Generation, Spontaneous. See SPONTANEOUS GENERATION.

Gen'erator, (1) An apparatus for generating carbonic acid gas for charging soda-fountains or bottles with aërated water. (2) In chemistry, a term used to denote the elements or compounds from which a more complex substance is obtained. Thus ethyl, alcohol, and acetic acid are the generators of acetic ether; and benzoic acid and glycocoll are the generators of hippuric acid. (3) In distilling, a retort in which volatile hydrocarbons are distilled from liquid or solid matters. (4) In electricity, a dynamo-electric machine (q.v.). (5) In steam, a vessel in which steam is generated from water, for use in a steam-engine, a heating apparatus, etc. The term was first applied to the Perkins steam boiler, in which water in small quantity was heated to a high temperature. It is now specifically applied to a class of instantaneous generators. The name is now rapidly coming into use for all apparatus for generating steam, being held to be more correct than the usual term. See STEAM.

Genesee (jĕn-ĕ-sē') River, a remarkable stream rising in Pennsylvania, and flowing nearly 200 miles north through western New York into Lake Ontario, seven miles north of Rochester. The Genesee is famous for its extraordinary falls. Three of these occur within a distance of 1½ miles, two are respectively 68 and 90 feet high, and the Portage Falls are 110 feet high. The river has also a sheer fall of 95 feet at Rochester, utilized for water-power; and another cascade, a few miles below, is almost as high.

Geneseo, N. Y., a village and county-seat of Livingston County, 30 miles from Rochester, on the Genesee River and the Erie R.R. The State Normal School and Wadsworth Public Library are situated here. It is an agricultural town and manufactures gloves, mittens, flour, and machines. Pop. (1900) 2,400.

Gen'esis (Greek), creation, birth, origin. The first book of the Pentateuch is named in the Hebrew canon *B'reshith* (in the beginning), from the expression with which it commences; from the 70 translators of Alexandria (those who produced the Greek version known as the Septuagint) it received the name it is now commonly known by. Genesis consists of two great but closely connected divisions: (1) The history of creation, the fall of man, the flood, the dispersion of the human race, chap. i–xi. (2) The history of Abraham, Isaac, Jacob, and Joseph, including notices of the descendants of Abraham and Isaac in their collateral lines, chap. xii.–l. It would be entirely to mistake the character of the history of Genesis to view it as having other than a sacred purpose; yet even in a secular point of view there is no record that can be brought into competition with it. There is absolutely nothing in the whole range of ancient literature which could supply its place if this document were lost; while it is further to be observed, that if confidence cannot be placed in its authenticity, no reliable information exists on many subjects with which it is desirable man should be acquainted, and after which there is an intense longing in the human mind; as, for instance, the origin and early history of the race, a subject which, without the information supplied by Genesis, must be involved in impenetrable darkness.

Genêt, or Genest, Edmond Charles Edouard, ĕd-môṅ shärl ā-doo-är zhĕ-nā, French diplomat: b. Versailles, France, 8 Jan. 1765; d. Schodack, N. Y., 14 July, 1834. In 1777 he translated into French a Swedish history of King Eric XIV. of Sweden, in 1789–92, was French *chargé d'affaires* at St. Petersburg, and from 1793–4, when he was recalled at Washington's request because of attempts to compel the United States to a war with England, was French minister to the United States.

Genet, jĕ-nĕt', a civet (q.v.) of the genus *Genetta;* also a trade-name for the fur of this animal, or of some other fur like it. The best known is the common genet *(G. vulgaris)*, of the Mediterranean region, called «berbe» in the south of France. It is a very beautiful and graceful animal, gray, with many dark patches, and a full furry tail, banded with black and white. The size is about that of a house-cat. Their fur is made up into tippets, muffs, etc., but is of no great value, and often domestic cat-skins are substituted under the same name.

Genet'ic Psychology, the science of the mind as dealing through observation, and where possible, through experiment with the growth and development of consciousness or intelligence in dumb animals, children, and adult human beings. It is one branch of that experimental psychology which the German philosopher Lotze was the first to inaugurate.

Gene'va, Ill., a city and county-seat of Kane County, about 33 miles from Chicago, on the Chicago, B. & Q., and Chicago & N. R.R.'s. It was settled in 1832 and was incorporated as a city in 1887. It is a popular residential section for Chicago merchants. The manufactures include windmills, glucose, sadirons, flour, and boxes. The city owns and operates its own electric-light plant and water supply. Pop. (1900) 2,446.

Geneva, Neb., a city and county-seat of Fillmore County, 60 miles west of Lincoln, on the Burlington & M. R. R.R. The State Industrial School for Girls is located here. Pop. (1900) 1,534.

Geneva, N. Y., city in Ontario County, on Seneca Lake and the Seneca and Cayuga Canal; and on the Lehigh Valley and the New York Central R.R.'s; 50 miles southeast of Rochester. Geneva has extensive manufactories of stoves, steam boilers, optical goods, cereals, canned goods, etc. There are also large nurseries and greenhouses here, occupying about 10,000 acres of land. The city is the seat of Hobart College, established in 1822 by the Protestant Episcopal denomination. The Delancey Divinity School, the Delancey School for Girls, and the State Agricultural Experiment Station are located here. Geneva was chartered as a city in 1898 and is governed by a mayor, elected every two years, and a unicameral council. The city owns and operates the waterworks. The assessed property valuation is $6,000,000. The population in 1890 was 7,557 and in 1903 11,228. In the 18th century the Indian village of Kanadesoga was located near the present site of Geneva. General James Clinton attacked and destroyed the village in 1779.

Geneva, Switzerland, a canton, bounded on the north by the canton of Vaud and the Lake of Geneva, and on the east, west, and south by the territories of France. In addition to the territory thus bounded, the communes of Celigny, Le Coudre, and Petit Bois, enclosed by Vaud, belonged to this canton, which is one of the smallest in the Swiss Confederation, the area being only 108 square miles. The whole canton belongs to the basin of the Rhône, and the only streams of importance are that river and the Arve, which joins it a little below the town of Geneva, the capital of the canton. The territory of Geneva having, by the arrangements of the Congress of Vienna, obtained an accession of 15 communes, detached from France and Savoy, was admitted a member of the Swiss Confederation in 1814, and ranks as the 22d canton. A constitution, somewhat aristocratical in its nature, was framed, and continued in force till 1830, when a considerable modification of it took place. In 1841, in consequence of a popular tumult, the original constitution was abandoned for one in which the democratic principle is completely predominant. This new constitution was modified under popular pressure in 1847. All religious denominations are declared to have perfect freedom, but two of them are paid by the state — the Roman Catholics, amounting to rather more than a third of the population, and the Protestant National Church. The language spoken is French. Pop. (1900) 131,674.

Geneva, Switzerland, the capital of the canton of the same name; at the western extremity of the Lake of Geneva, where the Rhône issues, here crossed by several bridges, and dividing the town into two portions. The more important public buildings are the Cathedral or Church of St. Pierre, a Gothic structure of the 10th, 11th, and 12th centuries; the town-house in the Florentine style; the Musée Rath, containing a collection of pictures, etc.; the university building, nearly opposite the botanic garden, rebuilt in 1867–71, and containing the public library, founded by Bonivard in 1551, and now numbering over 90,000 volumes; and the Museum of Natural History. In literature and science Geneva has long occupied a distinguished place, and it has been the birthplace or the residence of many eminent men, including Calvin, Beza, Knox, Le Sage, Necker, De Candolle, Rousseau, Sismondi, etc. Geneva early adopted the principles of the Reformation, and chiefly through the teaching of Calvin the town acquired an important influence over the spiritual life of Europe, and became the centre of education for the Protestant youth of Great Britain, France, and Germany. Pop. (1901) commune, 105,139, including suburbs.

Geneva Arbitration, or **Geneva Award,** the settlement of the Alabama claims by five arbitrators, appointed by the President of the United States, the queen of Great Britain, the king of Italy, the president of the Swiss Confederation, and the emperor of Brazil. These rulers, in the above order, named as arbitrators Charles Francis Adams, Lord Chief Justice Sir Alexander Cockburn, Count Federigo Selopis, Mr. Jacques Staempfli, and Baron Itajuba. J. C. Bancroft Davis, and Lord Tenterden, respectively, represented as agents the United States and Great Britain. The tribunal met at Geneva, Switzerland, 15 Dec. 1871, and Count Selopis was made president. The United States claimed damages both for direct and for indirect losses, and for injuries occasioned by 13 vessels. The tribunal decided to allow only direct losses caused by the Florida and the Alabama, with their tenders, and by the Shenandoah during part of her cruise. Various rules of international law were laid down which supported most of the contentions of our government. On 14 Sept. 1872, the tribunal "awarded to the United States a sum of $15,500,000 in gold as the indemnity to be paid by Great Britain to the United States as the satisfaction of all the claims referred to the consideration of the tribunal." The English representative cast the only dissenting vote, but Great Britain accepted the decision and paid the award within a year.

Geneva Bible, a translation of the Bible into English, made and published at Geneva, chiefly by English Protestant refugees. It was the first English Bible which adopted the Roman instead of the obsolescent black type, and the first which recognized the division into verses; it was the first also which omitted the Apocrypha. From its stating (Genesis iii. 7) that our first parents made themselves "breeches," it is sometimes called the Breeches Bible. See BIBLE.

Geneva College, Pa., a coeducational institution in Beaver Falls, founded in 1848 under the auspices of the Reformed Presbyterian Church; reported at the end of 1900: Professors and instructors, 15; students, 206; volumes in the library, 4,500; productive funds, $114,000; grounds and buildings valued at $175,000; income, $11,000; president, W. P. Johnston, A.M., D.D.

Geneva Convention (1864 and 1868), international agreements for mitigating the sufferings of war. The first was initiated by the efforts of two Genevans: a physician named Dunant, who wrote a sickening description of the military hospitals at the battle of Solferino; and a public-spirited citizen named Moynier, who formed societies in various places to urge the neutralization of field ambulances, and called the attention of European governments to it. The majority of these sent representatives to an international conference held at Geneva under the presidency of Gen. William Henry Dufour, the eminent Swiss soldier and statesman. The agreement adopted was signed 22 August; all the European states have since joined in it, and Persia has acceded. The articles are in substance: (1) Ambulances and military hospitals shall be inviolable while containing sick or wounded; (2) so shall their staff; (3) whether they are occupied by the enemy or not; (4) if the attendants choose to leave the hospitals, they can only take their private property, not the relief appliances, except ambulances and their contents; (5) a house with a sick or wounded soldier shall be neutral and not subject to have soldiers quartered in it, or to requisitions with specified exceptions; (6) the convalesced shall be sent back to their own country under parole for the remainder of the war; (7) hospitals and ambulances, to claim these rights, must carry a uniform flag with a red cross on a white ground as well as their national flag, and the staff must wear a like badge on their arms; (8) special arrangements to be made by the commanders. In 1868 a second convention at Geneva adopted a supplementary convention, to extend the principles of the first to naval warfare, and amplify the first. It provided on the latter point that the medical and surgical staff should receive their regular pay if they remained after occupation by the enemy, and if they left should do so at a time fixed by the commander; that military requisitions should be modified according to the expenditures of the given places in harboring the wounded, and to charities extended toward them; that the paroling home of convalesced soldiers shall not include officers, as they could make their knowledge very serviceable without serving in the field. The marine rules were, that hospital ships, merchant vessels with wounded on board, and boats rescuing men in the water, shall be inviolable, on consideration of carrying their red-cross flag and their crews wearing the red-cross arm badge, that government hospital ships shall be painted white with a green stripe, and private societies white with a red stripe; and that whenever one party in a naval war has sound reason to believe the other is abusing the convention, the first may suspend it till the other proves its honesty, and if proof is not given, may suspend it for the duration of the war. See RED CROSS SOCIETY; WAR.

Geneva, Lake of, or **Lake Leman** (Latin, *Lacus Lemanus*), the largest of the Swiss lakes, extending in the form of a crescent, with its horns pointing south, between France and the cantons of Geneva, Vaud, and Valais; length, 55 miles; central breadth, about 6 miles; area, 331

GENEVA, SHOWING MT. BLANC.

square miles; greatest depth, 900 feet. It is 1,150 feet above the sea. On the north the shore is low, and the ground behind ascends gradually in beautiful slopes. On the south, and particularly at the east end, the shore is rocky and abrupt, and lofty precipices often rise sheer from the water's edge. It contains various species of fish. The water is remarkably pure and of a beautiful blue color. The Rhône, which enters the eastern extremity, a muddy, turbid stream, issues from the western extremity perfectly pellucid, and likewise of the finest blue.

Geneva, University of, a Swiss university founded in 1559, as the Academy of Geneva, and called a university only since 1873. It has 1,100 students, mostly from abroad, and the principal studies are medicine and philosophy. Women have of recent years been admitted on the same conditions as men. It is the European centre of French Protestant culture and influence.

Geneviève, zhĕn-vē-āv, **Saint,** the patron saint of Paris: b. near Nanterre, Paris, 423; d. Paris 3 Jan. 512. When yet very young she took a vow of perpetual virginity and subsequently she went to Paris. The city was about to be deserted when Attila with his Huns broke into France; but Geneviève assured the inhabitants of complete security if they would seek it in fervent prayers. Attila took his course from Champagne to Orleans, returned hence into Champagne without touching Paris, and was defeated in 451. By this event Geneviève's reputation was established. In a time of famine she went along the river Seine from city to city, and soon returned with 12 large vessels loaded with grain, which she distributed gratuitously among the sufferers. Her remains were placed in the subterranean chapel which Saint Denis had consecrated to the apostles Paul and Peter. Clovis by her request built a church over it, which was afterward called by her name, as was also the abbey founded there. Another church, consecrated to this saint, was built near the church of Notre Dame. By a decree of the National Convention, 1791, this edifice was named the Pantheon, but its original name was restored officially in 1851. Her relics, which were preserved in the former till its destruction at the Revolution, are now in the church of Saint Etienne du Mont. Her fête is held on 3 January.

Geneviève, Saint, Duchess of Brabant, wife of Siegfried, count palatine in the reign of Charles Martel (about 750). Being accused by her intendant Golo of adultery during her husband's absence, on his return she was condemned to death; but the vassal to whom her execution was entrusted allowed her to escape, and she lived six years in a cavern upon nothing but herbs. She was finally found, and carried home by her husband, who in the meantime had become convinced of her innocence. This legend is the subject of one of the finest and most perfect of the German popular tales, which appears to have been written by Emmich about 1472. The story has been retold by Tieck and Maler Müller, and dramatized by Raupach.

Genga, Girolamo, jē-rō'lā-mō jĕn'gä, Italian painter and architect: b. Urbino 1476; d. 1551. He was for many years a pupil of Luca Signorelli, whom he assisted in numerous pictures, and also of Perugino; painted a 'Resurrection' in the Church of Saint Catharine of Siena at Rome; and found a generous patron in the Duke Francesco Maria of Urbino, who finally appointed him court-architect. Among his architectural works were the church of St. John the Baptist at Pesaro, the restoration of the palace courtyard there, and the bishop's palace of Sinigaglia. With the versatility of the Renaissance, he wrote on the fine arts, and was a musician and sculptor.

Genghis Khan, jĕn'gĭs khăn, or **Jenghis Khan,** Mongol conqueror: b. near the Onon River, Mongolia, 1162; d. 18 Aug. 1227. His father was chief over 30 or 40 clans, but paid tribute to the Tartar Khan. He succeeded his father when only 14 years of age, and made himself master of the neighboring tribes. A great number of tribes now combined their forces against him. But he found a powerful protector in the great Khan of the Karaite Mongols, Oung, or Ung, who gave him his daughter in marriage. After much intestine warfare with various Tartar tribes Genghis was proclaimed Khan of the United Mongol and Tartar tribes.

He now professed to have a divine call to conquer the world, and the idea so animated the spirit of his soldiers that they were easily led on to new wars. The country of the Uigurs, in the centre of Tartary, was easily subdued, and Genghis Khan was now master of the greatest part of Tartary. In 1209 he passed the great wall of China, the conquest of which country occupied him more than six years; the capital, Yenking, now Peking, was taken by storm in 1215 and plundered. The murder of the ambassadors whom Genghis Khan had sent to the king of Kharism (now Khiva) occasioned the invasion of Turkestan in 1218 with an army of 700,000 men; and the two cities of Bokhara and Samarcand were stormed, pillaged, and burned. Seven years in succession was the conqueror busy in the work of destruction, pillage, and subjugation, and extended his ravages to the banks of the Dnieper. In 1225, though more than 60 years old, he marched in person at the head of his whole army against the king of Tangut (southwestern China), who had given shelter to two of his enemies. A great battle was fought, in which the king of Tangut was totally defeated with the loss of 300,000 men. The victor remained some time in his newly subdued provinces, from which he also sent two of his sons to complete the conquest of northern China. At his death in Mongolia, his immense dominions were divided among his four sons. A great part of the empire, however, came into the hands of Kublai, who is considered as the founder of the Mongol dynasty in China. The only memorial of the conqueror now known to exist is a granite tablet discovered among the ruins of Nertschinsk. The inscription in Mongol has been deciphered by Schmidt of Saint Petersburg. It had been erected by Genghis Khan in commemoration of his conquest of the kingdom of Saratogal (better known as Karakitai).

Genii, jē'nĭ-ī, among the ancient Romans, were protecting spirits, who were supposed to accompany every created thing from its origin to its final decay, like a second spiritual self. They belonged not only to men, but all things animate and inanimate, and more especially to places, and were regarded as effluences of the divinity, and worshipped with divine honors. Not only had every individual his genius, but likewise the whole people. The statue of the national genius was placed in the vicinity of the Roman forum, and is often seen on the coins of Hadrian and Trajan. The genius of an individual was represented by the Romans as a figure in a toga, having the head veiled, and the cornucopia or patera in the hands; while local genii appear under the figure of serpents eating fruit set before them. Quite different are the genii whose Arabic name, *Djinn* or *Jinn*, was translated by the Latin term *genius*, for want of a better word, or from the casual similarity of the sounds. See FAMILIAR SPIRITS.

Genista, jē-nis'ta, a genus of low, branching sometimes spiny shrubs, belonging to the pea family, with simple leaves and yellow flowers. There are about 80 species, a few of which are cultivated for ornament. See BROOM; DYEWEED.

Genius, in Roman mythology, a tutelary deity. See GENII.

Genlis, Stéphanie Félicité Ducrest de St. Aubin, stā-fā-nē fā-lēs-ē-tā dü-krā dė sāṅ ō bāṅ zhōṅ-lēs, COMTESSE DE, French writer: b. Champcéri, Burgundy, 25 Jan. 1746; d. Paris 31 Dec. 1830. At the age of 16 she was married to the Comte de Genlis, and in 1770 was made lady-in-waiting to the Duchesse de Chartres. In 1782 the Duc de Chartres, afterward known as Egalité, appointed her "governor" of his children, including Louis-Philippe. She wrote a variety of works for her pupils, among others: 'Theatre of Education' (1779–80), a collection of short comedies; 'Annals of Virtue' (1781); 'Adèle and Theodore, or Letters on Education' (1782); 'The Vigils of the Château' (1784). On the breaking out of the Revolution she took the liberal side, but was ultimately compelled to seek refuge (1793) in Switzerland and Germany. When Bonaparte became consul she returned (1799) to Paris and received from him a pension. Her writings fill some 90 volumes. Among them are: 'Précis de la Conduite de Madame de Genlis' (1795); 'Chevaliers du Cygne' (1795); 'Madame de la Vallière'; the romance, 'Mademoiselle de Clermont' (1802); 'Memoirs' (1825); 'Baron d'Holbach's Dinners.' The last contains a great deal of curious but malicious information concerning the freethinkers of the 18th century.

Gennesaret, jě-něs'a-rět, **Lake** or **Sea**. See GALILEE, SEA OF.

Genoa, jěn'ō-a (ancient GENUA), Italy, a fortified city, situated on the Gulf of Genoa, at the foot of the Apennines, the capital of the province and the most important seaport. While worthy of its title, "Genoa the Superb," as viewed from the sea, it is in reality built awkwardly on irregular rising ground, and consists of a labyrinth of narrow and intricate streets. Of the palaces the most famous are the ducal palace formerly inhabited by the doges, now appropriated to the meetings of the senate; and the Doria, presented in 1529 to the great Genoese citizen Andrea Doria, whose residence it was during his presidency of the republic. The palaces Brignole-Sale, Reale, Durazzo-Pallavicini, Spinola, Balbi-Senarega, and others possess great interest on account of their historical fame and architectural beauty. Many of them contain galleries of paintings: the Brignole-Sale has works by Van Dyck, Rubens, Albrecht Dürer, Paolo Veronese, Guercino, etc. Among the churches are the Cathedral of St. Lorenzo, in the Italian Gothic style; the Church of St. Ambrogio (1589), containing pictures by Guido Reni and Rubens. The marble municipal palace, built in the Late Renaissance style, with a magnificent vestibule, courtyard, and galleries, and the palace of the Dogana must also be mentioned. Genoa has a university, founded in 1243, a library of 116,000 volumes; also numerous technical schools, and institutions of higher education. The hospital, the asylum for the poor (capacity 2,200), the deaf and dumb institution, and the hospital for the insane are among the finest institutions of their kind in Italy. There are numerous excellent philanthropic foundations, as the Fieschi, an asylum for female orphans. The public library contains 50,000 volumes; and there are the Academy of Fine Arts, founded (1751) by the Doria family; the Carlo Felice Theatre, one of the finest in Italy; and the Verdi Institute of Music. Genoa is the commercial outlet of a wide extent of country, of which the chief exports are rice, wine, olive oil, silk goods, coral, paper, macaroni, and marble. The imports are principally raw cotton, wheat, sugar, coal, hides, coffee, raw wool, fish, petroleum, iron, machinery, and cotton and woolen textiles. The annual exports of Genoa are valued at nearly $20,000,000, the imports are returned at more than $75,000,000. Pop. (1901) 234,800.

The history of Genoa may be traced back in legendary traditions to a time preceding the foundation of Rome. It was one of the most considerable cities of the Ligurians, and is mentioned by Livy (under the name of Genua) as being in friendly relations with Rome at the beginning of the second Punic war. It was subdued and partly destroyed during that war by a Carthaginian fleet under the command of Mago. The Romans rebuilt it, and it afterward became a Roman municipium. After the decline of the Roman empire in the West it fell into the hands of the Lombards, and with them became subject to the Franks. After the downfall of the empire of Charlemagne, Genoa erected itself into a republic, and till the 11th century shared the fortunes of the cities of Lombardy.

If Genoa had adopted a wise colonial system she would have held the first rank among the commercial nations at the end of the Middle Ages. After the conquest of Constantinople by Mohammed II. in 1453, the Genoese soon suffered for the aid they had imprudently afforded the Turks. Mohammed took from them their settlements on the Black Sea in 1475, and at length all access to this branch of trade was denied them by the Turks.

While the power and commercial rank of Genoa were attaining their height by means of their foreign trade and acquisitions of territory the city was internally convulsed by civil discord and party spirit. The hostility of the democrats and aristocrats and the different parties among the latter occasioned continual disorders. In 1339 a chief magistrate, the doge, was elected for life by the people, but he had not sufficient influence to reconcile the contending parties. A council was appointed to aid him; yet after all attempts to restore order to the state, there was no internal tranquillity; indeed, the city sometimes submitted to a foreign yoke in order to get rid of the disastrous anarchy which the conflict of parties produced.

In 1528 the disturbed state regained tranquillity and order which lasted till the end of the 18th century. The form of government established was a strict aristocracy. The doge was elected to be the head of the state. The nobility were divided into two classes — the old and new. To the old belonged, besides the families of Grimaldi, Fieschi, Doria, Spinola, 24 others who stood nearest them in age, wealth, and consequence. The new nobility comprised 437 families. The doge might be taken from the old or new nobles.

Little by little Genoa lost all her foreign possessions. Corsica, the last of all, revolted in 1730 and was ceded in 1768 to France. When the neighboring countries submitted to the French in 1797 the neutrality which the republic had strictly observed did not save the fluctuating government from ruin. Bonaparte gave to them a new constitution formed on the principles of the French representative system. Two years afterward a portion of the Genoese territory fell into the hands of the Austrians; but the fate of Genoa was decided by the battle of Marengo. A provisional government was established, and in 1802 it received a new constitution as the Ligurian republic and acquired some increase of territory, and had in 1804 a population exceeding 600,000. Its naval force, which was so formidable in the Middle Ages, at last dwindled down to a few galleys and barques; the land force became almost equally insignificant.

On the overthrow of the French empire Genoa was occupied by the British, with whose permission the ancient constitution was re-established. But the Congress of Vienna in 1815 assigned Genoa with its territories to Sardinia, stipulating that it should have a sort of representative constitution. In 1821 it joined for a moment the revolutionary movements of Italy. In the spring of 1849, after the defeat of Charles Albert at Novara and the conclusion of a truce with the Austrians, a revolutionary outbreak took place, the national guards occupied the forts, and the garrison was compelled to withdraw. A provisional government was formed and the independence of the republic was proclaimed. But a large body of Sardinian troops under Gen. Della Marmora, soon appeared before the city; a bloody struggle ensued and the forts and principal points of the city were taken by the royal soldiery. Meanwhile a deputation was sent to Turin, which returned with the amnesty of the king, excluding the chief leaders of the movement, who, however, escaped on board an American vessel. In April the city was disarmed and the monarchical government restored. Following the fortunes of the Sardinian states, Genoa became a portion of the kingdom of Italy. Pop. (1901) 234,710.

Genoa, Gulf of, a large indentation in the north shore of the Mediterranean, north of Corsica, having between the towns of Oneglia and Spezia a width of nearly 90 miles.

Genre (zhŏn-r) **Painting**, in art, from the French *genre* (sort or kind), which was originally employed to designate pictures of which the subjects were copied directly from nature, such as landscapes, scenes of every-day life, animals, fruit, and even portraits; in contradistinction to those which were more the product of the imagination, such as historical, religious, and purely ideal paintings. The term is now restricted to denote scenes of every-day life, such as Hogarth and Wilkie loved to depict. A genre painter is not confined to low subjects, nor need his paintings be vulgar in the ordinary acceptation of the word, though the great modern masters in this style, the Dutch, have owed their inspiration and fame to scenes of very humble and often coarse life. This style of painting was not unknown to the ancients. Pyreicus, a Greek painter of the time of Alexander the Great, painted barbers' shops, cobblers' stalls, and the like, and according to Pliny, his pictures were highly prized. In Italy the painters who have worked in this style are Caravaggio, Manfredi, Salvator Rosa, Benedetto Castiglione, etc. But the art received its highest development in the Netherlands; Teniers the younger, Jan Van Mill, D. Ryckaest, Rembrandt, Nicolas Maas, Gerard Dow, Jan Steen, the Van Ostades, Brauwer and Bega, are among the best exponents of the style. In Spain the most notable genre painters are Velasquez and Murillo; and in Great Britain, after Hogarth and Wilkie, already mentioned, come Leslie, Mulready, Maclise, Egg, Millais, Faed, and others. The British school has sought to lend a dignity to the style by the introduction of the dramatic element. See Painting.

Genseric, jĕn'sėr-ĭk, king of the Vandals: d. 477 A.D. Under Genseric the Vandals first became formidable at sea, and gained possession of parts of the islands of Sicily, Sardinia, and Corsica. In 455, on the invitation of the Empress Eudoxia, Valentinian's widow, who sought his assistance against Maximus, he landed at Ostia and marched to Rome, which he stormed and gave up to pillage for 14 days. On his departure he carried off the empress herself and her two daughters, one of whom he married to his son Hunnerich.

Gen'tian, the dried rhizome and root of *Gentiana lutea*. This is the yellow gentian of Europe, a tall mountain perennial, growing abundantly in southern and middle Europe and Asia Minor. The chief source of supply to the drug market is collected from Switzerland, southern France, and the hilly portions of Germany. The main constituent of the root is a bitter glycoside, gentiopicrin. It also contains sugar, gums, and salts. The action of gentian is that of a simple bitter and it is used to improve the appetite and thus secondarily affect the general constitution.

Gentile, Da Fabriano. See Fabriano, Gentile da.

Gen'tiles, in Scripture, all the nations of the world, excepting the Jews. In modern usage all the nations excepting Jews and Mormons. In the Old Testament it is the rendering of the Hebrew word *goim*, peoples, nations, the plural of *goi*, a nation, a people. At first it was used as a mere ethnological word, and quite respectfully, but as the Jews became more conscious of their privileges they employed it more and more scornfully of the nations around (Gen. x. 5; Isa. lxvi. 19; Jer. xiv. 22). In the New Testament Gentiles is the rendering of the Greek *ethne*, the plural of *ethnos*, a number of people living together, a nation. St. Peter, moved by a vision, was the first of the Twelve to preach to the Gentiles (Acts x.), but the Apostle of the Gentiles was Saint Paul (Gal. ii. 15).

Gentry, Meredith Poindexter, American politician: b. Rockingham County, N. C., 1809; d. 1866. In 1839 he was elected to Congress as a Whig, and he was also a representative from Tennessee in 1841–3, 1845–7, and 1847–53. In 1862 and 1863 he was a member of the Confederate Congress. He was a student of political history and well known as a speaker both in and out of Congress, a eulogy of Henry Clay being among his noteworthy public utterances.

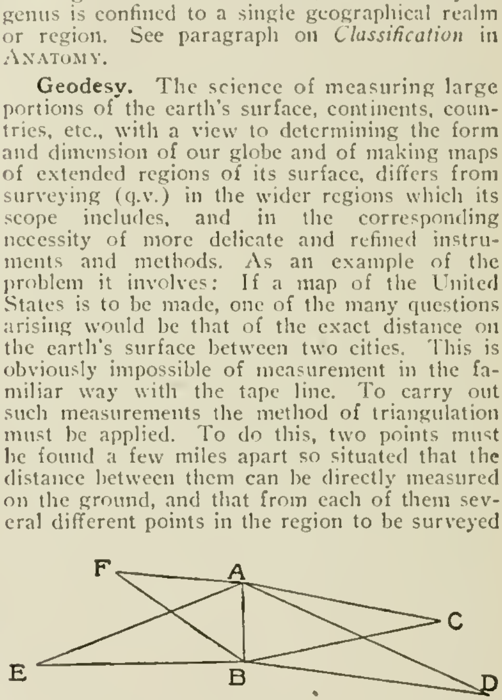
Gentz, Wilhelm Karl, vĭl'hĕlm kärl gĕnts, German painter: b. Neuruppin, Brandenburg, 9 Dec. 1822; d. Berlin 23 Aug. 1890. He traveled in Spain, Morocco, and Egypt, depicted Oriental civilization and the life of the desert with increasing insight and success, and at first turned his attention to the rendering of biblical scenes in the spirit of the actual East. Of the works of this period are: 'Christ in the House of Simon'; 'Christ among the Pharisees and Publicans.' Despite the skill with which he rendered the brilliant light effects peculiar to those regions, his work was slow in making its way. Ultimately, however, he was ranked not at all inferior to the most distinguished French colorists. He was a professor in the Berlin Academy, from 1877 a member of the Senate; and obtained the great medals of Berlin (1866), Vienna (1873), and Munich (1876). In 1873 he visited Palestine to make local studies for his greatest achievement, 'Entry of the German Crown Prince into Jerusalem, 1869,' which was completed in 1876 and hung in the National Gallery of Berlin. Other of his canvases are: 'Mecca Caravan at Prayer'; 'Meeting of Two Caravans in the Desert'; 'Evening on the Nile'; 'Funeral Celebration at Cairo'; 'Serpent Charmer'; 'Alley of Sphinxes in the Thebaid'; 'Bazaar in Algiers'; 'Palm Sunday in Early Christian Times.' He published 'Briefe aus Aegypten und Nubien' (1853).

Genuflection, jĕn-ū-flĕk'shŏn, the act of bending the knee in reverence or adoration. In the Roman Catholic Church the members genuflect when passing before the tabernacle where the Blessed Sacrament is reserved. If the Blessed Sacrament is exposed a double genuflection (on both knees) is usual. Genuflection is used at various times during the church services. The early Christians prayed standing on Sundays, and from Easter till Pentecost, and only bent the knee in sign of penance; hence a class of penitents were known as *Genuflectents.* In the rubrics of the Anglican Church double genuflection, or kneeling, is enjoined in some parts of the service.

Genung, John Franklin, American clergyman and scholar: b. Wilseyville, N. Y., 27 Jan. 1850. He was graduated from Union College in 1870, from the Rochester Theological Seminary in 1875, and from the University of Leipsic, Germany, in 1881; was for a time active in the ministry of the Baptist Church, and later was appointed professor of rhetoric in Amherst College. His publications number: 'Tennyson's In Memoriam: Its Purpose and Structure' (1883); 'Practical Elements of Rhetoric' (1886); 'Hand-Book of Rhetorical Analysis' (1888); 'The Epic of the Inner Life,' a new translation, with annotations, of the Book of Job (1891); 'Outlines of Rhetoric' (1893); 'The Working Elements of Rhetoric' (1902).

Genus, jē'nŭs, in zoology and botany, a systematic term applied to any group of species (q.v.) lower in rank than a tribe, sub-family, or family. A genus may be composed of a single, several, or many species. Genera usually differ from species in structural details, while species differ in size or color, or in the structure of some special organ or portion of the body. It is, however, often difficult to draw the line between genera and species. As an example of a genus may be cited *Equus*, or the horse genus, represented by *Equus caballus*, the domestic horse; *Equus asinus*, the ass; *Equus zebra*, the zebra, etc. A genus may be represented by species inhabiting different continents, but usually a genus is confined to a single geographical realm or region. See paragraph on *Classification* in ANATOMY.

Geodesy. The science of measuring large portions of the earth's surface, continents, countries, etc., with a view to determining the form and dimension of our globe and of making maps of extended regions of its surface, differs from surveying (q.v.) in the wider regions which its scope includes, and in the corresponding necessity of more delicate and refined instruments and methods. As an example of the problem it involves: If a map of the United States is to be made, one of the many questions arising would be that of the exact distance on the earth's surface between two cities. This is obviously impossible of measurement in the familiar way with the tape line. To carry out such measurements the method of triangulation must be applied. To do this, two points must be found a few miles apart so situated that the distance between them can be directly measured on the ground, and that from each of them several different points in the region to be surveyed



are visible. Let AB be the two points chosen and C, D, E, F, etc., some of the distant points. The line AB is called the *base line* of the triangulation, and is measured by means of rods closed in wooden cases to protect them from rapid changes of temperature, which are successively placed end to end from the point A to the point B. Recently it has been found that steel tape can be used much more expediently and with all the precision that is required for the purpose. Having found the exact length of the base line, a theodolite is mounted at A and vertical rods or signals are erected at B C, so that the angle BAC can be measured with the greatest possible exactness. Then the theodolite is carried to the point B and the angle is measured in like manner. If practicable the theodolite may also be mounted at C in order to measure the remaining angle of the triangle. The sum of the angles should come out 180°, this being the sum of the angles of any plane triangle. These three measurements will show any error in the measurement of the angles. Knowing the three angles and of the side of the triangle, the computation of the two remaining sides is a very simple one in trigonometry.

Commonly there will be a number of points, C, D, E, F, etc., which can be determined at the same time. Having done this, any of the lines from A or B to C, or between any two of the other known points, may be used as a new base line and the distance of yet other visible points measured in the same way. These, again, can be used as new base lines, and so on indefinitely. This method is especially expeditious in mountainous regions, where observations can be made from peak to peak at distances sometimes exceeding 100 miles.

Measures of this sort have been carried on or are in progress in most civilized countries. In our own country a system of triangles has been extended from the Atlantic to the Pacific coast, near the parallel of 40° latitude, by the United States Coast and Geodetic Survey. The same survey has carried a line of triangles along the Gulf of Mexico and up the Atlantic coast to the Eastern States, and they are in progress through other parts of the country. The result of these measurements is that the exact position on the earth's surface of a great number of high or prominent points are defined so that they can be laid down on maps. This done, the process of triangulation and surveying can be applied to determine the position of intermediate points, cities, towns, etc., and to determine the course of rivers or valleys.

In order to obtain the most exact result from a geodetic survey of the kind described, the exact form and size of the earth must be known. These cannot be determined in the best way through observations in any one country, but require a combination of the geodetic surveys of various countries as widely separated as possible. With a view of securing co-operation in the solution of the problem, an International Geodetic Association was formed, comprising the United States and the leading countries of Europe. This association, represented by members from the various countries, meets from time to time to carry out the co-operative work of the association, and decide upon the best way of combining the several geodetic surveys.

A fundamental point in which geodesy differs from surveying is in the combination of measurements of the earth's surface, with observations of the stars; the object of the combination is the determination of the curvature of the earth's surface and the size of our globe.

The principle involved will be readily seen by a little careful thought. It is obviously impossible to determine with any exactness the curvature of the earth's surface by observations made solely on that surface. But the surface of the ocean, which is taken as the basic one, is everywhere perpendicular to the plumb-line. It follows that the angle between the directions of the plumb-line at two points will be equal to the curvature of the ocean surface between the points. By skilful astronomical observations it is possible, on any part of the solid earth where an instrument can be mounted, to determine the exact declination in the celestial sphere from which the plumb-line points, which is, in fact, the zenith. The declination of the zenith is the latitude of the place; it follows, that if the latitude of two points north and south of each other is accurately determined, and found to be one degree, for example, the distance between them is the measure of one degree on the earth's surface. This distance can be determined between any two points which are connected by a geodetic measurement. The difference of longitude may also be determined astronomically by telegraph and by geodetic measurement of the earth's surface. The relation between the two measures shows the curvature in the east and west direction.

One of the most difficult questions connected with the figure of the earth is that of the exact ellipticity or flattening of our globe. The precise figure of the earth itself does not admit of definition on account of the irregular outlines of the mountains. Hence, as a basis of all exact statements, geodesy takes, as a standard body representing the earth, the figure that would be formed by the surface of the ocean if the continents were removed so that the ocean would cover the whole globe. It is clear that if the earth did not rotate on its axis, the form assumed by an ocean covering it would be that of a sphere. But, owing to the rotation, the equatorial regions of the earth are expanded and the polar regions contracted so that the ideal form is that of an ellipsoid. If all parts of the earth were of the same density this ellipsoid would be easily determined; but owing to the inequality of density of different parts of the earth, the figure of the ocean itself is not an exact ellipsoid. The best that can be done is to make the calculations assuming it to be such, and to make the best allowance that we can for such small deviations as may be discovered.

When Newton propounded the law of gravitation, the flattening of the earth at the poles was seen to be a natural result. But the French contended that the earth was actually elongated toward the poles. To settle the question one of the most celebrated expeditions in geodetic history was sent to Peru to measure an arc of the meridian near the equator, and another expedition went to Lapland to measure one near the poles. The results showed Newton's theory to be correct, and since that time there has been no doubt on the subject. But the difficulty of determining the exact length of a degree and the irregular variations in the figure of the earth, which we shall soon mention, are such that the determinations by geodetic measures have not been altogether satisfactory. Another method is afforded by the force of gravity, as determined by the length of the seconds pendulum. It is well known that gravity is less in the equatorial regions of the earth than at the polar regions, from two causes. One is the centrifugal force of the earth's rotation, and the other is the greater distance of the centre of the earth's surface at the equator. The result is that a clock pendulum, swinging exact seconds near the pole, would lose several seconds a day when taken to the equator; hence, a pendulum which would beat exact seconds must be made continually shorter as we approach the equator. The determination of its length in various latitudes thus becomes an important problem in geodesy. When it is known, the ellipticity or flattening of the earth may be determined from it.

What makes all the problems associated with this so complex are the small irregularities in the direction and force of gravitation wherever measures and determinations have been made. It is always found that when the latitudes of places are determined by the direction of the plumb-line, which is the only astronomical method, they seldom agree with the differences between the places as determined by geodetic measurements. The reason is, that the plumb-line is deflected by the attraction of mountains and denser portions of the interior of the earth which do not admit of exact computation. These irregularities are greater in mountainous regions, in the Himalayas sometimes rising to 30 seconds. But even in plain countries deviations of 2 or 3 seconds are found. The errors arising from these deviations would not be important in themselves, the difficulty being that they operate like a small error in a foot rule when the latter has to be used for measuring a very long stick of timber. In such a case an error even so small as one eighth of an inch in the rule would amount to an error of a foot in measuring a pole 100 feet long. As the measurement of a whole continent, even of the earth itself, has to start from short base lines, the error may be multiplied many fold in the final result.

Simon Newcomb.

Geodetic Arcs. Historical and other evidence clearly indicates that from the earliest times man has inquired and speculated about matters relative to the shape and magnitude of the earth, but it is also evident that his original crude ideas were not developed up to the point of even a fair approximation to the facts until advancing civilization developed the simpler operations of land surveying into the application of the more complicated principles of geodetic science.

The practice of land surveying appears to have originated at a very ancient date. In a papyrus manuscript bearing a date earlier than 1700 B.C., the author states that his work is a compilation from older manuscripts. According to this work and others of a similar character and of equal antiquity, the practice of land surveying tended to change the original conception of the Ionic Greeks—a circular flat earth surrounded by water—to a conception that recognized the earth as a sphere; but the important step from plane to spherical surveying does not appear to have been made until the time of Aristotle (384-322 B.C.); while the honor of the first actual application of the principles of the new science of geodesy to measurements made for determining the curvature of the earth's surface, belongs to the members of the Alexandrian School. This work, comprising two measurements of the earth's radius, was accomplished about the beginning of the 2d century B.C. The principle employed consisted in the measurement of a long north and south line according to some predetermined unit of length, and then observing the altitude of the sun or some star as seen from the two ends of the measured line. The difference of the measured altitudes gave the curvature of the arc of the great earth-sphere represented by the measured line, expressed in degrees, and from these values the circumference or the radius of the sphere was computed.

It is very remarkable that this principle is practically the same as that employed for the same purpose at the present time, although in its modern application a greater accuracy is attained by the addition of a great mass of details in the accessory methods.

After the measurements made by the Alexandrian School, about a thousand years elapsed before a similar attempt was made by any body of scientific men. This work was executed by the Arabs in Mesopotamia, about 825, and was followed after another long lapse of eight centuries, through the middle ages, by several measurements executed by various nations, the principle of geographical triangulations being introduced in connection with refined measurements about the year 1617.

Modern geodesy, or the science as it exists at the present time, however, really began with the discovery of the law of gravitation by Newton during the latter part of the 17th century, when he demonstrated, that on account of its revolution on its axis, and its lack of perfect rigidity which subjected it to its own attraction, the earth must assume the form of a sphere slightly flattened at the poles. This theoretical form was apparently contradicted, however, by the measurement of a meridional arc in France between 1683 and 1716, which indicated the form of the earth to be that of an elongated sphere. In order to settle the subsequent controversy relative to the matter, and in the interest of science in general, two geodetic expeditions were placed in the field—one in the equatorial region of Peru (1735-1741), and the other in the polar region of Lapland (1736-1737). The data obtained from the work of these expeditions showed that one degree of arc in Lapland was greater, therefore flatter, than one degree of arc in Peru, and not only conclusively proved the correctness of the Newtonian theory, that the curvature of the earth's surface was flatter near the poles than near the equator, but served to establish a sure foundation on which the theory and practice of geodesy has continued to advance with ever increasing accuracy in its results.

On account of the methods employed, the earlier measurements were confined to meridional arcs, but the modern methods of measurements and computations are such, that the measurements of arcs of parallel of latitude and oblique arcs are also utilized in the determination of the size and shape of the earth. The instruments and methods used for this purpose are the same as those employed in the work of primary triangulation designed as a basis for an accurate map, and nearly all the geodetic arcs obtained in recent years have been measured during the progress of surveys made chiefly for the construction of accurate maps and other practical purposes, by the more important nations of the world. See articles under the titles: Coast and Geodetic Survey, Methods and Publication of; Geological Survey, Methods and Publication of; and Map.

The accompanying map shows the principal modern geodetic arcs which have been completely measured in different parts of the world, and affords a comparison of the work done by the United States with that of foreign countries. The two arcs already completely measured in the United States are those of the thirty-ninth parallel of latitude, and the eastern oblique arc. The arc along the thirty-ninth parallel extends across the country from Cape May, N. J., to Point Arena, Cal., a distance of 2625 statute miles (4225 kilometers). Its triangulation includes 10 base lines having an aggregate length of 53.5 miles, one of them being nearly 11 miles long. In the Rocky Mountain region many of the triangle sides are over 100 miles in length, and some of the triangulation stations are more than 14000 feet (4300 meters) above the level of the sea. To fix the position of this arc on the surface of the earth, and to determine the true direction of the lines of triangulation, the latitude was accurately determined at 109 stations, the longitude at 29 stations, and the azimuth at 73 stations.

The eastern oblique arc extends from Calais, Maine, to New Orleans, La., a distance of 1623 miles (2612 kilometers). The triangulation includes six base lines. The latitude was determined at 71 stations, the longitude at 17, and the azimuth at 56. The measurement of the arc is a result obtained from the triangulation which forms the primary control of the surveys of the Atlantic Coast executed by the United States Coast and Geodetic Survey.

Of the work now in progress, the principal measurement is that of an arc of the ninety-eighth meridian west of Greenwich. This work is practically completed within the limits of the United States, and preparations are being made for its extension northward into Canada, and southward into Mexico.

The principal arcs measured in foreign countries are the Anglo-French meridional arc extending from the north of the British Isles southward through France and Spain into Africa; the great Russian meridional arc extending from the Arctic Ocean to the northern boundary of Turkey; the European latitudinal arc extending from the southern part of Ireland eastward into central Russia; and the great Indian meridional arc extending from the southern point of the Peninsula of India northward to the Himalayas.

The total length of all the arcs completely measured in all parts of the world during the modern period amounts to a little more than two-fifths of the girdle of the earth along a great circle.

The exact form of the earth as given by these measurements is such, that with considerable exactness all parallels of latitude are circles, and all meridional great circles are ellipses. The dimensions and form of the spheroid, or more properly, ellipsoid of revolution given by these coordinate circles and ellipses are usually stated in terms of its equatorial and polar radii, or diameters, and the two most notable computations of these dimensions are those made by Bessel in 1841, and those made by Clarke in 1866. The dimensions as determined by these computations and the compression values deduced therefrom, which are applied to all calculations in connection with modern geodetic work, and in the preparation of maps for exact surveys, are given in the table on the following page, both the Bessel and Clarke computations being given in meters and English statute miles.

	Bessel (Meters)	Clarke (Meters)	Bessel (English statute miles)	Clarke (English statute miles)
a. Equatorial Radius	6377397	6378206	3962.72	3963.23
b. Semipolar Axis....	6356079	6356584	3949.48	3949.79

Both sets of dimensions very closely approximate to the truth, but the number of recent measurements is insufficient to determine which of the two is more nearly correct. It is quite probable that the true dimensions lie between the two. A very clear idea of the small amount of flattening at the poles indicated by the figures of either set may be had by constructing a globe approximately five feet in diameter. In order to represent the shape of the earth, the equatorial diameter of the globe will have to be made one-fifth of an inch longer than its polar diameter. The consequent distortion from a perfect sphere will be unappreciable to the eye unaided by the use of measuring instruments.

In the case of the earth itself the amount of distortion can be determined only by the use of the most delicate astronomical instruments, and by linear measurements with errors no greater than one in one million. See articles: GEODESY; MAP; and PROJECTION.

Geodetic Surveying. See SURVEYING.

Geoffrey (jĕf'ri) **of Mon'mouth** (called also GEOFFREY AP ARTHUR), English chronicler: b. probably at Monmouth about 1100; d. Llandaff 1152 or 1154. According to Leland he was educated at Monmouth, in a convent of the Benedictines, whose society he entered. He was afterward made archdeacon of Monmouth, whence he was, in 1152, raised to the bishopric of Saint Asaph. The state of affairs in North Wales induced him to retire to the court of Henry II. He wrote various works; but his 'Historia Regum Britanniæ' is his most important production. This is now known to be, as the compiler states, chiefly a translation from Armorican manuscripts discovered in Brittany by Walter Calenius, an archdeacon of Oxford. It contains a pretended genealogy of the kings of Britain from the time of the fabulous Brutus, or Brute, the Trojan, to the death of Cadwallader, king of Wessex, in 688. It was first printed by Ascenius, at Paris, in 1508. An English translation by Aaron Thompson, at London in 1718, was reprinted in Bohn's Antiquarian Library, 1848. We are indebted to Geoffrey for preserving, and perhaps reconstructing, the legends of Arthur and his knights, the exquisite fiction of Sabrina introduced into Milton's 'Masque of Comus,' the subject of Shakespeare's 'King Lear,' and many of the finest episodes in Drayton's 'Polyolbion.'

Geoffrin, Marie Thérèse Rodet, mä-rē tā-rēs rō-dā zhō-frăṅ, the holder of a noted Parisian literary salon: b. Paris 2 June 1669; d. there 6 Oct. 1777. By the grace and vivacity of her manners, aided by a refined and cultivated taste, she drew around her all the fashion, wit, and learning of Europe. Early left a widow, with an opulent fortune, her charities to the poor, and her benevolent aids to literature, endeared her as much to society as her wit and virtue delighted. In her house the best society in Paris was assembled. Cultivated minds of every description found access to her. None could there claim a preference: the mistress of the house herself was far from desiring any precedence; she was only amiable and animating. Three of her friends, Thomas, Morellet, and D'Alembert, dedicated particular writings to her memory, which, with her treatise, 'Sur la Conversation,' have been republished.

Geoffroy Saint Hilaire, Etienne, ā-tē-ĕn zhō-frwä săṅ-tē-lār, French naturalist: b. Etampes, France, 15 April 1772; d. Paris 19 June 1844. He was educated at the colleges of Navarre and Lemoine, and became a favorite pupil of Haüy. At the age of 21 he obtained the chair of zoology in the Parisian Jardin des Plantes. As a member of the Egyptian expedition in 1798 he founded the Institute of Cairo, and returned about the end of 1801 with a rich collection of zoological specimens. In 1807 he was made a member of the Institute, and in 1809 professor of zoology at the Faculty of Sciences. He devoted himself especially to the philosophy of natural history. Among his principal works are: 'The Principle of Unity in Organic Composition' (1828); 'Philosophy of Anatomy' (1822); 'Natural History of the Mammifers' (1819–37); 'Ideas of Natural Philosophy' (1838).

Geoffroy Saint Hilaire, Isidore, French physiologist and naturalist, son of the preceding: b. Paris 16 Dec. 1805; d. there 10 Nov. 1861. He devoted himself to natural history, and in 1824 was appointed assistant to his father at the Jardin des Plantes. He was elected to the Academy of Sciences in 1833, and afterward became successively inspector-general of the university, member of the council of instruction, and professor of zoology at the Academy of Sciences. One of his chief works, 'History of Anomalies of Organization in Man and the Animals' (1832–7), adds valuable confirmation to the theories of his father. He was the means of founding the Acclimatization Society of Paris. He paid much attention to the domestication of foreign animals in France, as appears from his treatise 'Domestication et Naturalisation des Animaux utiles' (1854), and advocated the use of horse flesh as food in his 'Lettres sur les substances alimentaires' (1856). He also published an excellent life of his father under the title 'Vie, Travaux, et Doctrine scientifique d'E. Geoffroy Saint Hilaire' (1848).

Geognosy, jē-ŏg'nō-sĭ, a name under which are included those branches of geology which have to do strictly with the elements of which the earth, the sea, and the air are composed, and their various combinations. Hence it more particularly deals with rocks and rock-forming materials, and embraces much that is included in the study of petrography (q.v.). See GEOLOGY.

Geographer of the United States. The Continental army in the Revolution had a geographer to make maps and plans; and on 4 May 1781 Thomas Hutchins (q.v.), a protégé of Franklin's, was on his recommendation appointed geographer to the Southern (Greene's) army. After the peace, Hutchins was retained as United States geographer, in connection with the surveys of the western lands ceded by the

States; the first official note of the office is in the draft of the general land bill reported 26 April 1785, where it is referred to as existing, and shortly afterward Hutchins is referred to as occupying it. He was to supervise the State surveyors appointed by Congress, suspend them if unsatisfactory, and report to Congress. He was reappointed in 1788, for two years, but died the next year.

Geograph'ical Conquests. The 3d century after the discovery of America drew to its close with a veil of darkness still shrouding half the globe from the eye of civilized man. A Strabo or a Ptolemy, if questioned in 1800 as to how much of the earth's surface he could describe with accuracy, would have had to confess that he was quite familiar with only one of the grand divisions, and that one embracing only a tithe of the land of our planet. He might perhaps have claimed that he could make a tolerable map of South America, whose interior had been partly opened up by the zeal of the Jesuit missionaries. It would, however, have been full of great voids representing regions unknown to him. He would have been able also to construct a map of Asia, approximately reproducing its main features, but his outlines would have been merely the framework of blurred and empty pictures. The Himalayas had not been measured — the Andes figuring as the highest mountains on the globe. There was a boundless area within the Chinese empire untrodden by Europeans. In Asiatic Turkey, Persia, and in Afghanistan, in Turkestan, and the Pamir, there were whole regions removed from the ken of cartographers. Scant information existed regarding Japan, Farther India, and the Malay Archipelago; next to nothing was known about Korea, and the interior of Arabia was almost a blank. Australia was still floating as a cloud on the horizon. Most of the lands north of America had not yet been discovered, and the Antarctic realm had barely been touched.

The accurate knowledge of Africa was limited in the main to a narrow strip along the coast. As for the interior, comprising about one fifth of the earth's land surface, geographical learning had hardly begun to outgrow its mediæval estate. Cartographers had been groping their way amid the confused reports of traders, slave dealers, and missionaries. The feature of Equatorial Africa regarding which the most correct conjecture had obtained for centuries, was the source of the Nile, which river, in accordance with the teachings of Ptolemy and the old Arab geographers, was represented on the maps as issuing from some lakes in the heart of the continent, fed by the Mountains of the Moon. Geographers knew of a great river that flowed by Timbuktu, the Queen of the Desert, and which they called the Niger, a name handed down from the time of the ancients. It had long been supposed that this stream had a western course and that the Senegal and Gambia formed its delta. A counter theory was that it flowed east to a large lake, a view based in part on vague reports about Lake Tchad. Still another theory regarded the Niger as one of the great arms of the Nile. The Kongo was known only in the last portion of its interminable course, though as far back as the 17th century the opinion had been entertained that it issued from the same quarter of the continent as the Nile. The Sahara remained untraveled by Europeans, except near its margin, and the great lakes of Africa were known only through tradition or vague report.

In North America, the region between the Mississippi and the Pacific and north of New Mexico still belonged in great part to the realm of fancy. British America remained in great part unexplored, and the coast of Alaska had barely been grazed. There were whole regions, like the Adirondack wilderness, included within the bounds of the original States of the American Union, which were still sealed to geographers.

Nearly 300 years after the tracing of the coast line of Africa was completed by the voyages of the Portuguese, the systematic exploration of the interior may be said to have commenced in 1788 with the foundation in London of the African Association, an event which inaugurated a new era in the history of geographical discovery. This society had the good fortune to command almost at the start the services of the intrepid Scotchman, Mungo Park. Before this, it is true, the pioneer of modern African exploration, Sir James Bruce, had made his memorable journey along the Blue Nile, and the ornithologist, Le Vallant, had traveled in the hunting grounds of South Africa. Just before we hear of Mungo Park, the record of discovery also tells of a narrow wedge driven toward the heart of the continent in the journey of Browne from Assuan to Darfur. The African Association assumed for one of its first tasks the unraveling of the mystery of the Niger. The journeys of Mungo Park (who perished in the stream in 1806), of Clapperton and Denham, and of Lander, covering together the period from 1795 to 1830, revealed the course of the river. The French, meanwhile, explored the Senegal and Gambia. At this time English explorers began to push from the Guinea coast into the warlike kingdoms of Ashanti and Dahoney. In 1826 the ill-fated Laing, and in 1828 Caillié, succeeded in reaching Timbuktu, that mysterious seat of Islamism which had for centuries fascinated geographers. (See Figs. 1 and 2.)

The close of the 18th century was the beginning of a new era in the annals of American exploration. The travels of Alexander von Humboldt between 1799 and 1804 in the basins of the Orinoco and Magdalena, and in the Andes and Mexican Cordilleras, mark an epoch in the history of geography and natural science. His work was taken up and extended to other regions, especially Brazil, by eminent naturalists like Maximilian of Wied, Spix, Martius, Auguste de Sainte-Hilaire, Orbigny, and Pöppig. These had worthy successors in the brothers Schomburgk (British Guiana), Darwin (Patagonia, Tierra del Fuego), Ave-Lallemant (Brazil), Tschudi (Andes, Brazil), Castelnau (Brazil, Bolivia, Peru), and Burmeister (Brazil, Argentina).

By the acquisition of the Louisiana territory in 1803 the United States came into possession of a boundless domain, in great part as far removed from the knowledge of white men as the heart of Africa. (See Figs. 5 and 6.) An exploring expedition was immediately sent into this *terra incognita* under Lewis and Clark, who proceeded up the valley of the Missouri, crossed the divide of the Rocky Mountains, and followed the Columbia down to the sea. The explorations of Pike, Long, Bonneville, Catlin, Nicollet, and Frémont, the opening of overland routes to Utah and California, and the government survey for a Pacific railway made deep rifts in the trans-Mississippi region; but its greatest wonders were to remain enshrouded till the tide of colonization had begun to sweep over the whole area. It was not till 1832 that the Mississippi river was traced to its source by Schoolcraft.

The exploration of the Arctic regions, in the hope of finding a north water route for the trade with the East, had lost much of its fascination by the 18th century. Russia alone prosecuted it systematically in the course of that century, accomplishing a great work in tracing the coast line of Siberia. About the beginning of the 19th century the idea of a Northwest Passage was revived in England and the dream of reaching the pole began to be entertained. (See FIGS. 3 and 4) A great and persistent onslaught on the frozen North was inaugurated in 1818. The labyrinth of islands, peninsulas, and ice-bound passages north of the American continent yielded up its intricacies to the assaults of Parry, the two Rosses, Sir John Franklin (to whose tragic end Arctic discovery owed much of its rapid progress), McClure, Kane, McClintock, and Hayes. The exploration of Arctic British America was prosecuted on land with heroic energy by Franklin, Back, Richardson, Beechey, Dease, Simpson, and Rae. Parry in an attempt to reach the pole in 1827 dragged his sledges over the floating ice fields to the parallel of 82° 45', eclipsing all previous records by more than a degree of latitude. In 1831 James Clark Ross solved the mystery of the position of the north magnetic pole, which he located in the peninsula of Boothia. McClure entered the Arctic Ocean through Bering Strait in 1850, proceeded east, was beset for years in the ice, joined hands in 1854 with an expedition which had come in the opposite direction, and thus carried off the laurels of the Northwest Passage. While a great breach was being made in the Arctic fastnesses, Bellingshausen, Weddell, Dumont d'Urville, Sir J. C. Ross, Wilkes, and others extended geographical discovery into the Antarctic regions. Ross discovered Victoria Land, with its active volcanoes, and in 1842 advanced beyond the 78th parallel. During this same period the cruel depths of Australia, whose coast had been explored by Flinders in 1801-3, were invaded by Sturt, Eyre, and the ill-fated Leichhardt.

A flood of light was thrown on the geography of Northern and Central Asia in the first half of the 19th century by the journeys of Ermann, Humboldt, Middendorf, Huc (who entered Lhassa, the holy city of Tibet), and others; while men like Webb, Moorcroft, and Wood scaled the heights of the Himalayas and the Pamir, and reached the head streams of the Indus, Ganges, and Amu Daria. From 1848 Mount Everest, with the 29,002 feet given to it by the trigonometrical measurement of Sir Andrew Waugh, figured as the highest point on the globe. Among the naturalists who were attracted to the Himalayas, the name of the botanist Hooker stands pre-eminent. The most distinguished traveler in southwestern Asia in the early part of the century was Burckhardt, who succeeded in entering the holy places of Mecca and Medina. In 1829 Ararat was ascended by Parrot. In 1832-3 Alexander Burnes performed his famous ride from India to Bokhara. The travels of Crawfurd and MacLeod in the second quarter of the century dispelled in part the obscurity hanging over farther India. Between 1835 and 1849 the naturalist Junghuhn explored Java and parts of Sumatra. Among his successors in the Malay Archipelago were St. John and Wallace.

Down to the time of the French Revolution, Europe had hardly dared to cast a covetous eye on the interior of Africa. Portugal, England, and France held sway at a few stations along the coast. The sturdy Boers near the Cape of Good Hope, alone represented actual colonization by Europeans. The Revolution brought in its train Bonaparte's conquest of Egypt, the first great onslaught on African territory on the part of Christendom in modern times. The consequences of the French domination, brief as it was, were far-reaching in the loosening of Turkey's hold upon that country. Another result of the wars of the Revolution was the supplanting of Dutch dominion at the Cape by that of England. An army of ardent missionaries now made their way into the interior of South Africa. While England was laying the foundations of an empire at this end of Africa, France suddenly invaded the north and conquered Algeria (1830-48). A few years before this invasion, Mehemet Ali, viceroy of Egypt, brought Nubia and Kordofan under his sway. This ambitious potentate, who, for the first time since the days of Saladin, made the aggressive power of Africa felt in another continent, in his role of modernizer of Egypt, sent various scientific expeditions to explore the Nile, which was now traced almost to the equator. To this period of African exploration belong the travels of Rüppell, the brothers Abbadie, Beke, and Krapf in Abyssinia.

With the middle of the 19th century commences an extraordinary era in the history of geographical discovery. The world begins to close in upon the dark interior of Africa which is assailed on every side, and in the course of a generation the great features of the continent are unfolded almost in their entirety. In 1847 the German missionaries Krapf and Rebmann discovered the snow-capped peaks of Kilima-Njaro and Kenia, near the equator. In 1849 Livingstone discovered Lake Ngami, in the heart of South Africa, at a distance of 1,000 miles from Cape Town. In the course of the next seven years he extended his explorations to the Upper Zambesi, of which mighty stream hardly anything had hitherto been known, followed it up, struck out west along the edge of the Kongo basin (a circumstance unknown to him), made his way to the Portuguese possessions on the Atlantic, then, turning back, followed the Zambesi down stream, discovered the Victoria Falls, the rival of Niagara, and came to the shores of the Indian Ocean. While Livingstone was drawing a luminous trail across South Africa from sea to sea, Heinrich Barth was lifting the veil from the depths of the continent on the other side of the equator by his extraordinary journeys in the west half of the Sudan. In the sixth and seventh decades of the century large accessions were made to the knowledge of the

Nile basin and the surrounding regions, including Abyssinia, by the travels of Petherick (who explored the basin of the Bahr-el-Gazal), Munzinger, Beurmann, Heuglin, and others. In the meanwhile the French were pushing into West Africa on the side of Senegambia, Du Chaillu traveled in the country back of the Gabun and through the wilds of the Ogowe, the home of the gorilla and the pygmy Obongo; Burton scaled the peak of Kamerun, and Von der Decken explored what is now British East Africa.

Just as Barth was emerging from the scorching suns of Central Africa, laden with the knowledge of countless peoples, in another continent three equally intrepid Germans proceeded to explore the most elevated region of the globe. The brothers Schlagintweit crossed the Himalayas and the Karakoram, traversed the lofty plateau of Tibet, and surmounted the Kuenlun, reaching heights to which no traveler had ever climbed.

Soon after Livingstone's traverse of South Africa, the beginning was made of those discoveries which unraveled the most interesting problem presented by the geography of that continent. In 1858 Burton and Speke, despatched by the Royal Geographical Society in quest of a great reservoir of fresh water which was believed to exist somewhere in the region whence the Nile issued, discovered Lake Tanganyika. Before the close of that year, Speke discovered a still larger lake, the Ukerewe, or Victoria Nyanza, which he assumed to be a reservoir of the Nile, though as yet its outlet remained to be found. To what river system, if any, Lake Tanganyika belonged was a problem which was to wait still many years for a final solution. In 1859 Livingstone came to the shores of a third great lake, the Nyassa, a feeder of the Zambesi. Within the next five years the question of the sources of the Nile was approximately settled by the explorations of Speke, Grant, and Baker. The last named, ascending the river from Egypt in 1864, discovered the lowest of the Nile reservoirs, the Mwutan Nzige, or Albert Nyanza. What Ptolemy had laid down on his famous map 1,700 years before was found to be substantially correct, and the discovery later on of snow-clad mountains near the Albert Nyanza, culminating in Ruwenzori, substantiated what the Greek had taught regarding the Mountains of the Moon.

The problem of the Nile was closely interwoven with that of the Kongo, the greatest mystery that still confronted geographers outside of those presented by the polar regions. The Nile question, indeed, could not be regarded as completely settled till the watershed between the two rivers had been determined. Of the Kongo basin, equal in extent to that of the Mississippi, but a mere fraction was known to the world. A boundless maze of tropical forests and rivers had thus far escaped the eye of Europeans. Geographers were not even agreed as to whether the Kongo issued from the heart of the continent or whether it was not rather in the nature of a coast river. Livingstone applied himself with heroic resolution to the task of ascertaining the parting of the waters that found their way to the Mediterranean and those that flowed toward the Atlantic. In 1867–8 he discovered the Chapula, the east head stream of the Kongo, and its two large reservoirs, Mweru and Bangweolo, and in 1871 stood on the banks of the great river that hurries past Nyangwe, but not possessed of the information that would assure him beyond doubt that it could be no other than the Kongo.

During these years wide explorations were made in Central Africa, north of the equator, by Rohlfs, Nachtigal, and Schweinfurth. Nachtigal, a worthy successor of Heinrich Barth, succeeded in making his way into Wadai, a Mohammedan state in Sudan, a goal the pursuit of which had cost the lives of two eminent explorers, Vogel (1856) and Beurmann (1863). Schweinfurth penetrated into the cannibal regions west of the equatorial Nile, and in 1871 came to the Welle, whose west course convinced him that he had traveled beyond the bounds of the Nile.

These journeys were coincident with a remarkable epoch in the geographical annals of America. The explorations of Dall revealed the extent of the Yukon; the mountain systems of the West were explored by Wheeler, Whitney, and Hayden; Powell discovered the grand cañon of the Colorado; Washburne and Hayden made known the marvels of the Yellowstone. The knowledge of British America was at this time greatly extended by the travels of Bell, Selwyn, Dawson, and others. Simultaneously with the exploration of the mountains of North America, the geological structure of the Andes was laid bare by Reiss and Stübel, who ascended the volcano of Cotopaxi to its summit.

While the rest of the world was engaged in prying open the recesses of the continents, the Russians were displaying extraordinary activity in the exploration of their vast Asiatic domain and the regions bordering on it. In the first 15 years of the reign of Alexander II., Semyenov, Valikhanov, Radlov, Ostensacken, Syevertsov, Fedtchenko, and Kaulbars assailed that mighty mountain barrier composed of the Altai, Alatau, Tian-Shan, Alai Tagh, and the Pamir, which shuts off the elevated desert region of Central Asia from the plains of western Turkestan and Siberia. During the same period Shishmarev, Mattussovski, and Pavlinov penetrated into Mongolia, and Palladius into Manchuria. The Russian advance into Central Asiatic highlands met with a prompt response from beyond the Himalayas, whence Hayward, Shaw, and Forsyth pushed into eastern Turkestan, while the pundit Nain Singh made a memorable traverse of Tibet.

When Japan and China, soon after the middle of the 19th century, opened their portals to the world, the work of exploration, previously inaugurated by dauntless missionaries and naturalists, proceeded with a new impetus. Great journeys were made in China by Blakiston, Pumpelly, Ney, Elias, Bastian, Cooper, and Richthofen, who belong to the foremost ranks of Asiatic explorers. In the decade beginning with 1861 explorations were made in the Caucasus, by Radde, in northern Arabia by Palgrave, and in Turkestan by Vámbéry and Lagrée, and Garnier traced the course of the Mekong as far up as the Chinese province of Yunnan. Contemporaneous with these travels were the remarkable journeys performed in Australia by Burke and Willis, MacKinlay, Stuart, and Forrest, whose exploits were emulated by Giles and Warburton.

The year 1871 is memorable in the history of geographical discovery for the dramatic episode of the finding of Livingstone by Stanley. The meeting by the waters of Tanganyika was followed by the exploration of the north end of the lake which was found to have no outlet in that direction. Livingstone then returned to the scene of his recent labors, the Luapula-Lualaba basin. On 1 May 1873, he expired on the shores of Lake Bangweolo, which he had discovered and which he had become convinced belonged to the Kongo system. In 1874 Cameron discovered that Lake Tanganyika was connected by an outlet, the sluggish Lukuga, with the river formed by the Lualaba and Luapula. This river (which Livingstone had reached in 1871 at Nyangwe) was found by Cameron to flow at too low a level to admit of its belonging to the Nile system. This fearless traveler was prevented by the hostility of the natives from descending the stream and verifying his belief that it was the Kongo. It was reserved for the dauntless spirit of Stanley to bring the mightiest of African rivers within the ken of mankind. In November 1876 he embarked at Nyangwe in a fleet of canoes, and performing an unprecedented voyage which twice carried him across the equator, he reached the tides of the Atlantic in August 1877. And now came the great task of exploring the Kongo tributaries, which enlisted the energies of Stanley, Capello and Ivens, Buchner, Pogge, Wissman, Grenfell, Wolf, Brückner, and Van Gèle.

While the veil was being lifted in this quarter, new light was thrown on the regions west of the Upper Nile by the travels of Junker, Casati, Gessi, and Lupton, the country between the Ukerewe and the coast was opened up by Fischer, Thomson, and Johnston, the naturalist Emil Holub traveled in the Zambesi region, and the explorations of Brazza between the Ogowe and the Kongo laid the foundations of a new French colony. Between 1878 and 1881 Serpa Pinto made his traverse of South Africa, Oskar Lenz performed a journey from Tangier to Timbuktu and thence to the Senegal, and Matteuci crossed from Egypt to the Gulf of Guinea. At this time began the extraordinary career of Emin Bey (Eduard Schnitzer), administrator, explorer, naturalist, and linguist, in the region of the equatorial Nile. This heroic commander, the peer of the great Gordon, was cut off for years from the world by the Mahdist uprising, till at last Stanley succeeded in reaching him by way of the Kongo and Aruwimi, an exploit which recalled the days of the Conquistadores. In 1887 the Rudolf lake was discovered by Teleki. In 1889 Meyer reached the summit of Kilima-Njaro.

During the years which revealed the sources of Africa's greatest rivers the exploration of the mighty tributaries of the Amazon was prosecuted by Chandless. A little later Crevaux won laurels in the same field, and to him succeeded Karl von den Steinen and Ehrenreich.

The decade which witnessed the solution of the Kongo problem, the last great mystery that had remained hanging over the equatorial zone, was marked by renewed activity in Arctic research. The passage leading north from Baffin Bay, beginning with Smith Sound, appeared to promise access to an open polar sea, the theory of whose existence had been put forth by Kane. The American expedition under Capt. Hall in 1871 proceeded up this channel, and the splendidly equipped British expedition under Sir George Nares in 1875 followed in its wake; but Kane's theory was not verified. Some of Nares' men in 1876 reached the parallel of 83° 20', eclipsing Parry's record by more than half a degree. Lieut. Lockwood of the ill-starred Greely scientific mission in 1883 made a farther gain of four minutes. In 1873 the Austrian expedition of Weyprecht and Payer discovered Franz-Josef Land. In 1878-9 Nordenskjöld immortalized himself by accomplishing the Northeast Passage.

While Stanley and his successors were opening up the exuberant forest realm of Equatorial Africa, the arid expanse of Central Asia, stretching from the Pamir on the west to the highlands of Manchuria on the east, and embracing the desert of Gobi (Shamo), the Tarim basin, with the Takla Makan desert, and the ranges of the Tian-Shan, Kuenlun, Altyn Tagh, and Nan-Shan, was attracting the most intrepid explorers from all parts of the world. This illustrious roll includes the great Przhevalski (whose name is borne by the former town of Karakol, in Turkestan, where he died in 1888); Sosnovski, Mushketov, Kostyenko, Potanin, Regel, the pundit Krishna (who removed the long-existing doubt regarding the identity of the Sanpo and Brahmaputra), Pyevtsov, Bell, Bogdanovitch, Roborovski, Carey, the brothers Grum-Grzhimailo, Rockhill, Younghusband, Bonvalot, and Henry of Orleans. These had distinguished successors in the last decade of the century in Dutreuil de Rhins, Littledale, the young Swedish geologist Sven Hedin, Obrutchev, Futterer, Holderer, and Deasy. Among the host of ardent explorers who have traveled in China since 1875 are Sosnovski, Baber, Gill, Széchényi (son of the great Hungarian patriot, Count Stephen Széchényi), Kreitner, Easton, Hosie, Colquhoun, Henry, and Younghusband. It is only since 1880 that the geography of Korea has emerged from its obscurity.

In the last quarter of the 19th century the dimensions of the unknown in Alaska, the Northwest Territories, and Labrador were vastly reduced by the explorations of Muir, Allen, Schwatka, Dawson, Ogilvie, Russell, Low, and others. In 1888 the first crossing of Greenland's great ice cap (in its southern part) was accomplished by Nansen. In 1892 Peary and Astrup made a sledge journey of more than 1,000 miles over the northern end, and determined the extension of the island in that direction. In 1893-5 the gap between the North Pole and the highest latitude ever before reached (Lockwood's 83° 24' in 1883) was bridged almost half over by Nansen's drift voyage and sledge journey, which carried him to the parallel of 86° 14'. This record was eclipsed in 1900 by the expedition of the Duke of Abruzzi, which reached 86° 33'. The results of these expeditions render it improbable that any extensive land mass remains undiscovered within the Arctic Circle. As the physical conditions prevailing at the North Pole cannot be materially different from those observed in the near vicinity, the reaching of the pole itself may now be regarded as a goal belonging to the realm of adventure rather than to that of scientific discovery.

In the same year in which Peary and Astrup crossed the fathomless ice cap of Greenland the gigantic glaciers of the Karakoram were explored by Sir William Martin Conway, who climbed to an elevation of about 23,000 feet, eclipsing the record of all former travelers. In 1897 Aconcagua, probably the loftiest peak of the Andes, was scaled to its summit by Zurbriggen, the Swiss guide, and Vines, the geologist of Fitzgerald's expedition, the elevation obtained for it by barometric measurement being 23,080 feet. In 1898 Conway accomplished the ascent of Illimani, one of the rivals of Aconcagua.

At the close of the 19th century the attention of the world was once more turned, after a long interval, to the Antarctic regions. The British expedition under Borchgrevink succeeded in locating the south magnetic pole, and attained to the parallel of 78° 50', surpassing by 40' the "farthest south" achieved by Ross in 1842. Within the Antarctic Circle remains by far the greatest unknown area on the globe. Outside of the polar realms the physical map of our planet, barring minor details, is nearly complete. When the 19th century opened, geographical science had half a world to conquer. At its close this conquest may be said to have been well-nigh achieved.

Geographical Distribution of Animals. It is a familiar fact that certain kinds of animals dwell in very limited districts, others in larger areas, perhaps throughout a whole continent; but that any considerable change in one's location on the face of the earth brings him into contact with a more or less different fauna. This is the more certain and conspicuous if a sea or mountain range or desert intervene between the two points of observation. In general it is plain that species of animals of all sorts have, as a rule, a comparatively limited habitat; genera often a more extended one; while the higher groups may have a wide or even cosmopolitan range. These areas of life for similar animals are more likely to spread in directions of latitude than of longitude, so that the northern hemisphere (*Arctagæa*) is more different faunistically on the whole from the southern one (*Notogæa*) than are, for example, Europe and the United States. The science which deals with the causes and principles of this body of facts is called Zoogeography, under which head the subject is considered in detail.

Geographical Societies are associations formed with the view of obtaining and disseminating geographical knowledge. This is attained, in the first instance, by members undertaking distant travels, at their own expense in some cases, in others assisted by the funds of the society or grants from government; and, in the second instance, by lectures delivered and works issued under the auspices of the society, or by papers read and commented on at the periodical meetings. In point of seniority the first of these associations is the Société de Géographie of Paris, founded in 1821. The German Gesellschaft für Erdkunde held its first sittings in Berlin in 1828, under the presidency of Ritter, and has counted among its members many of the most famous of modern geographers. By far the most important of these institutions, however, is the Royal Geographical Society, established in London in 1830. The principal travelers and geographers of Great Britain, or indeed of the world, are or have been connected with this society, and such names as those of Livingstone, Burton, Baker, Speke, Barth, Wallace, Cameron, Stanley, Thomson, Johnston, Bent, Curzon, Markham, Nansen, and many other well-known travelers, are to be found attached to papers in its 'Journal' (1831–80, 50 vols.) and 'Proceedings' (ceased in 1892), or in the 'Geographical Journal,' which it has issued since 1893 in monthly parts, and which includes the society's proceedings. It has a capital of $200,000, and large sums are devoted annually to aid the cause of geographical research, or as awards and recognition of services rendered to the science. The Russian Geographical Society, founded at St. Petersburg in 1845, has greatly extended our knowledge of Central Asia and Asiatic Russia. Following the lead of other nations, Italy has her Società Geografica, founded at Florence in 1867, and issuing an annual 'Bollettino.' The American Geographical Society (q.v.) was founded at New York in 1852. The Royal Scottish Geographical Society was founded in 1884. It publishes an excellent monthly magazine, and its members number between 1,500 and 1,600. The Royal Geographical Society has a membership of between 3,000 and 4,000.

Geographical Society of Baltimore, organized in 1902 for the study of geographical science. It acquired over 1,000 members during the first year of its existence. Daniel C. Gilman was the first president of the Society.

Geographical Society, The American, a society established in 1852 to encourage geographical exploration and discovery and to disseminate new geographical information. See AMERICAN GEOGRAPHICAL SOCIETY.

Geographical Society, The National, an American organization with headquarters at Washington, D. C. It was formed in 1888, and offers annual lecture courses in Washington upon popular geographical subjects. The 'National Geographic Magazine' is published monthly by the Society, which had 3,000 members in 1902.

Geographical Society of Philadelphia was organized in 1891, and in 1893 a charter was granted to the Geographical Club of Philadelphia, of which Angelo Heilprin was the first president. The present title was resumed in 1897. The Society confers annually the Elisha Kent Kane gold medal, as a reward for geographical work. In 1902 the Society had 430 members.

Geographical Society, Royal, was founded at London in 1830 to aid in scientific research in geography, and received a charter in 1859. It has published numerous papers, books, and magazines, and expended large sums of money to encourage research. See GEOGRAPHICAL SOCIETIES.

Geography, by derivation, means "description of the earth." Humboldt's interpretation, which, beyond the gathering of data for mapping the topographical and drainage features of a region, added a study of meteorological and climatic conditions, of the character of soils, and of the distribution of life both animal and vegetable, was the first true impulse given to modern geographical research. For a comprehensive knowledge of the earth the aid of all branches of natural science is sought. Geography, while it is specifically the science or knowledge of the earth, is dealing with phenomena and studying laws which belong to the universe. One of its important functions is the investigation of the reciprocal relations existing between man and his physical surroundings. The average text-books have fallen far below such a standard. Cartography and statistics form the sum and substance of these treatises. Maps constitute an essential feature of geography, but are commonly read with less intelligence than the working drawings of an engineer or architect. Lists of cities with their populations, and the names of rivers, bays, mountains and islands are of great value in the way of information, but they are of secondary importance. It concerns the student of geography less to know that New York is a city of three millions and a half of inhabitants and the greatest seaport of America than to discover the causes which have led to such growth and development. The physical or social reasons for the fixing of political boundaries are of greater interest than the mere location of or changes in the boundaries themselves. Happily a change for the better may be observed. The recognition some years ago of the scientific and practical value of geography by German scholars, and the systematic work done by them have already borne fruit. Departments of geography have been established in universities and higher institutions of learning. Geographical societies have been organized in all the leading countries of the world, and a broader interest in the subject has been aroused.

Historical.— When Columbus (q.v.) made his first voyage of discovery, popular belief maintained that the earth was flat, though the scholars of the time recognized its spherical form. The first people to add to a knowledge of distant lands were the Phœnicians. They had founded colonies as early as 1200 B.C., and exerted much influence upon the progress of civilization. Herodotus, the father of history and geography, and himself a great traveler, records a Phœnician expedition in the 7th century B.C., which, staring from the Red Sea, returned by way of the Pillars of Hercules and the Mediterranean, having circumnavigated Africa. While the story has been doubted, the incidents of the narrative give it much color of probability. Herodotus leaves an account of the conception of the earth's extent in the 4th century B.C. The scanty knowledge of the time comprised the coast regions of the Mediterranean Sea extending vaguely to the north and south, with the Atlantic Ocean and the Persian empire constituting the western and eastern boundaries. Strabo's voluminous work on geography, at the dawn of the Christian era, itself a valuable treatise, is of special importance in affording a glimpse of the efforts of earlier geographers, whose books are lost. Eratosthenes, the most remarkable of these scholars, made wonderful advances in mathematics and astronomy. He measured the obliquity of the ecliptic, described the earth as a sphere revolving on its own axis, and constructed maps with parallels of latitude and longitude. Beyond influencing the belief of a few learned contemporaries, his work was practically unavailing. Ptolemy, who lived in the 2d century A.D., was the supreme authority in astronomy and geography, not only in his own time, but during the Middle Ages. In accordance with his system, which was really a compilation of the views of earlier writers, the centre of the universe was the earth, around which the various heavenly bodies revolved. The travels of Marco Polo in the 14th century and the introduction of the mariners' compass were instrumental in changing the whole history of the human race. See EXPLORATION.

Though the knowledge of our world progressed by leaps and bounds, it is interesting to note what a large proportion of that knowledge has been the result of modern investigation. Explorers on the sea had by the end of the 18th century become familiar with the range of the ocean, the outline of the continents and many islands, but at the beginning of the 19th century four fifths of the land area were unknown. Africa, with the exception of a narrow rim of coast, was indeed a "Dark Continent." Little had been added to our knowledge of Asia since the days of Marco Polo. West of the Mississippi, North America was a *terra incognita*, and the existence of the Rocky Mountains was not suspected. Even the coast of Australia was not completely traced, and nothing had been learned of its interior. South America, which was better known than any continent except Europe, is now the least explored of all the large land masses. With the advent of the 20th century scarcely one eleventh of the land surface remains unexplored. Excepting a few interior tracts, the only portions yet unconquered lie around the North and South Poles, and these are rapidly yielding to persistent effort.

While the unity of geography should never be overlooked, the subject is commonly divided into different branches, the chief of which are mathematical, physical, and political geography.

Mathematical Geography considers the earth as a globe, with its motions and their effects, and teaches the methods of representing the whole or portions of the earth's surface on globes or maps. Observation and careful measurements have proved the earth to be spheroidal in shape. As it is flattened at the poles, it is not a perfect sphere, nor even a perfect ellipsoid, but a ball with slight irregularities of surface. Its longest diameter is 7,926.6 miles, and its shortest 7,899.6 miles. The circumference is approximately 24,000 miles.

The axis of rotation of the earth is its shortest diameter. The ends of the axis point to opposite parts of the sky, and these, called the poles of the heavens, seem to stand still while the rotation of the earth causes an apparent revolution of the sky from east to west. The whole system of determining position and direction is established by the earth's rotation. The great circle midway between the poles is the equator. Great circles extending north and south through the poles are meridian circles. Distance from the equator toward either pole is called latitude, and is measured along a meridian. Zero is at the equator, and the quarter circle north or south is divided into 90°. Small circles parallel with the equator are parallels of latitude. The equator and parallels are continually moving from west to east, and the meridians, which cross them at right angles, are carried in succession directly beneath the sun. All points on any meridian turn around the axis at the same rate, but the actual distance traversed varies from nothing at the poles to more than 1,000 miles per hour at the equator. The uniform rotation of the earth provides a means of measuring time. The sun crosses the meridian or midday line of any place midway between the hours of rising and setting, and the interval between 2 successive noons is called a day, which is divided into 24 equal parts or hours. It is always noon on some meridian, but never on more than one at the same instant. As a complete rotation through 360° occupies 24 hours, meridians 15° apart vary one hour in local time. A person traveling toward the east completely around the world gains a day, but if he make the same journey in a westerly direction he loses a day. Distance east or west is measured on the equator or a parallel, and is called longitude. Some prime meridian, usually that of Greenwich, is the zero, and measurements are made 180° east and west. The length of a degree of latitude is a little more than 69 miles, but as the meridians converge toward the poles, degrees of longitude diminish in length as the distance from the equator increases. If the latitude and longitude are unknown, the former is determined by observing the altitude of the pole of the heavens, while the latter is obtained by comparing, with the aid of a chronometer, the exact moment at which the sun crosses the meridian with the local time of the prime meridian at the same instant. Tables, showing the relative positions of heavenly bodies for each day in the year, are calculated in advance and enable captains of vessels to find their position at sea. See EARTH.

The imaginary network of meridians and parallels can be actually drawn upon a globe. The outline of the continents and the location of places may thus be depicted with great accuracy. A map is much more convenient than a globe, but, as the surface of a sphere cannot be spread out flat, no map is ever absolutely correct. Various projections are employed to modify the distortion. Mercator's projection, and others similar in plan, are modifications of the result obtained by drawing lines from the centre of a sphere through the parallels and meridians to the surface of a cylinder touching the sphere at the equator. This style of projection is employed for navigators' charts, for while areas are distorted, a straight line drawn between any two points correctly represents direction. Several hemispherical projections upon a flat background are used. These, though approximately preserving dimensions, distort directions. For limited areas the conical projection is of value. The meridians and parallels appear as they would if traced on a transparent cone placed on the globe.

Physical Geography deals with the earth in its relation to nature. The surface is irregular, the hollows being filled with water, and the projecting parts forming the dry land. It is surrounded by a gaseous envelope. The solid portion is often called the geosphere or lithosphere; the liquid layer, the hydrosphere; and the outer mantle, the atmosphere. See AIR; ATMOSPHERE; VAPOR.

The earth is believed to be a cooling and contracting body. With a reduction in size the outer crust becomes wrinkled. The crests of these wrinkles protrude above the water, which fills the troughs. Though many changes have affected these ridges and furrows, the general arrangement of the elevated and depressed portions of the earth is believed to have been nearly permanent. Without altering the relative positions of the exposed land masses and the oceanic basins, a comparatively slight increase in the depth of the latter would cause more land to be uncovered. Or were the bed of the ocean to be raised slightly, the sea would flow over the coast regions and accessible low-lying valleys. Were the solid crust uniformly smooth, it would be completely drowned by a continuous sea about two miles in depth.

By the present arrangement, the land area constitutes 28 per cent of the surface. The ocean covers about 72 per cent, but by evaporation and condensation, some of the water is distributed over the continents to be retained in lakes or returned to the sea by rivers. Though special names are given to different portions of the ocean, it is a continuous body of water.

The surface temperature of the ocean varies with the latitude. Ice floes and icebergs form in the polar seas, while an average temperature of 80° is maintained in the tropical ocean. The daily or seasonal range is not great in any latitude. Even in the tropics heat does not extend far below the surface, and the ocean as a whole is a mass of cold water.

The amount of dissolved salts in sea water averages 3.5 per cent. The salinity is not uniform, as portions are regularly freshened. These are chiefly the belts of equatorial rains, the regions affected by the melting ice of the polar seas, and those near coasts receiving the drainage of large land areas. As heat expands sea water, thus reducing its density, it generally happens that the surface water is salter than the colder layers below. The distribution of heat and the modification of climate effected by ocean currents is of vast importance. Nearly half the sun's heat in the Torrid Zone is carried to higher latitudes. The Arctic regions receive more heat from the Gulf Stream than they do directly from the sun. The western coast of Europe from the North Cape to Gibraltar has a climate much warmer than that of the opposite coast of North America, and this work of the Gulf Stream is in a measure duplicated on the western coast of North America by the Japan current. Cold currents from the southern ocean soften the climate of the western tropical coasts of Africa and South America. If the water completely covered the earth, a double wave caused by the attraction of the moon would, on account of the earth's rotation, travel around the globe every day. This ideal arrangement of tides is not realized except in the southern ocean, and, with a general movement to the west, the tidal wave is deflected northward in the other oceans.

In determining the height of mountains or any part of the land surface, it is necessary to have some common level as a basis of comparison. For this purpose the surface of the sea has been chosen, but on account of the many movements to which the ocean is subjected and because of the attraction exerted by elevated land masses, its surface is not level, and all comparative heights are of doubtful value. Efforts have been made to determine the mean level of the whole surface. While much has yet to be accomplished in securing the requisite data, it has been quite clearly shown that such a line lies about 10,000 feet below present sea-level. The abysmal area below this line is of equal extent with the area above it. As the exposed continental area occupies 28 per cent of the earth's surface, it follows that 22 per cent is covered by water less than 10,000 feet in depth. Quite a large part of this region slopes gently away from the coast line to a depth of 100 fathoms, forming the continental shelf. The area of this submerged shelf is very nearly the same as that of the low costal plains of which it is a continuation. Were the level of the sea to be reduced 600 feet, 10,000,000 square miles would be added to the land area, and the present exposed surface would sustain a loss somewhat greater were the sea to rise an equal amount. The proportion of land is much greater in the northern than in the southern hemisphere, and the large land masses have their greatest width in the north.

The destructive agencies are so active that in a short time all the land would disappear and be distributed over the bed of the ocean, were it not for the upheavals due to the contraction of the crust. From causes, concerning which all geologists do not agree, lines of weakness are developed, and portions of the crust are forced up into mountain ranges or broad plateaus, while other adjacent portions are depressed. The outer rocks or those forming the slopes of a young mountain range are composed of the sediment of older rocks. They are the result of processes of destruction and reconstruction, which are to be at once renewed. For no sooner are new areas exposed than the sun either by direct heat, or through the agency of wind, frost, rain, or running water, proceeds to carve the surface into new forms, carrying away the waste to cover the rocks with soil for the support of vegetation or to fill up the hollows of the sea. Rain not only attacks the rocks by force of impact and solution, but by moving broken fragments from higher to lower levels it uses them as cutting tools. The surface water and that flowing from springs form little streams, which uniting produce rivers. In its upper course, which is the steepest, the work of a stream is purely destructive. It is cutting a gorge or valley in the high land. As the slope becomes more gradual, it is alternately depositing its load of stones and gravel or sweeping them away to some lower point. In its final stretch through a nearly level area it is building up an alluvial plain. Deltas and many interior valleys, like that of the Mississippi, are thus formed. Rivers carry away immense quantities of solid material, and are continually cutting down or extending their basins. The tendency of river work is to reduce the land to a dead level, and a subdued surface is usually an indication of old age.

Relief, or the vertical aspect of a land area, is the result of the forces of upheaval and erosion, which are continually at work. The arrangement of mountains, plateaus and valleys varies in the different continents, and upon the arrangement, climate, the possibilities of development, and the history of a country largely depend. The principal mountain ranges are, however, so disposed that all of the large drainage areas are tributary to the Atlantic Ocean or its arms. Asia, the largest continent, has the greatest average elevation and the highest point of land.

The many changes in the inorganic world profoundly affect the organic world and the distribution of life. In turn, the very processes of nature are largely influenced by living organisms. The spread of any species, animal or vegetable, is promoted or retarded by such geographical features as oceans, mountains, plains, deserts, and climate, but marine animals, by withdrawing dissolved carbonate of lime from the sea water, have constructed mountains of limestone, and vegetation retards the work of denudation, regulates rainfall and modifies the rate of evaporation. Plants alone are able to construct organic from inorganic material, and animal life is dependent directly or indirectly upon plants for food.

All plants and animals are adapted to certain environments and could not live if the essential conditions were changed, but every form of life does not of necessity reach every region suited to it. Natives of one country when carried to another frequently develop with amazing rapidity, even to the extent of crowding out indigenous species. In the tropics, the forests contain a variety of forms, and the large animals live singly or in families. In the temperate zones many plants and animals for mutual protection are gregarious. Forests often contain only one kind of tree, and the variety is never great. Grasses do not grow singly as in hot climates, but form a sod. Animals move in herds and fish in shoals.

Natural distribution has been greatly modified by man. In some regions the large land animals have been exterminated, and vast forest tracts have been removed. Domestic animals and cultivated plants have replaced the native species. Man alone of living creatures is able to rise superior to his environment, to conquer and control adverse geographical conditions. This faculty is acquired, and is the result of long development. Primitive man was undoubtedly as helpless as other animals. The same sort of barriers that retard the migration of species, have also affected the growth of nations, and no thorough conception of history, which is a record of man's development, can overlook the fundamental importance of geography. It was not until the barriers were broken down and until isolation gave way to intercourse with other peoples that civilization made safe and permanent advances.

Political Geography deals merely with the distribution of the human race in different communities, but an intelligent study of the boundaries of states involves an acquaintance with natural geographical conditions and the history of the inhabitants. It has been proposed to divide history into three periods. The first, known as the Fluvial, includes the growth of nations developing in fertile river deltas, with such scanty means of intercourse as the streams afforded. The Mesopotamian nations of Assyria and Babylon, the Egyptians, and the Hindus, are well-known examples. As the sailor became more venturesome, and skirted the shores of large inland seas, the Mediterranean period succeeded the Fluvial. Columbus and Vasco da Gama inaugurated the last, or the Oceanic period. Such a view is at least not inappropriate in tracing the development of commerce.

Commercial Geogrophy is the most practical branch of the subject. It means a knowledge of the distribution of the world's products, of existing demands for these commodities, and satisfactory means of transportation and exchange. The Phœnicians were the first great traders. Their horizon was practically limited by the shores of the Mediterranean, although they sailed beyond its confines, and many of the goods with which their ships were laden were brought to Syria by caravans. The Phœnicians were succeeded by the Carthaginians and the Greeks, but the typical merchants of the Mediterranean class were the Venetians. Their supremacy in the world's commerce was unquestioned until, at the close of the 15th century, the Atlantic succeeded the Mediterranean as the highway of trade. The centre of the world's commerce then passed in succession from Portugal to Spain, and then on to Holland, the Hanseatic towns and London. To-day commerce is not a monopoly, but is world-wide. In volume of trade the United States is surpassed by no other nation, but competition is keen, and the successful merchant of the future must be well versed in that knowledge of which geography forms the basis.

The growth of commerce has been in direct ratio to the extent and rapidity of geographical discovery. Some of the conditions, which are favorable or unfavorable to trade, are quite obvious. An indented continental outline and navigable rivers reaching the interior are most desirable features. In these respects, Europe and North America are fortunate. Asia also is penetrated by arms of the sea, but her largest rivers, like the northern streams of North America, are practically useless, because they are tributary to an inhospitable frozen sea. Africa has no breaks in its contour, and its rivers reach the sea by dropping from a plateau. Though lying next to Europe, it baffled both the curiosity and the greed of her adventurers until the latter half of the 19th century. South America is not wanting in inlets, and her river systems are remarkable, yet very little is known of the interior. It becomes evident that latitude is an important factor in the case of both Africa and South America. The torrid heat, the burning desert, and the deadly fever were obstacles which the African explorer dreaded. The stagnation of South America is also explained when its tropical position is considered. Aside from topography and climate, the character of the inhabitants has much to do with the success of commercial intercourse.

Commerce has expanded because man has been able to meet and to overcome natural obstacles. He has to a great extent eliminated time and distance, by cutting canals through isthmuses, by connecting the shores of the oceans by continental railroads, by the substitution of steam vessels for those propelled by the wind, and by girdling the globe with the telegraph. He has modified climate both as to rainfall and healthfulness by the planting or removal of trees, and by drainage of the ground. By irrigation, he has made the arid waste productive and fruitful. At the beginning of the 19th century, the merchant was obliged to visit the region in which he desired to purchase his commodities, and to carry with him the money for payment. Now, by the aid of a cosmopolitan system of credit, he may within a few hours buy in one part of the globe and sell in another without leaving his office.

F. B. Greene, A.M.,
Secretary, Geographical Society of Philadelphia.

Geological Society of America, an association of geologists organized in 1888. It was the outgrowth of the geological section of the American Association for the Advancement of Science. The society has a restricted membership of 300. A quarterly bulletin is issued under its auspices.

Geological Survey, United States, a bureau of the Interior Department created for the purpose of preparing a map of the United States, classifying the public lands, examining the geological structure, mineral resources, and the products of the country. To these duties have since been added those of investigating the extent to which the arid lands of the West can be redeemed by irrigation, segregating the irrigable from the non-irrigable lands, and the selection of sites for reservoirs and canals for the purposes of irrigation. The maps made by the Geological Survey are all on a large scale, and have a degree of accuracy and a minuteness in detail incomparably greater than ordinary maps. The smallest scale is 1-250,000, or about 4 miles to the inch, and this scale has been employed for regions of the West which are thinly settled, and where the topography is mountainous. But it has been superseded by scales of 2 miles and 1 mile to the inch, the latter for populous regions with slightly or moderately diversified topography, like Massachusetts and New Jersey. The maps are engraved on sheets which, with the 4-mile scale, embrace 1° of latitude and 1° of longitude. The 2-mile maps embrace tracts of half the above linear or one fourth the areal dimensions; the 1-mile maps embrace one fourth of the above linear and one sixteenth the areal dimensions. The topography is represented by "contours" or "grade curves"; that is, by lines of equal altitude above the sea. The contour intervals are uniform for each sheet, but vary in different sheets according to the character of the country. In some tracts the contour intervals represent a difference of elevation of 200 feet, these being in very mountainous countries, while in flat countries and on large-scale sheets they may be as small as 20 feet. The general construction and methods of all maps are, however, the same.

There are three principal branches of the geological survey: (1) Geology proper; (2) topography; (3) irrigation surveys. The geological branch investigates the stratigraphy, the geological structure and history, the lithology, mineralogy, and palæontology, the ores and mines, and in general the natural economics, resources, and physical geography of the country. The topographic branch prepares the maps; the irrigation branch investigates the possibilities of irrigation and selects the irrigable lands and sites available for reservoirs and canals. The work of the topographic branch is the basis of the work of the other two, and all the results of the latter are projected on the maps. The publications of the survey are: (1) the annual report of the director, which, besides the administrative report, contains memoirs on geologic subjects by members of the survey, and is distributed according to the regulations of the Interior Department; (2) monographs on the leading subjects of special investigation by the geologists; (3) bulletins on more limited special subjects of research; (4) an annual volume of mineral statistics. The last three are distributed gratuitously only to designated libraries and to learned corporate societies, which send their own publications in exchange. Otherwise they are sold by the director and the money deposited in the treasury. See GEOLOGY; IRRIGATION; TOPOGRAPHY.

Geological Survey, Methods and Publications of the. The preceding article states in a general way the functions of this Survey as originally defined by Congress, together with subsequent modifications which included within the scope of its duties the study of the hydrographical conditions relating to water power, and to the irrigation of the arid lands of the western states.

As the geologic and hydrographic work depends upon the topographic work, the preparation of a suitable topographic map received primary consideration, and the general lines of operations extended to secure it were very definitely outlined from the earliest period of the Survey, so that at the present time over 900,000 square miles, or 30 per cent. of the total area of the United States, exclusive of Alaska, has been surveyed and mapped for this purpose.

In the execution of the field work the procedure has conformed to the general methods employed in accurate trigonometrical surveys; but the enormous extent of the territory surveyed; the great diversity and the peculiar arrangement of the natural features of the country, and the necessity for executing the work as expeditiously as possible, and yet consistent with all the requirements of thorough accuracy, have tended to develop methods which are not only specially applicable to the work of the Survey, but also form a group of comparatively new methods available for any other line of topographical work. These methods may be briefly outlined as follows:

The surveying and mapping operations conform to the general plan which divides the whole area of the country into a series of quadrangles each of which is equal to a square degree, that is, each quadrangle is bounded on the east and the west by a degree of longitude, and on the north and the south by a degree of latitude.

The surveying operations consist in the extension of a system of primary and secondary triangles with tertiary triangulation points over the whole country, accompanied by three systems of level lines, supplemented by a system of road and stadia traverse.

The primary triangulation has been planned for the control of the work over the whole country, thus insuring the accurate ultimate meeting of fragmentary surveys which may be initiated a hundred or even a thousand miles apart. In this work, the triangles are expanded from accurately measured base lines, and connect various points of reference the geographical positions of which have been accurately determined by the most approved astronomical methods. The astronomical work consists of: (1) the measurement of the zenith distances of stars by means of delicate zenith telescopes, for the determination of latitude; (2) the exchange of telegraphic time signals between unknown astronomical positions and a known astronomical position, such as a first class observatory, for the determination of the differences of longitude; and (3) the observation of circumpolar stars for the determination of the azimuth of a line, such as a base line, or the side of a primary triangle. The base lines are measured by means of base bars, iced bars, or steel tapes, proper allowances being made for sag, pull, etc., and the measurements repeated several times in order to reduce the probable error to a minimum of less than 1 in 1,000,000. The elevations of the various stations are established by lines of precise levels run from the datum of mean sea level determined by means of accurate tide gauges. The angles of the triangles connecting these stations are measured by means of theodolites equipped with high power terrestrial telescopes. From the data thus obtained, the lengths of the sides of the various triangles are computed and the entire system of triangulation plotted on the topographic map to furnish the primary control for the secondary detail.

The secondary triangulation is usually executed by means of the plane table, and new points located so as to give from one to three good tertiary triangulation points per square mile. The elevations of these points, usually hill summits, are determined by the measurement of vertical angles of elevation and depression, depending upon spirit levelling, while the lower relief of the country is determined by lines of secondary spirit levels run six miles apart with intermediate lines of flying levels run three miles apart with sufficient accuracy to allow them to close on the secondary levels within the limits of one or two feet.

Traverse Lines.—Where the country is covered with dense forests, or where the surface relief is insufficient for triangulation purposes, both the primary and secondary control consists of a system of primary traverses checked by primary triangulation locations, or by astronomically determined positions. These traverses are run by compass and plane table, and a secondary system of traverse line consisting of odometer and stadia measurements of roads is interwoven with the plane table work. The data obtained from the secondary traverses is plotted upon the plane table sheets during the progress of the work, and is subsequently adjusted upon the final map between the check points established by the primary traverse, or by the plane-table triangulation, the distances between which are so short—1 to 4 miles—that errors of location are scarcely perceptible upon map scales of one inch to one or two miles.

The work of primary triangulation and precise levelling is usually executed a season in advance of the topographic sketching, while the secondary triangulation, traverse work, and lines of flying levels are immediately followed by the topographic sketching, both classes of work being done by members of the same party. The data obtained from the secondary triangulation and traverses is then plotted upon a sketch sheet. This data is of such a character that each sheet includes from two to five trigonometric locations; from four to eight inches of road traverse; and one or more instrumental elevations, per square inch. Equipped with a sketch sheet thus prepared, the topographer places himself at a point of known elevation and sketches on the sheet by eye with the aid of a hand level the plan of the contour line which passes through his position. In open country, the contours may be located in this manner quite accurately for a distance of half a mile in either direction from his position, corresponding to a total distance of an inch upon the sketch sheet. In wooded country where the figure of the contour cannot be seen beyond his immediate position, he proceeds by road carefully observing the variations of the slope, and determines the differences of elevation for short distances between check points by means of the aneroid, and sketches in the plan of the contour according to the data thus obtained. In cases where the number of accurately determined elevations are insufficient, more locations are fixed by vertical angulation, or by flying levels as the work of sketching progresses. In this manner a system of contours is built up along the roads and water courses, and if the lines do not practically fill up the entire sheet, the topographer walks into the spaces within the road circuits, and by means of stadia lines for long distances, or by pacing for short distances, determines the positions of the contours required to complete the sheet. The sketches thus obtained are inked in, either in the field or at the office, and are then reduced to the scale of the final map by photography and form the copy for the engravers.

The great topographic map of the United States now being thus prepared by the Survey, is published in atlas sheets of approximately uniform size, 16½ by 20 inches, on which the mapped area occupies a space 17½ inches in height, and 11½ to 16 inches in width according to the latitude. The division of land represented by an atlas sheet is called a "quadrangle," and is always bounded by parallels of altitude and meridians. Although the sizes of the sheets are always the same, three different scales are employed in the mapping of the surveyed areas in order to serve different purposes and to suit various conditions. A scale of 1 : 62500, very nearly one inch to one mile, is used for mapping the thickly settled, or industrially important sections of the country. The sheets on this scale cover an area of 15′ of latitude by 15′ of longitude. A scale of 1 : 125000, very nearly one inch to two miles, is used for mapping the greater part of the country. The sheets on this scale cover an area of 30′ of latitude by 30′ of longitude. A scale of 1 : 250000, very nearly one inch to four miles, is used for mapping the desert regions of the western states, and gives sheets which include an area of 1° of latitude by 1° of longitude.

This map is printed in three colors and shows the following named classes of natural and artificial features: (1) *Water*, including seas, lakes, ponds, rivers, creeks, canals, swamps, etc., are shown in blue. (2) *Relief*, including mountains, hills, valleys, cliffs, etc., are shown in brown contours. (3) *Culture*, or the works of man, such as villages, towns, cities, roads, railroads, boundary lines, etc., are shown in black. The features shown in blue and black are self-explanatory. In the case of the brown contour lines, each contour passes through points which have the same altitude above mean sea level, and a series of such lines arranged one above the other at regular vertical intervals, but appearing on the map at irregular intervals, that is, close together where the slopes are steep, and far apart where the slopes are gentle, accurately delineates the general configuration of the country, and gives the elevations of all points above the level of the sea. The vertical interval adopted varies according to the character of the country mapped. In a flat country it may be as small as 10 feet, while in a mountainous region it may be as large as 200 feet. Usually, every fifth contour is made heavier than the others, and is accompanied by figures giving its elevation above the level of the sea. The heights of many other points, such as the intersections of ordinary roads and highways, railroad crossings, and stations, the summits of uplands, hills, and mountains, and definite bench marks, are also given in figures which are placed close to the points to which they refer, and are correct to the nearest foot. Each sheet is designated by the name of a principal town, or the name of some prominent natural feature within the district represented, and the names of the adjoining published sheets are printed on the margins. Explanations of the various conventional signs used are printed on the back of each sheet, and materially assist in the reading of the map.

This topographic map is the base on which the facts relating to the geology and the mineral resources of a quadrangle are represented, and constitute the sheets of the Geologic Atlas of the United States published by the Survey. The price of the topographic sheets is five cents each when the number purchased is less than 100 copies, and two cents each when they are ordered in lots of 100 or more copies. In the Geologic Atlas the topographic and the geologic sheets of a quadrangle are bound together, and, accompanied with a textual description of the district represented, constitute a folio of the Atlas. These folios are sold for twenty-five cents each, except those that have received special treatment and are unusually comprehensive. The price of such varies according to the character of the information afforded, the number of the maps in the folio, etc. All communications relative to these maps, or any other publication of the Survey should be addressed to The Director, United States Geological Survey, Washington, D. C.

The accompanying map is a small portion of the Housatonic quadrangle which includes portions of Massachusetts, New York, and Connecticut. It affords a general idea of the topographical treatment; but, being printed only in black and white, it fails almost completely to give a true idea of the actual beauty of the original sheet as printed in the three conventional colors already described.

The methods by which these maps are reproduced for publication utilize the most approved processes and refined manipulations of the photographic and lithographic arts as applied to map making. As has been heretofore stated, the plane table sheets are roughly inked in and then turned over to the photographic division of the Survey, where they are reduced to the scale of publication. These reductions are made with the greatest care and are absolutely free from any of the inaccuracies which usually result from the use of poor lenses, poor glass plates, etc., in ordinary photographic manipulations. Each sheet contains all of the features of the quadrangle, that is the water, relief, and culture, in black and white. From a sheet thus prepared, the engravers make an exact tracing on a sheet of transparent gelatine and transfer copies of the same to three stones, one for each color of the final print. In this way, the engraver of a particular class of features has the positions of the other two classes of features on his stone also, and is thereby enabled to arrange the figures, letters, etc., which belong to his class in such positions that they will not conflict with the figures, letters, etc., belonging to either of the other two classes. When the three stones have been engraved, an impression print from each one is taken in a hand press, with lithographic ink, and transferred to three smooth stones from which the final map is printed by three successive color printings in a power driven cylinder press. In this final work, an exact superposing or absolutely perfect register of the three prints is sought for and obtained by the most careful adjustment of the positions of the stones in the press, the use of well seasoned paper, etc., and any sheet which exhibits a discrepancy of register exceeding one two-hundredths of an inch, barely the width of a very fine line, is discarded and destroyed. As examples of the art of modern map making, these sheets are practically unrivalled in their particular class by any other similar maps in the world. The importance of the topographical and geological publications of the survey cannot be overestimated. The maps form the basis of all the state and county maps of the United States published for commercial purpose. Their accuracy is such that they are readily available for use in connection with the preliminary work of railroad, canal, and other surveys, and for purposes of verification in damage suits and other legal proceedings before the various tribunals.

Portion of Housatonic Quadrangle

It is true that the work of the survey costs the Government hundreds of thousand of dollars annually, but the returns through the various industrial channels, and through the development of the natural resources of the country, amounts to hundreds of millions.

This is especially the case relative to the work and publications of the geologic department, without which the high economical development of the mineral resources of the country would be practically impossible.

In the matter of the use of instruments, such as the plane table, stadia, and tape, and in the application of precise but rapid methods in the execution of the particular class of surveying practiced, the various publications of the survey set the standard for this country and are invaluable not only to the student-engineer, but also to the actual worker in the field. These publications may be obtained by application to the Director of the Survey at Washington, D. C.

Geology is the science of the Earth's history. In common with myths of creation that appear in the folk-lore and religions of all peoples, geology recognizes the essential fact of changes which make up a history; but it differs from the myths in being well-ordered knowledge based on observation, in interpreting natural phenomena according to the laws of the material world, and in seeking causes among the forces of the physical universe. Guesses at the beginning or the end are not part of the science, which deals only with those eras that are recorded in the rocks.

Geology is a very comprehensive science, embracing some knowledge from each of the chief natural sciences. The Earth, a planet, may be studied as a member of the solar system and in comparison with stars; and in so far geology joins astronomy. The Earth is composed of elements, associating and combining according to the laws governing physical and chemical activity; thus geology includes physics and chemistry as applied to rocks, seas, and air. The Earth has been and is the home of multitudes of living beings, whose development has been conditioned by her changes and is part of her history; organic evolution, as studied through comparative botany and zoology, is, therefore, part of geology. A great geologist has defined geology as astronomy, physics, chemistry, and biology applied to the Earth.

Aims of Geology.— The aims of geologic research may be classed as three: (1) To discover the principles, the forces, and the processes of the Earth's development; (2) to trace the history of the physical world and of its organic inhabitants; (3) to advance the exploitation of natural resources for the benefit of mankind. Those views which are now current and which represent the present advancement of the science are briefly suggested in the following paragraphs, but for a more complete treatment the reader must be referred to the books and articles mentioned in the bibliography.

A Fundamental Principle.— The causes which are now effective in producing changes in the Earth have been in operation throughout all known eras of her history, and the past is to be interpreted in the light of the present. This general principle applies to all departments of the science, and is the foundation upon which all knowledge of the past is built up. If the substance of the Earth ever formed part of a nebula, it condensed according to causes now operating in nebulæ. If it was once a molten globe, it cooled and solidified as a molten globe now would. Upon the cool Earth, rains have ever fallen, streams have always flowed, seas have been gathered into basins about lands; and the processes now active on the continents, in the oceans, and within the rock mass have been active continuously, but in greater or less degree.

The intensity of geologic processes is unequal at the present time in different parts of the world, and during past eras has varied from age to age for each and every zone. The most familiar process, that of erosion, which comprises all the chemical and physical effects of the atmosphere upon land surfaces, produces very different results in lowlands and in highlands, in humid regions and in deserts, in the tropics and beneath the pole star; and during the past it has varied in the nature and intensity of its activity, as the governing conditions were more or less favorable. In these respects erosion may be considered as an illustration of the variability of other processes, all acting under immutable laws.

Geologic Forces.— The natural forces which are involved in geologic processes are: (1) Radiant energy of the sun, namely, light and external heat; (2) gravitation, both terrestrial and general; (3) chemical energy; and (4) the vital force.

Summary of Effects.— It may promote a clearer understanding of the operation of these forces to give some illustrations of their effects, before making a fuller statement of the processes of geologic change. Sunlight and heat directly act on rocks in deserts, where they are unhindered by vegetation and moisture. The brilliant glowing days and the radiantly clear nights result in changes of temperature which cause rocks to expand and contract and in consequence to crumble. The sands of Sahara are in part grains thus broken from granite. Less direct, but more widely effective, is the action of the sun through the agencies of the atmosphere, the winds, snows, frost, rains, and running streams, all of which are started and kept in motion by the sun. In life also the sun's energy is manifest.

Gravitation, as it is expressed in the force by which all things are attracted toward the Earth's centre, is familiar to us. Winds are influenced by it, rains obey it, and streams flow in accordance with the laws of its attraction. Thus gravitation and sun force cooperate in the movements of the atmosphere. Gravitation holds the oceans in their beds and the firm Earth to its form. It is the cause of pressure within the Earth, and immediately or remotely of the Earth's internal heat. The manifestations of pressure and heat are therefore attributable to it, and these include a great range of phenomena.

Chemical energy, which controls combinations of elements, and of which we avail ourselves in manifold ways, governs the constitution of minerals, the composition of the air, and that of the sea. It is effective when rocks, like an iron bar, rust at the surface of the Earth, as it is also when they change in structure and recrystallize within the Earth. All ores are chemical compounds and owe their concentration in valuable ore bodies to chemical reactions.

The vital force has animated myriads of creatures, which have built their shells or skeletons, each according to his kind, and left them as grains in great rock masses. Strata many hundreds of feet thick and many thousands of square miles in extent are composed of such remains, which thus form stupendous monuments to the activity of the vital force. But this is not all. Living creatures are liable to change according to environment, and obey a great law of adaptation and progress, the law of evolution. They have, therefore, changed as the conditions of life have changed; they have evolved from lowest to higher forms, and are evolving. Finding their remains in strata according to a definite sequence, we are able for that place to trace the progress of evolution; and comparing stages of evolution as discovered in strata in different provinces or continents, we can ascertain in how far the succession of events affecting life was the same or was different, in Europe, for example, and America. Though differences are discovered, likenesses are surprisingly general and close, and it is believed that the parallel developments of life in different continents have occurred nearly simultaneously, age for age. Thus the time scale of geologic history is based on the evolution of living forms through vital force.

Geologic Processes.— The forces which have been described are active, and long have been, in three realms — in the atmosphere, in the seas, and in the solid rocks. They interact in each realm, and in each give rise to a group of characteristic phenomena. Thus there is an interaction or process which goes on in and beneath the atmosphere, where air and moisture affect the surface of the land, and which is called *erosion*. A second process is active in lakes and seas, in and beneath the waters; it is called *sedimentation*. And a third is that which is manifested in the movement and distortion of rock masses, and which is known as *deformation*.

Erosion.— The process of erosion may be briefly described as the process of land sculpture, the effects being observed in the forms of plateaus, mountains, hills, slopes, valleys, and plains. The forces involved have already been stated as sunlight, sunheat, chemical energy, and gravitation. The process involves several distinct sub-processes, which are broadly classified under the four heads of weathering, transportation, corrasion, and aggradation. The active agents by which the forces are applied are, primarily, the air and water in its various forms, and, secondarily, vegetation and other organisms, with their products of decay. The materials affected are rocks, and these, being aggregates of chemical compounds more or less compactly bound together, differ greatly in the degree of resistance which they offer to the same activities. Limestone, for example, being readily soluble in water containing carbonic acid, occasions valleys in a region of vegetation and moist climate, whereas sandstone maintains ridges. In an arid district these relations may be reversed.

Taking up the sub-processes of erosion we may briefly describe them, considering that of weathering first. Changes of temperature, such as ensue when brilliant sunlight is followed by clear nights, occasion sufficient change of volume in rocks to cause them to crack and shatter, as has been stated. The expansion of water in freezing widens crevices. Chemical changes in rocks are brought about at and near the surface of the ground, chiefly through water, the common solvent, which becomes particularly efficient when it contains carbonic acid or other organic acids resulting from decay. With many minerals water forms a chemical combination by which they become hydrated, as it is called, and their volume is thereby increased. Feldspar, a constituent of many crystalline rocks, is especially liable to this change, and the force of expansion due to the chemical combination is sufficient to dislocate and loosen the bonds that hold the grains together. Consequently, such rocks crumble anad form a loosened, porous covering to the sounder rock remaining beneath. This porous material, being hydrated, is more readily attacked by carbonic acid; and soluble carbonates of iron, lime, magnesia, soda, potash, etc., are formed and taken into solution. Certain insoluble constituents (chiefly quartz, silicate of alumina, and oxide of iron), remain mixed in various proportions, and constitute what are commonly known as sand, loam, and clay. The rocks which are not usually recognized as crystalline, such as sandstone, mud rocks or shales, and limestones, are broken down, in part mechanically, through heat and frost, and in part chemically. Limestone, as already stated, is peculiarly liable to solution. Those silicious rocks known as quartz, sandstone, and quartzite are especially resistant, and where they occur in masses always maintain hills, which stand higher than the worn surface of other rocks, or where they have become broken may be carried to great distances and form beds of white and brown pebbles, so commonly found.

The sub-process *transportation* is effective in distributing the products of weathering. Gravitation is the essential force, and the mantle of soil which accumulates through the mechanical and chemical activities that have been enumerated, is moved ever downward in one way or another. On steep slopes and cliffs gravity acts simply upon any loosened block, whose diminishing support finally fails and allows it to fall. Of soil resting even on gentle slopes, a mass softened by water may creep downward, or, loosened, move in such volume and so far that we recognize it as a landslide. These, however, are minor effects. In arid regions wind, the chief carrier, moves the sands of the desert, whose billows have been likened to the sea. Greatly predominant, however, the world over, is the work of running water, which from the tiny rivulet that gathers from the rain falling on a field to the great floods of the Mississippi or Ganges, is always laden with a greater or less burden of earth held in suspension, or with substances taken from the rocks by solution. The effects of this almost universal activity are incredible. It must be credited with having changed the face of the Earth again and again in the long lapse of geologic ages, and with having swept away the greatest mountain ranges and reduced continents to flat plains.

Corrasion, the third sub-process, is the wearing of stream channels. Waters gathering on a soil-covered slope wash with them particles of sand and clay. Where they fall over any inequality, they deepen the hollow beneath it, and undermine their tiny banks. Gathering volume and velocity, they acquire force to work more vigorously, and if not checked develop deep gullies. The stream at any place in its course where it has sufficient velocity, sweeps along whatever sand and clay has been carried thus far, and scours the hard rock bottom. The effect is that of a file, and the channel is deepened. If the resistant rock is a rim underlain by softer beds, the waters dig out the channel below and form a gorge, at whose upper end is a cascade, perhaps a Niagara. They may completely file through or undermine the hard rock, and thus in time lower the level of the channel to a position determined temporarily by some rock rim farther down the stream, and ultimately by the level of the sea. There is no limit to this activity of the stream short of that slope from sea-level on which the waters can no longer keep the channel clear of sediment.

The cut which any stream makes is narrow, and it may become a deep canyon without growing very wide; but the rocks differ very much in their capacity to maintain steep cliffs or slopes; none of them endure forever. Wherever cliff faces stand boldly up, atmospheric activities loosen and undermine each jutting point, and as each falls, exposing another, the cliff recedes. When the retreating cliff becomes a slope, branching gullies develop and grow like twigs at their heads, since not only the main stream is engaged in sinking its channel, but every tributary, including the smallest rivulets, is doing the same according to its power. Growing, branching, multiplying, they become widely effective, and in time attack the entire land surface, however extensive. Throughout the early stages of this process, while channels are narrow, slopes are steep and the surfaces of highlands are broad; the landscape is then said to be young. When the streams have carried on their work so far that valleys are wide, slopes gentle, and the highlands but narrow ridges, it is said that the topography has become mature. And when, the process continuing, the highlands lessen in altitude until they become eminences scarcely rising above the valley plains, the phase is called aged.

Aggradation is a word which may be translated as valley filling. It applies to that sub-process of erosion whose effects are seen in bottom lands and flood plains along rivers. The sand and clay which are transported by rapid streams are dropped where the current slackens, it may be at a distance from the sea and high above it, or along the lower reaches of the river. The one is but an interruption in the journey of the sediment from the heights; the latter is a more prolonged but not necessarily a final stop. The winding course of a mud-loaded stream, like that of the lower Mississippi, is caused by the shoals which form in eddies and, diverting the current, cause it to cut away the opposite bank. Thus shifting, a channel wanders widely and widens the valley. By deposits made during moderately high water a heavily loaded river also builds up its banks till they stand above the adjacent flood plain, and in time of floods it may break through them and spread a fresh deposit over great stretches of fertile plain. Every spring has its story of broken levees along the Mississippi, and that river is not peculiar in this respect. The ultimate character of all valleys, if development goes on unhindered, is that of flood plains as extensive as are the lands, and valleys thus become stored with alluvium, which in course of geologic changes goes to form sedimentary rocks beneath the sea.

A phase of erosion which is not included in the above statement is that carried on by the sea along the shores where it attacks the land. The power of the sea is derived chiefly from the winds, and depends upon their prevailing direction and the distance throughout which they blow across its surface, for the winds raise the waves, which gather force as the effect is continued over wide stretches, and the dash of the waves on the shore is the effective eroding activity. The land resists according to its altitude and the coherence of the rock masses, in some places developing bold headlands, and elsewhere becoming fringed by extensive beaches. The attack of the sea is delivered in a horizontal plane at and just below the water surface, and its effect, when sufficiently continued at one level, is to cut away whatever is higher, and to produce a bench, at the inner margin of which rises a cliff or slope. The material that is worn away is carried by undertow and shore currents and distributed along the coast in favorable locations to form beaches, and beneath the sea as widespread deposits. These phenomena belong to the process next to be described — that of sedimentation. The effects upon the land depend not only upon the resistance offered to the sea, but also upon the continuance of the process. If a shore has been newly established it follows all the sinuosities of the surface contour, retreating far landward in deep valleys, projecting far seaward about headlands and islands. But when the sea has cut and built at the same level during a long time, it may have carved away the headlands and extended beaches across the bays, and thus have straightened the shore line. There are, therefore, youthful shores and aged shores, as there are youthful canyons and aged valleys or plains.

Sedimentation.— Sedimentation may be described as that process which results in layers of sediment spread under water. In a special sense the name is applied to the process as carried on in lakes and seas, and to the strata which are thus produced, but in a more general sense it may include methods of deposition of material borne by streams, by ice, and by winds, and may thus cover a large part of the effects above included in the process of erosion. In this article it is used in the more special sense, sedimentary strata being considered to be lacustrine or marine in origin.

The sub-processes of sedimentation are *sorting*, *distribution*, and *deposition*. They are effected by moving waters, and thus depend upon the winds, tides, and ocean currents. All of these movements are directly or indirectly effects of gravitation, which is, therefore, the force to which sedimentation is ultimately due.

The work of waves in eroding the land was referred to in a previous paragraph. Through their constantly repeated attacks the pebbles and sands of beaches are abraded and reduced in size, and the finer is stirred up and carried away from the coarser. Every wave agitates and washes the material of a beach, and the successions of waves constitute a grinding and sorting mill of great efficiency. That material which may be moved by the onrush of the waves is swept along the beach in the direction of the prevailing winds or heaviest storms. That which is fine enough to be taken up by the undertow is carried down under the sea and distributed to a greater or less distance from the shore over the bottom. This work of the waves is exceptionally well illustrated in the beaches that fringe the Atlantic coast of the United States from Long Island to Florida, and in the mud which is deposited over the sea bottom even to a distance of 100 miles southeast of it; for this is a coast on which the waves break with great power, under the influence of the prevailing southeasterly winds, and which is composed of soft rocks that offer comparatively feeble resistance. It is therefore a coast of aged aspect, characterized by long, slender, wave-built beaches, and it contrasts strongly with the young rock-bound coast of Maine.

Where any great river, such as the Mississippi, brings its burden of sand and clay and delivers it to a sea in which the waves have but moderate power, as in the Gulf of Mexico, the river builds a delta, which interferes with the course of waves and currents, and is attacked by them. The form and extent of the delta are a result of the conflict between the river and the sea. The currents of the latter receive a considerable part of the river's burden directly, they may wear away other portions which the stream deposited when conditions favored, and they carry the material on to some place where it settles. Thus the South Atlantic ocean current circulates into and around the Gulf of Mexico from south to north and east, and receiving much clay and sand from the rivers whose mouths it passes, deposits it in eddies along the coast of Alabama and Florida; another part is swept on through the Straits of Florida, where the constricted Gulf stream flows swiftly, and is carried out to form a great bank where the Atlantic deepens north of the Bahama Islands.

Another kind of sediment, consisting chiefly of carbonate of lime, is derived from marine waters through chemical or organic agencies. Lime is known to be readily soluble when combined as a bicarbonate, and to be relatively insoluble as a monocarbonate. It enters into solution as the former, and is deposited in the form of the latter as a calcareous mud. The chemical and organic conditions which govern this process are not thoroughly understood. It is known that under some circumstances the change from bicarbonate to monocarbonate may occur through chemical agencies alone, and that in other cases it is carried out through the agency of organisms which live in the sea. Whatever the process, the result is the formation of vast accumulations of calcareous mud, which are chiefly of marine origin and distribution. The South Atlantic ocean current again affords an example; it sweeps through the Caribbean, bearing a multitude of marine organisms, many of which secrete calcareous parts from the water, and, dying, leave their shells to sink to the bottom. From lands composed largely of limestone flow hard waters that may throw down a limy mud, as is the case in the Everglades of Florida; and this also becomes sediment, which the current sweeps on with the organic remains and with the delta silts of the great rivers. The result is the deposit now forming in every deep hollow of the Caribbean, of the Gulf, and along the Atlantic slope of North America.

In the aspects of the coast of North and South America, from Newfoundland to Brazil, are comprised illustrations of most of the processes of marine sedimentation. There is the coast of Maine, through whose deep embayments sweep swift tidal currents, and onto whose shores play powerful waves, grinding and distributing chiefly coarse pebbles and sand. There is the coast of Long Island, New Jersey, and the Carolinas, whose beaches of clean, white, sorted sand stretch for miles, shutting in the estuaries into which the small rivers deliver their sediment, and enclosing the land within a wave-built barrier. Outside, beneath the shallow ocean, reaches a broad flat, which extends out to the margin of the continent, and on this is spread a small amount of mud, sorted from the sands brought by the undertow and distributed by tidal currents. In the Gulf of Mexico and the Caribbean are found, on a large scale, the conditions of delta building and of marine distribution of fine mechanical and organic sediments. Chiefly by processes such as these the sedimentary rocks have been formed throughout geologic ages.

Sedimentary deposits in estuaries and lakes are similar in many respects to those of seas, but as waves are less effective in these smaller water bodies, the sorting is less complete; shore currents are also less active, and materials are carried to less distance from their source; and that which is swept out from shore is usually fine silt only. Lake deposits are closely related to river deposits, especially in regions where torrential streams sweep detritus from hills far out onto plains and into the margins of lakes; and there are vast accumulations, as in the western United States, of which it is not yet surely known to what extent they are lacustrine or how much is fluviatile.

Chemical deposits may be formed in seas or lakes whenever peculiar conditions favor the separation of a substance held in solution. The commonly accepted view is that the substance must be present in amount sufficient to form a saturated solution, so that it is thrown down by evaporation. Such is the case with enclosed lakes having no outlet, like Great Salt Lake. But there are other circumstances, as when carbonate of lime is deposited from spring waters or from ocean waters without organic agency, where saturation is not the condition, yet the substance separates. Waters circulating in a nearly enclosed sea, like the Mediterranean, and subject, as it is, to excessive evaporation, may reach a condition of concentration short of saturation, yet adequate to cause precipitation; mechanical agitation, as that of the waves, may suffice to dissociate a loosely united compound like bicarbonate of lime, and thus to precipitate the monocarbonate (the exact chemical conditions are open to discussion and to experiment); but great bodies of chemical sediments exist, and among them carbonate of lime or limestone, sulphate of lime, or gypsum, and rock salt are the chief ones.

Deformation.— In geology the verb to deform is used in its exact sense — to change form — and not with the more commonly recognized meaning — to put out of shape or disfigure. The geologic process of deformation is therefore one of change of form, and may involve altering by pressure the shape of a stone, a bed or body of rock, a mountain mass, a continent, an ocean basin, or of the whole earth. It is a universal process, which has been effective throughout all time, though not always equally so. The earthquake and the volcano are effects of very local deformation, with intense activity and under special conditions; but the process is far more general than are earthquakes or volcanoes.

Terra firma — the firm earth — appears to be a rigid, unyielding sphere only because we are able to observe but small areas, and these for but brief times. The rounded form, flattened at the poles, is determined by the balance of gravitation with the centrifugal force due to rotation on an axis. Were the attraction of gravitation more or less, the form would still be round, but would differ from the present; and so also, if the rate of rotation were to change so that a day were longer or shorter. This is so not because the earth is soft inside, but because it is so large a mass. The effect of mass may be seen in drops of mercury on a glass plate; tiny ones are nearly perfect spheres, larger ones are much flattened. If the earth were a solid sphere of granite, and could be supported at rest on a pedestal, it would flatten down to a thin sheet.

The rounded form of the whole earth being an effect of balancing forces, we may inquire what features of the surface are, similarly, effects of equilibrium. Are the ocean bottoms underlain by heavier material than that of the continents? And is that the reason why they have sunk so low in balance with the high-standing lands? Balance water and oil in a U-shaped glass tube, and this idea of the heavier ocean beds and lighter continents may become clearer. It is that which is now most commonly accepted as the probable explanation of the extensive inequalities of the earth's surface. Yet it has also been made evident that the earth is on the whole a rigid body; one line of reasoning being that if it were not there must be tides in the land as there are in the ocean, yet observations with delicate instruments have failed to detect land tides; another that earthquake shocks travel through the spheroid at a rate at which only a highly rigid substance could transmit them. This rigidity is conceived to be an effect of pressure which is due to weight of all the mass tending toward the centre. We have seen that the ocean basins are believed to crowd heavily downward, and to hold higher the lighter continents, so that the measure of the rigidity (which is called viscosity or resistance to change of form) is less than the weight of masses beneath ocean basins; but it is obvious that the viscosity is sufficient to sustain large high masses, probably those of mountains, not balanced by masses in lower positions. Time is an important element in these problems, the earth yielding to a sufficient pressure, as tar yields, slowly.

This sphere, whose mass is yielding, yet up to certain limits firm, is stored with energy in the form of internal heat, and is subjected to strains due to external attractions, to cooling, and to the gradual effects of erosion and sedimentation, removing mountains and other elevated masses from their positions on the continents to zones of deposit beneath the margins of the seas. The equilibrium is, therefore, liable to disturbance, which is expressed in movements of one sort or another. Whatever the nature of these movements, they all come within the process of deformation. Gravitation is the ultimate cause, but the immediate causes in any particular case may be obscure, and the search for them includes the most difficult problems of modern geology. Deformation is, therefore, better known by its effects, and through those it must be described.

Turning first to those evidences of movement within rock masses, the more obvious ones are found in forms which we know have been broken or stretched. Pebbles which have been cracked and separated while yet firmly embedded in the rock are not of uncommon occurrence, and there are those which have been pressed out, as one might a ball of wax, until they form long, thin, flattened lenses. Fossil shells whose original forms can be accurately determined are found similarly broken apart or stretched while yet embedded in the matrix of limestone or shale.

Again, rocks whose original character may have been massive or bedded are found to have recrystallized and to have assumed a lamellar structure, like that of a pack of cards. This occurs through a movement which is very like that of cards pressed between the palms and slipped one on the other. Such movements occur on a grand scale at depths beneath the surface of two miles or more and throughout masses of rock which are cubic miles in volume.

Again, it is known that many rocks, such as sandstones and limestones, were originally spread in flat sheets of great extent, as compared with their thickness, even though the latter may amount to several thousand feet. These sheets may be found to be flexed in a series of parallel folds, forming alternating troughs and arches, to be crumpled as though pressed from several directions at once, and to be dislocated and thrust over one part upon another. The compression involved in such folding amounts sometimes to a very notable shortening of an arc of the earth's crust. It is estimated, for example, that in eastern North America the space between the Cumberland plateau on the west and the Blue Ridge on the east, corresponding to the great Appalachian valley and the Alleghany ridges, has been shortened by at least 40 per cent, so that what was 100 miles across is now but 60. And, similarly, the zone of the Alps is estimated to have been shortened by compression by an amount of 74 miles.

Less obvious, but not less certainly effective on a grand scale, are the vertical movements by which ocean basins are deepened, while continents are left standing higher, and mountain systems are perhaps actually elevated in continental areas. The history of continents shows that they may not have maintained from time to time the same extent of land above sea-level, but on the contrary have been submerged now here, now there, now more, now less. These changes are attributed to deformation, in consequence of which ocean basins have varied in size, so that they at one time might contain all the waters, but at other times were relatively not so deep below the continents, which were in part overflowed. The general tendency of deformation is to lessen the earth's size, to shorten the radius, and the grand movements are movements of subsidence, but minor ones, such as the growth of mountain ranges, may be in part or whole movements of uplift, that is, lengthening of the radius.

The phenomena of erosion and sedimentation which have been described afford a means of tracing movements of subsidence and of relative uplift, not only in the present age, but through all the ages of which the sedimentary rocks yield records. As is explained more fully in a succeeding paragraph on the relations of geologic processes, erosion, the process of leveling down altitudes, must come to an end unless renewed by relative uplift. The successions of sedimentary rocks which may be observed in many parts of the world show that everywhere erosion has been at times active, and at other times inactive for lack of the essential condition of elevated lands, and therefore that there have been similar alternations of epochs of relative uplift, which set in motion the activities of erosion, and epochs of constant level, which allowed that process to run down.

Thus from many points of view there are geological phenomena which show that the process of deformation has been of world-wide occurrence, and that it has been more or less effective from time to time during all recognized geologic ages.

Relations of the Geologic Processes.— We have enumerated three geologic processes — erosion, sedimentation, and deformation — in the order in which they are most easily recognized. Erosion goes on daily and before our eyes, and the phenomena which result from it are familiar. Sedimentation is so linked with erosion, and so closely related to the nature of our shores, that many of its phenomena are as easily recognized. Deformation alone is somewhat difficult to grasp; yet if we enumerate the processes in the order of their natural sequence, we must begin with deformation, for it is the initial process, from which the others result. Were the earth a perfectly smooth sphere the waters would be spread over it, erosion would fail for lack of land surface, and there would be no sediments available for the process of sedimentation. Only when, through deformation, the ocean basins should originate, could lands emerge. Even then, if those lands retained their smooth, flat form near sea-level, the opportunity of erosion would be very limited, and the amount of sediment supplied very scanty. Not until lands attained notable altitude above sea-level could the processes of weathering and of transportation deeply affect rock masses and convey any considerable volume of sediment to the sea. Only then could sedimentary rocks accumulate in large volume or of great extent.

Again, although there were elevated lands, the process of erosion tended constantly to reduce their altitude, and thus ever to lessen its own opportunity. If the altitude once established by deformation had not been renewed by subsidence and relative uplift, it must constantly decrease until the mountains had become worn to low hills, and in the lapse of ages to plains. This, indeed, has repeatedly occurred: the continents have seen one generation of mountains succeed another and each one waste away to lowlands. Deformation, therefore, is essential to the renewal of erosion.

And still again, if there be a basin occupied by a sea and so situated as to receive sediment from the land, that basin may in time be filled and its area added to the land, unless, through subsidence of the bottom, its depth be constantly increased. There was, for example, at one time, in the eastern United States, the basin of a shallow bay of the great interior sea which covered part of North America in the Devonian Age. In that shallow basin sediment 10,000 feet deep accumulated, and the ripple marks which occur on the surfaces of the rocks from the bottom to the top of that great thickness, show that it was ever near sea-level. That it could so gather, the bottom must have sunk about as fast as rivers from the adjacent land poured in the mud.

The three processes, therefore, are related to one another in a natural sequence, deformation being the initiative process, erosion the destructive process, and sedimentation the reconstructive process.

CLASSES OF ROCKS.

In General.— Although rocks are of many kinds, which may often be distinguished by the aid of special knowledge only, yet there are four great classes of rocks, which are easily recognized as a rule. Each class comprises those kinds which result from a distinct process, the classification being according to conditions of genesis. One class is due to deformation, one to erosion, and one to sedimentation; and the fourth may be the product of deformation alone or of deformation acting after either of the other two processes. The classes are: (1) igneous; (2) surficial; (3) sedimentary; and (4) metamorphic rocks. Rocks which are thus classified include not only the compact firm substances commonly called rocks, but also beds of ash, gravel, sand, or clay, of loose and incoherent texture. A rock, geologically speaking, is any aggregate of one or more mineral substances.

Igneous Rocks.— Igneous rocks are those whose constituent minerals crystallize from a highly heated condition. They were the earliest rocks, and have developed within the earth's mass at all times down to the present. Their initial condition is commonly described as molten, but only because that is the familiar condition of lavas, a well-known class of igneous rocks. When deeply buried within the earth, they are hot, but may be restrained by pressure from melting, water and gases are mingled with the other constituents, and the condition is probably one of potential fusion and solution. When fusion occurs, either through rise of temperature or lessening pressure, the molten mass behaves like a confined liquid, and pressing into any planes of weakness separates adjoining rock masses. Moving in the direction of least resistance, it rises toward the surface, which it may or may not reach. In the former case volcanic phenomena ensue, and the rocks are said to be extrusive. In the latter case the igneous mass cools and remains buried, and in course of time may be exposed through the process of erosion. It then exhibits the characteristic relations which it has assumed through being pressed in among masses of older rocks, and is called intrusive. The chemical and physical conditions of a magma, as the material of an igneous rock before crystallization is called, are not well understood. From one and the same magma different minerals crystallize out at different pressures and temperatures, and as pressure and temperature vary greatly in the ascent of the magma from deep within the earth to the surface, various kinds of igneous rocks may be formed at different stages of the journey. Thus it is possible to have a continuous series ranging from superficial extrusives down to deep-seated intrusives. The lavas and ash rocks may be taken as the types of the former, and granite as the type of the latter. Within the magma, prior to crystallization, chemical changes appear to go on, and it is observed that a sequence of eruptions in one and the same volcanic region, and presumably from the same magma, may consist of successively varying rocks. One of the purposes of the study of igneous rocks through the methods of petrography, is to ascertain the phenomena of chemical and physical change which magmas undergo, and so to approach the problem of the chemistry and physics of the earth's interior.

Surficial Rocks.— Surficial rocks are products of erosion. Their constituents result from the decomposition of igneous or sedimentary rocks, and the surficial rock masses are formed in various ways, according to the agent by which they are transported to a place of deposit — wind, water, or ice. In composition they differ most markedly from the igneous rocks in that the elements which form soluble compounds, such as the alkaline earths, lime, magnesia, and iron, are removed in solution. Surficial rocks, therefore, consist to a large extent of the insoluble constituents, quartz, silicate of alumina, and oxide of iron. These occur in mixtures, which constitute gravel, sands, clays, and loams of various kinds.

Surficial rocks laid down by water are chiefly river deposits, and come under the general name of alluvium. They are familiar to every one in the bottom lands of streams large or small. Surficial rocks which are spread by wind are little known in districts of even moderate rainfall and vegetation, but in arid regions where dust, resulting from the disintegration of rocks through heating and chilling, is unprotected, they become important. They are exemplified by the sands of the desert. Again, upon the seashore, the effect of winds may be observed in sand dunes; and under special conditions (probably when through the action of glaciers great quantities of finely ground rock meal were provided where streams issued from the ice), the wind has spread over vast areas a sheet of fine dust, which forms the fertile soil of areas of the western plains of North America. A similar deposit of wide distribution occurs in the valleys of China. The peculiarly fine and homogeneous clay has been called loess, and there has been much discussion as to the relations which wind and water have borne in transporting it.

Surficial rocks laid down by ice are broadly classified into those which are produced by ice alone, those which are the product of ice and water together, and those which are produced by waters flowing from the ice. In general they are distinguished from sedimentary rocks chiefly by their heterogeneous composition, since through the action of glaciers in plowing and grinding the surfaces over which they move, rock fragments of various kinds and sizes become mixed, whereas the effect of water is to sort rock debris in distributing it.

Sedimentary Rocks.— Sedimentary rocks are those which are deposited beneath bodies of water which are either still or moving with moderate currents, such as affect lakes and seas. They are laid down in characteristically bedded deposits called strata, which may generally be distinguished from all other forms of rock masses, though sometimes the sediments of a lake or estuary so closely resemble those of a river that no distinction is possible. Along this line sedimentary and surficial rocks grade one into the other. The method of formation of sedimentary rocks has already been described in treating of the process of sedimentation, to which the reader is referred.

Metamorphic Rocks.— The word metamorphic means altered, and in its largest sense, when applied to rocks, would cover all those which are not in the original igneous condition. But it has come to have a narrower meaning, and usually designates a class derived from igneous or sedimentary rocks through the action of heat and moisture and pressure, usually at some depth beneath the earth's surface. That igneous masses which have cooled as intrusives beneath the surface should be subjected to such alteration is easily understood. Sedimentary rocks though formed at the surface may, through the processes of deformation and sedimentation, becomes so deeply buried as to be subject to the same influences. In any case, the process is one of recrystallization under special conditions of pressure, and often of slow movement, and the result is that the rock assumes a more or less crystalline texture, and frequently a thinly laminated structure described by the word schist. Metamorphic rocks are of various kinds, according to the material from which they are derived and according to the degree of metamorphism, which may range from a scarcely perceptible alteration of the original rock to such complete recomposition and rearrangement as to totally obscure the original character.

THE CRUST AND THE INTERIOR.

Some Physical Considerations.— The cooling globe, of which the interior is still very hot, was until recently universally considered to consist of a hard crust over a molten liquid interior, and this view still prevails generally among well-informed people. It is not, however, that which is held by students of the physics of the earth.

It is a general law that, within certain limits, a heated substance may be restrained from melting if confined under sufficient pressure. Pressures within the earth are an effect of gravitation, all substances pressing inward toward the centre, according to their weight. The results are given in the following table, and may be seen to be enormous.

VARIATION OF TERRESTRIAL DENSITY, GRAVITY, AND PRESSURE ACCORDING TO THE LAPLACIAN LAW.

[By R. S. Woodward, 1890.]

Depth in miles	Density	Acceleration of gravity	Pressure in atmosphere	Pressure in pounds per square inch
0	2.75	1.0000g	1	15
1	....	....	400	6,000
2	....	....	800	12,000
3	....	....	1,210	18,150
4	....	....	1,620	24,300
5	2.76	1.0006g	2,020	30,300
10	2.78	1.0012g	4,200	63,000
15	2.79	1.0018g	6,390	95,850
20	2.81	1.0024g	8,600	129,000
50	2.89	1.0060g	22,000	330,000
100	3.03	1.0116g	45,300	679,500
500	4.18	1.0379g	236,000	3,540,000
560	4.36	1.0389g	318,000	4,770,000
610	4.50	[a] 1.0392g	354,000	5,310,000
660	4.65	1.0389g	391,000	5,865,000
1,000	5.63	1.0225g	672,000	10,080,000
2,000	8.28	0.8312g	1,700,000	25,500,000
3,000	10.12	0.4567g	2,640,000	39,600,000
3,959	10.74	0.0000g	3,000,000	45,000,000

[a] This is the maximum value, and the corresponding depth, 610 miles, is the depth at which a given mass would have the greatest weight.

From these estimates it is inferred that the pressure within the earth is sufficient to restrain the mass as a whole from melting, and that a fluid globe within an external hard crust is physically impossible, in spite of the high temperature of the interior.

Under pressures which exceed their crushing strength, the condition of rocks must be one of greater density than at the surface. In fact, the earth having been measured and weighed, it is known that the density of the whole is approximately five and a half times that of water, or about twice that of the rocks occurring at the surface. Hence it is evident that the interior is much denser than the exterior, or, in other words, rocks within yield to the compression.

Direct evidence of the rigidity of the earth's mass has been found through studies of the tides and of earthquakes. Were the earth liquid it must be subject to tidal movements, as are the seas, but observations with very delicate instruments have failed to detect any such earth tides. On the other hand, earthquake shocks recorded by appropriate instruments are known to be transmitted directly through the sphere, as well as around it, and at a speed through the mass greater than that with which they pass around. This fact is taken by physicists as sufficient evidence of great elasticity of the earth's mass, which is consistent only with great rigidity. Thus along several lines of reasoning from the laws of physics, there is evidence that the earth is solid, not fluid, within; and this conclusion is sustained by the phenomena of deformation observed through the methods of geology. Movements of the earth's surface recorded in the development of continents, of lands, and of ocean basins have been so gradual that, considering the great mass of the globe, they are possible only on a rigid sphere. These considerations do not disregard the facts of igneous rocks and volcanic activity, which are, however, to be explained as intense and local results of special stresses set up through the process of deformation.

That portion of the earth's mass which is of most interest to man, and with which he is best acquainted, lies within the moderate depth of six miles from the surface. Here occur all the phenomena of mechanical and chemical change which result in mineral deposits of use and value. The relations of pressure to strength of material are of great importance, and through them the superficial crust is divided into three zones.

The uppermost is that in which all rocks are under such moderate pressures that when forced to move, in process of deformation, they break. Consequently in this uppermost zone, which has a depth of perhaps a mile, cracks and crevices are of general occurrence.

Beneath this superficial zone of fracture, but not distinctly divided from it, is another, in which weak rocks, such as the clay rocks, are constrained by pressure to maintain a coherent mass without open cracks, while other rocks of greater rigidity, such as quartzite, may still break apart. This is the zone of flow and fracture. Under such weight, beds of hard rock may be folded, as one may bend layers of wax, and folds may be pressed one over another till strata are overturned and the order of succession becomes inverted.

A third zone is known as the zone of flow. It lies at a depth of four miles and more below the surface, and is that in which no rock is capable of breaking, because the pressures exceed the crushing strength of any rock. When movement occurs, the masses change form as wax would. This zone is one in which and beneath which there can be no spaces not filled by rock materials, and beneath which, therefore, atmospheric waters cannot penetrate.

Beneath the zone of flow the materials are in that condition of heat and pressure which constitutes the state of potential fusion, referred to in describing igneous rocks; but the conditions so far exceed any which can be observed, that our apprehension of them must long remain in the state of hypothesis, rather than in that of knowledge.

The term crust may well be applied to the three zones of fracture, of flow and fracture, and of flow. The lower limit of the latter can not be defined, but within a thin film, at the most a score of miles deep, is the vast unknown interior.

Some Chemical Considerations.— Chemical reactions, involving exchanges of constituents between substances, are accompanied by changes of temperature and of volume. Burning is a reaction which gives off heat. When carbon is the substance burned, the product is carbon dioxide, CO_2; now we may heat CO_2 to a temperature at which it separates, or dissociates, into two gases (CO and O or carbon monoxide and oxygen), and in this change heat is absorbed; that is to say, in the presence of low temperature the reaction and the effects are the reverse of what they are in the presence of high temperature. If we consider the change of volume involved in different chemical reactions, we shall find those in which there is expansion, and others in which there is shrinkage. When lime is slaked, water combines with the lime and the combined volume is greater than that of the two before combination. The same reaction and result occur when moisture affects feldspar in granite, and combines with or hydrates it. The force of expansion is sufficient to burst the bonds which confine the feldspar crystal in the granite. If we heat the hydrated substance, we can drive off the water; and if the heating occurs under pressure the water is driven off at a lower temperature, because dehydration involves shrinkage, and therefore is promoted by pressure. These illustrations may serve to introduce the general law of chemical reactions as affected by heat and pressure, namely, that between two substances that reaction will tend to occur which meets least resistance or is most effectively aided by the environment.

If we consider the earth's crust as a scene of chemical changes we find that both temperature and pressure increase to a notable degree from the surface downward, and applying the above law we may expect that those reactions which involve liberation of heat and expansion of volume will tend to occur near the cool surface, whereas those resulting in absorption and contraction will be favored in the warmer zones below. The chief effects of weathering in the superficial zone of rocks are the substitution of water, oxygen, and carbonic acid for silica in combination with iron, lime, magnesia, and the alkalies. Some insoluble oxides result, but silica and carbonates go into solution and pass downward into underlying permeable rocks, where they are deposited in great quantities. Beneath the zone of weathering there is thus a zone of cementation, in which the cavities in rocks become filled. If reactions take place the resulting minerals are those whose constitution is favored by high temperature and great pressure. Carbonates, which in combining expand and give off heat, are formed at less depths than silicates, which contract and absorb heat as they form. The zone of cementation grades downward into that of recrystallization, where chemical changes are brought about chiefly by movements within rock masses, and are altogether such as involve absorption of heat and produce heavy minerals.

If the physical and chemical conditions which have been separately suggested be associated as they are in the earth, we may state the effects in the following way:

and the frequency of overtakes. It may have been sufficient to result in general melting, but more likely was insufficient to raise the temperature of the mass to a high degree. This suggestion does not disregard the existing internal heat of the earth, but it has been shown by calculation that that temperature is adequately accounted for by gravitative concentration of the spheroid without external collision.

The earth, according to these considerations, entered upon its present phase of a solid globe with watery and airy envelopes, possibly from a previous condition characterized by somewhat higher temperature, possibly by aggregation of cold matter. When, if ever, a hot earth and a steaming atmosphere gave place to a cold earth with waters gathered in oceans (or when the growing planet had reached approximately its present mass), then began that chapter of history which may be recorded in existing rocks and which it is the object of geology to elucidate.

Zone	Depth	Physical conditions	Chemical conditions
Of fracture and weathering.	0 to 1 mile.	Many open spaces and relatively large crevices; comparatively free circulation of water.	Active oxidation, hydration, carbonation, and desilicification.
Of flow and fracture and cementation.	From near the surface to 4 miles.	Open spaces relatively small and growing smaller with greater depth, till only capillary openings remain.	Cementation by deposition of oxides, carbonates, sulphides, and silica.
Of flow and recrystallization.	3 to 6 miles.	Only capillary and subcapillary openings.	Alteration of rocks with development of heavy silicates.

GEOLOGIC HISTORY.

General Statement.— The astronomer, the geographer, and the biologist consider the earth's history from distinct points of view, the first regarding it as that of a planet, the second as that of oceans and continents, the third as that of organisms. The geologist's account comprises the later phases of astronomical history, includes all geographical changes, and furnishes the fundamental data for the understanding of organic evolution.

The astronomical history of the planet has since Kant and Laplace been based on the nebular hypothesis, according to which the solar system has resulted from the segregation of a homogeneous nebula, and the material of each planet has condensed from a gaseous condition to that which it now has. Intense heat must result from such condensation, and therefore the earth is thought to have cooled from a molten state. Mathematical tests recently appear to show that a homogeneous nebula could not condense to form a system in which the planetary masses should be distributed as they are in the solar system, and also that at the high temperature and great speed of rotation which are necessary to the hypothesis, the earth could not have held so light an element as hydrogen, which is an abundant constituent of terrestrial substances. An alternative hypothesis formulated by Chamberlain, suggests that small cold bodies, designated planetessimals, moving in a common orbit, have coalesced by overtake, rather than by opposed collision. The heat resulting from such a mode of aggregation may have been more or less, according to the size of the bodies

Permanency of Continents and Oceans.—The student of ancient terrestrial geography approaches his subject with a theory of permanent ocean basins and continents; the Indian, Atlantic, and Pacific, Eurasia, Africa, and the Americas are regarded as primeval features of the earth's surface. Yet it is known that every continental area has been submerged beneath marine waters more or less, again and again. The apparent contradiction of theory and knowledge lies in the fact that the words continent and ocean basin have a popular meaning and a technical one, which are not quite the same. In a popular sense the shore line divides the one from the other; in a technical sense a continent may (and now generally does) extend out under the shallow sea to a terraced slope that descends into the depths of the ocean basin proper. In other words, the ocean basins are too small at present to hold all the waters, which therefore overflow upon the margins of the continents. The basins, having been more or less capacious from age to age in the past, have now held, and again not held, all the waters, which accordingly have withdrawn from the lands, or have submerged them. But these changes have not affected the existence of the basins and continents as a whole.

Geologic Time.— The age of the Earth is inconceivable. This seems to be equally true whether we consider the eons which have elapsed since the planet became an individual in the solar system, or only the eras that have passed since it assumed its present physical characters as recorded in the rocks. That eminent physicist, Lord Kelvin, proceeding on the assumption that the earth has cooled from a gaseous condition, has calculated that not more than 40,000,000 years, nor less than 20,000,000 years, have passed since condensation began. But we have already seen that the assumption is not surely correct, and geologists have uniformly contended that far more time was necessary for the events of which they observe the evidence. The estimates based on geological phenomena and comprising only the time covered by them, have rarely been less than 100,000,000 years, and larger ones are probably reasonable.

Before proceeding to state the divisions of time which geologists recognize, it is desirable to suggest the evidence upon which they base their distinctions. It is a simple principle that where sediments have been deposited, layer upon layer, the bottom strata are the oldest. And this principle underlies all determinations of relative geological age. It may be applied to any succession of rocks, however thick, which may be observed in a continuous exposure. In regions where the strata lie horizontally, such observations are limited to a few hundred feet, or at most to a few thousand. But strata are often observed to be tilted so that their edges are exposed in a horizontal surface, and there is then the possibility of examining the relations of strata many thousand feet thick.

A second principle rests upon the evidence of interruptions in the accumulation of sediments such as occur when the sea bottom is for a time elevated above the water and is exposed to the process of erosion. Features of a landscape are then cut upon the strata, and a record is made of the topographic aspects of the land. If the surface is again submerged, and stratified rocks are again laid down upon it, the evidence of interruption remains, and the two series of sedimentary rocks are said to be unconformable. It not infrequently happens that during the interval the underlying set has been deformed, has undergone more or less profound changes of character, and is evidently very much older than the overlying sequence. A great interval of time is then represented at the unconformity between the two rock masses, but the record of it can be compared only to torn or missing pages of an ancient manuscript.

Evidences of sedimentation or of erosion enable us to ascertain the succession of events in any one province, that is so far as we can trace and identify the same strata and the same unconformities, but this possibility is limited by many conditions. On comparing the sequences of strata, even of adjacent provinces, marked differences are found and the simply physical phenomena fail as a basis of correlation of events of history which occurred in separated regions.

A third principle rests upon the evolution of organisms. Late in the 18th century an English engineer, William Smith, who was in charge of a canal dug across tilted strata in southern England, observed that many of the beds contained marine shells; that certain kinds of shells occurred particularly in the lower and older beds, and other kinds in the younger and upper beds; and that these differences as to the kinds of shells were definite and constant. Hence he concluded that wherever he might find shells characteristic of a certain stratum he had a representative of that particular bed, even though he could not trace its continuity from place to place. Thus William Smith laid the foundations for one of the great generalizations of geology, which is that in sediments of each epoch of the earth's history since life began were buried the remains of creatures characteristic of that general time; and these remains becoming fossilized serve to identify the strata in which they may be found with the epoch during which the organisms lived. Hence it follows that fossils are used to compare and correlate the events of geologic history in one province with those in another province within any one continent, and also from continent to continent. But correlation even by faunas is not an accurate matching. Faunas of different provinces are rarely closely alike, their migration has been influenced by physical changes, their evolution depends upon the environment which was undergoing change and was shifting. Correlation by faunas, therefore, involves comparisons of developing migrating associations whose likenesses are derived from a more or less nearly related common stock or stocks. Like methods of correlation by physical evidence it is of highest value only within short range; but of all methods, it is that which at present must be relied on for the greatest ranges.

Great sequences of strata, each of which is characterized by peculiar associations of fossils, have been found throughout Europe, and parallel sequences have been identified throughout North America. In other continents also closely related systems of strata are known. Each great sequence thus marked by peculiar remains of life is named and is thought to correspond to a particular geologic period, although the limits of time divisions are indefinite to the extent that correlation is approximate. The errors, however, are small in comparison with the vast lapses of time represented, so that we may say with Huxley that geologic systems were relatively contemporaneous, though not absolutely so.

The recognized systems are enumerated below in the order in which they would be found in a column were they all to occur in any one province, the oldest at the bottom, the youngest at the top. Their names are taken in most instances from districts in which the strata occur typically, or from characteristics of the rocks themselves. The time division corresponding to a system is here called a period. Periods are grouped to constitute eras, and these are named according to the condition of development of the living forms, except the first, the lifeless era. Thus we have the Azoic, lifeless era, the Eozoic, dawn life era (or the Proterozoic, fore life era, or Agnotozoic, unknown life era), the Paleozoic, ancient life era, the Mesozoic, middle life era, and the Cenozoic, modern life era.

Each system is divided into series, some of which have received names that are used alike in Europe, America, and elsewhere wherever the fossils characteristic of the series are found, while others are identified by name in a particular province only. The Quaternary is divided into Pleistocene and Recent, the former term designating collectively the Glacial epochs. The Tertiary of Europe and North America includes the Eocene, Oligocene, Miocene, and Pliocene series, enumerating from earlier to later. These cover the most familiar cases of

Within each series there are many minor subdivisions which represent conditions in local districts of each province, and for these again distinctly local names must be chosen. The common practice is to give to each such minor division of a rock sequence the geographic name of a place at or near which the particular formation is to be seen in typical character, and this name is applied to that formation as far as the latter can be traced continuously. There was formerly an attempt to recognize the details of geologic systems throughout wide areas, even throughout continents. The geology of North America having been studied first in a thorough manner in New York State, names which were selected from New York localities were applied to formations in distant territories. The "Potsdam sandstone" and the "Trenton limestone" are much-abused examples of this practice. But it has been found necessary to recognize the great complexity of the geologic record by giving distinctive names, and the labor of reducing the multitudinous details to that orderly historic record which they no doubt express must proceed slowly with the development of more complete knowledge of the physical and biological conditions of the past.

Aspects of Physical History.— No attempt can be made to condense an account of geologic history into these few paragraphs, but a general view of the subject may be given. We have seen, in considering geologic processes, that deformation is the initiative process, and that all other phenomena are more or less remote effects of the gravitation of the earth's mass toward its centre. Therefore the first question we may put to the historic record is: What have been the chaanges in the internal energy of the earth during recorded geologic time? The commonly accepted view that the earth has cooled from an excessively heated condition, since the formation of the oldest known rocks, is not sustained by geological evidence. It is true that the oldest rocks — those of the Archean — are predominantly igneous rocks, that is to say, they have crystallized from a molten state. There is, however, abundant evidence that the areas in which they are now observed have been very deeply denuded in process of erosion, and therefore that these ancient rocks have come to the surface from great depths, at which at the present time similar rocks are presumably quite as hot as they were. The igneous character of these ancient rocks is, therefore, entirely consistent with the hypothesis of a cool surface at the time of their crystallization. Moreover, there occur with them small but significant amounts of sedimentary rocks, which in chemical and mechanical characters resemble those of later, even of the latest, epochs, and which therefore indicate that the conditions of temperature were not markedly different from those which now exist. We may consider it improbable that the internal energy of the earth has since the beginning of the Algonkian undergone such great changes as are commonly conceived.

Again, it is frequently supposed that the earth's energy as expressed in the development of mountain ranges, was far more intense and effective in earlier geologic periods than now. But each epoch of mountain growth, and there have been many, is recorded in the sediments which resulted from erosion of the uplifted land masses, and from the volume and character of the sediments we may infer the magnitude of the uplift. Studied from this point of view, the sedimentary strata give no reason to suppose that mountains greater than those which now exist have ever diversified the surface. On the contrary, it appears that there have in the past been long ages during which no mountains developed, and that these ages alternated with epochs of shorter duration, during which mountain growth was an active phenomenon. The Algonkian period, whose duration was probably equal to that of all time since its close, may have included several such alternations of quiescence and activity. It certainly was in some districts, as in that of Lake Superior, characterized not only by vigorous but even by volcanic mountain growth. The Cambrian and Ordovician periods, on the other hand, were not thus marked, and sediments, changing as they do from the mechanical products of erosion to those of a marine origin laid down in widespread seas, indicate that the land stood long at a constant level with reference to sea, and that the elevations of an early date were later reduced to wide plains, which were submerged as they subsided. During the Silurian and Devonian there were cycles of erosion resulting from local uplifts, in alternation with epochs during which the processes were relatively at rest; but these appear to have been of shorter duration. The greater part of the Carboniferous, from its earliest epoch on toward the close, was, like the Cambrian, a time of constant level, followed by subsidence of lands and expansion of seas. The closing epoch of the Carboniferous period and of the Paleozoic era initiated an activity which continued into the Triassic and resulted in extensive lands diversified by mountain chains.

During the Jurassic and Cretaceous these were eroded to low plains, and the surfaces of the lands were widely submerged beneath the broad Cretaceous seas. The Tertiary, like the Upper Silurian and Devonian, had its minor cycles, culminating in a broader extension of the lands; and at the present time we live in an epoch of vigorous mountain growth, when the aspects of the earth are most varied and the conditions of environment and climate are most favorable to a great variety of plants and animals.

Much stress has been laid upon sedimentary rocks in the preceding brief statement, because it is through the orderly relations of stratified beds, and through the fossils which they contain, that we are able to make out something of the geologic record. In order that the reader may gain a clearer idea of the manner of distribution of sediments following upon the great fluctuations in the distribution of lands and seas, the following maps of North America showing the geographical conditions of widely separated epochs, are herewith introduced.

Paleography is that branch of geology which deals with the geography of past times. The appended paleographic maps of North America are based on physical and faunal evidence, which is acceptable as showing the general geographic condition during a geologic age; they are not refined enough to give the geography of a particular epoch. The limits of seas and lands, even where most accurately mapped, were changing, and in no case can one of these maps represent the geography of the continent at a definite date.

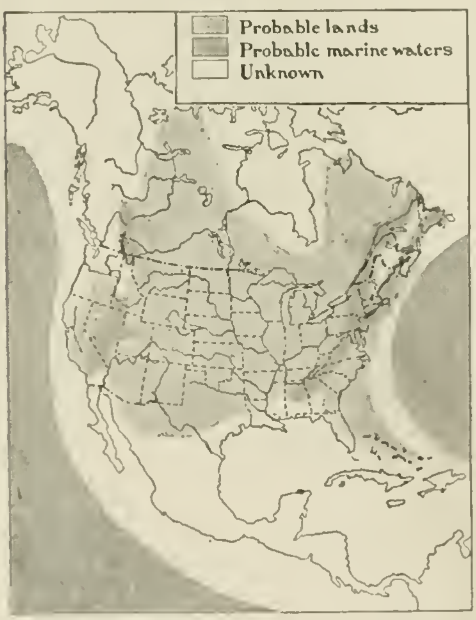

Fig. 1.— Geography of North America during the early Cambrian. Preceding this stage land areas had long been extensive; following this stage they became less by general planation and submergence.

Aspects of Climatic History.— Climatic conditions of the past are known to have been variable. There are evidences of extremely luxuriant plant growth, indicative of warm and moist climates, and in alternation with these occurred ages during which chemical sediments, such as salt and gypsum, were laid down in quantities consistent only with great aridity.

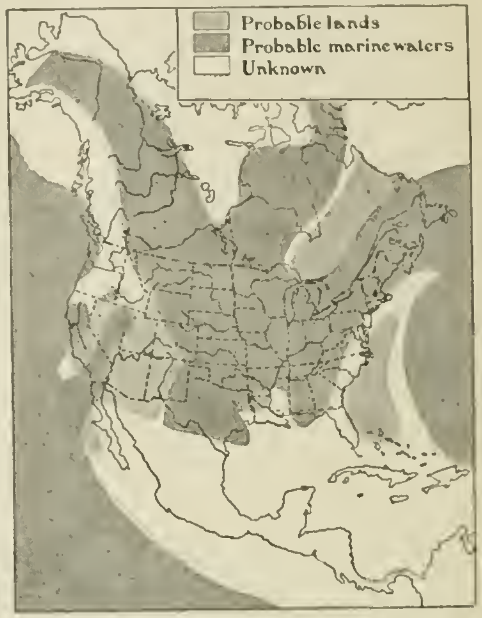

Fig. 2.— Geography of North America late in the Ordovician. About this time the continent was probably more extensively submerged than at any later epoch; extensive emergence followed.

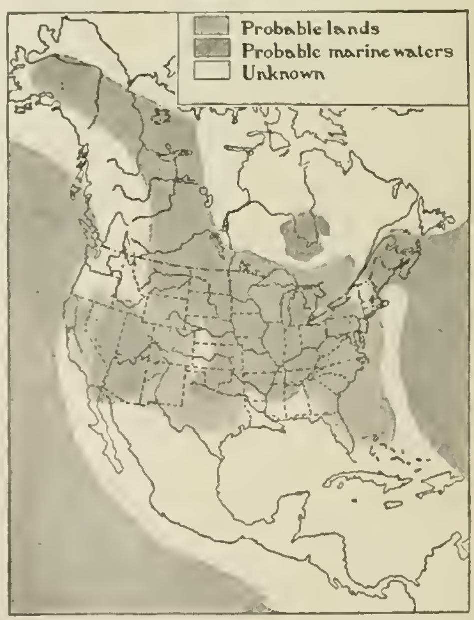

Fig. 3.— Geography of North America late in the Devonian. Preceding this stage land areas had been more extensive, particularly in the eastern United States; following this stage the seas expanded to the condition shown in the next map.

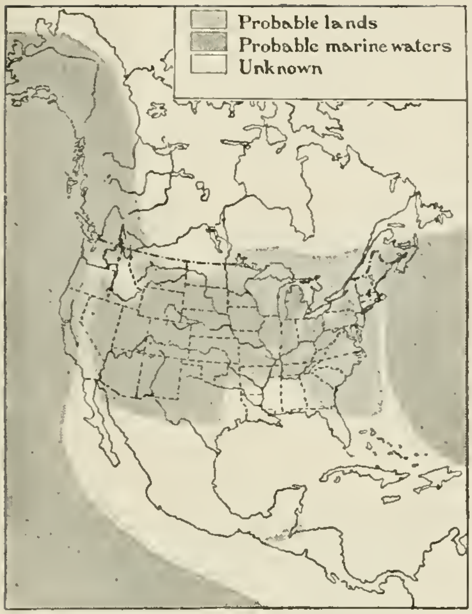

FIG. 4.— Geography of North America during the Mississippian age. At this stage the late Paleozoic seas probably had greatest extent.

FIG. 6.— Geography of North America during the Permian and Triassic ages. This map represents the passage of the continent from Paleozoic to Mesozoic aspects. From Mississippian to Triassic time the net effect of conflicting movements was the general withdrawal of marine waters from the continent, and the later stages of that phase are here represented. Marine deposits also occur in fresh water areas.

Again, there are records of tropical vegetation within the present Arctic Circle, and also of a general ice mantle extending in Europe and America as far south as the fortieth parallel of latitude. Extensive glaciers occurred in Aus-

FIG. 5.— Geography of North America during the Pennsylvanian (Coal Measure) age. Preceded by more extensive seas, this stage was characterized by emerging lands. Marsh, river, and marine deposits alternate in areas shown as fresh water.

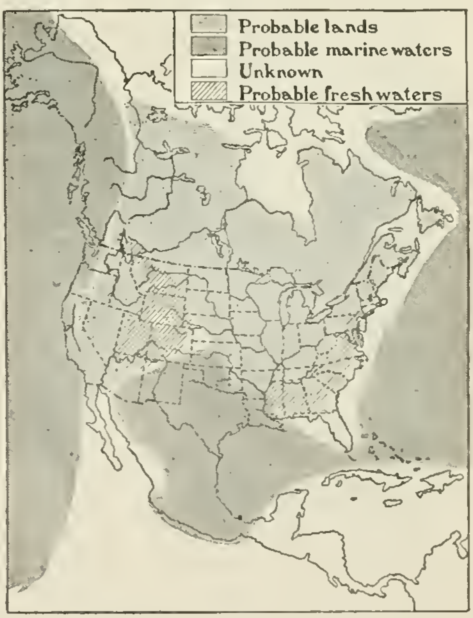

FIG. 7.— Geography of North America during the Lower Cretaceous. Preceding this stage, namely, during the early Mesozoic, land areas had been more extensive than at any time since Algonkian. This map represents the first stage of the Cretaceous submergence which increased to its maximum, see next map.

FIG. 8.— Geography of North America during the Upper Cretaceous. This map represents the culmination of the submergence which occurred during Cretaceous time.

FIG. 9.— Geography of North America during the Tertiary. Accompanying the withdrawal of marine waters from the areas over which they had spread in Cretaceous time, there were effective mountain growths which continued intermittently through the Tertiary and into the Pleistocene, and which resulted in the present distribution of ranges. In the provinces of the Rocky Mountains and Great Plains river and lake deposits of unusual extent accumulated. The map is a composite picture, not one of any definite stage.

tralia and South Africa late in Carboniferous time, where but a short time previously tropical conditions had prevailed, as they do now. Various hypotheses have been framed to account for these special conditions, some of them depending upon changes of astronomical relations of the earth to the sun, others upon altitude of lands above sea, and one upon the constitution of the atmosphere. The last named appears at present to afford the most reasonable basis of explanation, though the hypothesis is by no means established as true in all its phases. It rests upon the physical and chemical properties of carbonic acid (CO_2), and upon the fact that this substance is present in our atmosphere in very small quantities. Physical researches have shown that even the small amount present has a potent influence in absorbing the heat of the sun and raising the temperature of the atmosphere. That is to say, it thickens the atmospheric blanket about the earth. A slight in-

FIG. 10.— Geography of the Pleistocene ice sheets in North America. During the Pleistocene ice sheets developed about three centres in northern Canada and with fluctuations sufficient to characterize several glacial epochs extended at their maximum to the limits shown on this map.

crease in the minute percentage present would suffice greatly to extend the climatic conditions of the temperate and tropical zones toward the north and south poles, whereas a diminution to one half of the present quantity would bring on the conditions of the glacial epoch. Carbonic acid is the most active reagent of the atmosphere entering into decomposing rock masses, and must be taken into combination in relatively great quantities during periods of active erosion. When so combined it occurs in solution in waters in the form of bicarbonates, and in large part passes to the sea. As periods of erosion are not indefinitely continued, but in course of time cease through the activity of the very agencies of erosion, that process runs down, and in time the absorption of carbonic acid becomes relatively insignificant. The amount of carbonates conveyed to the sea may, however, by that time have been sufficient greatly to promote the activity of organic and chemical agents, through which monocarbonates are deposited, especially as limestone, and the second molecule of carbonic acid is set free. The latter is then returned to the atmosphere, which may thus become re-enriched. This idea is the central one of the carbonic acid hypothesis of climatic variation; but with it are combined many auxiliary facts and conditions which greatly strengthen it and serve to explain many of the minor cycles of variation whose record is noted in the rocks and in the life forms which they contain. The whole hypothesis rests upon the periodic activity of the earth's internal forces, already described in speaking of the growth of continents and mountain ranges; and thus climatic change is traced to deformation, the initiative process of all physical conditions of the earth.

It is estimated somewhat indefinitely that 40,000 years have passed since the climate was such that the southern part of the latest great ice sheet occupied Lake Erie and, retreating, permitted the cataract of Niagara to begin its existence at Lewiston. From that place the river has since cut back its gorge to the present site. That time, 40,000 years ago, may be regarded as the close of winter in one of the great cycles of climatic change. It would be interesting to know how long the seasons of that cycle are. Are forty thousand years a month, a springtime, or more? Do we live in the early vernal season of a great era and is the climate to grow warmer during many tens of thousands of years to come? Or is the summer of this cycle well advanced and will a glacial winter again sheathe the north temperate zone in ice?

Aspects of Organic Environment.— The evolution of organic life is properly a subject for distinct treatment, and not to be considered in this connection, except to point out the influence which changes of environment may have had. As far back as early in the Algonkian period, that is to say near the beginning of well-recognized geologic history, there were deposits of carbonates and of carbonaceous material which seemed to indicate the existence of organisms, and trails made by some low forms crawling upon soft mud are abundant in later Algonkian strata. The beginning of the Cambrian period is, however, the first time at which fossils were preserved in large numbers and of varied species. Six of the nine classes of creatures now recognized are represented in strata of that period, and the vertebrates appeared in the next. The other two classes are not of such organisms as would leave remains likely to be preserved. The variety and exuberance of life shows that evolution had been going on during long ages prior to the Cambrian, and that conditions had long been favorable for organic activity. In this connection it should be noted that during the Algonkian, so far as the record goes, land areas had been extensive and sea basins had probably been correspondingly deep and limited. During the Cambrian and succeeding Ordovician periods, occurred one of the greatest submergences not only of North America but also of Europe, and the expanses of shallow seas afforded great realms in which the conditions were favorable to life. These two periods are also characterized the world over by a predominance of deposits of limestone, which according to the atmospheric hypothesis above suggested should have resulted in warm climates appropriate to exuberant life development.

If we were to trace the great changes in living forms which occurred in passing from the Ordovician to the Devonian, from the Carboniferous to the Triassic, from the Cretaceous to the Tertiary, we should find that each accompanied and probably resulted from the great variations of habitat and of climate. Epochs during which seas were wide and temperatures high promoted development and resulted in great diversity of genera and species. Epochs during which seas were limited to deep basins afforded very narrow areas in which competition was fierce and opportunity limited, and the low temperatures resulting from erosion of extended land areas were unfavorable. It is along these lines of suggestion that the geologist is now seeking for the explanation of the stages of organic evolution and of the unequal progress which has been made from one age to another.

APPLIED GEOLOGY.

Scope of the Subject.— The scientific principles of geology relate to rocks and minerals which are useful to man and afford a means of determining their origin, their forms of occurrence and extent, and the peculiar relations of rock masses or structure which have led to concentration, notably of metallic ores. All classes of mineral products fall within the scope of applied geology. Gravels, sands, and clays of surficial deposits, massive rocks quarried for building and ornamental purposes, coals, and other bedded strata, and the ores of iron and of the precious metals, all these are products of genetic conditions which when understood afford clues that promote discovery and direct exploitation. Inasmuch as only exceptional occurrences are valuable, whereas it is generally supposed that mineral wealth is common, the service of applied geology is as frequently to prevent unprofitable operations as to aid those which may yield results. The essential knowledge belongs in part to each of the sciences of geology, mechanics, physics, and chemistry, and to be reliable should be aided by wide experience in observations underground, as well as of geological phenomena in general. The application of principles must rest upon an intelligent understanding of the conditions of formation of a rock mass or deposit, and accordingly economic minerals are classified by the conditions of genesis.

Classification of Economic Minerals.— Classifications of economic minerals, and especially of ore deposits, have been much discussed, and are still debated. One which is adequate for all general purposes follows the classification of rocks already given, and comprises three classes of economic rocks and minerals: Those of igneous origin, those of sedimentary origin, and those of chemical origin by the agency of underground waters.

Igneous rocks have value as useful and ornamental stones, such as granite, serpentine or verde antique, trap rocks for road metal, etc., and occur in large masses, which as a rule are quarried by the simplest processes. Metalliferous ores, which are directly of igneous origin, though commonly supposed to be most abundant, are in fact of limited occurrence. Titaniferous iron ores such as are found in the Champlain district of New York, are igneous rocks peculiarly rich in iron. Ore bodies of other metallic compounds in some instances occur in such relations to igneous masses as apparently to have been formed from gases or waters accompanying the eruptions; but the chief part which igneous rocks play in relation to ores lies in the fact that they contain the metals in appreciable though minute quantities, and yield them to underground waters by which the metalliferous minerals are concentrated in ore bodies.

The class of sedimentary deposits of value includes many clays, sands, building stones, etc.; some iron ores; and coals. The class is characterized by the stratified structure of all materials contained in it. The strata are usually of great extent and moderate thickness, and their dimensions may be observed by tracing and measuring them throughout their appearance at the surface, or outcrop. From these observations the distribution of the strata where they extend beneath the surface, even to considerable depth, may be inferred. It may easily be understood how this method of looking underground is applied to any one tilted stratum, such as a coal bed; and though the operation becomes more complex, the principle remains the same when many beds of known succession are considered. The same method of observing the normal succession and thickness of strata and of drawing inferences as to the extent of formations underground is applied in districts where the layers have been bent into forms of troughs and arches, which are usually long, narrow, and parallel. Any stratum occurring at the surface bears known relations to all those below it, and thus the depth to any other stratum beneath any particular one seen may be estimated. Through many such estimates the form of the trough corresponding to any one stratum may be worked out and delineated by maps, drawings, or models. These principles, based on the regularity of stratification and of sequence of strata, are of most service in regard to coal beds and artesian waters, serving in the former case to afford a basis on which the amount of coal and the methods of mining may be determined in advance; and in the latter case to determine the depth at which an artesian flow of water may be reached. Good topographic and geologic maps are essential preliminaries to such economic investigations if the latter are to be reliable and of value.

Ore Deposits through Underground Waters. — Underground waters circulate deeply downward, laterally and upward in the earth's crust. They dissolve constituents of nearly all minerals, including gold, some of them readily, at surface pressures and temperatures, others in notable quantities only at pressures and temperatures of deeper zones. In circulating they bring together solutions which may differ in composition and may cause chemical reactions; or they may bring solutions into contact with wall rocks that exert similar chemical influences. The results are precipitation of metalliferous minerals in cavities, or the replacement of the wall rock itself by the ore. To these activities most ore deposits are due.

The metallic elements are contained in igneous rocks which are the original sources, but usually in minute quantities and disseminated through large masses and in compounds not available as ores. The universal combinations of iron and other bases with silica are obvious examples, as is also the frequent occurrence of pyrites or "fool's gold." Processes of chemical alteration, solution, and deposition are necessary steps toward concentration, and they may be more or less complex or often repeated. The reagent which accomplishes these chemical reactions is primarily that rain water which percolates beneath the surface and becomes ground water. Charged with oxygen and carbonic acid, it enters the superficial part of the zone of fracture, and is there active in producing oxides and carbonates and displacing silica, as already described. The important reaction upon metalliferous ores is the oxidization and carbonation of sulphides. Descending through the zone of cementation, where it may deposit much or all of the substances taken into solution, the water is warmed or heated, and is under constantly increasing pressure as it sinks deeper. It thus becomes a more active solvent for metalliferous minerals, and in the deep zone of recrystallization, where the movement is through capillary and subcapillary spaces, and is very slow, it may become even more potent. Its course in circulating, however deep and roundabout, is toward an outlet at the surface, and is ultimately upward. Among the ascending waters there may well be those which have escaped from the magmas of the interior and with substances in solution have joined the meteoric waters. The circulating underground solutions are directed in movement by the spaces in and between rock masses, spaces which are very minute in the deeper part of the zone of flow and fracture, and which are larger in the stronger rocks and nearer the surface. The larger ones, which are called trunk channels, are those in or near which ore bodies may form. The courses of descending and ascending waters are also controlled by relatively impervious beds, such as strata of clay, or shale, or schist, which may be too weak to maintain openings and too dense to absorb solutions. The spaces between rock masses are usually effects of deformation, fissures, faults, and folds, which are detected and traced through the fact that along them the rocks have departed from the relative positions or succession which they originally had, or have been brought into contact by intrusion, in the case of eruptive rocks. To understand the character of the structure, whatever it may be, involves primarily an understanding of the nature and original relations of the rock masses.

Large ore bodies if developed in open spaces can only occur in the zone of fracture and in the upper part of the zone of flow and fracture. If they are formed by replacement of the country rock by metalliferous minerals, their limits are determined by the mechanical, physical, and chemical conditions that in the individual case favored replacement. The relative parts played by descending, ascending, and laterally flowing solutions are unlike in the different cases, but are of practical significance in estimating the position and extent of ore bodies. The chemical reactions which may result in formation of ore minerals from gases, from solution, or by replacement, are controlled by pressure, temperature, and environment, in ways that are not fully understood and that are being actively investigated. It is, however, clear that the exceptional concentrates are to be sought in general in regions of disturbance, and, so far as the precious metals are concerned, especially in districts affected by intrusive igneous rocks; further that ore bodies are usually related to water channels which may best be followed through an understanding of the structure by which they were determined; and that within ore deposits processes of oxidation, carbonation, solution, and reprecipitation are in progress and produce the richest accumulations of ores.

II., 1892); Wright, 'Ice Age in North America' (1893); Zittel (Eastman's), 'Text-Book of Paleontology' (1896).

General Bibliographies.— The literature of the several branches of geological science is voluminous, but there are many articles published in serials which are of interest to the general reader. Reference to all the literature may be had through the following bibliographies: Darton, 'Catalogue and Index of Contributions to North American Geology 1732-1891' (Bull. U. S. Geol. Survey No. 127); Warman, 'Catalogue and Index of the Publications of the United States Geological Survey 1880-1901' (Bull. U. S. Geol. Survey No. 177); Weeks, 'Bibliography of North American Geology, Paleontology, Petrology, and Mineralogy for the years 1892-1900, Inclusive' (Bull. U. S. Geol. Survey No. 188).

The official bulletins, annual reports, and professional papers of the United States Geological Survey contain many special articles, and may be had on application to the director, Washington, D. C.

BAILEY WILLIS,
U. S. Geological Survey.

Geomancy, jē'ō-măn-sĭ (Greek, *gē*, the earth, and *manteia, divination*), a kind of divination formerly practised. Sparry, in his translation of Cattan's 'Geomancie' (written about the middle of the 16th century, and translated in 1591), says: "Geomancie is a science and art which consisteth of points, prickes, and lines made instead of the foure elements, and of the starres and planets of heaven. . . And this arte may be made on the earth or on white paper, or uppon any other thing whereon it may commodiously be done, so that the prickes and lines may be knowen." See DIVINATION; FUNG-SHUI.

Geomet'rical Mean of two numbers is that number the square of which is equal to the product of the two numbers; thus, the geometrical mean of 9 and 16 is 12, for $9 \times 16 = 144 = 12^2$. Hence the geometrical mean of two numbers is found by multiplying the two numbers together and extracting the square root of the product.

Geometrical Optics. See MIRROR; LENS; OPTICS.

Geometrical Progression. A series of quantities is said to be in geometrical progression when the ratio of each term to the preceding is the same for all the terms, that is when any term is equal to the product of the preceding term and a factor which is the same throughout the series. This constant ratio or factor is termed the *common ratio.* See PROGRESSION.

Geometridæ, jē-ō-mĕt'rĭ-dē, a family of moths whose larvæ walk by arching the body and so bringing the hinder feet (prolegs) close up to the forward (thoracic) feet, and again reaching forward. Hence they are called "loopers," "inch-worms," etc. See MEASURING-WORMS.

Geometry. The characteristic aspiration of scientific man is to conceive the universe as a genuine cosmos. Of scientific generalizations, one of the most obvious and important, and one which is at the same time historically among the first, has reference to *order*, namely, that the universe presents or at least suggests two grand order-types: order of coexistence or of side-by-side, that is, order-in-Space; and order of succession or of before-and-after, that is, order-in-Time. These seem to be logically independent. Which one, if either, is the more fundamental remains undetermined. The two combine to give the category of motion, and accordingly the world presents alike to the sense and to thought two complemental aspects, the static and the dynamic. To these and their combination correspond the fundamental sciences. The mentioned order-types taken in the abstract are the subject-matter of mathematics: the former yielding pure geometry, the latter pure analysis; the two together, analytico-geometry and geometrico-analysis.

By perusal of the articles that immediately follow, the reader may gain some notion of the wondrously diverse and manifold significance assumed by the term geometry in modern times. The view thus gained may be further matured and enriched by reference to such other articles of this work as: CURVES, HIGHER PLANE; CURVES OF DOUBLE CURVATURE, THEORY OF; SURFACES, THEORY OF; MENSURATION; HYPERSPACES; ANALYSIS SITUS; QUATERNIONS; CALCULUS OF VARIATIONS, THE; CALCULUS, THE INFINITESIMAL; HARMONIC ANALYSIS; EQUATIONS, DIFFERENTIAL; INVARIANTS AND COVARIANTS. Some of these latter are indeed primarily analytic. They nevertheless serve to illustrate, not only the unity of mathematics in general, not merely the complemental relationship in which the two grand divisions, geometry and analysis, stand to each other, but in particular the universal pervasiveness of geometric concepts and methods.

CASSIUS J. KEYSER,
Adrian Professor of Mathematics, Columbia University.

Geometry, History of the Elements of. The history of the science of geometry begins in Greece. It is true that mensuration was developed to a considerable extent at an early period in Egypt, Babylonia, and India, and that this work involved the measurement of angles in the astronomical observations of the people of these countries, but the abstract science of form never attained any prominence before the Greek period. In Egypt, for example, the harpedonaptæ (rope stretchers) knew the right-angled triangle whose sides are 3, 4, 5, and stretched their ropes to lay out a right angle in much the same way that a modern surveyor erects a perpendicular by the help of his chain; but there is no evidence that the Egyptians thought of proving the Pythagorean theorem. Herodotus testifies to the fact that the Egyptians divided the land that was subject to the overflow of the Nile, into quadrilaterals, and therefore they must have had some knowledge of elementary surveying. Indeed, long before this time Ahmes (see ALGEBRA, HISTORY OF THE ELEMENTS OF) gave certain rules, partly incorrect, for measuring areas and volumes, in particular an interesting one for the area of the circle, $a = (d - \frac{d}{9})^2$. All of this work was, however, very elementary, and the rules were merely the result of unscientific observation.

In Greece the science of geometry may be said to have begun with Thales (q.v.), who was born at Miletus, c. 640 B.C., and who died at Athens in 548. Brought up in contact with the learning that drifted from the East to the shores of the Mediterranean, in his younger days devoted to those commercial pursuits that made Miletus a centre of wealth, he traveled extensively, and devoted his later years to philosophy. From Egypt he seems to have taken back to Ionia whatever of primitive geometry was known, and his school at Miletus was devoted to the study of philosophy, astronomy, and the science of form. Thales is supposed to have proved the propositions concerning the equality of vertical angles, the sides opposite the equal angles of a triangle, the determination of a triangle by one side and two angles, the bisection of a circle by a diameter, and the nature of an angle inscribed in a semicircle. His most famous pupil was Pythagoras (q.v.), who was born at Samos in 580 and died in southern Italy in 501. A man of great personal magnetism, a mystic, and versed in the lore of the Orient, Pythagoras made his school at Crotona, the mathematical centre of his time. Although none of his works are extant, if, indeed, he wrote any, it is known that he proved the famous theorem which bears his name (Euclid I., 47), a proposition known empirically to the Egyptians, at least for special cases. Pythagoras also gave much attention to the study of proportions and irrational quantities, always from the standpoint of geometry. He also knew the size of the angle of a regular n-gon, and the stellar pentagon was made the badge of his order.

The century following Pythagoras was one of discovery. Among the most noted geometers was Hippocrates of Chios, c. 440 B.C., who must not be confounded with the great physician who wrote on the mystic number 7. Hippocrates, who had come in contact with the Pythagoreans, wrote the first Greek text-book on mathematics, and designated the geometric figures by letters placed at the angles. To him is due the first example of the quadrature of a curvilinear figure, a proposition known as the lunes of Hippocrates. The theorem asserts that if semicircles be described on the three sides of a right-angled triangle in such way as to form lunes on the two shorter sides, the area of the lunes equals that of the triangle. In his attempt to duplicate the cube he showed that the problem can be solved if two mean proportionals can be found between c and $2c$, where c is the edge. This problem was one of the three famous ones of antiquity, the others being to square the circle and to trisect any given angle. It is now known that these problems, easily solved if the necessary instruments are allowed, cannot be solved merely by the use of an unmarked ruler and a pair of compasses. Contemporary with Hippocrates lived Hippias of Elis, to whom is probably due the quadratrix which Dinostratus afterward studied and named. About the same time Antiphon and Bryson sought the quadrature of the circle by means of inscribed and circumscribed polygons, the number of sides being successively doubled, and with them begins the theories of limits and of exhaustions.

The influence of Plato (429–348 B.C.) on elementary geometry was greater than is usually supposed. He found the science in a disordered state, a mass of unrelated propositions, very likely covering much of plane geometry as found in Euclid. His philosophic mind led him to the attempt to put the science on a more satisfactory foundation by insisting upon accuracy of definition, upon a limited number of postulates (including axioms), and upon definite bounds to plane geometry. As a result, only those figures capable of construction by the help of an unmarked ruler and the compasses are recognized as belonging to the field of elementary geometry. To the school of Plato is also due the analytic method of attack in geometry, including the *reductio ad absurdum*. Although not himself a great discoverer in mathematics, two of Plato's pupils reached high eminence in geometry. Of these the first was Eudoxus, who extended the theory of proportion, founded the doctrine of similar figures, gave much attention to the problem of the golden section, applied the method of exhaustions to the mensuration of solids, and wrote the first text-book upon stereometry. The second was Menæchmus, who, in his attempts to solve the duplication (or Delian) problem, discovered the conic sections. The study of the five regular polyhedra also occupied the attention of Plato's pupils, so much so that they received the name of Platonic bodies.

The influence of Aristotle was directed to the encouragement of the study of the history of geometry and the applications of mathematics. As a result, his followers began to collate the work of the earlier Greeks and to consider its relation to physical problems. Elementary geometry now enters the text-book period, and several attempts at works of this character appear in the fourth century, B.C. This movement culminated in the works of Euclid (q.v.), a man of whose personal life we know practically nothing save that he taught and wrote in Alexandria c. 300 B.C. Probably of little originality in the way of mathematical discovery, Euclid had a genius for compilation, and this showed itself in the Στοιχεία (connected series), or *Elements,* as it was called in later times. This famous work is devoted principally to plane geometry, and it has formed the basis of practically all elementary treatises up to the present time. The natural effect of Euclid's work was to give the impression that the field of elementary plane geometry was exhausted. Mathematicians therefore directed their energies to the applications of geometry, to stereometry, and to conics. Archimedes (q.v.), writing at Syracuse c. 240 B.C., opened the great field of mathematical physics and carried the study of elementary geometric solids to its greatest height among the Greeks. To him is also due the limits $3\frac{1}{7}$ and $3\frac{10}{71}$ for π, the study of the spiral that bears his name, and the quadrature of the parabola. Apollonius of Perga (q.v.), "the great geometer," wrote eight books on conics c. 225 B.C., and set a standard which still influences the text-books in analytic geometry. Of the minor geometers who followed Apollonius, two may be mentioned. Nicomedes (c. 180 B.C.), who invented the conchoid, a curve which easily solves the trisection problem, and his contemporary, Diocles, whose cissoid furnishes an easy means for duplicating the cube. Of the later Greek geometers the most noteworthy is Hero of Alexandria (see HERO OF ALEXANDRIA), whose personal history, like that of Euclid, is practically unknown, and to whom it is difficult to assign a date even within a century. His most interesting contribution to elementary geometry is the formula for the area of a triangle in terms of the sides,

$$\Delta = \sqrt{s(s-a)(s-b)(s-c)}.$$

Possibly contemporary with Hero lived Menelaus, whose theorem, known in the Middle Ages as the *Regula sex quantitatum,* has made his name well known. His most important discovery, however, was the projective property of the anharmonic ratio. By this time the age of discovery in geometry had passed in Greece, and the efforts of the Neopythagoreans at Alexandria were productive of little that is remembered. Pappus (c. 300 A.D.), an Alexandrian mathematician and geographer, may be called the last of the Greek geometricians who showed any originality. He suggested the theory of involution of points, restated the projective property discovered by Menelaus, and discovered the theorem (which also bears the name of Guldin) concerning the volume generated by a plane figure revolving about an axis.

The Orientals contributed but little to elementary geometry, their interests being rather directed to algebra (q.v.) and trigonometry (q.v.), with astronomy as the leading application for their advanced mathematics. Brahmagupta, a Hindu, born in 598, generalized the Hero formula, showing that the area of an inscribed quadrilateral is expressed by

$$A = \sqrt{(s-a)(s-b)(s-c)(s-d)},$$

but aside from problems in mensuration, geometry played but little part in India. The Bagdad school of c. 800 was chiefly interested in geometry only as it concerned trigonometry, and its greatest contribution to the science consisted in the preservation of the works of the Greeks. Euclid, for example, was first made known to Christian Europe in the Middle Ages through a translation from the Arabic by Adelhard of Bath, c. 1120.

Among the first books on mathematics to be printed was Euclid's 'Elements' (1482), a fact which made this famous work again a standard. The appearance of this classic had the same effect as in the later centuries of Greek culture, to encourage commentators rather than investigators. In the way of original work, only such minor efforts as the study of stellar polygons and the geometry of a single opening of the compasses characterized the closing decades of the Middle Ages and the opening years of the Renaissance. Not until Kepler (q.v.) suggested the principle of continuity (1604), and Cavalieri set forth the method of indivisibles (1629; published in 1635), and Desargues began the theory of modern geometry (1639), was there any material advance in the subject. When, however, this advance was undertaken it was so vigorous as to lead from elementary geometry to higher fields. In the latter part of the 19th century there was a renaissance of investigation in the elementary domain, leading to an interesting but not very productive study of the geometry of the circle and the triangle, notably in the work of Lemoine and Brocard. The 19th century also saw an exhaustive study of non-Euclidean geometries (q.v.), those based on other postulates than those of Euclid. This study began with the works of Lobachevsky and Bolyai (qq.v.), and has led to very interesting results, hardly to be ranked, however, in the domain of elementary geometry.

DAVID EUGENE SMITH,
Professor of Mathematics, Teachers College, Columbia University, New York.

Geometry, Cartesian.—Between number and the properties of number, on the one hand, and space and the properties of space, on the other, there is, strictly speaking, no *resemblance*; and the science of number, *i.e.*, algebra or analysis, and the science of space, *i.e.*, geometry, are essentially, psychologically, and logically independent doctrines. But despite their fundamental unlikeness and independence, there is between the two, broadly speaking, a fact-to-fact *correspondence*. For example, there subsists, or may be established, a unique and reciprocal, or one-to-one, correspondence between the real numbers and the points of a straight line or other curve; between the real numbers and the lines of a flat pencil (see PROJECTIVE GEOMETRY) or the tangents to a curve; between the pairs of real numbers and the points or the lines of a plane; between the triplets of real numbers and the circles of a plane or the points or planes of space; between the quartets (permutations four at a time) of the real numbers and the lines or the spheres of space (see LINE GEOMETRY AND ALLIED THEORIES). The theory of the correspondence thus simply exemplified, the logically organic body of propositions setting it forth, is the *science* called analytic or algebraic geometry. It is often called coördinate geometry from the fact that the set of numbers determining or corresponding to a geometric element are called the coördinates of the element. By virtue of the correlation between analytic facts and geometric facts, it is frequently possible, when facts of the one type are known, to infer the corresponding facts of the other, and so to investigate space analytically (algebraically, arithmetically) and to investigate number geometrically. Under either of these aspects, analytical geometry appears as a *method*: analytic investigation of geometry, geometric investigation of analysis. Usually it is the former aspect under which the doctrine is regarded, geometry being the subject-matter, and analysis the means or instrument of research.

The science presents numerous branches or varieties. These differ among themselves in various ways. Two varieties may differ in respect to what is often called their 'spaces,' *i.e.*, in respect to the domains, fields, regions, or extents (as curve, surface, space) containing the configurations with which they deal. Thus arise such distinctive designations as geometry of (on, in) a plane, or plane geometry, geometry on a surface or a curve, geometry of space. Again, a given 'space' or domain may be conceived in countless ways. It may be conceived as the assemblage of its points or of its lines or of its circles, and so on. Accordingly two geometries relating to a same 'space' or domain may yet differ in respect to their *primary* elements, in respect, *i.e.*, to the elements of which the configurations investigated are regarded as composed. So arise, for example, such distinct theories as the point, line, circle, . . . , geometries of the plane, and the point, line, plane, circle, sphere, . . . , geometries of space. Once more, as will appear in this and related articles herein cited, a chosen element in any given domain may be referred to different kinds of configurations of reference; it may, in other words, be determined by, made to correspond to, or be associated with, different kinds of *coordinate systems.* Upon the choice of coordinate system depends, *ceteris paribus*, the analytic form of a given geometric theory. Accordingly, two geometries that are identical in content may differ in form, in algebraic guise or garb.

The primitive, by far the oldest, variety of analytic geometry, the parent of all other varieties, is the Cartesian, so called from its founder, René Descartes (1596–1650). Though originally a plane geometry, its procedure is equally adapted, and has been extended, to spaces of every dimensionality in points (see HYPERSPACES). It is characterized partly by its primary element, the point, and partly by its coordinate system, which will be explained below. Descartes' geometry, contained in his *Discours de la méthode pour bien conduire sa raison et chercher la vérité, dans les sciences*, published in 1637, is to be regarded, on account of its influence on mathematics and upon knowledge in general, as one of the very greatest contributions ever made to science. Descartes was not indeed the first to apply algebra to geometry. That had been done by «the great geometer,» Apollonius of Perga (about 260–200 B. C.), who had referred the conic sections to their tangents and diameters, expressing the relations by linear equations between areas. In the 14th century Oresme and others had applied numbers («latitudo» and «longitudo,» precursors of the modern ordinate and abscissa) to refer a point to two chosen rectangular lines or axes. The point was confined, however, to the first quadrant. In this way the straight line, the circle and the parabola were studied. Other predecessors of Descartes were Vieta (1540–1603), Cavalieri (1598–1647), Roberval (1602–1675), and the brilliant Fermat (1601–1665), who more nearly than any other approaches Descartes in his understanding of the analytic method. Even Fermat, however, had apparently not seen, what Descartes saw, the possibility of referring at once to a single coördinate configuration different curves of different orders.

The following paragraphs give a very brief account of the elements of Cartesian, or ordinary analytical, geometry with special reference to the straight line and the conic section and the simplest configurations of space.

THE PLANE.

Cartesian Coordinates.—Any two straight lines, as XX' and YY', are assumed as lines of reference, or *coordinate axes*. The former is X-axis or axis of *abscissæ*, the latter is Y-axis or axis of *ordinates*. The point O is the *origin* of *distances;* the (half) line OX, the *origin* of *angles*. Distances on or parallel to the X-axis are regarded *positive* (+) if measured *rightward*, *negative* (−) if *leftward*. Distances on or parallel to the Y-axis are regarded *positive* if measured *upward*, *negative* if *downward*. Angles are regarded *positive* or *negative* according as they are conceived to be generated by *counter-clockwise* or by *clockwise* rotation. (See TRIGONOMETRY.) Conceive drawn all lines parallel to the X-axis and all parallel to the Y-axis. Any pair of these lines, one of the former set and one of the latter, determine (intersect in) a point, and all points of the plane are thus determined. Conversely, any point determines (is the common point of) a pair of the lines, and all the pairs of the parallels are

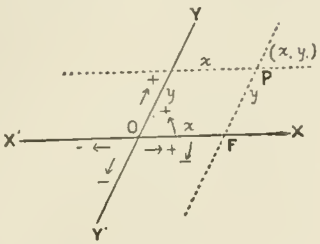

FIG. 1.

thus determined. Obviously any line-pair or its *point* determines two real numbers: the distances OF and FP in terms of any convenient unit. These, denoted respectively by x and y, are named respectively the *abscissa* and the *ordinate*, together the *coordinates*, of the point. Conversely, any *pair* of real numbers determine a point. It is thus seen that, by means of a pair (system) of axes, a one-to-one correspondence is established between the *points* of the plane and the assemblage of real number *pairs*. Any such point and its pair of coordinates are said to *correspond*; the point is said to depict or represent its pair of numbers geometrically, and the number pair is said to represent the point arithmetically or algebraically or analytically.

Transformation of Cartesian Coordinates.—It is plain that (the unit being the same) the coordinates of a point referred to one pair of axes will not coincide with its coordinates referred to a different pair. Formulæ for expressing the old in terms of the new coordinates are exceedingly useful. To find such formulæ, consider first the case where the old and new origins coincide. Denote by α and β the angles made with OX by OX' and OY' respectively. Let x and y be the old, and x' and y' the new, coordinates of any point P, and denote the

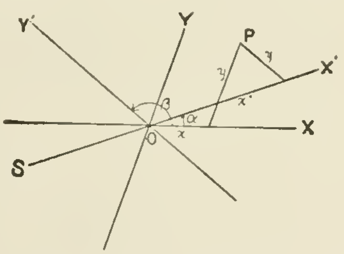

FIG. 2.

angle XOY by ω. The formulæ in question are readily seen to be: $x \sin \omega = x' \sin (\omega - \alpha) + y' \sin (\omega - \beta)$, $y \sin \omega = x' \sin \alpha + y' \sin \beta$. If the origins do not coincide and if h and k be the coordinates of the new origin O' with reference to the old axes, the formulæ of transformation are found by adding $h \sin \omega$ and $k \sin \omega$ respectively to the right-hand members of the foregoing equations. Most commonly the axes are assumed to be *rectangular*. In that case, $\omega = 90°$, $\sin \omega = 1$, $\beta = (90° + \alpha)$, and the equations of transformation become: $x = x' \cos \alpha - y' \sin \alpha + h$, $y = x' \sin \alpha + \cos \alpha + k$. The equations for effecting the *inverse* transformation are found by solving for x' and y' the equations of the *direct* transformation.

Polar Coordinates.—Though it is never necessary, it is often convenient, to employ other than Cartesian coordinates to determine the position of a point. Of such other coordinate systems, the most familiar is the *polar*. About any point O (as center), called the *pole*, suppose drawn all possible concentric circles; also suppose drawn out from the pole all possible *rays* (half-lines). Any circle and any ray determine (intersect in) a point, and all points of the plane are thus determined; conversely, any point determines (is common to) a circle

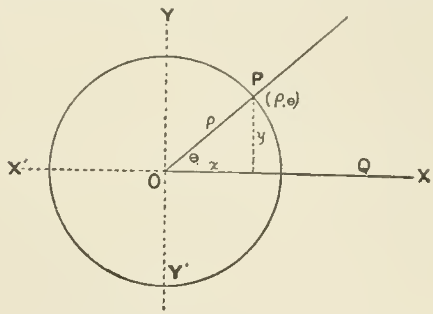

FIG. 3.

and a ray, and all pairs of such lines (circle and ray) are thus determined. A circle is given by its radius ρ, and a ray by its angle θ made with a fixed ray, as OQ, called the *initial line* or *polar axis*. All the circles are obtained by letting ρ vary from 0 to ∞, and all rays by allowing θ to vary from 0 to 2π or 360°. Obviously, to any pair of values (within the ranges of variation mentioned) of ρ and θ there corresponds one point, and conversely. The pair of numbers (ρ, θ) determining or determined by a point P are called the *polar coordinates* of P. In particular, ρ is called the *radius vector*, and θ the *vectorial angle*, of P.

Transformations from Cartesian to Polar Coordinates.—We present here only the simplest and most important case, *viz.*, that wherein the Cartesian axes are rectangular, the origin coinciding with the pole, and the positive half of the X-axis with the polar axis. Let P be any point. It is clear, Fig. 3, that the equations of direct transformation are: $x = \rho \cos \theta$; $y = \rho \sin \theta$. Solving these for ρ and θ, the equa-

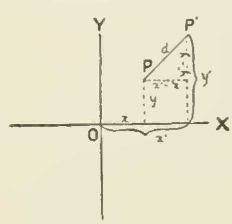

FIG. 4.

tions of the inverse transformation are found to be: $\rho = \sqrt{x^2 + y^2}$; $\theta = \tan^{-1}\dfrac{y}{x}$.

Distance between Points.—Henceforth the axes will be assumed to be rectangular. Let P and P' be any two points, of coordinates

(x, y) and (x', y') respectively. From Fig. 4, by the Pythagorean theorem, $d^2=(x-x')^2+(y-y')^2$, whence the distance between any two points (x, y) and (x', y') is found to be $d=\sqrt{(x-x')^2+(y-y')^2}$. Transforming to polar coordinates (ρ, θ) and (ρ', θ'), and reducing, there results $d=\sqrt{\rho^2+\rho'^2-2\rho\rho'\cos(\theta-\theta')}$, in agreement with the Law of Cosines. (See TRIGONOMETRY.)

Division of Line-segment in Given Ratio.—Suppose P divides the segment P_1P_2 in the

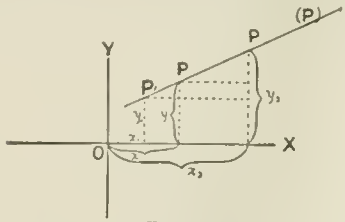

FIG. 5.

ratio, $m_1:m_2$. By hypothesis, $P_1P:PP_2=m_1:m_2$; hence, from similar triangles,

$$m_1:m_2=(x-x_1):(x_2-x)=(y-y_1):(y_2-y);$$

these equations, solved for x and y, yield

$$x=(m_1x_2+m_2x_1):(m_1+m_2)$$

and $$y=(m_1y_2+m_2y_1):(m_1+m_2).$$

If the division be *exterior*, *i.e.*, if P be *outside* the segment, as at (P), one term of the ratio is negative, and the formulæ are

$$x=(m_1x_2-m_2x_1):(m_1-m_2),$$

$$y=(m_1y_2-m_2y_1):(m_1-m_2).$$

If P be the interior mid-point, $m_1=m_2$, and $x=(x_1+x_2):2$, $y=(y_1+y_2):2$. If $m_1=-m_2$, P is the exterior mid-point and its coordinates are both infinite unless the segment is parallel to an axis, in which case but one of the coordinates is infinite.

Locus of Equation.—An equation, $f(x, y)=0$, between the variables x and y, *defines* a system or aggregate or assemblage of *pairs* of numbers, *viz.*, the assemblage of pairs of values of x and y that satisfy the equation. To each of such pairs of (real) values, a system of axes and a unit of distance being chosen, there corresponds a point. The assemblage of all the points so determined constitute the (real) *locus* of the equation. In general, as x or y varies continuously, y or x will vary continuously, and accordingly the corresponding point will trace a continuous path, some *curve*, the locus in question. Conversely, if a point move subject to some geometric condition, its path will be a curve such that the coordinates of its points and of no other satisfy some equation. An equation and its locus or curve are each said to represent the other, and, from the properties of either, corresponding properties of the other can be inferred. An equation defines its locus, a locus defines its equation. Any equation, $f(x, y)=0$, is, of course, satisfied by countless pairs of values of which either (or both) is imaginary or complex. To such a pair no real or «visible» point of the plane corresponds. Nevertheless, in order that the geometric and analytic languages shall be coextensive, it is customary to say that any pair of numbers of which at least one is complex represents an «imaginary point» of the plane. Accordingly the locus (in generalized sense) of an equation is composed of a real part and an imaginary part, the latter consisting of all imaginary points whose coordinates satisfy the equation. The intersection of two loci or curves consists of the points (real and imaginary) whose coordinates satisfy the equations of both curves. The foregoing remarks respecting equations in Cartesian coordinates apply equally to equations in polar coordinates.

The Straight Line and the Linear Equation.—Let (1) be any line through the origin, and denote by θ its angle with OX, and let $m=\tan\theta$. Obviously the x and y of any (every) point of (1) and of no other point are connected by the equation $y=mx$, which therefore defines, and is called the equation of, line (1). To each line through O there corresponds one value of the *slope* m, and conversely. Any line not through O is parallel to a line through O. Hence (2), parallel to (1), represents any line not through O. Clearly by adding b to any y of (1) the corresponding y of (2) is found, while corresponding x's are the same. Hence the equation of (2) is $y=mx+b$. The quantity b is called the *Y-intercept* of the line; if b is zero, (2) goes through O, and conversely. The equation represents a line for every pair of real values of m and b; conversely,

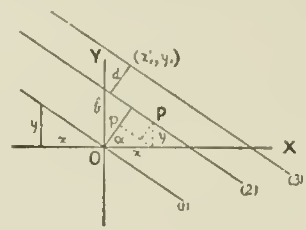

FIG. 6.

every line has a slope and a Y-intercept (positive or negative). Hence every equation of 1st degree in x and y represents a straight line, and conversely. Solving the equation $y=0$ of the X-axis and the equation of (2) as simultaneous, the intersection is found to be $\left(-\frac{b}{m}, 0\right)$, or $(a, 0)$, whence the equation of (2) may be written $\frac{x}{a}+\frac{y}{b}=1$, called the *intercept* or *symmetric form*, a being the X-intercept. The equation $y=mx+b$ is called the *slope form*. Other forms are readily obtainable, of which one of the most important is the so-called *standard* or *normal* form, $x\cos\alpha+y\sin\alpha-p=0$, readily deducible from the figure, where p is the length of the perpendicular (normal) from O to (2), α is the angle indicated, and P is any point of (2). The *general* equation

$$Ax+By+C=0$$

can be reduced to any of the foregoing forms. To reduce it to the normal form, it suffices to multiply by the *normalizing factor*, $1:\sqrt{A^2+B^2}$, yielding

$$\frac{Ax}{\sqrt{A^2+B^2}}+\frac{By}{\sqrt{}}+\frac{C}{\sqrt{}}=0.$$

where $\cos\alpha = A:\sqrt{}$, $\sin\alpha = B:\sqrt{}$, $p = -C:\sqrt{}$, that sign before the radical being chosen which renders the constant (or absolute) term negative. A line is determined by yet other pairs of data, as by its slope m and a given point (x_1, y_1) or by two points (x_1, y_1), (x_2, y_2), and its equation assumes corresponding forms, which may be called respectively the *point-slope* form and the *two-point* form. The former plainly is $y - y_1 = m(x - x_1)$. The necessary and sufficient *condition* that this line shall pass through (x_2, y_2) is $y_2 - y_1 = m(x_2 - x_1)$. Combining the two equations by division, there results the two-point form, $(y - y_1):(y_2 - y_1) = (x - x_1):(x_2 - x_1)$, equation of the line fixed by the points (x_1, y_1), (x_2, y_2).

Distance from Point to Line.—The equation of any line (3), parallel to (2), Fig. 6, is $x\cos\alpha + y\sin\alpha - p' = 0$, where $p' = p + d$. The condition that (x', y') be on (3) is $x'\cos\alpha + y'\sin\alpha = p'$. Subtracting p from both members, we find $d = x'\cos\alpha + y'\sin\alpha - p$, distance from (x', y') to $x\cos\alpha + y\sin\alpha - p = 0$.

Angle between Lines.—Let ϕ be the angle between two lines whose slopes are m_1 and m_2. Then $\tan\phi = \pm(m_1 - m_2):(1 + m_1m_2)$. If $\phi = 0$, then $\tan\phi = 0$, and $m_1 = m_2$, condition of parallelism. If $\phi = 90°$, then $\tan\phi = \infty$, and $1 + m_1m_2 = 0$, whence $m_1m_2 = -1$, condition of perpendicularity.

The Circle and Its Equation.—About any point (a, b) as center describe a circle of any radius r. Let $P(x, y)$ be any point of the circle. A glance at the figure shows that x and y are connected by the relation

$$(x-a)^2 + (y-b)^2 - r^2 = 0,$$

equation of the circle. By comparison with the equation $x^2 + y^2 + 2Ax + 2By + C = 0$, the

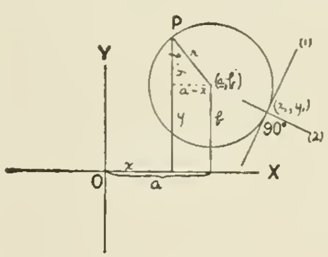

FIG. 7.

latter is found to represent a circle of center $(-A, -B)$, and radius $\sqrt{A^2 + B^2 - C}$. If the radicand be negative, the radius and hence the circle is imaginary. The tangent (1) to the circle at the point (x_1, y_1) is

$$(x_1 - a)(x - a) + (y_1 - b)(y - b) - r^2 = 0;$$

the normal (2) is

$$(y_1 - b)(x - x_1) - (x_1 - a)(y - y_1) = 0.$$

If the center be at the origin, the circle is $x^2 + y^2 = r^2$, the tangent at (x_1, y_1) is $x_1x + y_1y - r^2 = 0$, and the normal is $y_1x - x_1y = 0$. The line $y = mx + c$ is tangent to $x^2 + y^2 - r^2 = 0$ when and only when the distance from O to the line is r, *i.e.*, when $c = \pm r\sqrt{1 + m^2}$; hence $y = mx \pm r\sqrt{1 + m^2}$ is tangent to the circle and as m varies completely envelops the circle. Similarly it may be found that for every value of m the line $y - b = m(x - a) \pm r\sqrt{1 + m^2}$ is tangent to the circle of center (a, b) and radius r. This equation (in slope form) of the tangent is sometimes called the *magic* equation of the tangent. By transformation of coordinates or otherwise the polar equation of the circle of center (ρ', θ') and radius r may be found to be $\rho^2 - 2\rho'\rho\cos(\theta - \theta') + \rho'^2 - r^2 = 0$.

The Conic Sections: Ellipse, Parabola, Hyperbola.—The equation of the path, locus, or curve generated by a point (x, y) which so moves that the ratio of its distance from a fixed point (called the *focus*) to its distance from a fixed straight line (called the *directrix*) is a constant e (called the *eccentricity*) is of the form $Ax^2 + By^2 + Cxy + Dx + Ey + F = 0$; conversely, the locus of every equation of second degree is a curve of the kind in question. All such curves are called *conics* or *conic sections*, because any one of them is the intersection of a plane and a cone, where by cone is meant the surface that may be generated by a straight line revolving about a fixed point (vertex) and making a constant angle with a fixed line (axis) through the point; conversely, every such intersection is a conic, curve of second degree. The conics, of the very greatest importance alike in pure and in applied mathematics (cf. ASTRONOMY), were studied by the ancients (cf. APOLLONIUS), who conceived them as intersections of plane and cone. There are three species of conics, a conic being named *ellipse* (E), *parabola* (P), or *hyperbola* (H), according as the eccentricity $e <, =,$ or > 1. The foregoing equation represents an E, a P, or an H, according as $4AB - C^2$ is *positive*, *zero*, or *negative*. Among the conics of any species are *degenerate* or *degraded* or so-called *improper* conics of that species. The degraded form of E is any pair of imaginary straight lines intersecting in a real point (center of the conic, vertex of the cone); any pair of parallel real straight lines is a degraded P; and any pair of non-parallel real lines is a degenerate H. By suitable transformations of coordinates the equation of any conic may be made to assume a simplest, named *standard*, form. The standard forms of the species are presented below.

Ellipse.—The standard form of the E is $\frac{x^2}{a^2} + \frac{y^2}{b^2} = 1$, in which a is the half *major*, and b the half *minor*, *axis* of the E. The focus

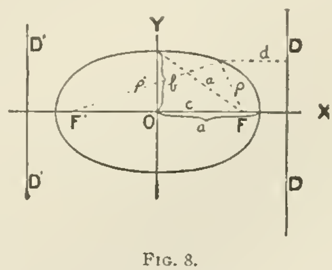

FIG. 8.

and directrix are respectively F and DD or F' and $D'D'$. The equations of the directrices are $x = \pm a:e$; $e = c:a$. The sum of the focal radii of any point of E is $\rho + \rho' = 2a$, a property often taken as definition of the E, instead of the relation $\rho = ed$. If $b = a$, the E is a circle;

hence the circle is an E of coincident foci and eccentricity zero. The area of E is πab.

Hyperbola. — The standard equation is $\frac{x^2}{a^2}-\frac{y^2}{b^2}=1$, where a is half of the *transverse*, and b is half of the *conjugate, axis*. The equation represents the curve composed of the two branches (1) and (2). For any point,

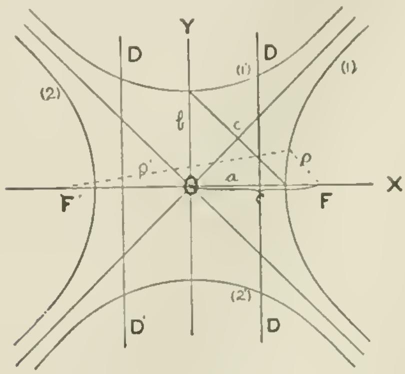

Fig. 9.

$\rho'-\rho=2a$, a defining property of the H. The H composed of (1') and (2') is called *conjugate* to the other one and has $\frac{x^2}{a^2}-\frac{y^2}{b^2}=-1$ for its equation. The two oblique lines through O *tangent* to both H's at ∞ are named *asymptotes* of the curves. The equations of the asymptotes are $y=\pm\frac{b}{a}x$. The corresponding lines of the E are imaginary, $y=\pm i\frac{b}{a}x$. If $a=b$, the H, $x^2-y^2=a^2$, is called equiaxial or equilateral or *rectangular*, its asymptotes being at right angles. It is related to the general H as the circle to the general E.

Parabola. —The standard equation is $y^2=4px$. The equation of the directrix is $x=-p$; the coordinates of the focus are $(p, 0)$; for any

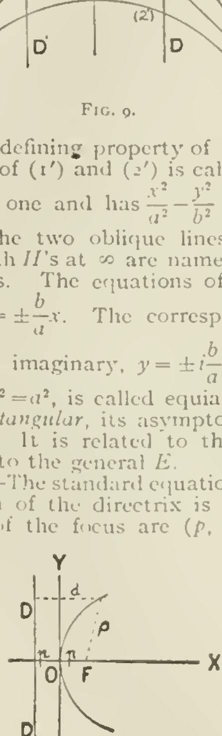

Fig. 10.

point $\rho=d$. The second focus and the center lie at ∞ on the axis of the curve.

For some account of plane curves of higher order or degree, see the article Higher Plane Curves, and for elaborate and detailed treatment of the analytical geometry of the plane, including exhaustive discussion of the conics, see works cited in bibliography below. We add here a note introducing the Cartesian geometry of

Space.

Coordinate Configurations. — Space is tridimensional in points, three independent data being necessary and sufficient to determine the position of a point. Of such data the simplest are the distances, Cartesian rectangular *coordinates*, x, y, z, of a point P from three fixed planes XOY, YOZ, ZOX, each perpendicular to the other two. These *coordinate planes* determine three lines, called *coordinate*

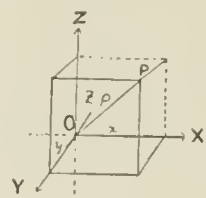

Fig. 11.

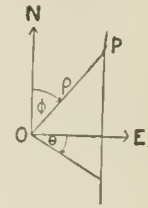

Fig. 12.

axes, having a common point O, the *origin*. Positive directions are indicated by the arrow heads. The polar coordinates of a point P, Fig. 12, are the radius vector ρ, and the vectorial angles θ and ϕ, reckoned respectively from the pole O and the *polar axes* OE and ON. If the pole coincide with the origin, and the polar axes with OX and OZ, then $x=\rho\cos\theta\sin\phi$, $y=\rho\sin\theta\sin\phi$, $z=\rho\cos\theta$, $\rho=\sqrt{x^2+y^2+z^2}$, $\tan\theta=y:x$, $\cos\phi=z:\rho$, formulæ of transformation from either system to the other. If α, β, γ are the direction angles (made respectively with OX, OY, OZ) of the radius vector ρ of any point P, Fig. 11, then $x=\rho\cos\alpha$, $y=\rho\cos\beta$, $z=\rho\cos\gamma$, and $1=\cos^2\alpha+\cos^2\beta+\cos^2\gamma$, sum of squares of *direction-cosines* of ρ. Any linear equation $Ax+By+Cz+D=0$ represents a plane. The symmetric equation of a plane is $\frac{x}{a}+\frac{y}{b}+\frac{c}{z}=1$, a, b, c being the axial intercepts extending from O to the plane. In normal form the equation of the plane is $x\cos\alpha+y\cos\beta+z\cos\gamma=p$, where p is the length, and $\cos\alpha$, $\cos\beta$, $\cos\gamma$ are the direction-cosines, of the perpendicular from O to the plane. To convert $Ax+By+Cz+D=0$ to the normal form it suffices to multiply it by the normalizing factor, $1:\sqrt{A^2+B^2+C^2}$, the new coefficients $A:\sqrt{\quad}$, $B:\sqrt{\quad}$, $C:\sqrt{\quad}$, being $\cos\alpha$, $\cos\beta$, $\cos\gamma$, and $D:\sqrt{\quad}$ being $-p$. The angle θ between two planes $Ax+By+Cz+D=0$ and $A'x+B'y+C'z+D'=0$ is determined by the relation

$$\cos\theta=(AA'+BB'+CC'):\sqrt{(A^2+B^2+C^2)(A'^2+B'^2+C'^2)},$$

whence the planes are parallel when and only when $A:A'=B:B'=C:C'$, and are perpendicular when and only when $AA'+BB'+CC'=0$. The equations of any two of the planes containing a line, *together* represent the line. Accordingly in space the line has *two* equations. Its simplest equations are those of any two of the three planes containing the line and being perpendicular respectively to the coordinate planes as $x=mz+p$, $y=nz+q$. Such a pair are unsymmetric. Symmetric equations of the line directed by α, β, γ, and going through the point (x_1, y_1, z_1) are

$$(x-x_1):\cos\alpha=(y-y_1):\cos\beta=(z-z_1):\cos\gamma,$$

in number three of which but (any) two are independent. The angle θ between two lines whose direction-cosines are proportional to

L, M, N and L', M', N', respectively, is determined by the relation

$$\cos\theta = (LL' + MM' + NN') : \sqrt{(L^2+M^2+N^2)(L'^2+M'^2+N'^2)},$$

whence the lines are parallel if and only if $L:L' = M:M' = N:N'$, and are perpendicular if and only if $LL' + MM' + NN' = 0$. The angle θ between a line of direction-cosines proportional to L, M, N and a plane

$$Ax + By + Cz + D = 0$$

is given by the relation

$$\sin\theta = (AL + BM + CN) : \sqrt{(A^2+B^2+C^2)(L^2+M^2+N^2)},$$

whence the line and plane are parallel if and only if $AL + BM + CN = 0$ and are perpendicular if and only if $A:L = B:M = C:N$. The necessary and sufficient condition that the line $x = m_1z + p_1$, $y = n_1z + q_1$, shall intersect the line $x = m_2z + p_2$, $y = n_2z + q_2$, is that $(m_1 - m_2):(n_1 - n_2) = (p_1 - p_2):(q_1 - q_2)$.

The literature of the analytical geometry of space, herewith barely introduced, is extensive. For some account of further developments of the subject, see the articles SURFACES, THEORY OF, and CURVES OF DOUBLE CURVATURE, THEORY OF, in this Encyclopedia. In the doctrine above introduced the point is employed as element. Some account of the theories that arise on choosing for element some other geometric entity, as the plane, the line, the sphere, etc., may be found in the articles, GEOMETRY, MODERN ANALYTICAL, and GEOMETRY, LINE, AND ALLIED THEORIES, in this work.

Bibliography.—College text-books of analytical geometry abound. One of the scientifically best American texts is W. B. Smith's 'Coordinate Geometry.' The most comprehensive English works are Salmon's 'Conic Sections' and 'Geometry of Three Dimensions' (both of which have been translated into French by O. Chemin, and supplemented and translated into German by Wilhelm Fiedler), and Frost's 'Solid Geometry.'

CASSIUS J. KEYSER,
Adrain Professor of Mathematics,
Columbia University.

Geometry, Elementary. Geometry is the science of space. Its object is the study of the properties of forms (configurations, figures) of every conceivable kind. The subject is thus endless in two ways: in the first place, the number of configurations is infinite—this is so even if we restrict ourselves to curves and surfaces; in the second place, any one type of figure has an inexhaustible variety of properties.

Elementary geometry may be roughly described as the study of the simpler or more evident properties of the simpler configurations. Specifically, the title refers to the body of geometric truths incorporated by Euclid in his famous 'Elements.' The text-books on elementary geometry used throughout the civilized world for the last twenty centuries are in fact merely revisions of the 'Elements'; so that the subject itself is often referred to, especially in England, as the study of Euclid. The majority of the theorems refer to points, straight lines, and planes, with their combinations. Of curves, only the circle is considered, and of surfaces, those related to the circle (spherical, cylindrical, conical).

It is not the object of this article to give a résumé of the standard theorems of elementary geometry, but rather to indicate some of the more significant general features, especially in the light of the more recent developments.

LOGICAL FOUNDATIONS.

The most prominent aspect of elementary geometry is the logical aspect: a great number of propositions, termed theorems, are deduced from a comparatively few propositions assumed at the outset and termed axioms or postulates. In the ideal treatment of the subject, all the assumptions should be enumerated explicitly, so that, if the question is asked, «Are the theorems of geometry true,» the mathematician can answer correctly, «Yes, if my postulates are true.» As to whether the postulates are true, that is not a matter for the mathematician as such to consider, but rather comes within the province of the physicist, psychologist, or philosopher.

The ordinary course in geometry, modeled after Euclid, does not carry out this ideal. Assumptions are continually being made as they may be needed for the purpose of proof, in addition to those explicitly enunciated as axioms and postulates. For example, in the first proposition of Euclid, dealing with the construction of an equilateral triangle on a given segment AB, circles are drawn with centres A and B and common radius AB, and it is then assumed that these circles intersect. The only justification given is the diagram or the appeal to spatial intuition. Again, in dealing with the congruence of triangles, it is assumed that a triangle may be moved about without altering its sides or angles, though the stated axioms do not even mention displacement. In spite of himself, Euclid's treatment is (partly) physical or intuitional, instead of purely mathematical, that is, purely logical.

It is only within the last few years that the ideal has been (practically) attained; that is, a set of explicit assumptions (termed axioms or postulates indifferently) drawn up, from which the propositions of ordinary geometry follow by purely logical processes. Geometry becomes then a branch of pure mathematics. As Poincaré expresses it, in this ideal treatment «We might put the axioms into a reasoning apparatus like the logical machine of Stanley Jevons, and see all geometry come out of it.»

Many contributors have aided in this development, among whom may be mentioned Gauss, Lobachevsky, Pasch, Veronese, and especially Peano and his co-workers in symbolic logic, Pieri and Peano. The most elaborately worked out system is that of Hilbert (1900). We give a brief account of his axioms.

Geometry deals with three systems of objects or elements termed *points*, *lines* (used here in sense of straight lines), and *planes*, connected by certain relations expressed by the words *lying in*, *between*, etc. It is not necessary for the development of the subject that these words should suggest visual images: in fact the concrete nature of the elements and relations is to be eliminated from the discussion. To emphasize this abstract aspect, it is convenient to use symbols, say capital letters for points, italics for lines, and Greek letters for planes. The axioms are arranged in five groups as follows:

I. *Axioms of Association or Connection.*— 1. Any two different points A, B determine a line a. (Such points are then said to lie on the line.)

2. Any two different points on a line determine that line.

3. In any line there are at least two points, and in a plane there are at least three points not on a line.

4. Any three non-collinear points A, B, C determine a plane α.

5. Three non-collinear points of a plane determine that plane.

6. If two points A, B of a line a are in a plane α, then every point of a is in α. (The line is then said to lie in the plane.)

7 Two planes α, β which have a point A in common have at least a second point B in common.

8. There exist at least four points not in one plane.

II. *Axioms of Order.*—These deal with the relation expressed by the term *between*.

1. If A, B, C are points of a line and B is between A and C, then B is between C and A.

2. If A and C are points of a line a, then there exists on a at least one point B between A and C, and at least one point D such that C is between A and D.

3. Of any three collinear points, one and only one is between the other two.

These three axioms deal with the line, while the fourth deals with the plane.

4. If A, B, C are any three non-collinear points, and a is a line in their plane passing through a point of the segment AB, but not through A or B or C, then a contains a point of either the segment AC or the segment BC.

III *Axioms of Congruence.*—The first five axioms of this group relate to congruent segments and congruent angles. For example, a segment AB is congruent to itself and to the reversed segment BA; and segments congruent to the same segments are congruent to each other. Finally, the sixth is a metrical axiom concerning triangles: if two sides and the included angle of one triangle are congruent respectively to two sides and the included angle of another triangle, then the remaining angles are also congruent.

The fact that the remaining sides are congruent is not included as a part of the axiom because it may be proved. The other cases of congruent triangles are theorems. In Euclid the above statement is a theorem, but this is possible, as already observed merely on account of unstated assumptions relating to displacement. Euclid's axiom that all right angles are congruent, in Hilbert's system becomes a theorem.

IV. *The Axiom of Parallels.*—This contains only the so-called *Euclidean axiom*, in the form: Given a line a and a point A not on a, then in the plane α determined by a and α there is only one line through A which does not intersect a.

V. *Axioms of Continuity.*—The continuity notion is analyzed into two parts of which the first (1) is stated in the axiom of *Archimedes:* 1. On a straight line consider any two points A, B and a point A_1 between them; construct the points A_2, A_3, . . . , in order, so that A_1 is between A and A_2, A_2 between A_1 and A_3, etc., and so that the segments AA_1, A_1A_2, A_2A_3, . . . , are congruent; then among the points so constructed there exists a point A_n such that B is between A and A_n. That is, by repeatedly laying off a given segment however small any assigned point of the line will be passed after a finite number of steps.

This axiom is sufficient for the development of the usual theorems of geometry. However the space to which the theorems apply would not be continuous in ordinary sense. It would in fact contain only those points of the space considered in analytical geometry whose coordinates are rational or expressible by radicals of the second order. To identify with continuous space it is necessary to add a final axiom (2) relating to convergent point sets, or else the so-called axiom of completeness which states that the system of elements (points, lines, planes) cannot be enlarged by adjoining other elements in such a way that all the previous axioms are preserved.

The fact that this set of axioms is sufficient is shown by actually deducing the usual body of theorems. This is done in Hilbert's 'Grundlagen.' Diagrams are here used, it is true, but only for convenience; the proofs can be given without any reference to the diagrams. Often the deduction of those results which are evident to the intuition is long and complicated. This is the case, for example, in showing that a triangle (or any simple polygon) has the properties expressed by the terms inside and outside. It must be shown from the axioms that the given triangle brings about a division of the points in its plane into three classes, namely, points P, points I, and points O, such that any two I points or any two O points may be connected by a broken line not containing any P point, while any broken line from an I point to an O point necessarily contains P points. To the intuition, of course, the P points are the points on the perimeter of the triangle, the I points are those inside, and the P points are those outside.

In the development it is important to observe that some theorems depend upon only part of the axioms. Thus from group I alone it follows that two planes having a point in common necessarily have a line in common, and that a line and a point determine a plane. The property of triangles and polygons stated above follows from group I and II. The theory of proportion may be established without employing group V. The theorem that if two triangles in one plane have their sides respectively parallel, the lines joining corresponding vertices are either parallel or concurrent (a special case of *Desargues'* theorem), can be proved without using axiom III 6 if and only if the spatial axioms in addition to the plane axioms are employed.

An important result which has been obtained recently is that while the areas of plane polygons may be treated without appealing to the continuity axioms, this is not possible with the volumes of polyhedrons. The difference is observed in Euclid's proofs: the proposition that triangles having the same base and altitude are equal in area is demonstrated by adding or taking away congruent parts from congruent figures, while the corresponding proposition concerning triangular pyramids is proved by the method of limits, or the equivalent method of exhaustion. That this difference in treatment is not avoidable was established by Dehn (1901), who showed that there exist polyhedrons of equal volumes which cannot be formed by the addition or subtraction of respectively congruent polyhedrons. In plane geometry this formation applies to any two polygons with the same area.

The most fundamental question concerning the set of axioms is that of *consistency.* In the development of geometry no contradiction has thus far presented itself; but will this always be the caes? Can it be shown that no inconsistency can ever arise? The only known method of answering this question depends upon establishing a correspondence between the geometrical elements and certain numerical entities, and showing that any inherent contradiction in geometry would involve contradictory relations among these entities. The question is thus transferred to the field of Arithmetic. Are the axioms of number (commutative, associative, distributive, etc.) inconsistent? No direct proof has yet been devised.

Another question to be considered is the independence of the axioms. If any one axiom can be deduced from the others, it may be omitted from the list and introduced as a theorem. It is therefore desirable that the axioms should express mutually independent statements. The standard method employed in proving the independence of an axiom or group of axioms consists in devising a set of objects of any kind which, when considered as elements, fulfill the relations expressed in remaining axioms, but for which the axiom or group in question is not satisfied. Thus the fact that the axiom of parallels (IV) cannot be deduced from the other axioms is shown by the non-Euclidean geometry of Lobachevsky. Similarly, the independence of axiom VI is proved by means of the non-Archimedean geometries of Veronese and Hilbert. Various apparently artificial systems have been devised in this connection, which, while not amenable to the intuition, are conceivable and mathematically true because based on assumptions which may be shown to be free from inconsistency.

The set of axioms presented above is of course not the only one which may serve as foundation for ordinary geometry. Thus the axiom of parallels may be replaced by the statement that the sum of the angles of a triangle is two right angles. In general the propositions of a given collection may be derived from various sets selected from the total collection. In the present case the possibilities are endless.

Geometry may also be founded on other primitive (undefined) concepts than those introduced above. Thus in the discussions inaugurated by Helmholtz and continued by Lie and Poincaré, the principal concept is that of transformation (displacement, rigid motion) and the axioms include the group property (the resultant of two displacements is itself a displacement). The straight line is then no longer, as in Hilbert's system, a primitive concept, but receives definition: if in a displacement two points are fixed, there are an infinite number of fixed points forming, by definition, a straight line (the axis of rotation).

In the usual intuitional treatment the concept of general surface is assumed as a starting-point and the plane is then defined as a surface such that if any two of its points are joined by a straight line, the latter lies entirely in the surface. This obviously states more than is required for the determination of the surface. To meet this objection the plane is sometimes defined as generated by drawing straight lines from a fixed point A to all the points of a straight line a. To obtain the entire plane it is necessary to add the line through A parallel to a. This definition is therefore unsatisfactory, because parallel lines require in their definition the previous definition of the plane. Peano has met the difficulty by this definition: Consider three fixed points A, B, C not in a straight line; take a fixed point D within the segment BC, and on the segment AD take a fixed point E; a plane is then generated by the lines (rays) from E to every point of the perimeter ABC. It may then be proved that a straight line connecting any two points of such a surface lies on the surface.

Problems and Constructions.

The only instruments whose use is implied in the postulates of elementary geometry are the ruler (straight-edge), for drawing straight lines, and the compass, for drawing circles. Only those problems are considered as coming within the domain of elementary geometry which can be solved by a finite number of operations with these instruments. Such constructions are termed *Euclidean*, or sometimes simply *geometric.* An example is the construction for bisecting an angle. With the vertex V as centre and any radius describe a circle cutting the sides of the angle in points A and B; with these points as centres and any (sufficiently large) radius describe circles intersecting in points C and D; the line joining C and D necessarily passes through V and bisects the given angle.

However, many problems arise which cannot be solved in this way. A well-known example is the problem of trisecting an angle. For centuries the Greek geometers and their followers sought for a solution; only within the present century has it been shown that such attempts must necessarily fail. The statement that the problem is impossible does not deny that lines trisecting the given angle exist, but means simply that such lines cannot be obtained by a construction employing a finite number of straight lines and circles.

No one has yet succeeded in demonstrating this impossibility by purely geometric means. The question arises naturally in elementary geometry, but apparently cannot be answered by elementary methods. We give now an outline of the algebraic method for deciding whether a given problem comes within the class of possible or the class of impossible problems.

Any line segment may be represented by a segment, namely, the ratio of the given segment to an assumed unit segment. Conversely, any number then represents a segment. Consider now the elementary operations of arithmetic or algebra in relation to geometric constructions.

If a and b denote given segments, or the corresponding numbers, the sum $a+b$ is constructed by transferring the segment b, by means of the compass, so that it is collinear and adjacent to a. The difference $a-b$ is also readily constructible.

The product $x=ab$ may be defined by the proportion $1:a=b:x$. The proper construction is then suggested by the theorem that a line parallel to the base of a triangle divides the sides proportionally. Draw any triangle with 1 and a as two of the sides; along the first side prolonged if necessary lay off segment b; from the terminal point draw a line parallel to the base of the triangle; this cuts off on the second side a segment equal to the required x. The quotient $y=a/b$ is obtained similarly from the proportion $b:1=a:y$. Hence all rational expressions, that is, expressions formed by a finite number of additions, subtractions, multiplications, and divisions are constructible.

Furthermore, extraction of square roots is possible. For $z=\sqrt{a}$ may be defined by $1:z=z:a$. Hence if on $1+a$ as diameter a semicircle is described, the perpendicular at the end of the unit segment is the required z. Therefore,

Theorem I.—Any expression involving only rational operations and the extraction of square roots can be constructed with ruler and compass.

Expressions which cannot be reduced to this form cannot be constructed. This we now prove in the form of the converse:

Theorem II.—Any segment which can be constructed with ruler and compass is expressible algebraically by rational operations and the extraction of square roots.

For any such construction consists in drawing a finite number of straight lines and circles and finding their intersections. Employing Cartesian coordinates (see GEOMETRY, CARTESIAN), the equation of a straight line is of the form $ax+by+c=0$, and that of a circle is of the form $x^2+y^2+ax+by+c=0$. The intersection of two straight lines leads to the solution of two equations of the first degree, which requires only rational operations. The intersections of a straight line and circle, or of two circles, depends on the solution of quadratic equations and leads to radicals of the second degree.

We proceed to apply these theorems to several examples.

Consider first the problem of bisecting an angle. The given angle θ and the required angle $\frac{\theta}{2}$ may be determined by their cosines. Let $a=\cos\theta$ and $x=\cos\frac{\theta}{2}$ From trigonometry $\cos\theta=2\cos^2\frac{\theta}{2}-1$, that is, $2x^2-1=a$. Hence $x=\sqrt{\frac{1+a}{2}}$. Therefore, by Theorem I, the problem is elementary. The formula also indicates a definite method of construction.

In the *trisection* of a given angle we require the formula $\cos\theta=4\cos^3\frac{\theta}{3}-3\cos\frac{\theta}{3}$. Here $\cos\theta=a$ is known, and $\cos\frac{\theta}{3}=x$ is required. The equation of the problem is

$$4x^3-3x-a=0.$$

When solved by Cardan's formula this leads to cube roots. But before Theorem II can be applied it must be shown that no expression involving only square roots can satisfy the equation. This is true in the present case by the following general theorem taken from the theory of equations:

Theorem III.—An irreducible equation whose degree is not a power of two cannot have a root expressible by radicals of the second degree. (The term irreducible equation is here employed to describe an equation $f(x)=0$ with rational coefficients whose left member cannot be factored rationally.)

In general the algebraic questions which arise in this connection require for their complete discussion the powerful Galois Theory of Equations. See EQUATIONS, GALOIS' THEORY OF.

A second of the so-called famous problems of elementary geometry is the *Delian problem*, or the duplication of the cube. Given a cube with side a, to construct a cube with side x having double the volume. The equation of the problem is $x^3=2a^3$. Theorem III and then Theorem II apply. The corresponding problem concerning the square, leading to the equation $x^2=2a^2$, is easily solved: the side of the required square is simply the diagonal of the given square.

Regular Polygons.—The construction of a regular polygon of n sides is equivalent to the division of a given circumference into n equal arcs. The only cases treated by Greek geometers and the ordinary text-books are, for prime numbers, $n=3$ and $n=5$; from these constructions of the regular triangle and pentagon, combined with the construction for bisecting an angle, the constructions for the cases 2^κ, $3\cdot 2^\kappa$, $5\cdot 2^\kappa$, $3\cdot 5\cdot 2^\kappa$, where κ is any integer, are easily found.

No advance was made, that is, no new constructible polygons were discovered, until Gauss, about a century ago, applied the algebraic method. The equation of the problem may be put into the form

$$x^{n-1}+x^{n-2}+\ldots+x+1=0,$$

which is then termed the *cyclotomic equation.* When n is a prime number the equation is irreducible. Hence by Theorem III the construction is possible only when $n-1$ is a power of 2. That is, n must be of the form $2^\mu+1$. Prime numbers of this type are necessarily of the form $2^{2^\nu}+1$, and are known as *Fermat primes.* The values $\nu=0$ and $\nu=1$ give the familiar cases $n=3$ and $n=5$; the first new case, arising from $\nu=2$, is $n=17$. The construction for the regular polygon of 17 sides is complicated, but the steps are indicated definitely by the algebraic solution of the cyclotomic equation, which is in fact solvable by square roots.

The general result on regular polygons is as follows: The regular polygon of n sides can be constructed with ruler and compass if, and only if, the prime factors of n are 2 repeated any number of times and distinct Fermat primes. The first impossible cases are $n=7$ and $n=9$.

Quadrature of the Circle.—This most famous problem of geometry requires the construction of a square having the same area as a given circle. That this is impossible (that is, that the construction cannot be effected with the ruler and compass) was not definitely shown until 1882, although the failure of innumerable attempts had led many to suspect the true result. The *rectification* of the circle, that is, the construction of a straight line having the same length as a given circumference, is an equivalent problem, and hence also impossible. This is so on account of the theorem that the area of a circle equals one half the product and the radius into the circumference.

The ratio of the circumference to the diameter is the same for all circles: the constant thus arising has been generally denoted by the symbol π since the time of Euler. It was proved, quite simply, by Legendre that π is not rational (i.e., cannot be represented exactly by the ratio of any two integers, and hence, in particular, cannot be represented by a terminating decimal). The difficulty consists in showing that π is *transcendental*, that is, is not the root of any algebraic equation

$$a_0x^n + a_1x^{n-1} + \ldots + a_n = 0,$$

where n is a positive integer, and the coefficients are any integers. This was finally proved by Lindemann in 1882, after Hermite in 1873 had shown that e, the base of the Napierian system of logarithms, is transcendental. The two numbers are connected by the remarkable relation $e^{i\pi} = -1$, where i is the imaginary unit number $\sqrt{-1}$. Since π cannot satisfy any algebraic equation, it certainly cannot be expressed by square roots. Hence Theorem II proves the impossibility.

Approximate Constructions.—The problems considered cannot be solved exactly by ruler and compass, but they can be solved to any required degree of approximation. Thus a simple approximate solution of the rectification problem is the following: Let O be the centre and AB any diameter of the given circle. At the middle point E of AO construct a perpendicular cutting the circumference in C and D. On AB prolonged lay off $EF=CD$. Draw FD, and on this line lay off $FH=AB$. Then the segment HD is approximately one fourth the circumference. The error is less than one part in 5000.

Other Instruments.—The problems considered may be solved exactly if other instruments in addition to ruler and compass are allowed. Thus the trisection and duplication problems (like all problems depending on cubic and biquadratic equations) can be solved by the instruments for drawing parabolas or other conics, or by appropriate linkages. The quadrature of the circle, being a transcendental problem, cannot be effected by any instrument which draws algebraic curves. It can be solved by various transcendental curves (quadratrix, sinusoid, cycloid); or by the integraph (an instrument which draws the curve $y=\int f(x)dx$, where $y=f(x)$ is a given curve).

We consider now various restrictions which may be imposed on Euclidean constructions.

(1) *Ruler Constructions.*—Here only the straight-edge is allowed. For the possibility of such a construction it is necessary but not sufficient that the corresponding algebraic expression should be rational. If two parallel lines are given, then through a given point a line may be drawn parallel to given lines by a ruler construction. But this is not the case when a line is to be drawn through a given point parallel to a given line. The impossibility proof, based upon projection, may be carried out by pure geometry.

(2) *Mascheroni Constructions.*—Here only the compass is allowed. A straight line is considered as known when two of its points are determined. Mascheroni, in 1797, showed that all problems which can be solved by the ruler and compass can be solved by the compass alone.

(3) Poncelet and Steiner have shown that, if a single fixed circle with its centre is given, all elementary constructions may be carried out by means of the straight-edge. Again, if a ruler with parallel edges may be employed (it is then, for instance, possible to place the instrument so that each edge goes through an assigned point), all elementary problems may be solved without the compass.

(4) Hilbert considers constructions with the straight-edge and *sect-carrier.* The latter denotes a compass used not to draw circles, but merely to lay off a given segment on a given line. All such constructions can be carried out by the straight-edge and a movable unit sect. The test for deciding the possibility or impossibility of a problem in this sense is exceedingly complicated, depending on the higher theory of algebraic numbers.

Geometrography.—A problem of elementary geometry can usually be solved in a variety of ways by the ruler and compass. Thus for the Apollonian problem (to construct a circle touching three given circles) over one hundred distinct solutions have been worked out (Apollonius, Poncelet, Steiner, Lemoine, Study, etc.). How can we compare these as regards simplicity? It is necessary to adopt some standard or measure of simplicity. One method, for instance, would be to take the number of lines and circles as the measure of simplicity.

A more complete (but still somewhat artificial) discussion has been elaborated by E. Lemoine in his 'Geometrography.' Constructions are analyzed into the following elementary operations: Operation C_1 consists in placing one point of the compass on a given point in the plane of construction; including a given length between the points of the compass is then denoted by $2C_1$; placing a point of the compass on an undetermined point of a line is operation C_2; drawing a circle is C_3; making the edge of the ruler pass through an assigned point is operation R_1, and through two assigned points is $2R_1$; finally, drawing a straight line is operation R_2. Any construction may then be represented by a symbol $l_1R_1 + l_2R_2 + m_1C_1 + m_2C_2 + m_3C_3$, where the coefficients represent the numbers of elementary operations involved. The *simplicity* is measured by $l_1 + l_2 + m_1 + m_2 + m_3$, and the *exactness* by $l_1 + m_1 + m_2$ (the preparatory operations). The number of lines employed is given by l_2 and of circles by m_3.

In the case of the construction for the bisection of an angle explained above the symbol is $3C_1+3C_3+2R_1+R_2$. The construction which leads to the smallest possible value for the *simplicity* is termed the geometrographic solution. There may be more than one solution of this kind.

Instructor in Mathematics, Columbia University.

Geometry, Line-, and Allied Theories.—For geometric purposes space may be conceived in an endless variety of ways (see CARTESIAN GEOMETRY), *i.e.*, as the manifold of all the geometric entities of *any* given kind contained in it. In particular, it may be viewed as the assemblage (manifold, aggregate, plenum) of its points or of its planes or of its lines. According as one or another of these views be adopted as fundamental, any configuration, as a curve or a surface, will present as fundamental the corresponding aspect, *i.e.*, it will appear as the *locus* (assemblage) of its points or as the *envelope* (assemblage) of its tangent planes or as the *envelope* (assemblage) of its tangent lines. These various views or aspects are not independent. Each involves the others, but they are not coordinate: one of them being assumed as fundamental or *primary*, the others appear as derived or *secondary*. Space accordingly admits of various geometric theories distinguished by and taking their names from their primary elements. Line-geometry contemplates space as primarily composed of lines, employs the line as fundamental element, and has for its subject-matter the relations and properties of line configurations. Thus the rôle of the right line in this doctrine is quite analogous to that of the point or the plane in the older geometries. The plane, too, has a line-geometry (see GEOMETRY, MODERN ANALYTICAL), but the line and the point theories of the plane, being analytically identical, are best treated simultaneously as dual aspects of a single doctrine.

The honor of having been the first to make formal and systematic use of the right line as primary element in the geometry of space belongs to Julius Plücker (1801–1868), whose 'Neue Geometrie des Raumes gegründet auf die Betrachtung der geraden Linie als Raumelement,' 1868–69, is the first great contribution to the subject. The idea of employing the line as space element had indeed occurred to him at a much earlier date. (Cf. his 'System der Geometrie des Raumes,' 1846.) His first memoir on the subject, entitled 'On a New Geometry of Space,' was published in English in 1865 and may be found in vol. 14 of 'The Proceedings of the Royal Society of London and elsewhere. Certain important line systems, as congruences and complexes (names given by Plucker), had indeed been previously studied to some extent by others. The notion of congruences of lines naturally first presented itself in geometric researches in optics, and in fact the first appearance of the concept of the line complex seems to be that found in the 'Traité d'Optique' of the physicist, Étienne Louis Malus (1775–1812). The point-plane and line-line correlations or null-systems established by the linear complex were considered in 1827 by the Italian geometrician Giorgini (('Memorie dei XL.,' vol. 20), and in 1833 by Moebius in a memoir entitled 'Über eine besondere Art dualer Verhältnisse zwischen Figuren im Raume' ('Crelle's Journal,' vol. 9–10). Nevertheless the invention of the line geometry of space is, as said, to be properly ascribed to Plucker. His work in this field is the beginning of a great epoch in the science of analytical geometry. The undying influence of that work is due neither to its content nor, strictly speaking, to its method, important as these are. It is rather due to its spirit, which is the spirit of freedom, emancipating alike from traditional concepts and traditional modes of procedure. Since Plücker's time the science begun by him has been greatly refined and vastly extended, and out of it have come great and growing kindred doctrines, as the sphere and the circle geometries of space, and allied theories in spaces of higher dimensionality. The following paragraphs present a brief account of the elements of some of these theories, especially of line geometry, together with some indications of further developments and references to the corresponding literature.

Line Coordinates.—In Cartesian coordinates (see GEOMETRY, CARTESIAN) the line is determined by any pair of its projecting planes, *e.g.*, by the pair $x=rz+\rho$, $y=sz+\sigma$; conversely, any such pair determines a line. Accordingly the position of the line depends upon four independent quantities or *coordinates*, r, s, σ, ρ; the line has four degrees of freedom, space contains a fourfold infinity, ∞^4, of lines; in lines it is 4-dimensional: a being who thought in lines as «naturally» as man thinks in points would regard (our) space as having four instead of three dimensions. Linear transformation of Cartesian coordinates converts the line coordinates r, s, σ, ρ into the coordinates r', s', σ', ρ' (of the same line) where these are fractions whose terms are linear functions of r, s, σ, ρ, and $r\sigma-s\rho$; and, accordingly, an equation of degree n in r, s, σ, ρ is converted into one of degree $2n$ in those quantities. In order that the new and the old equations should be of the same degree in the old coordinates, Plücker introduced a fifth coordinate η, where $\eta=r\sigma-s\rho$. There are numerous other systems of line coordinates, and in his above-cited first paper Plücker himself presents no less than eight distinct systems. Of all the systems those that are *homogeneous* are at once the most artistic and convenient. These naturally present themselves as follows: If x_i and ξ_i ($i=1$, 2, 3, 4) denote respectively the homogeneous coordinates (see GEOMETRY, MODERN ANALYTICAL) of a point and a plane referred to a fundamental tetraedron, then the equation $\xi_1x_1+\xi_2x_2+\xi_3x_3+\xi_4x_4=0$, or $\Sigma\xi_ix_i=0$, will serve to represent the plane ξ_i (as locus of points) or the point x_i (as envelope of planes). It is at the same time the condition that the point x_i and the plane ξ_i shall be united in position, each containing the other. The line determined by two planes ξ_i and η_i is represented by the pair of equations $\Sigma\xi_i x_i=0$, $\Sigma\eta_i x_i=0$. It is equally determined by any two planes of the axal pencil $\Sigma(\xi_i+\lambda\eta_i)x_i=0$. Of these the simplest are the four of which each contains a vertex of the tetraedron of reference. Their equations are

$$\begin{array}{l} * \ +q_{12}x_2+q_{13}x_3+q_{14}x_4=0, \\ q_{21}x_1+\ *\ +q_{23}x_3+q_{24}x_4=0, \\ q_{31}x_1+q_{32}x_2+\ *\ +q_{34}x_4=0, \\ q_{41}x_1+q_{42}x_2+q_{43}x_3+\ *\ =0, \end{array}$$

where $\rho q_{jk}=\xi_j\eta_k-\xi_k\eta_j$, ρ being a proportionality factor; *e.g.*, $\rho q_{12}=\xi_1\eta_2-\xi_2\eta_1$. As $q_{jk}=-q_{jk}$, there are but six numerically distinct coefficients q. These are connected by the quadratic identity $q_{12}q_{34}+q_{13}q_{42}+q_{14}q_{23}=0$; as, moreover, only their ratios are essential, the six q's are equivalent to but four independents. Accordingly the q's may be, and for the sake of symmetry are, adopted as *six homogeneous coordinates of the line regarded as the axis* (*envelope*) *of a pencil of planes*.

The line has another aspect; it may be viewed as locus of its points, determined by any pair of them as x_i and y_i. So viewed, it is represented by the pair of point equations $\Sigma x_i\xi_i=0$, $\Sigma y_i\xi_i=0$. The line is equally determined by any two points of the range $\Sigma(x_i+\lambda y_i)\xi_i=0$ and in particular by any two of the four points in which the line pierces the faces (planes) of the fundamental tetraedron. Of these points the equations are

$$\begin{array}{l} * \ +p_{12}\xi_2+p_{13}\xi_3+p_{14}\xi_4=0, \\ p_{21}\xi_1+\ *\ +p_{23}\xi_3+p_{24}\xi_4=0, \\ p_{31}\xi_1+p_{32}\xi_2+\ *\ +p_{34}\xi_4=0, \\ p_{41}\xi_1+p_{42}\xi_2+p_{43}\xi_3+\ *\ =0, \end{array}$$

where $\sigma p_{kj}=x_jy_k-x_ky_j$. The six p's satisfy an identity like that of the q's, the ratios of the p's are alone important, and, again with a view to symmetry, the p's are chosen as the *six homogeneous coordinates of the line conceived as a locus* (*range*) *of points*.

It is readily found that the line p_{jk} and the line q_{jk} are one and the same when and only when $p_{12}:q_{34}=p_{13}:q_{42}=p_{14}:q_{23}=p_{34}:q_{12}=p_{42}:q_{13}=p_{23}:q_{14}$. Accordingly, disregarding both the locus and envelope aspects of the line, we may employ for its coordinates any six quantities r_{jk} which, ρ and σ being proportionality factors, satisfy the relations: $r_{12}=\rho q_{12}=\sigma p_{34}$, $r_{13}=\rho q_{13}=\sigma p_{42}$, $r_{14}=\rho q_{14}=\sigma p_{23}$, $r_{34}=\rho q_{34}=\sigma p_{12}$, $r_{42}=\rho q_{42}=\sigma p_{13}$, $r_{23}=\rho q_{23}=\sigma p_{14}$. The identity connecting the r's may be written (after Koenigs) $\omega(r)=2(r_{12}r_{34}+r_{13}r_{42}+r_{14}r_{23})=0$.

Passing from homogeneous to Cartesian point coordinates, *i.e.*, from a finite tetraedron to an infinite one having three of its faces mutually perpendicular and for the fourth the plane at ∞, there result the six homogeneous line coordinates employed by Plücker. The transition is effected by substituting x', y', z', 1 respectively for x_1, x_2, x_3, x_4, and x'', y'', z'', 1 for y_1, y_2, y_3, y_4; the Plücker coordinates accordingly are:

$$p_{12}=x'y''-x''y',\ p_{13}=x'z''-x''z',\ p_{23}=y'z''-y''z',$$
$$p_{14}=x'-x'',\quad p_{42}=y''-y',\quad p_{34}=z'-z''.$$

If we replace x'', ... by $x'+dx'$, ..., *i.e.*, if we regard the line as determined by consecutive (neighboring, infinitely near) points, the Plücker coordinates assume the form adopted by Sophus Lie. The primes being omitted, the Lie line coordinates are: $p_{12}=xdy-ydx$, $p_{13}=xdz-zdx$, $p_{23}=ydz-zdy$, $p_{14}=-dx$, $p_{42}=dy$, $p_{34}=-dz$.

The general coordinates r_{jk} admit of further generalization. They may be replaced by linear functions of them; *i.e.*, if $r_{jk}=C_{jk\cdot 1}v_1+C_{jk\cdot 2}v_2+\ldots+C_{jk\cdot 6}v_6$, where the determinant of the C's does not vanish, the six variables v_i may be employed as line coordinates. The v's satisfy a quadratic identity $\xi(v)=0$, into which $\omega(r)=0$ is converted by the foregoing transformation. A simple special case of this transformation yields an elegant system of line coordinates introduced by Felix Klein. Replacing the v's by x's, the special transformation is: $x_1=r_{12}+r_{34}$, $ix_2=r_{12}-r_{34}$; $x_3=r_{13}+r_{42}$, $ix_4=r_{13}-r_{42}$; $x_5=r_{14}+r_{23}$, $ix_6=r_{14}-r_{23}$; where $i=\sqrt{-1}$. The Kleinian line coordinates are $x_j\ (j=1,\ldots,6)$. The identity connecting them is $\Sigma x_j^2=0$.

Condition of Intersection of Lines.—The two lines may be conceived as loci, or as axes, or one as a locus and the other as an axis. In the first case, suppose the lines are determined respectively by the point pairs (x_i, y_i), (x'_i, y'_i). The lines p and p' will intersect when and only when the four points lie in a plane, for which the necessary and sufficient condition is

$$\begin{vmatrix} x_1 & x_2 & x_3 & x_4 \\ y_1 & y_2 & y_3 & y_4 \\ x_1' & x_2' & x_3' & x_4' \\ y_1' & y_2' & y_3' & y_4' \end{vmatrix}=0,$$

which on expansion yields $p_{12}p'_{34}+p_{13}p'_{42}+p_{14}p'_{23}+p_{34}p'_{12}+p_{42}p'_{13}+p_{23}p'_{14}=0$. Of this condition the first member is

$$\frac{1}{2}\left[\frac{\partial\omega(p)}{\partial p_{12}}p'_{12}+\ldots+\frac{\partial\omega(p)}{\partial p_{42}}p'_{42}\right]$$
$$=\frac{1}{2}\left[\frac{\partial\omega(p')}{\partial p'_{12}}p_{12}+\ldots+\frac{\partial\omega(p')}{\partial p'_{42}}p_{42}\right].$$

Denoting this *polar* form by $\omega(p, p')$, the condition that the two lines (loci, point ranges) p and p' shall have a common point is $\omega(p,p')=0$. In like manner, the condition that the lines (envelopes, axal pencils of planes) q and q' shall have a common plane is $\omega(q,q')=0$. If one of the lines be regarded as a locus, the other as an envelope, the condition of intersection is $\Sigma p_{jk}q'_{jk}=0$ or $\Sigma q_{jk}p'_{jk}=0$. Disregarding the aspects of the lines r and r', the condition is $\omega(r,r')=0$. The preceding transformation from r's to v's converts $\omega(r, r')$ into $\xi(v, v')$, where $2\xi(v, v')=\frac{\partial\xi}{\partial v_1}v_1'+\ldots+\frac{\partial\xi}{\partial v_6}v_6'$. Hence the condition that the lines v, v' shall intersect is $\xi(v, v')=0$. In Klein coordinates, the condition for the intersection of the lines x and x' is $\Sigma x_jx_j'=0\ (j=1,\ldots 6)$.

Pencils and Hyperpencils.—Let v_i' and v_i'' be any two intersecting lines. These determine a flat pencil, *viz.*, that whose vertex is the common point of v' and v'' and whose lines lie in the plane of v' and v''. All and only the coordinates of the lines of the pencil are given by the formula $v_i = \lambda v_i' + \mu v_i''$. For, first, $\xi(v) = \xi(v')\lambda^2 + 2\xi(v', v'')\lambda\mu + \xi(v'')\mu^2$, and, by hypothesis, $\xi(v') = 0$, $\xi(v'') = 0$, $\xi(v', v'') = 0$; hence $\xi(v) = 0$, and v_i represents a line for all values of the parameters λ and μ. Secondly, if v_i''' be *any* line cutting v' and v'', $\xi(v', v''') = 0$, $\xi(v'', v''') = 0$; hence $\xi(v, v''') = 0$, for $\xi(v, v''') = \lambda\xi(v', v''') + \mu\xi(v'', v''')$; therefore the lines v_i belong to the pencil. Thirdly, these are *all* of the lines of the pencil, for it is easily proved that the ratio, $\lambda : \mu$, can be determined so that the corresponding v_i shall cut *any* given line not contained in the plane of the pencil.

Koenigs has suggested the name hyperpencil (*hyperfaisceau*) to denote alike the totality of lines of a plane and the totality (sheaf, bundle) of lines through a point. A hyperpencil is determined by any three lines (not in a same pencil) of which each intersects the other two. If three such lines be v_i', v_i'', v_i''', then all and only the coordinates of the hyperpencil are given by the formula $v_i = \lambda v_i' + \mu v_i'' + \nu v_i'''$, λ, μ, ν being parameters. The hyperpencil will be a sheaf or a plane of lines according as the given lines determine but one point or three points.

Line Systems in General.—Just as, for example, in ordinary analytical geometry, we study systems (loci) of points represented by equations in point coordinates, so in the present subject we are concerned with line systems represented by equations in line coordinates. The line, we have seen, depends on four independent variables, coordinates, or *parameters*. The totality of lines in space may be called the 4-parameter system; it contains ∞^4 lines, a line in it has four degrees of freedom, one degree for each of the free (unconditioned) parameters or coordinates. One condition on the four parameters renders them equivalent to but three independent ones; hence the lines represented by one equation constitute a 3-parameter system, called by Plücker a line *complex*. A complex contains ∞^3 lines, a line in a complex has but three degrees of freedom. A 2-parameter system or *congruence* (Plücker), containing ∞^2 lines, allowing the line two degrees of freedom, is defined by a pair of equations. A triplet of equations represents a 1-parameter system, a ruled surface, or, better, a *line series* (*Série réglée*, Koenigs); it contains ∞^1 lines; in such a system the line has but one degree of freedom. Finally, a 0-parameter system, defined by four simultaneous equations, contains but a *finite* number of lines. In order, then, that five or more equations should represent a common system of lines, it is necessary that their coefficients satisfy some condition or conditions.

The Linear Complex.—The complex defined by an equation of degree n is said to be of nth degree. If $n = 1$, the complex is called *linear*. The general equation of the linear complex is $c_1v_1 + c_2v_2 + \ldots + c_6v_6 = 0$, or, briefly, $\Sigma c_jv_j = 0$, where $\xi(v) = 0$. How are the lines distributed? Let $v_i = \lambda v_i' + \mu v_i'' + \nu v_i'''$ be an arbitrary hyperpencil. In order that a line of the hyperpencil shall belong to the complex, it is necessary and sufficient that $\Sigma(\lambda v_i' + \mu v_i'' + \nu v_i''') = 0$, a single linear condition on the (two independent) ratios $\lambda : \mu : \nu$. Hence a single infinity of the lines of the hyperpencil belong to the complex. For if $u_i' = \lambda_1 v_i' + \mu_1 v_i'' + \nu_1 v_i'''$ and $u_i'' = \lambda_2 v_i' + \mu_2 v_i'' + \nu_2 v_i'''$ be any two of them, then plainly all lines of the pencil (u', u'') belong to the complex. On the other hand, no other line u''' does so belong, for, if it did, then every pencil determined by u''' and the lines of (u', u''), *i.e.*, all lines of the hyperpencil, would belong to the complex. Hence the proposition: *The lines of a linear complex are so distributed that every hyperpencil in space contains a pencil of lines (and no other line) belonging to the complex.* These pencils are called the pencils of the complex. The proposition admits of various equivalent statements of which one of the most illuminating is: *Given a linear complex, each point of space is the vertex of a pencil of lines of the complex and contains no other line of it; in each plane there is a pencil of lines (but no other line) of the complex.* In the former case the plane containing the pencil of the point is called the *polar* (plane) of the point; in the latter, the vertex of the pencil in the plane is called the *pole* (point) of the plane. Thus a linear complex serves to pair the points and planes of space as poles and polars, any pole and its polar being united in position. If a point P and a plane π be united in position, the pole P' of π and the polar π' of P are also united. Not only, however, are points and planes paired, but lines are paired with lines. The line common to two poles corresponds to the line common to their polars. Two such corresponding lines are called *conjugates* with respect to the complex. To a range of points (poles) corresponds an axal pencil of planes (polars), the base of the range and the axis of the pencil being conjugate lines. A line cutting two conjugates belongs to the complex, and all lines of the complex that cut a given line cut its conjugate also. If two lines intersect, so do their conjugates. Every line of the complex is its own conjugate, self conjugate, and conversely. If a point moves along a line of the complex, the polar plane turns about the same line. This is a special case of the proposition that if a point glides along any line, the polar plane rotates about the conjugate line. Hence if P_1, P_2, P_3, P_4 be any four positions of the moving point and if π_1, π_2, π_3, π_4 are the corresponding planes, then the anharmonic ratios are equal, *i.e.*, $(P_1P_2P_3P_4) = (\pi_1\pi_2\pi_3\pi_4)$. In general: if C denote any configuration of points, lines, and planes, the polars, conjugates, and poles (with respect to a given complex) constitute a configuration C'. C and C' are called *reciprocal* configurations. The points, lines, and planes of either correspond uniquely and respectively to the planes, lines, and points of the other. In particular, if C is a polyedron, so is C'. The edges of either are conjugates of the edges of the other; the vertices and faces of either are respectively the poles and polars of the faces and vertices of the other. The vertices of either lie in the (polar) faces of the other.

Invariant of Complex, Special Complex, Directrix.—The condition,

$$2\xi(v, v') \equiv \frac{\partial\xi}{\partial v_1'}v_1 + \ldots + \frac{\partial\xi}{\partial v_6'}v_6 = 0,$$

that the line v shall intersect the line v', represents a *special* complex, viz., that of which all the lines cut a given line v', called the *directrix* of the complex. The complex $\Sigma c_j v_j = 0$ is, then, special when and only when $\frac{\partial\xi}{\partial v_1'} : \frac{\partial\xi}{\partial v_2'} : \ldots : \frac{\partial\xi}{\partial v_6'} = c_1 : c_2 : \ldots : c_6$. These equations yield the values of (the ratios of) the v_j' in terms of the c_j. Substituting those values in $\xi(v')$, there results a homogeneous quadratic $\Omega(c)$, so that $\xi(v') = \Omega(c)$. Hence $\Omega(c) = 0$ when and only when $\xi(v') = 0$; hence the necessary and sufficient condition that $\Sigma c_j v_j = 0$ shall represent a special complex is that $\Omega(c) = 0$. In such case the coordinates of the directrix are the coefficients c_j. The expression $\Omega(c)$ has been named by Klein the *invariant of the complex* $\Sigma c_j v_j = 0$. The complex is, therefore, special or non-special according as its invariant vanishes or does not. If $\xi(v)$ be reduced to the Plucker type $\omega(v) = 2(v_1v_4 + v_2v_5 + v_3v_6)$, the invariant assumes the form $\Omega(c) = 2(c_1c_4 + c_2c_5 + c_3c_6)$. In case the above-mentioned Klein coordinates are employed, the form of the invariant is $-\Omega(c) = \Sigma c^2_j$ $(j = 1, \ldots, 6)$.

Pencil of Complexes, and Line Congruence.—The system of lines *common* to two complexes is named line *congruence*. It is plain that the lines of the congruence determined by two complexes $\Sigma c_j v_j = 0$ and $\Sigma c_j' v_j = 0$ are common to the complexes of the pencil $\lambda\Sigma c_j v_j + \mu\Sigma c_j' v_j = \Sigma(\lambda c_j + \mu c_j')v_j = 0$ of complexes and that the congruence is equally determined by any two complexes of the pencil. Does the pencil include special complexes? If so, how many? The condition, $\Omega(\lambda c + \mu c') = 0$, for special complexes, is quadratic in the ratio $\lambda : \mu$ of the parameters, and hence yields two values for that ratio, which may be real and distinct, real and equal, or imaginary. Accordingly, every pencil of complexes contains two and but two special complexes, real and distinct, coincident, or imaginary. The directrices of the special complexes are cut by all and only the lines of the congruence and are called the *directrices of the congruence*. Conversely, the assemblage of lines that intersect two given lines is a congruence. Hence a congruence is often defined to be the totality of lines intersecting two fixed lines. The directrices of a congruence are conjugate lines with respect to every complex of the corresponding pencil of complexes. In case the discriminant of the foregoing quadratic is zero, the directrices coincide. The (double) directrix is a line of the congruence. That discriminant is called the *invariant of the congruence*. The vanishing of the invariant signifies coincidence of the two special complexes and of their directrices. It may happen that the quadratic is identically zero. Then all complexes of the pencil are special, and the directrices constitute a pencil of lines.

Angle of Complexes; Involution.—Let a, b, c, d be any four values of the parameter $\lambda : \mu$ of the above pencil of complexes. The anharmonic ratio $(abcd)$ may be called the anharmonic ratio of the four corresponding complexes. If l be a line of the congruence, π a plane of l, and P_1, P_2, P_3, P_4 be the poles of π as to the complexes a, b, c, d respectively, then the anharmonic ratio $(P_1P_2P_3P_4) = (abcd)$. Also, if π_1, π_2, π_3, π_4 are the polar planes of a point P of l with respect to the four complexes, then $(\pi_1\pi_2\pi_3\pi_4) = (abcd)$. Hence $(\pi_1\pi_2\pi_3\pi_4) = (P_1P_2P_3P_4)$, and these equal ratios remain *constant* as π rotates about (P glides along) l and also as l varies its position in the congruence. We may suppose that b and d correspond to the *special* complexes of the pencil, and denote by F and F' the points common to l and the directrices, and by ϕ and ϕ' the planes determined by l and the directrices. Then $(P_1FP_2F') = (abcd) = (\pi_1\phi\pi_2\phi')$. Denote this anharmonic ratio by r. The corresponding angle, $A = (\log r) : 2\sqrt{-1}$, has been named by Klein the *angle of the complexes* a and c. If a and b be so taken (and that is possible) that $A = 90°$, whence $r = -1$, then the two corresponding complexes are said to be *orthogonal* or *in involution*. The geometric significance of this relationship is that, when and only when it subsists between two complexes, each contains the conjugates of its lines with respect to the other. This subject of involution is intimately connected with the general doctrine of linear systems of linear complexes, but it cannot be further pursued here.

Hyperpencil of Complexes.—Such we may call the system $\Sigma(\lambda c_j + \mu c_j' + \nu c_j'')v_j = 0$ determined by three independent complexes. $\Sigma c_j v_j = 0$, $\Sigma c_j' v_j = 0$, $\Sigma c_j'' v_j = 0$. The name, system of three terms, is often employed instead of hyperpencil. The ∞^1 lines common to the three fundamental complexes are obviously common to all complexes of the hyperpencil. They constitute a ruled surface of second order. That the surface is of second order appears from the fact that the number of points in which it is pierced by a line u_j, *i.e.*, the number of solutions of the equations $\Sigma c_j v_j = \Sigma c_j' v_j = \Sigma c_j'' v_j = \xi(v) = \xi(v, u)$, is two. The surface is in general an *hyperboloid of one sheet:* in special case, a *hyperbolic paraboloid*. The lines constitute, however, but one system of generators. What of the other system? To answer, observe that the condition, $\Omega(\lambda c + \mu c' + \nu c'') = 0$, that the hyperpencil shall contain special complexes, yields ∞^1 pairs of values of the (two independent) ratios $\lambda : \mu : \nu$. Hence the hyperpencil includes ∞^1 special complexes. The directrices of these constitute the second system of generators. These last are not lines common to the hyperpencil, on which account it seems better (after Koenigs) to call the lines common to the hyperpencil not a ruled surface, but a demi-quadric or series of lines.)

Complex of Higher Degree.—An equation $f_n(v) = 0$ of degree n in line coordinates v_j defines a complex of degree n. Any line-pencil of space contains n lines of such a complex, so that the degree of a complex may be geometrically defined to be the number of lines common to the complex and an arbitrary pencil. The lines common to a complex of nth degree and a hyperpencil constitute a *cone* of *order* n if the hyperpencil is a *sheaf*, and envelope a plane *curve* of *class* n if the hyperpencil is a plane of lines. The cone is called *cone of the complex;* and the curve, *curve of the complex*. Every point of space is the vertex of such a cone, and every plane contains such a curve. As above seen, if $n = 1$, the cone degenerates into a plane (pencil of lines) and the curve degrades into a point (pencil of lines enveloping it). The 'Neue Geometrie' of Plucker is chiefly devoted to the *quadratic* complex, $n=2$, and many of its cardinal properties are there discovered. For the literature of the subject, including the general doctrine of complexes, the reader is referred to the works above cited and to the bibliography below. We give next a very brief account of certain closely

Allied Theories

the study of whose connections and general comparative anatomy is one of the most instructive and fascinating chapters in the development of modern geometry.

Plane Geometry of the Point in Four-space.—Space that is 4-dimensional in points is also 4-dimensional in *lineoids* (ordinary 3-dimensional spaces). It is 6-dimensional in lines and also in planes. Hence in 4-space the *point* and the *lineoid* are *dual* (reciprocal) elements, and so are the *plane* and the *line*. The lineoid contains ∞^4 lines; the point, ∞^4 planes. The lineoid contains ∞^3 points and as many planes; the point contains ∞^3 lineoids and as many lines. Hence in 4-space, the point, plane, and line geometries of the lineoid are respectively dual to the lineoid, line, and plane theories of the point. Between any two of these pairs of reciprocal geometries there is a fact-to-fact correspondence, and the algebras of any such pair are identical. The emphasis here falls upon the fact that the line geometry of the lineoid (*i.e.*, ordinary line geometry) is precisely the same analytically as the geometry of the 4-space point regarded as the assemblage of its (generating) planes. For an introductory detailed account of the elements of the latter theory, and of the mentioned parallelism, see 'The Plane Geometry of the Point in Point-space of Four Dimensions' ('American Jour. of Math.,' vol. 25).

Geometry of (Ordinary) Space in Pentaspherical Coordinates.—The square of the tangent-distance from a point to a sphere is named the *power of the point with respect to the sphere.* Denote by x_k $(k=1, \ldots, 5)$ the powers of a point with respect to five fixed mutually orthogonal spheres. The x_k satisfy the identity $\Sigma x_k^2=0$. To any set of values of their ratios there corresponds a definite point and conversely. The quantities λx_k are called *pentaspherical point coordinates.* Their discovery and introduction into geometry are mainly ascribable to Gaston Darboux (cf. his memoir 'Sur une class remarquable de courbes et de surfaces algébriques,' 1873), but in part also to Felix Klein and Sophus Lie (cf. 'Mathematische Annalen,' vol. 5). In these coordinates the equation of a sphere is linear, *viz.*, $\Sigma m_k x_k=0$ $(k=1, \ldots, 5)$; conversely, every such equation represents a sphere. The radius is $\rho=(\sqrt{\Sigma m_k^2}):\Sigma(m_k \div R_k)$, where the R_k are the radii of the fundamental spheres. Certain analytic correspondences between line geometry (in Klein coordinates) and point geometry in pentaspherical point coordinates are immediately obvious. For example: in the former $\Sigma x_j^2=0$ $(j=1, \ldots, 6)$ is the identity satisfied by the line coordinates x_j; in the latter, $\Sigma x_k^2=0$ $(k=1, \ldots, 5)$ is the identity connecting the pentaspherical point coordinates; in the former, $\Sigma m_j x_j=0$ represents a linear complex; in the latter, $\Sigma m_k x_k=0$ represents a sphere; in the former, $\Sigma m_j^2=0$ means that the complex is special; in the latter, $\Sigma m_k^2=0$ signifies that the sphere is a point; and so on and on.

Sphere Geometry of Space.—In this doctrine, due to Sophus Lie, the sphere is taken as primary element. To pick out a sphere from among all the spheres of space, it is necessary and sufficient to know four independent things about it, as the (three) coordinates of its center and the length of its radius. Hence the sphere, like the line, has four independent coordinates, it has four degrees of freedom, and sphere geometry, like line geometry, is 4-dimensional. We have seen that every equation $\Sigma m_k x_k=0$ in pentaspherical point coordinates x_k represents a sphere, and conversely; hence the five coefficients m_k may be taken as *homogeneous sphere coordinates,* their ratios being equivalent to four *independents.* The system may be rendered homologous to that of the six line coordinates by introducing a sixth sphere coordinate m_6 by the definition, $im_6=\sqrt{\Sigma m_k^2}$, where $i=\sqrt{-1}$ and $(k=1, \ldots, 5)$. The *six* homogeneous, sphere coordinates m_j $(j=1, \ldots, 6)$ satisfy the quadratic identity $\Sigma m_j^2=0$, identical in form with that connecting the Klein line coordinates. The condition that the *spheres m* and *m'* shall be *tangent* is $\Sigma m_j m_j'=0$, which is precisely like the condition, $\Sigma x_j x_j'=0$, that the *lines x* and *x'* shall *intersect*, a most interesting and fruitful principle of correspondence discovered by Lie in his brilliant memoir, 'Über Complexe, in besondere Linien- und Kugel-Complexe, mit Anwendung auf die Theorie partieller Differentialgleichungen' ('Mathematische Annalen,' vol. 5, 1871).

Circle Geometry of Space.—In this beautiful and growing theory, principally due to the French mathematicians E. Cosserat, C. Stéphanos, and G. Koenigs, the circle is employed as primary or generating element of space. In this element, space is 6-dimensional, like point 4-space in lines or planes. A circle is determined as the intersection of two spheres, as $\Sigma m_j x_j=0$. $\Sigma m_j' x_j=0$ $(j=1, \ldots, 5)$. It is equally determined by any two spheres of the pencil or range, $\Sigma(m_j+\lambda m_j')x_j=0$, of spheres containing it, and, in particular, by any two of the included five of which each is orthogonal to one of the fundamental spheres. The equations of those special spheres correspond to the five λ-values that render the coefficients $m_j+\lambda m_j'=0$ in succession. For the sake of symmetry, the *ten* coefficients $p_{ik}=(m_i m_k'-m_k m_i')$ are taken as homogeneous coordinates of the circle. That the ten are equivalent to the necessary and sufficient number *six* of independents is seen in the facts that only their ratios are essential and that they satisfy five (equivalent to three independent) quadratic identities of the form $\omega_a(p)=2(p_{\beta\gamma}p_{\delta\epsilon}+p_{\beta\delta}p_{\epsilon\gamma}+p_{\beta\epsilon}p_{\gamma\delta})=0$. The circle geometry of space is not parallel to the line geometry of ordinary space, but it is parallel, in a fact-to-fact fashion, to the line and the plane geometries of point 4-space.

Theory of Circles Orthogonal to Sphere.—Two spheres m_k and m_k' $(k=1, \ldots, 5)$ are *orthogonal* when and only when $\Sigma m_k m_k'=0$; hence there are ∞^3 spheres orthogonal to a given sphere. A *circle* is *orthogonal* to a *sphere* when and only when any two (and hence all) of its generating spheres are orthogonal to the sphere. There are, accordingly, ∞^4 circles orthogonal to a given sphere. A one-to-one correlation subsists between such circles and the lines of space. If, in the assemblage of spheres orthogonal to a given sphere, four mutually orthogonal spheres be taken as fundamental or coordinate spheres, any equation $\Sigma m_k x_k = 0$ $(k = 1, \ldots, 4)$ will represent a sphere of the assemblage, and conversely. Hence a pair of such equations will define a circle orthogonal to the fixed sphere, and conversely. It is immediately plain that the coordinates of the circle regarded as element of the assemblage of circles orthogonal to a given sphere are analytically precisely the same as the line coordinates of space. Hence the geometry of such a circle assemblage is analytically identical with line geometry. The first chapters of such a circle geometry are found in the doctor's dissertation (at Columbia University, 1904), 'The Geometry of Circles Orthogonal to a Given Sphere,' by Mr. C. S. Forbes.

Bibliography.—The literature of line geometry and allied theories is extensive and is rapidly increasing. In addition to the foregoing citations, may be mentioned the following works, which together with further citations contained in them constitute a complete bibliography of the subject: Cayley, 'On the Six Coordinates of a Line' (Collected Papers, vol. 7); Klein, 'Einleitung in die höhere Geometrie' and various memoirs by him in vol. 5 and subsequent volumes of *Mathematische Annalen;* Koenigs, 'La géométrie réglée et ses applications' (*Annales de la Faculté des Sciences de Toulouse*, vols. 3 *et seq.*); Cosserat, 'Sur le cercle considéré comme élément générateur de l'espace' (see preceding reference); Loria, 'Il passato ed il presente delle principali teorie geometriche'; E. Pascal, 'Repertorio die mathematiche superiori'; Sturm, 'Die Gebilde ersten und zweiten Grades der Liniengeometrie,' a synthetic treatise; Pasch, 'Zur Theorie der linearen Complexe' (Crelle's Journal, vol. 75); Study, 'Geometrie der Dynamen'; Jessop, 'Treatise on the Line Complex'; 'Encyklopädie der Mathematischen Wissenschaften,' vol. 3.

CASSIUS J. KEYSER,
Adrain Professor of Mathematics, Columbia University.

Geometry, Modern Analytical. No preliminary statement of the significance of this title could be quite satisfactory to any, much less to all. An adequate sense of its meaning can be gained only by study of the subject itself; and in this case, as in that of most other doctrines, it is better for the reader to end, than for the writer to begin, by an attempt at definition. Logically and historically modern analytical geometry is the outgrowth of Cartesian geometry (q.v.). The former, while in a sense it includes the latter as a special case, avails itself of many principles, processes, and points of view unknown to the older doctrine. It is the aim of this article to give a brief account of some of the modern notions and methods, with particular reference to the geometry of the plane. For further information the reader may consult the articles: GEOMETRY, CARTESIAN; CURVES, HIGHER PLANE; LINE GEOMETRY AND ALLIED THEORIES; CURVES OF DOUBLE CURVATURE, THEORY OF; SURFACES, THEORY OF; HYPERSPACES. As to related matter of pure geometry, see the articles: GEOMETRY, ELEMENTARY PURE; GEOMETRY, PURE PROJECTIVE; and GEOMETRY, NON-EUCLIDEAN. In the following, acquaintance with the elements of ordinary (Cartesian) geometry will be presupposed.

One-dimensional Spaces: Range and Pencil; Elements at Infinity.—Any geometric entity in a given space may be taken as generating element of the space, which is then regarded as the assemblage of all the elements of the chosen kind. A space being assumed, its dimensionality depends upon the choice of generating element and is the number of independent parameters, or coordinates, necessary for the determination of the element. This is what is meant, to take the most familiar examples, by saying that any surface, say a plane, is two-dimensional, and that ordinary space is three-dimensional, in points. Any space being assumed, it is always possible to select as element an infinity of different kinds of entities for any one (kind) of which the space shall have a prescribed dimensionality k. Thus the plane is two-dimensional in lines (see below), its dimensionality is 3 in circles, 4 in parabolas, 5 in conics, . . . , while the dimensionality of ordinary space is 3 in planes, 4 in lines or in spheres (see LINE GEOMETRY), 6 in circles, etc. A plane curve may in general be conceived either as a *locus*, assemblage of its *points*, or as an *envelope*, assemblage of its (tangent) *lines*. In either view the curve appears as a *one*-dimensional space, of points in the former view, of lines in the latter. Of such one-fold spaces, the simplest, and hence in a sense the most important, varieties are the *range* and the *pencil*, the former being the straight line regarded as the locus or assemblage of its points, and the latter being the point regarded as the envelope or assemblage of its lines (the lines through it). Commonly the line is called the *base* of its range, and the point is called the *vertex* of its pencil. In passing it may be pointed out that if a *pair* or *triplet*, . . . of points (lines) be taken as element of the line (point), the line (point) appears as a space of 2, or 3, . . . dimensions in such pairs, triplets, . . .

Let V and b respectively be any pencil and range. The plane being supposed Euclidean in respect to parallels (see NON-EUCLIDEAN GEOMETRY), V contains a single line parallel

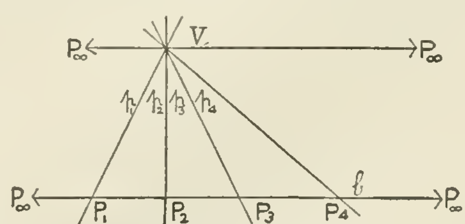

FIG. 1.

to b. Plainly, through any (finite) point of b there passes one and but one line of V; and, conversely, every line of V, except the mentioned parallel, passes through a (finite) point of b. In order to avoid the exception and render the one-to-one correspondence complete, a convention is made, namely, that every range shall be regarded as having one and but one *infinitely distant* point P_∞, called the *infinite point* of the range, and that the infinite point of any range is identical with that of any parallel range. Accordingly any infinite point of the plane is the vertex of a pencil of parallel lines, and the system of lines parallel to a given one constitute a pencil vertexed at ∞. The notion of parallel lines meeting at ∞ had occurred to Kepler, but the systematic introduction of the convention was made by Gerard Desargues (1593–1662), chief among the founders of modern *pure* geometry. From that convention it readily follows, by the theory of similar triangles, that the (infinite) distances from any two finite points of a range to its infinite point are *equal*. The locus of the infinite points of the plane is a straight line, called *the infinite line* of the plane. As for space, the locus of its infinite points is a plane. In general the locus of the infinite points in a point-space of n dimensions is a point-space of $n-1$ dimensions. If a range rotate (in a plane) about one of its finite points, every other point of the range will generate a circle; the path of the infinite point being a straight line, the latter appears as a circle of infinite radius; a perfectly natural phenomenon, for the curvature, $1:r$, of a circle of radius r, vanishes for $r=\infty$.

Non-homogeneous and Homogeneous Coordinates of Point and Line of Range and Pencil.—In a range choose a point O for *origin* of distances. Denote by d the distance from O of an arbitrary point P of the range. Let $x=\rho d$, where the factor ρ may have any chosen value whatever. To any value of x there corresponds a position of P, and conversely. Hence x may serve as coordinate of the elements of the range. If a pencil be paired with a range as above, x will equally serve for coordinate of the lines of the pencil; or, in the latter case, d may be taken to represent the tangent of the angle made by a varying line of the pencil with a fixed line o, called *origin* of angles. Any point (line) of a range (pencil) will be represented by a linear equation $ax+b=0$, the coordinate of the element being $-b:a$. Conversely any element is defined by such an equation. In general n elements will give rise to an equation of nth degree in x, and any such equation will represent n elements. These (points or lines) will be real or *imaginary* elements of the range or pencil according to the corresponding character of the roots of the equation. All the equations can be rendered *homogeneous* by replacing x by the ratio $x_1:x_2$ and clearing of fractions. The quantities σx_1 and σx_2, σ being any chosen finite quantity called proportionality factor, are described as *homogeneous coordinates* of the point (line) of the range (pencil). The position of the element depends on the ratio of the quantities, which is the same as the ratio of the x's, and the element is accordingly spoken of as the point or line (x_1, x_2). One obvious advantage of the homogeneity thus introduced lies in the artistic quality, notably the symmetry, which it lends to the analysis; for example, the equation of a point assumes the form $a_1x_1+a_2x_2=0$; in particular, the equations of the origin and P_∞ are respectively $x_1=0$ and $x_2=0$. Obvious analogous interpretations hold for the pencil. Indeed it is at once evident that the geometry of the range and that of the pencil are *analytically one*. The algebra remaining the same, either geometry passes over into the other on a mere exchange of notions: point (line) for line (point), pencil (range) for range (pencil).

Geometric Interpretation of Homogeneous Coordinates.—In case of the range assume two origins O_1 and O_2 instead of one and let them be δ apart. These divide the range into two parts, the short segment *between* and the long one (including P_∞) *not* between O_1 and O_2. Strictly, any point of the range other than O_1 or O_2 is between these points, for the range is a *closed* figure, but the meaning of the preceding sentence is sufficiently clear. Let it be agreed that a point in the shorter segment is on the positive side of both O's, whence, naturally, a point in the longer segment will be on the positive side of the remoter, and on the negative side of the nearer, O. Denote by x_1 and x_2 respectively the distances of any point P from O_1 and O_2. For any P, $x_1+x_2=\delta$. To any pair of x's satisfying that relation there corresponds a point, and conversely. Hence the homogeneous coordinates σx_1, σx_2 of a point of a range are the distances (multiplied by any finite constant) of the point from two chosen fixed points. Analogously for the pencil, where, however, distances are replaced not by the angles but by the sines of the angles made by the variable line p with two fixed lines o_1 and o_2 and where it is understood that an angle and its vertical angle are one and the same angle.

Anharmonic Ratio.—The ruling notion in the doctrine of the range (pencil) is the *anharmonic* (double or cross) *ratio* of four elements. If x_1, x_2, x_3, x_4 be any four numbers (say any four values of a continuous variable x), the expression $(\overline{x_1-x_2}\cdot\overline{x_3-x_4}):(\overline{x_2-x_3}\cdot\overline{x_4-x_1})$ is called the anharmonic ratio of the four values taken in the order x_1, x_2, x_3, x_4, and is conveniently denoted by the symbol $(x_1x_2x_3x_4)$. If a one-to-one correspondence be established between the continuum of x-values and the elements of a geometric continuum, the notion of the anharmonic ratio of any four x-values may be and is associated with the corresponding four geometric elements, as the points of a range, the lines of a pencil, the planes of an *axal pencil* (assemblage of all planes containing a same line), and so on. The *order* of the elements is essential. The 24 possible permutations of 4 elements yield six (in general distinct) values of their anharmonic ratio. The exchange of two *alternate* elements, as x_1 and x_4, *inverts* the ratio. Thus, if $(x_1x_2x_3x_4)=r$, then $(x_1x_4x_3x_2)=1:r$. To exchange two *consecutive* elements, as x_2 and x_3, takes the *complement* of the ratio to 1. Thus $(x_1x_3x_2x_4)=1-r$. The six values are r, $1:r$, $1-r$, $1:(1-r)$, $(r-1):r$, $r:(r-1)$.

Geometric Interpretation of Anharmonic Ratio in Range and Pencil.—Let x_1, x_2, x_3, x_4 be the distances of the points P_1, P_2, P_3, P_4 of a range from the origin. Then x_1-x_2, x_3-x_4, x_2-x_3, x_4-x_1 represent, in sign and magnitude, the distances $\overline{P_1P_2}$, $\overline{P_3P_4}$, $\overline{P_2P_3}$, $\overline{P_4P_1}$. Hence

$(x_1x_2x_3x_4) = (P_1P_2P_3P_4) =$ the *ratio* of the *distance ratios* $\overline{P_1P_2}:\overline{P_2P_3}$ and $\overline{P_1P_4}:\overline{P_4P_3}$. In case of a pencil, if the x's denote the tangents of the angles α_1, α_2, α_3, α_4 made by the lines p_1, p_2, p_3, p_4 with the origin, or fixed line, o, then x_1-x_2, . . . are the tangent differences $\tan\alpha_1-\tan\alpha_2$, . . . , and $(x_1x_2x_3x_4)=(p_1p_2p_3p_4)=\{(\tan\alpha_1-\tan\alpha_2)(\tan\alpha_3-\tan\alpha_4)\}:\{(\tan\alpha_2-\tan\alpha_3)(\tan\alpha_4-\tan\alpha_1)\}=\{(\sin\overline{\alpha_1-\alpha_2})(\sin\overline{\alpha_3-\alpha_4})\}:\{(\sin\overline{\alpha_2-\alpha_3})(\sin\overline{\alpha_4-\alpha_5})\}=$ the *ratio* of the *sine ratios* $(\sin\overline{p_1p_2}):(\sin\overline{p_2p_3})$ and $(\sin\overline{p_1p_4}):(\sin\overline{p_4p_1})$, where p_ip_κ means the angle between p_i and p_κ reckoned from the former to the latter.

Special Relations of Four Elements.—These correspond to equalities among the six anharmonic ratios, and conversely. By equating r in succession to each of the other ratios, the following special values of the ratios are found: 1, −1, 0, ∞, 2, ½, ω, and ω', the last two being the imaginary cube roots of − 1. If $r=1$, the six values are 1, 1, 0, 0, ∞, ∞; if $r=-1$, the six are −1, −1, 2, 2, ½, ½; if $r=\omega$ or ω', they are ω, ω, ω, ω', ω', ω'; finally, if $r=0$ or ∞, the six values are 0, ∞, 1, ∞, 1, 0. The special relations accordingly fall into three cases, *viz.*, $r=1$, $r=-1$, $r=\omega$. If $r=1$, either $x_1=x_3$ or $x_2=x_4$, *i.e.*, two of the points (lines) coincide. Hence this case is called the *coincident* case. If $r=-1$, then, if s_1 and s_2 are the intervals into which the range (pencil) is divided by a pair of alternates, one element of the remaining pair is in s_1 and the other is in s_2; the pair x_1, x_3 is said to be *harmonically* related to the pair x_2 x_4; and conversely. In particular if one of the points bisects the finite segment s_1 the alternate point bisects the other segment s_2, *i.e.*, it is the infinite point of the range. And if one line bisects the angle s_1, the alternate line bisects the supplementary adjacent angle s_2. The case, $r=-1$, called the *harmonic* case, is of great importance, leading to the theory of *involution;* all point (line) pairs of a range (pencil) that are each harmonic (conjugate) to a fixed pair are said to constitute an involution of points (lines.) The case, $r=\omega$, is called *equianharmonic* (by Cremona) because the six values fall into two triplets, instead of three pairs, of equals. This case serves as a door for the entrance of imaginary elements into the geometry of the range (pencil), for obviously four *real* points (lines) cannot have an imaginary anharmonic ratio.

Conjoined Range and Pencil.—From any line a range is cut by any pencil, as in Fig. 1. If the elements be paired so that each line

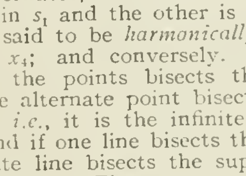

FIG. 2.

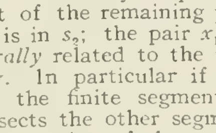

FIG. 3

corresponds to the point it passes through, the range and pencil are said to be *in perspective* or to be *conjoined.* *Two ranges* (Fig. 2) conjoined with a same pencil are said to be *in perspective;* the vertex of the pencil is called the *centre* of perspective. Also *two pencils* (Fig. 3) conjoined with a same range are said to be *in perspective;* the base of the range is named *axis* of perspective. If a range and a pencil are conjoined and if P_1, P_2, P_3, P_4 be any four points of the range and p_1, p_2, p_3, p_4 are the corresponding lines of the pencil, then, by definition of anharmonic ratio, $(P_1P_2P_3P_4)=(p_1p_2p_3p_4)$, a theorem which in another form was known to Pappus (about 300 A.D.). It follows that corresponding anharmonic ratios of any two perspective ranges (pencils) are equal.

If the elements of two ranges or pencils or a range and a pencil be paired in such way that corresponding anharmonic ratios are equal, the two systems are said to be *projective.* Obviously, if the anharmonic ratio of four elements of which three are known be given, the fourth element is uniquely determined. It follows that any two projective systems can be placed in perspective. To place two projective ranges P_1, P_2, P_3, P_4, . . . , and P_1', P_2', P_3', P_4', . . . , in perspective, it suffices to place P_1 on P_1' and to take for perspective center the common point of the lines joining P_2 to P_2' and P_3 to P_3'. Similarly for two projective pencils.

The Anharmonic Ratio as Coordinate.—Let $(abcx)=r$ be the anharmonic ratio of four elements of which a, b, c are *fixed* and x is *variable.* To each value of x, *i.e.*, to each point (line) of the range (pencil), there corresponds one value of r, and conversely. Hence the anharmonic ratio r may be taken as coordinate of the point (line) of a range (pencil), referred to three arbitrarily taken fixed points (lines) of it. Now, $(\infty\ 1\ 0\ x)=x$; hence, if x in case of a range denote distance from the origin, it appears that the ordinary *distance-coordinate* of a point is its anharmonic ratio referred to the infinite point, the point 1 and the origin, of the range. Similarly, if for fixed lines be taken two perpendicular lines (of which one is the ordinary origin) and the bisector of their angle, the anharmonic ratio of those lines and a (variable) fourth line is the tangent (coordinate) of the angle of this line and the origin. The anharmonic ratio is thus seen to be the coordinate par excellence of the element of any one-fold continuum.

Linear Transformation.—The importance of the anharmonic ratio in the theory of simple continua comes clearly to view in connection with the linear transformation of them. The general equation of such transformation is $x'=(ax+b):(cx+d)$. To any point (line) x corresponds one point (line) x'. Viewing the transformation as an operation on all the elements at once, we say that each element x is transformed or converted into an element x'. Obviously the range (pencil) is converted into itself as a whole, the arrangement of the elements being in general changed. It is plain, too, that the transformation can be used to pair the elements of a range (pencil) with those of a pencil (range) or to pair two ranges or two pencils. The three independent ratios of the coefficients a, b, c, d are the parameters of the transformation. Hence there are ∞^3 transformations. Any two of them are equivalent to a third, and so they constitute a *group* (see GROUPS, THEORY OF); and the parameters can be so determined as to convert any specified three elements into three specified elements. If x_1, x_2, x_3, x_4 be any four elements of a system (range or pencil) and if x_1', x_2', x_3', x_4' be the correspondents of the same or other system of the same or the other kind, then $(x_1x_2x_3x_4) = (x_1'x_2'x_3'x_4')$; *i.e.*, the anharmonic ratio is an absolute *invariant* (see INVARIANTS) under every transformation of the group. It is this property of invariance that lends the anharmonic ratio its great importance in geometry. Because anharmonic ratios are preserved by it, the linear transformation is called *projective:* any two systems paired by it are projectively related. Every transformation of a system into itself leaves two elements *fixed*. These are found by writing x for x' and then solving for x. The fixed elements, variously called the *poles*, *foci*, *double* or *conjugate* elements, of the transformation, will be real and distinct, coincident or imaginary, according as the *discriminant*, $D \equiv (d-a)^2 + 4bc$, is positive, zero, or negative; and the corresponding transformations are described respectively as *hyperbolic*, *parabolic*, and *elliptic*,—distinctions that cannot be here further pursued. In homogeneous coordinates the linear transformation is defined by the pair of equations $\rho x_1' = ax_1 + bx_2$, $\rho x_2' = cx_1 + dx_2$.

Range and Pencil; Dual Elements of the Plane.—Hitherto we have been mainly concerned with the line and the point (the range and the pencil) considered *in themselves*. These one-dimensional spaces are now to be viewed as *elements* of a twofold space, the plane. In Cartesian coordinates the equation of the line is $Ax + By + C = 0$, or $ux + vy + 1 = 0$. The equation, which represents the line as a *range* of points (x, y), contains *two* parameters u and v, which determine the range, or line. Hence the plane is two-dimensional in *ranges* (lines) as well as in *pencils* (points). Since one and but one line is determined by any pair of values of u and v, u and v may be employed as *coordinates* of the *line*. We may speak of the line (u, v) as of the point (x, y). If u and v vary and x and y do not, the equation *represents the point* (x, y) as a *pencil* of lines (u, v). We have here simple illustrations of three important *principles* of modern analytical geometry. As the equation of the line contains two independent parameters, we conclude that the plane is two-dimensional in lines. The dimensionality of any space in an element is always the number of independent parameters involved in the general analytic representation of the element. This principle of "enumerating constants" to determine questions of dimensionality is one of many principles introduced into analytical geometry by Julius Plucker (1801–1868). Another is that of *multiple interpretation* of equations. Thus we have seen that a same equation may be interpreted to represent now a point and now a line. Another great principle is that of *duality* or *reciprocity* introduced into *analytical* geometry by Plücker, though it was before employed in *pure* geometry by Poncelet (1788–1867) and his contemporary Gergonne, to the latter of whom geometric nomenclature is indebted for the word duality. Two elements e and e' of a given space are dual elements of it when its dimensionality is the same in both and when the analytic representations of e and e' are identical in form. Thus the point and the line (more properly, the pencil and the range) are reciprocal elements of the plane. The analogues for space are the point and the plane, the equation $ux + vy + wz + 1 = 0$ representing either a plane (u, v, w) as a field of points or a point (x, y, z) as a *sheaf* (*bundle*) of planes. The mentioned reciprocity of the point and the line is immediately evident in such familiar pairs of propositions as: two points (lines) determine a line (point); three points (lines) determine three lines (points). In general, to any proposition about points (lines) corresponds an immediately derivable proposition about lines (points). So arise two parallel geometries of the plane, or, say, two reciprocal aspects of one geometry. The two algebras are one, dually interpretable. Using two variables, as ξ, η, to denote either point or line, any equation $f(\xi, \eta) = 0$ will represent either a curve as an assemblage or *locus* of points or a curve as an assemblage or *envelope* of lines (tangents). The degree of the equation is called the *order* of the locus, *i.e.*, the number of points common to it and an arbitrary range, and it is called

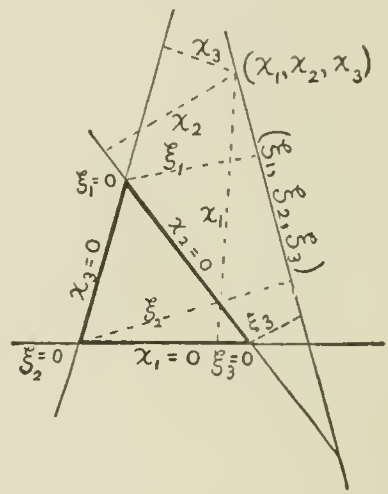

FIG. 4.

the *class* of the envelope, *i.e.*, the number of lines common to it and an arbitrary pencil. The two curves are in general not the same. But every curve, the point and line excepted, is conceivable as both a locus and an envelope and may at once be doubly generated as such: *i.e.*, by the figure of a point and a line through it so moving that the line is continuously tangent to the point's path at the point; such twofold genesis being another conception due to Plucker. Accordingly a curve has a point equation and a line (tangential) equation. For example, the ordinary point equation of the circle, centre at origin and radius r, is $x^2 + y^2 = r^2$; the line equation is $r^2(u^2 + v^2) = 1$. These are of the same degree, exemplifying the fact that every curve of *second* order is of *second* class, and conversely. In general, however, the order and the class of a curve are not equal; for example, the curve whose point equation is $x^3 + y^3 + 1 = 0$ has for line equation the sextic, $u^6 + v^6 - 2(u^3 + u^3v^3 + v^3) + 1 = 0$, and is accordingly of order 3 and class 6.

Homogeneous Point and Line Coordinates and their Geometric Interpretation.—By replacing x by $x_1:x_3$, y by $x_2:x_3$, u by $\xi_1:\xi_3$, and v by $\xi_2:\xi_3$, all equations of loci and envelopes may be rendered homogeneous. In particular the equation of the line (point) becomes $\xi_1x_1+\xi_2x_2+\xi_3x_3=0$. The three ξ's (x's), or arbitrary multiples $\mu_i\xi_i$ (m_ix_i) of them, on whose two independent ratios the line (point) depends, are called the *homogeneous coordinates of the line (point)*. Such coordinates admit of various closely allied interpretations of which the simplest is that, Fig. 4, in which the x's (ξ's) are the distances of the point (line) from the sides (vertices) of an assumed *fundamental* triangle, or triangle of *reference*, signs being so determined by convention that a point within the triangle is on the positive side of the three sides and that any two of the ξ's agree or do not agree in sign according as the corresponding line does not separate or separates the corresponding vertices. Such coordinates are often called *triangular* or *trilinear*. Plainly, they may be replaced by arbitrarily chosen multiples of them The x's (ξ's) are, of course, not independent. If Δ denote the area of the triangle and a_1, a_2, a_3 the lengths of its sides, the distances x satisfy the identity $a_1x_1+a_2x_2+a_3x_3=2\Delta$. An analogous identity connects the ξ's. The x's and the ξ's need not be referred to the same triangle, but when they are (and that is generally the most convenient convention), the foregoing equation of the line (point) signifies also that the line and point it represents are united in position. Homogeneous coordinates were first employed, from mechanical motives, by Möbius in his 'Barycentrischen Calcul,' 1827, and by Plücker, from geometric motives, in his 'Analytisch-geometrischen Entwickelungen,' 1828. The artistic and economical device of denoting several coordinates by a single letter distinguished by subscripts was introduced by Hesse (1811–1874), whose 'Analytische Geometrie des Raumes,' 1861, remains a model of elegance.

The Method of Abridged Notation, and the Conics.—This powerful method, simultaneously and independently introduced into geometry by Plücker (cf. 'Entwickelungen,' above) and by Bobillier (*Annales de Gergonne*, vol. 18, 1827–8), consists primarily in denoting by a single letter the left-hand member of the equation of a curve or surface, whence the curve or surface is represented by placing the letter equal to zero. The advantages of the method, as combining ideally with the method of parameters and as greatly economizing at once both physical and intellectual energy, are obvious. For an illustration, let $P^i\equiv x_1{}^i\xi_1+x_2{}^i\xi_2+x_3{}^i\xi_3$ and $L^i\equiv\xi_1{}^ix_1+\xi_2{}^ix_2+\xi_3{}^ix_3$, then the equations $P^i=0$, $L^i=0$ will respectively represent a point and a line. If $P'=0$ and $P''=0$ be two points, their range is represented by $P'+\lambda P''=0$, definite points of the range corresponding to definite values of the parameter λ; in like manner the pencil determined by two lines $L'=0$ and $L''=0$ is $L'+\lambda L''=0$. In general the points (lines) common to any two loci (envelopes) $C'=0$ and $C''=0$ are common to all the loci (envelopes) of the family $C'+\lambda C''=0$. If $\lambda'=(a\lambda+b).(c\lambda+d)$, the two pencils, $L'+\lambda L''=0$, $L'''+\lambda' L^{iv}=0$, are projectively related. Any pair of corresponding lines determine a point. By elimination of λ and λ', the equation of the locus, Fig. 5, of all such points is found to be $aL'L^{iv}-bL''L^{iv}-cL'L'''+$

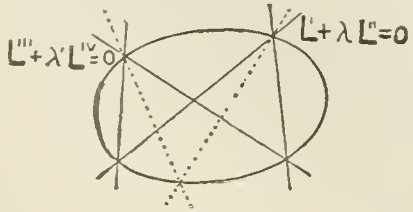

FIG. 5.

$dL''L'''=0$. This being of second degree in point coordinates, the locus is of second order, a conic containing the vertices of the given pencils. Reciprocally, the envelope, Fig. 6,

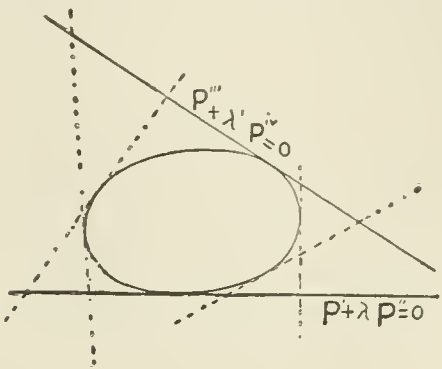

FIG. 6.

$aP'P^{iv}-bP''P^{iv}-cP'P'''+dP''P'''=0$, of the lines joining corresponding points of two projective ranges, $P'+\lambda P''=0$, $P'''+\lambda'P^{iv}=0$, is of second class, a conic touching the (bases of) the given ranges. The number and species of the conic depend on the ratios of the constants a, b, c, d. Obviously there are ∞^3 loci of second order (envelopes of second class) passing through two given points (touching two given lines).

Near-lying subjects such as the general conic, systems of conics, poles and polars, transformations, the circular points at infinity, circle and other geometries of the plane, cannot here be broached, much less the corresponding subjects in space.

Bibliography.—In addition to the works above cited, the following may be named as those which render the subject most readily accessible: Charlotte A. Scott, 'An Introductory Account of Certain Modern Ideas and Methods in Plane Analytical Geometry'; Fiedler's German edition of Salmon's 'Conic Sections' and 'Geometry of Three Dimensions'; Lindemann's 'Vorlesungen über Geometrie von Clebsch' (also in French, by Benoist).

CASSIUS J. KEYSER,
Adrain Professor of Mathematics, Columbia University.

Geometry, Non-Euclidean. The primitive meaning of Non-Euclidean Geometry was the system which follows from the denial of Euclid's Postulate: "Through a given point there is not more than one parallel to a given straight line,» when all of Euclid's other assumptions, explicit and unconscious, are retained.

It has sometimes been used in the sense of what Bolyai called Absolute Geometry and Lobachévski Pangeometry, namely, the system which simply dispensed with the above Euclidean Postulate, using neither it nor any contrary assumption; undifferentiated, therefore, as between Euclidean and primitive non-Euclidean.

When Euclid's tacit assumption, «the straight line is infinite,» is also dispensed with, we have Metageometry.

When this tacit assumption is denied, we have two new systems, to which the name non-Euclidean was immediately extended.

At present, by a non-Euclidean geometry is meant any system of geometry which, while differing in essential particulars from that of Euclid, is nevertheless in accord with experience and experiment, within the limits of the errors of observation. The space in which such a geometry is true is a non-Euclidean space.

The easiest way to get an appreciation of non-Euclidean geometry is to begin by following its early development historically.

The promise of its birth goes back almost to Euclid's very day, for it arose from endeavors to improve his treatment of the theory of parallels, which was the one point where his wonderful Elements had been criticised from antiquity. The attempts of Proklos and Claudius Ptolemæus to improve on Euclid here have been preserved to us. They were the first of a long line of geometers of every rank who have toiled over what they thought a blemish.

Such attempts may be classified under the three following heads:

1. *The Substitution of a Different Definition of Parallels.*—Euclid's own definition was: Two parallels are coplanar straights with no common point. It remains to this very day the only good definition of parallels for elementary geometry. The introduction of infinity in modern geometry gives its characteristic definition due to Desargues, 1639: Parallels are straights on a common point at infinity (figurative point). This has the advantage (1) of being freed from the necessity of specifying coplanarity, and (2) hence of giving an exact analogue for planes: Parallel planes are planes on a figurative straight; (3) of being wholly positive instead of chiefly negative; (4) of giving the dual in the plane of the fundamental «2 points determine a straight,» namely, «2 straights determine a point,» and hence the inestimable advantages of duality for the plane, including the doctrine of poles and polars.

But so far was the explicit use of infinity from being considered allowable in elementary geometry, that Borelli in 1658 objected to even so much of infinity as is implicit in Euclid's phrasing of «with no common point,» namely, «and which being produced ever so far both ways do not meet,» and so proposed as substitute: Parallels are straights with a common perpendicular

Géminos (about 100 B.C.) had defined parallels as straights everywhere equidistant, but Giordano da Bitonto (1680) saw that this presupposed the assumption of Clavius, 1574, that a line coplanar with a straight and everywhere equidistant from it is itself straight; so using a figure found in Clavius, made by joining together the ends of two equal perpendiculars to a straight, he tried to prove this join everywhere equidistant from the straight. This very figure reappears in Saccheri, of whom more anon.

Another definition is, Parallels are straights having the same direction. This also is worse than worthless.

2. *The Substitution of a Different Postulate.*—Of these the most famous is due to W. Ludlam, fellow of Saint John's College, Cambridge, who, in his 'The Rudiments of Mathematics' (1794), says: « The 12th axiom is not properly an axiom; but, instead of it, you may substitute the following simple proposition. Axiom: Two straight lines meeting in a point, are not *both* parallel to a third line.» This axiom has been persistently attributed to Playfair, despite the fact that he explicitly credits it to Ludlam in a note in his Euclid, on Prop. XXIX, where he says: «This axiom has been assumed by others, particularly by Ludlam, in his very useful little tract entitled 'Rudiments of Mathematics.' »

Other famous alternative postulates are those of Wallis, 1663: «To any triangle another triangle as large as you please can be drawn which is similar to the given triangle»; of Saccheri. «There is a triangle whose angle-sum is two right angles»; of Bolyai, F.. «Every three points are costraight or concyclic.»

3. *The Attempt to Deduce Euclid's Postulate from his Other Assumptions.*—The most famous is by Saccheri in his book 'Euclid Vindicated from Every Fleck' (Milan, 1733).

Ostensibly this is simply a very long demonstration of Euclid's Postulate by the indirect method, *reductio ad absurdum.* Denying this postulate and assuming a contradictory postulate together with all Euclid's other assumptions, if contradiction follows, this contradictory postulate is disproved. If thus the only possible alternatives to Euclid's Postulate are disposed of, it is demonstrated.

On the surface, then, it seems that Saccheri supposed himself to have proved the indemonstrable postulate.

If so, he has no claim to be the discoverer of non-Euclidean geometry. But upon a profounder study of his marvelous work, the suspicion comes that he knew the logical and mathematical truth of one at least of his non-Euclidean hypotheses and the consequent final and eternal indemonstrability of Euclid's Postulate. In that case, he cherished his work, just as we do, not for its fallacious conclusion, necessitated to get for his book the *imprimatur* of the Inquisition and of the Society of Jesus, Saccheri being a Jesuit, but for the beautiful non-Euclidean results which immortalize it.

The angles at the extremities of two equal perpendiculars are equal and either right, obtuse, or acute. These are Saccheri's three hypotheses: the hypothesis of right angle, the hypothesis of obtuse angle, the hypothesis of acute angle.

The first is Euclid. The last is the primitive non-Euclidean geometry.

This was consciously discovered by Schweikart in 1812 at Charkow, communicated to Bessel, and in 1818 a written statement of it sent to Gerling which he was afterwards asked to transmit to Gauss. He did so, and thus this precious document, the first published (not printed) non-Euclidean geometry, is still preserved. (Translated by Halsted, 'Science,' N. S., Vol. XII, pp. 842–846.) Two of its theorems are: (*a*) The sum of the three angles in the triangle is *less* than two right angles; (*b*) This sum becomes smaller the more content the triangle encloses.

The first to print a non-Euclidean geometry (1829–30) was a Russian–Lobachévski, professor of mathematics in the new University of Kazan.

In place of Euclid's Postulate he substitutes the following, which directly contradicts it: «All straight lines which, in a plane, radiate from a point, can, with reference to any given straight line in the same plane, be divided into two clasess—into *cutting* and *not cutting*. The *boundary lines* of the one and the other class are called *parallel to the given line.*»

If the length of the perpendicular from the given point to the given straight line be p, the acute angle it makes with either of the two parallels is denoted by $\Pi(p)$. With a suitable choice of the unit of length, $\tan \frac{1}{2}\Pi(p) = e^{-p}$.

Lobachévski never claimed to have discovered the non-Euclidean geometry before 1826, and the tell-tale title of his paper of 1826, 'Exposition succincte des principes de la Géometrie avec une demonstration rigoreuse du théorème des parallèls,' has never been explained.

Even in 1837 in Crelle's Journal he made the mistake of calling his discovery «Géométrie Imaginaire.»

How different the brilliant young Hungarian, John Bolyai, who in 1823 had written to his father Bolyai Farkas (Wolfgang Bolyai): «I have discovered such magnificent things that I am myself astonished at them. It would be damage eternal if they were lost. *From nothing I have created another wholly new world.*»

His brief exposition of this new world, with the same unflinching recognition of its momentous importance, he calls «The Science Absolute of Space.» It is the most extraordinary two dozen pages in the history of human thought. It was published in 1831 as an appendix to the first volume of a work by his father.

In this tiny appendix, with unparalleled boldness and power, the young Magyar hero squares the circle in Bolyai space, shows that the area of the greatest possible triangle (which has all its sides parallel and all its angles zero) is πi^2, where i is what is now called the space constant, shows how through a given point to draw a parallel to a given straight, and how to draw a perpendicular to one arm of any acute angle which shall be parallel to its other arm.

To get a sharp idea of this primitive non-Euclidean geometry, which may be named after either Lobachévski or Bolyai, contrast a few of its theorems with some of Euclid's:

Proposition 32, Book I of Euclid, is that the sum of the angles in every rectilineal triangle is *just exactly* two right angles. In Bolyai geometry, on the contrary, the sum of the angles in every rectilineal triangle is *less* than two right angles.

In the Euclidean geometry parallels *never* approach. In this non-Euclidean geometry parallels *continually* approach.

In the Euclidean geometry all points equidistant from a straight line are on a *straight* line. In this non-Euclidean geometry all points equidistant from a straight line are on a *curve* called the equidistantial.

In the Euclidean geometry the limit approached by a circumference as the radius increases is a *straight* line. In this non-Euclidean geometry this limit is a *curve* called the oricycle. Thus the method of Kempe's book, 'How to Draw a Straight Line,' would here draw not a straight line, but a curve.

In the Euclidean geometry, if three angles of a quadrilateral are right, then the fourth is *right*, and we have a rectangle. In this non-Euclidean geometry, if three angles of a quadrilateral are right, then the fourth is *acute*, and we never can have any rectangle.

In the Euclidean geometry two perpendiculars to a straight line remain *equidistant*. In this non-Euclidean geometry two perpendiculars to a straight line *spread away from each other* as they go out; their points two inches from the straight line are farther apart than their points one inch from the line.

In the Euclidean geometry every three points are either on one straight line or on one circle. In this non-Euclidean geometry there are triplets of points which are *neither costraight nor* concyclic. Thus three points each one inch above a straight line are neither on a straight line nor on a circle.

In 1867, after Riemann's death, was published an inaugural lecture he had delivered in 1854: 'On the Hypotheses which are at the Foundation of Geometry.' Here occurs for the first time the extraordinary advance that the straight line may be closed and finite; that space though unbounded may still be finite, that, for example, a finite number of our common building bricks might be written down which might be more than our universe could contain. This at once gave Saccheri's «hypothesis of obtuse angle» equal standing with his other two, giving a new genus of non-Euclidean geometry, the Riemannian, with two species, the elliptic and the spheric. These varieties of Riemann's space are also called the polar and antipodal forms of elliptic space, Euclid's space being called parabolic, and that of Bolyai and Lobachévski hyperbolic, space. Riemann gets his profound hold of this matter with the aid of two fundamental conceptions, that of a *manifold*, and that of what he called the *measure of curvature* of a continuous manifold having flatness in its smallest parts. This phraseology, especially the use of the word curvature, proved unfortunate, misleading philosophers and even mathematicians into supposing non-Euclidean spaces curved and necessarily contained in Euclidean spaces. How far this is from being the case is shown by the beautiful «Theorem of Barbarin»: «Each of the three spaces, Euclidean, Lobachévskian, Riemannian, contains surfaces of constant curvature of which the geodesic lines have the metric properties of the straight lines of the three spaces.» Riemann himself created point-manifolds with measure of curvature not zero utterly without reference to anything not contained in the manifold itself. Hence to avoid all appearance of implying for non-Euclidean spaces a curvature in Euclidean space, the phrase *space-constant* serves, it being equal to the reciprocal of the square root of Riemann's measure of curvature.

Lambert in his 'Theorie der Parallellinien' (1766), showed that Saccheri's «hypothesis of obtuse angle» holds on a sphere, and to-day pure two-dimensional spherics is not only the best Euclidean analogue of a Riemannian geometry, but inversely the geometry of two-dimensional antipodal Riemannian space gives the best insight into Euclidean spherics and spherical trigonometry. These reciprocal advantages will be found utilized in Chapter XV, *Pure Spherics*, of Halsted's 'Rational Geometry,' which may be taken as the simplest, most detailed, most complete Riemannian geometry in print.

But it must not be supposed that the surface of a sphere *is* a plane of antipodal Riemannian space. They have the same internal relations, abstraction made of all points not *on*, that is, *in* them. To realize how tremendously different they are in other respects, you have only to recall that the sphere has a triple infinity of points within it, including the center, while the antipodal Riemannian plane has no points within it, no points toward which it is concave.

In the polar form of Riemannian space two coplanar straight lines always intersect once and only once. A complete straight line does not divide a plane; a plane does not divide space, it is unilateral. In this space alone do we have complete, absolute point and plane duality.

Another genus of Euclidean analogues of non-Euclidean spaces was obtained by Klein by a variation of the absolute in Cayley's projective metrics. The coordinates employed in the projective foundation of metrics must be defined non-metrically. This is accomplished by means of the pure projective geometry of von Staudt founded on his famous quadrilateral construction, by which, entirely without any metrical presuppositions, order is assigned among the points of a line. This Cayley-Klein translation of non-Euclidean systems furnished a final proof that no logical outcome of a non-Euclidean geometry could ever be self-contradictory, since any self-contradiction in a non-Euclidean system would be but a like self-contradiction in the Euclidean system. Another equally sweeping but much simpler proof of this on the same principle is given by Poincaré in his remarkable book, 'Science and Hypothesis.'

To the genius of Helmholtz is due the conception of studying the essential characteristics of a space by a consideration of the movements possible therein. Felix Klein it was who first called the attention of Lie to this work of Helmholtz, and pointed out its connection with Lie's group-theory. In 1886 Lie gave briefly his weightiest results. The whole investigation, published in Vol. III of his 'Theorie der Transformationsgruppen,' 1893, was in 1897 awarded the first Lobachévski Prize, a great recurring prize founded at Kazan by contributions from all over the world in honor of the Russian creator of the first non-Euclidean geometry. If Hungary had a man like Vasiliev of Kazan, she too would be honoring herself by marking with a Bolyai Prize her pride in the greatest idea which ever originated in a Magyar brain.

Lie proves that free motion in the strict meaning of the word can happen in three and only three spaces, namely, the traditional or Euclidean space and the two kinds of non-Euclidean space, a Bolyai space, a Riemann space, of which latter there are two species. These four are thus the only spaces allowing free motion as a whole.

A new genus of non-Euclidean spaces, forms of space which do not allow free motion as a whole, called by Killing the Clifford-Klein spaces, may be said to have arisen from Clifford's unbounded surface of finite extent and zero curvature, whose connectivity and geometry are those of a plane Euclidean parallelogram whose opposite sides correspond point for point, these opposite pairs being considered as one point. The connectivity is that of an anchor-ring.

In this the moving on itself of the closed surface in its totality is sharply restricted, while the movements of a comparatively small area on the closed surface remain unrestricted. Clifford's surface is the locus in the polar form of Riemannian space of the point whose perpendicular to a given straight is congruent to a given sect, that is, of points at a constant distance from a given axis. This locus is a ruled quadric surface. The joins of the correlated points of two projective ranges whose bearers are not coplanar form a «ruled system» or regulus of straights no two coplanar. For were two coplanar, then two points on the bearer m and two on the bearer m_1 would all four be on this plane, and so m and m_1 coplanar, contrary to hypothesis.

Let the straights n, n_1, n_2 be any three of the elements of a ruled system, and N_2 any point on n_2. Put a plane on N_2 and the straight n_1, and let its pass with n be called N. The straight NN_2 cuts n, n_1, n_2 all three. Projecting the generating ranges of the ruled system (on the bearers m and m_1) from the straight NN_2 (or m_2) as axis produces two projective axial pencils, which having three planes m_2n, m_2n_1, m_2n_2 self-corresponding are identical. Therefore every pair of correlated points of the ranges on m and m_1 is coplanar with m_2; that is, m_2 cuts every element of the ruled system.

By varying the point N_2 we obtain ∞^1 straights, all cutting all the ∞^1 straights of the original ruled system and making on every two projective ranges. Of the straights so obtained no two cross, for that would make two of the first ruled system coplanar. Either of these two systems may be considered as generating a «ruled surface,» which is the bearer of both.

Each of the two systems is completely determined by any three straights of the other, and therefore so is the ruled surface also. From the construction follows that the straights of either ruled system cut all the straights of the other in projective ranges. So any two straights of either system may be considered as bearers of projective ranges generating the other system, or indeed the ruled surface. On each point of this ruled surface are two and only two straights lying wholly in the surface (one in each ruled system). The figure of two so united ruled systems, due to Monge, is one of the most noteworthy creations of modern geometry.

In Clifford's surface any two of the elements of the same ruled system have an infinity of common perpendiculars all congruent, as have also any element and the axis of the surface Clifford called all the elements of the same ruled system '*parallel*' to each other and to the axis.

Generalizing, a transformation in this polar space of three dimensions in which all straights of a certain straight-congruence remain fixed while any point is displaced along the straight of the congruence on which it lies is called a *translation*, and the straights of the congruence are called *Clifford Parallels.* From any point of either of two Clifford parallels a common perpendicular can be drawn to the two, and all such are congruent. Moreover, if a straight cut two Clifford parallels, the corresponding angles are congruent.

The Clifford parallels are of two kinds, according as the generators of the fundamental quadric which determine them are elements of one or the other of the two ruled systems of the quadric. Similarly translations are to be distinguished as of two kinds. Two successive translations of the same kind are equivalent to a translation, but two translations of different kinds are not equivalent to a translation.

From these considerations we get, even when the measure of curvature is taken as zero, by the side of ordinary Euclidean space three other types or species of the genus Clifford-Klein space, given by the use of translations alone. These may be studied from the Euclidean geometry: 1° Within a parallelopiped with three finite edges; 2° Within a parallelopiped one of whose edges becomes infinite; 3° Within a parallelopiped two of whose edges become infinite.

In the Clifford-Klein space corresponding to 1°, geodesics may have the finite length $la+mb+nc$, where a, b, c are the lengths of the edges of the parallelopiped and l, m, n are any three relatively prime integers. Geodesic surfaces may be like a plane, a cylindric, or an anchor-ring surface.

If, finally, the same considerations be applied to the case where the measure of curvature is a negative constant, there results an infinity of varieties corresponding exactly to the configurations considered by Poincaré and Klein in the theory of automorphic functions. The great importance of the Clifford-Klein space-forms rests upon this, that they show with especial clearness what a mighty difference it makes whether we, from the beginning, assume the geometric axioms as valid for space as a whole or merely for an every way bounded piece of space. In the first case we obtain, besides the Euclidean, only the three now well-known non-Euclidean space-forms. In the second case appears also a manifold, at present not yet dominated, of different space-forms, new non-Euclidean universes.

Bibliography.—A bibliography of non-Euclidean literature down to the year 1878 was given by Halsted, 'American Journal of Mathematics,' Vols. I, II, containing 81 authors and 174 titles, and reprinted in the collected works of Lobachévski (Kazan, 1886) giving 124 authors and 272 titles, which was incorporated in Bonola's 'Bibliography of the Foundations of Geometry' (1899), reprinted (1902) at Kolozsvár in the Bolyai Memorial Volume. Bonola adds the titles of 27 articles written by Halsted, a study and synthesis of which will be found in 'Euclid's Parallel Postulate' (Chicago, 1905, pp. i–x, 1–192). See also 'Report on Non-Euclidean Geometry' (American Association, 1899, and Supplementary Report on Non-Euclidean Geometry, 1901).

Saccheri, rediscovered, was first given to the world by a translation in the 'American Mathematical Monthly' (Vols. I and II). Lobachévski and Bolyai we have in the 'Neomonic Series,' published at The Neomon, Gambier, Ohio: (Vol. I); Vasiliev's 'Address on Lobachévski': (Vol. III); Bolyai's 'Science Absolute of Space': (Vol. IV); Lobachévski's 'Geometrical Researches on the Theory of Parallels': (Vol. V); 'Introduction to Lobachévski's New Elements of Geometry.' In French, 'La Géométrie non euclidienne;' par P. Barbarin, is a little gem. In German, for exposition, 'Nichteuklidische Geometrie,' von H. Liebmann (1905); for the sources, Stäckel and Engel, 'Die Theorie der Parallellinien' (1895); Engel, 'Lobatschefskij' (1899).

George Bruce Halsted,
Professor of Mathematics, Kenyon College, Gambier, Ohio.

Geometry, Pure Projective. *Introductory.*—Projective geometry, as the name indicates, has to do with the theory of projection. Pure projective geometry is that which is conducted by means purely geometric, without initial recourse to algebraic methods (see Geometry, Modern Analytical), and which makes only subordinate mention of properties other than projective. The adjective synthetic is frequently used as practically a synonym for pure.

The process of projection is of constant occurrence—*e.g.*, in photographing (the lens must be strictly rectilinear), in preparing a lantern-slide from the photographic plate, and in throwing the image upon a screen. Thus in passing from an object to its representation upon the screen there are three successive projections—a fourth enters with the visual image formed upon the retina when the screen is viewed. Fig. 1 serves to illustrate the process of projecting a line $ABCD$ into another $A''B''C''D''$.

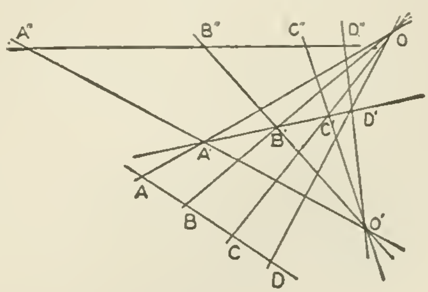

Fig. 1.

Reference to the figure will show that the length of a line is changed by projection AB is not equal to $A''B''$. Moreover, even the ratio of two lengths is changed. $AB \div BC$ is not equal to $A''B'' \div B''C''$. The study of projective geometry is the study of such properties of figures as are unaltered by successive projections. Lengths and ratios of lengths are not such properties, and by right enter only subordinately into pure projective geometry.

Historically considered, projective geometry arose by considering changes in lengths, and was thus far from pure. A theorem attributed to PAPPUS (q.v.) states that the *double ratio* of the lengths is unchanged by projection—thus,

$$\frac{AB}{BC} \div \frac{AD}{DC} = \frac{A'B'}{B'C'} \div \frac{A'D'}{D'C'} = \frac{A''B''}{B''C''} \div \frac{A''D''}{D''C''}.$$

It was upon such basis as this that the subject developed until VON STAUDT (q.v.) in his famous 'Geometrie der Lage,' published in 1847, showed how the development might proceed in a manner more truly in the spirit of pure projective geometry. From the publication of this book dates the modern point of view in treating projective geometry as a pure self-sustaining branch of mathematics. It is this point of view that is here adopted.

Fundamental Notions.—Properly to appreciate pure projective geometry it is necessary definitely to take a point of view radically distinct from that taken in ordinary elementary geometry. This may perhaps be done best by making a first appeal, as von Staudt did, to the physical sensation of sight. What characterizes ordinary geometry (which is usually called *metrical*, as opposed to projective geometry) is its close relation to the conceptions of rigid motion, of distance, and of measurement—in short, to things connected with the sensation of touch. Whereas projective geometry is intimately concerned with the look (Schein) or projection of objects and not with their actual dimensions. Thus in the figure the set of points A, B, C, D would have the same 'look' to an observer at O as would A', B', C', D'; and these in turn would appear the same from the point O' as would A'', B'', C'', D''. There is, however, one respect in which the idea of 'looking' must be generalized. If the view-point is situated between the points A', B', C' and A'', B'', C'', as in Fig. 2,

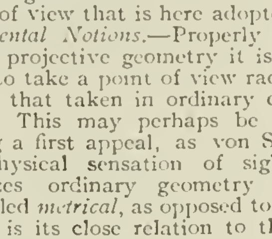

FIG. 2.

the sets of points are still said to 'look' the same, or to be projections of one another with respect to the point O'. Precisely herein lies the distinction between projective geometry and what has been called descriptive geometry (B. Russell, 'Principles of Mathematics,' p. 393). Namely, the former considers the line of vision or projection to be the whole line through the point of observation, whereas the latter takes it as merely a half-line and thus corresponds somewhat more closely to the real visual space.

The point, the straight line, and the plane are assumed as the fundamental geometric elements. They are denoted respectively by italic capitals A, B, C, . . . ; by lower case italics, a, b, c, . . . ; and by Greek letters, α, β, γ, . . . It may be noted that these elements are themselves projective, that is, appear respectively as points, line, and plane from any view-point not situated upon them. A circle has not this property: for when viewed from any point, not upon the line through its center and perpendicular to its plane, it appears noncircular. Hence the circle could not serve as a fundamental locus in pure projective geometry.

Fundamental Propositions. Parallelism.—There are a considerable number of immediately obvious relations connecting the fundamental elements, points, lines, planes. From among these it is necessary to select a certain number to serve as fundamental propositions or premises for future deductions. (Note. The propositions so selected may be called axioms or postulates. This, however, is not the place to discuss such matters, which belong to the foundations of mathematics. See LOGIC, SYMBOLIC.)

F. P. 1. Two points determine a line—the line joining them and upon which they lie.

F. P. 2. Two planes determine a line—their line of intersection and through which they pass.

F. P. 3. Three points not in the same line determine a plane—the plane passed through them and in which they lie.

F. P. 4. Three planes not passing through the same line determine a point—their point of intersection.

F. P. 5. A point and a line not passing through the point determine a plane.

F. P. 6. A plane and a line not lying in the plane determine a point—their point of intersection.

From these propositions follow a number of theorems:

Th. 1. If two points lie in a plane, the line joining them lies wholly in the plane. Proved from F. P. 3 and F. P. 5.

Th. 2. If two planes pass through a point, their line of intersection passes through the point. Proved from F. P. 4 and F. P. 6.

Th. 3. If two lines have a point in common, they determine a plane. Proved by F. P. 3 and Th. 1.

Th. 4. If two lines lie in the same plane, they intersect in a point. Proved by F. P. 4 and Th. 2.

Th. 5. If two triangles are so situated that the lines joining corresponding vertices meet in a point, the points of intersection of corresponding sides lie on a line.

The proof in case the triangles do not lie in the same plane is as follows: Let ABC and $A'B'C'$ be the triangles. As AA' and BB' meet in a point, the lines AB and $A'B'$ determine a plane (Th. 3, Th. 1) in which they intersect (Th. 4). But as AB lies in the plane ABC, and $A'B'$ in the plane $A'B'C'$, they can only intersect on the line common to these two planes. Hence the intersection of AB and $A'B'$ is on this line. Similarly BC and $B'C'$, and CA and $C'A'$, intersect on this line. The proof in case the triangles lie in the same plane is obtained by comparing each of them with a triangle out of their plane.

Th. 6. Converse of Th. 5. Proof similar.

Th. 7. If two triedral angles are so situated that the lines of intersection of corresponding faces lie in a plane, the planes determined by corresponding edges pass through a line. The proof follows that of Th. 5.

Th. 8. Converse of Th. 7. Proof similar.

From the point of view of elementary geometry theorem 4 is incorrect and should read 'if two lines lie in the same plane they either intersect or are parallel.' What has become of parallelism? Reflexion will disclose that for projective geometry there is no such thing as parallelism. For, consider two parallel lines upon a horizontal plane and project them upon a vertical plane (as is done in photographing a straight, flat railroad track). In the projection the lines meet upon the horizon (Fig. 3). Thus the property

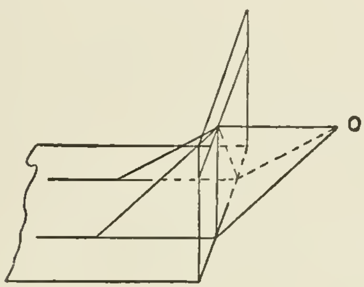

Fig. 3.

known as parallelism in elementary geometry is not unchanged by projection and cannot enter into projective geometry. From the visual point of view all lines seem to intersect. F. P. 2, F. P. 4, and F. P. 6 are subject to the same comment. From this it will be seen that the statements for projective geometry are much simpler than those for elementary geometry, inasmuch as no special cases or exceptions need be introduced to cover the possibility of parallelism. At first this might seem unnatural or even wrong, but it is in the true spirit of the subject and after a little usage appears as one of the principal beauties.

The expression is often used that parallel lines and planes meet «at infinity.» This is convenient in expressing the relations of projective to elementary geometry (§ 7), but it must not be allowed to introduce confusion. There is no such thing as distance, much less infinite distance or infinity, in pure projective geometry. (See, however, § 8.)

4. *Harmonic Elements. Duality.*—A set of points situated upon a line is called a *range*. A set of planes passing through a line is called a *pencil* of planes. A set of lines lying in a plane and passing through a point is called a *pencil* of lines.

It may be said that the fundamental construction of projective geometry is the construction of a harmonic range. Given a pair of points A, B on a line (Fig. 4) and a third point C. To find the fourth harmonic point D draw through C any line. In the same plane draw AE and BE cutting the line through C in F and G. Join F to B and G to A by lines intersecting in H. Draw the line connecting E and H, and let it cut the line AB in D. Then D is said to be the fourth harmonic point in the range $AB \cdot C$. It may be proved by the theorems given above that: 1° no matter how the construction be carried

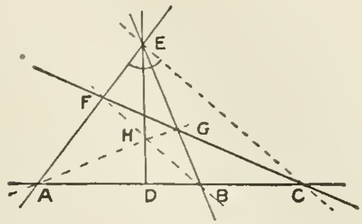

Fig. 4.

out, it always leads to the same point D; 2° if the three given points be $AB \cdot D$, the fourth harmonic is C, and hence the pair of points C, D may be said to divide the pair A, B harmonically; 3° the pair A, B also divide C, D harmonically, and hence the pairs $AB \cdot CD$ may simply be called harmonic pairs or a harmonic range.

A pencil of lines such as $E\text{-}AB \cdot CD$ which cuts a line in a harmonic range is by definition a harmonic pencil. It may be shown that if any line cuts a harmonic pencil, the range of points is harmonic. Similarly if a pencil of planes cuts one line in a harmonic range, it cuts every line in a harmonic range and is said to be a harmonic pencil. The harmonic property is thus evidently a true projective property, being unchanged by projection.

A characteristic of higher geometry is the frequent use of correspondences—that is, of methods for obtaining from a given group of theorems another group merely by substituting different words in the statement of the given theorem. The simplest of these correspondences is *duality*. There are several dualities established in projective geometry. Of these the most important are duality in space and duality in the plane.

Spatial duality is obtained by substituting respectively for 'point,' 'line,' 'plane,' the words 'plane,' 'line,' 'point,' and making such corresponding changes from 'pass through' to 'lie on' as may be necessary. In the fundamental propositions the duality appears. Thus F. P. 1 and F. P. 2 are dual statements. The same is true of F. P. 3 and F. P. 4 and of F. P 5 and F. P. 6. As this dual relation extends through all the fundamental propositions, it must extend through all propositions immediately derived from them. For, the proof of a dual proposition may be given by merely making in the proof of the given proposition the same changes as in its statement. As this may be done at every step, the two sets of propositions may be developed side by side, and the duality can never break down until the introduction of some additional definition or fundamental proposition which is not accompanied by its dual. Thus Th. 1 and Th. 2 are dual, and the proof of Th. 2 is the exact dual counterpart of the proof of Th. 1.

The duality in the plane may be obtained by substituting for 'point' and 'line' the words 'line' and 'point.' A 'range of points' becomes a 'pencil of lines' and *vice* *versa.* Thus Th. 1 and Th. 4, and in case the construction be confined to a plane Th. 5 and Th. 6, are duals. According to the definitions above given it did not appear that the harmonic pencil was the dual of the harmonic range. It is, however, possible to give for a harmonic pencil a construction which is the dual of that given for the range, and it may be proved that this construction is equivalent to the earlier definition. Therefore all theorems concerning harmonic properties have dual counterparts.

If four lines no three of which pass through the same point be drawn in the plane, they will intersect in six points. This figure is called the *complete quadrilateral* (the heavy lines of Fig. 4, except ED. The three dotted lines are the three diagonals). In a dual manner the six lines which may be drawn through four points (no three of which lie on a line) in the plane constitute the *complete quadrangle*. The properties of these two figures are much studied in plane projective geometry.

5. *Order, Continuity, Projectivity, Correlation.*—If three lines a, b, c, lying in a plane, pass through a point, they determine a certain *order* in which the pencil may be conceived as described by a movable line—the order *abc* to which *cba* is opposed. Two lines alone cannot determine the order of description: for it is possible to pass from one to the other in either of two ways. Similarly three points upon a line determine an order upon the line, and three planes through a line fix an order about that line: but two cannot (see § 7). Thus a new element, *order*, is added to the fundamental elements, point, line, plane. It is intuitively obvious that:

F. P. 7. Order is unchanged by projection. Thus if a point describe a range in the order ABC, its projection will describe the projected range $A'B'C'$ in the same order (see Figs. 1 and 2).

One more fundamental proposition, the so-called postulate of continuity, the importance of which is quite overlooked in all but the best and most recent works, may be stated as follows:

F. P. 8. If a line be ordered and if Y follow X in that order; if, moreover, the points of the segment XY be divided into two classes so that 1° every point of the segments belongs in one of the classes and 2° every point of one class precedes all points of the other class, then there must be a point Z in the XY such that every point which precedes Z lies in the first class and every point which follows Z lies in the second.

If one range may be obtained from another by successive projection, the two ranges are said to be projective. The relation between the ranges is called a *projectivity*. (Similar definitions cover the relations between ranges and pencils or between two pencils. For simplicity the treatment will be confined to ranges.)

Fundamental Theorem.—Three corresponding points A, B, C and A', B', C' determine uniquely the projectivity between two ranges. That three elements of one range may be projected into any three elements of another range may be seen from Fig. 2. That the projective relation is thereby uniquely determined follows from F. P. 8. In like manner the correspondence of four points, no three of which lie on a line, determines the projectivity between two planes (which may coincide); and five points determine the projectivity between two spaces (these must coincide).

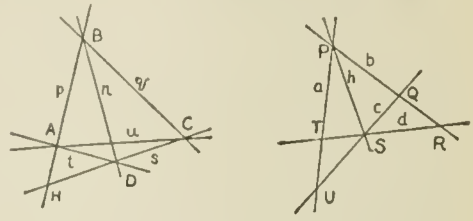

Plate I. Plate II.

Fig. 5

If the points of one plane are placed in correspondence with the lines of a second plane (which may be coincident with the first) in such a manner that to each point corresponds one line and conversely, and to the intersection of two lines corresponds the line joining their corresponding points, the relation is called a *correlation*. A correlation is completely determined by the correspondence of four given elements. (In the figure corresponding elements have the same letters.)

6. *Conics.*—If in one and the same plane a correlation be so established that when the point P corresponds to the line p, then conversely the line p corresponds to the point P, the correlation is called a *polarity*. Corresponding points and lines are *poles* and *polars* in the polarity. In general the poles do not lie on the polars: but certain of the poles do usually lie on their polars. The locus of the poles which lie on their polars is a curve to which the polars themselves are tangent and is called a *conic*. This definition is self-dual. A large number of theorems and their duals follow from the definition. For example, with their duals:

1. Pole, polar, and conic cut out a harmonic range on any line through the pole.

2. The locus of the intersections of corresponding lines of two projective pencils is a conic.

3. If a hexagon be inscribed in a conic, the points in which the three pairs of opposite sides intersect lie on a line.

This last is the famous Pascal's theorem, which with its dual, Brianchon's theorem, is very useful in the theory of conics. The second theorem is taken to define conic sections by many less modern writers. It is a very convenient graphical method. From it the various other properties may be deduced, though with much less directness and power than in the way here sketched. The first theorem is taken to define pole and polar by most of the writers who base conic sections on the second theorem. Another method of treating poles and polars is to consider projectivities not merely on a line but on a conic. The points of a conic are associated so that to each point A, B, C, ..., corresponds a point A', B', C', . . . Three pairs of corresponding points determine the projectivity. If it so happens that A', B', C', ..., correspond conversely to A, B, C, the projectivity is called *involutory* (just as the polarity was the involutory correlation, § 4) or merely an *involution.* The study of involutions on a conic leads to an elegant theory of poles and polars.

Quadric surfaces may be defined analogously to conic sections. The treatment of cubic curves on such surfaces has been considerably developed. The treatment of plane curves of order and class higher than conics may be developed to some extent synthetically, but is generally carried on analytically (see CURVES, HIGHER PLANE). The linear and tetrahedral line complexes and certain line congruences have received synthetic treatment. The analytical discussions are, however, better known (see GEOMETRY, LINE-).

7. *Relations to Metrical Geometry.*—If the word meet be changed to meet or are parallel, every theorem of projective geometry becomes a theorem of metrical geometry. But in order conversely to interpret a metrical theorem as a theorem of projective geometry, it is first necessary to state the theorem in terms unchanged by projection—that is, in terms of double ratios (§ 1). This is usually done in one of two ways.

First, if the point D retreats indefinitely, AD/DC approaches -1 and the double ratio

$$\frac{AB}{BC} \div \frac{AD}{DC}$$

approaches the simple ratio AB/CB. Thus any ratio in metric geometry may be turned into a double ratio and rendered projective by adding the point at infinity upon the line to the three finite points A, B, C. In the particular case of a harmonic range (§ 4) $AB \cdot CD$ if D be at infinity, C bisects AB. This introduction of a point at infinity also accounts for the fact that a pair of points AB suffice in metric geometry to determine an order on the line (§ 5). The order is that of $AB\infty$.

The relation between metric and projective geometry may be used to obtain metrical theorems from projective theorems by specialization of the figure, or to obtain projective theorems from metrical by generalizing the figure by projection. Thus the theorems «the diagonals of a parallelogram bisect each other» and «a diagonal of a complete quadrangle is divided harmonically by the other two diagonals» may be obtained one from another. (See Fig. 4.)

Second, the double ratio of four lines a, b, c, d may be written as

$$\lambda = \frac{\sin \measuredangle ab}{\sin \measuredangle bc} \div \frac{\sin \measuredangle ad}{\sin \measuredangle dc}.$$

If only a simple angle such as $\measuredangle bd$ is given, the two other lines of the pencil may be assumed to be the «minimal lines» or «lines to the two circular points» determined by

$$x \pm \sqrt{-1}\, y = 0.$$

The double ratio λ becomes

$$\lambda = e^{2\phi i} = \cos 2\phi + i \sin 2\phi,$$

$$\phi = \frac{1}{2i} \log \lambda.$$

Thus an angle ϕ has been expressed in terms of a double ratio λ by the introduction of the two circular points. If, in particular, ϕ is a right angle, $\lambda = -1$, and the pencil is harmonic.

The properties of circular points most necessary to establish the relation of metrical to projective geometry are: They lie on the line at infinity. All circles pass through them. The lines (imaginary) joining the center of a circle to the circular points are tangent to the circle. Thus the theorem «the locus of the vertex of a right angle (or any angle) whose sides pass through two fixed points is a circle through the fixed points» becomes «the locus of the vertex of a harmonic pencil (or any pencil of constant double ratio) whose sides pass through four fixed points (two of these correspond to the circular points) is a conic section passing through the four fixed points.»

8. *Relations to Analytic and Non-Euclidean Geometry.*—The fact that in metrical geometry the point 1 upon a line is half-way between the points 0 and 2 furnishes a clue for constructing a projective scale purely by harmonic constructions. Let three points A, B, C be arbitrarily assigned the numbers 0, 1, ∞. By finding the fourth harmonic to 0 with respect to 1 and ∞, a point is constructed to which the number 2 is assigned. In like manner all the positive integers may be located. The negative integer $-N$ is assigned to the point harmonically situated with respect to $+N$ and the pair 0, ∞. By projecting 0, N, ∞ into 0, 1, ∞ the points $1/N$, $2/N$, . . . can be located. Thus all the rational numbers are assigned to points on a line. By use of F. P. 8 it may be shown that to each point of the line corresponds a number rational or irrational or ∞, and to each number corresponds just one point.

To obtain a system of coördinates for the plane, assume two lines in the plane. Mark their intersection as 0 and upon each of them mark arbitrarily the points 1, ∞. Then to

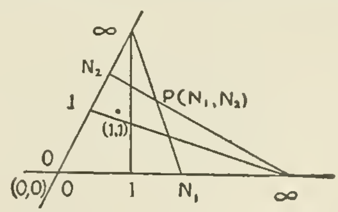

FIG. 6.

each point of each line corresponds one number. To find the coördinates of any point P of the plane draw lines connecting P to the two infinite points. The points in which these intersect the given two lines furnish the coördinates of P. A more convenient system may be obtained by rendering the coördinates homogeneous (see GEOMETRY, MODERN ANALYTICAL). Upon this purely projective basis all analytical geometry may be built up. The system is evidently that which is obtained by projecting the ordinary Cartesian system of coördinate axes into the system here assumed. In practically all treatises upon analytical geometry the coördinates are introduced as metrical quantities and are only later proved to be truly projective. Analytical projective geometry is closely related to Invariants and Covariants (q.v.), Geometry of Hyperspaces (q.v.), Modern Analytical Geometry (q.v.), Higher Plane Curves (q.v.), and Determinants (q.v.).

Projective geometry includes in itself not only metrical geometry, but the ordinary non-Euclidean geometries as well. This is seen from examining the fundamental propositions upon which those geometries are based, or, better, by following the analytical method of A. Cayley (q.v.), and defining distance in the various geometries as the logarithm of a double ratio. (See GEOMETRY, NON-EUCLIDEAN.)

9. *New Problems and Bibliography.*—It may well be said that pure projective geometry, which rose with von Staudt in 1847 and was carried on by numerous investigators during the next fifty years, has now reached a stage that is near finality, and that new problems are likely to be on neighboring fields. Thus at present there is a great deal of work on the foundations of mathematics. For pure projective geometry this means the determination of one or more sets of postulates and fundamental concepts which shall be 1° projective, 2° complete, 3° compatible, 4° independent and irreducible, and 5° as nearly self-dual as possible. This problem is not yet settled in a wholly satisfactory manner, despite the researches of Pieri, Schur, Moore, and Veblen. The fundamental propositions assumed in earlier sections are far from satisfying rigorously all these conditions. They are, however, sufficiently good for most purposes.

The theory of involutory projectivities has been satisfactorily developed as far as its application to transformations which leave a quadratic form fixed is concerned, but for the general case there remains much to be done. And so with many other special problems which might be enumerated.

Of late Wilczynski has been developing a projective theory of curves and surfaces which, though not wholly in touch with pure projective geometry, promises valuable additions to the subject.

A complete bibliography of memoirs and books may be found in the historical account of the subject by Ernst Kotter, 'Die Entwickelung der synthetischen Geometrie,' the first volume of which appeared in 1901. The work is not yet complete. The same is true of the 'Encyclopedie der mathematischen Wissenschaften' (vol. III, Pt. 1). The following text-books may be cited: von Staudt, 'Geometrie der Lage' (1847); 'Beiträge zur Geometrie der Lage' (1856–1860); Reye, 'Geometrie der Lage' (1892–1899), partly translated by Holgate, 'Geometry of Position' (1898); Boger, 'Geometrie der Lage' (1900); Sannia, 'Geometria proiettiva' (1895); Enriques, 'Lezioni di Geometria proiettiva' (1898), translated into German, 'Vorlesungen über projektive Geometrie' (1903). From the older standpoint: Steiner, 'Vorlesungen über synthetische Geometrie' (1898); Cremona, 'Projective Geometry' (1893, translated by Leudersdorf); Poncelet, 'Traité des Projections' (1866); Duporcq, 'Premiers Principes de Géométrie modernes' (1899).

EDWIN BIDWELL WILSON,
Instructor in Mathematics, Yale University.

Geophagy, jē-ŏf'a-jĭ, **Geophagism,** or **Dirt-eating,** the practice of eating some kind of earthy matter, as clay or chalk, common among uncivilized peoples, such as the South American Ottamacs, the Indians of the Hudson Bay country, the West Indian blacks, the negroes in some of the United States, and among the less civilized whites in the mountain districts of Tennessee and Kentucky. In some cases it is probably used to allay hunger, but it is also practised where the supply of food is sufficient. Among chlorotic young women a similarly depraved appetite is not uncommon.

George, surnamed «THE BEARDED,» duke of Saxony: b. 27 Aug. 1741; d. 17 April 1539. He was the son of Albert the Brave, the founder of the Albertine line of Saxony, and succeeded, in 1500, to the hereditary dominions of the Albertine house. Later on he became involved in the turmoils of the Reformation Period. He was not at first wholly hostile to reform, but thought that it could be better effected by means of papal edicts than by the revolt of Luther. Accordingly he became embittered by the uncompromising tone of Luther's later writings, and endeavored to suppress the Reformation in his dominions by violent measures. These, however, were unsuccessful, and in 1539, on the accession of his brother Henry, who was a Protestant, the Reformation was introduced into the dominions of the Albertine house of Saxony.

George, Saint, the especial patron of chivalry, and tutelary saint of England: d. Nicomedia 23 April 303. Though venerated both in the Eastern and Western Churches, his history is extremely obscure, the extant accounts containing very much less history than legend. The story in the 'Acta Sanctorum' ('Deeds of the Saints') is that he was born of noble Christian parents in Cappadocia, became a distinguished soldier, and after testifying to his faith before Diocletian, was tortured and put to death. He was adopted by the Genoese as their patron saint, and in 1222 the Council of Oxford ordered that his day (the 23d of April) should be observed as a national holiday in England. In 1344 an order was instituted in his honor by Edward III., and in 1350 this was made the Order of the Garter, of which accordingly Saint George is the patron.

George I. (GEORGE LOUIS), king of Great Britain, and Elector of Hanover: b. Hanover, Germany, 28 March 1660; d. Osnabrück 11 June 1727. He was the son of the Elector Ernest Augustus, by Sophia, daughter of Frederick, elector palatine, and granddaughter to James I. In 1682 he married his cousin, Sophia Dorothea, daughter of the Duke of Celle. The union was not a happy one. George I. was both a faithless and a jealous husband, and when his wife, who was guilty of some imprudences, brought on herself the suspicion of carrying on an illicit intrigue with Count Königsmark, he caused her to be imprisoned, and kept her in confinement for the rest of her life. The offspring of the marriage were George, Prince of Wales, afterward George II., and Sophia, the mother of Frederick the Great. In 1698 he succeeded to the electorate, and in this succession was joined in the alliance against France. The command of the imperial army was conferred upon him in 1707, but owing to jealousies among his confederates he resigned the command at the end of three campaigns. At the Peace of Rastadt Louis XIV. recognized the electoral dignity in the house of Lunenburg, as he had already by the Treaty of Utrecht recognized the succession of the same house to the throne of Great Britain, which event took place on the death of Anne in 1714, when the elector was in the 55th year of his age. His reign in England was disturbed first by a rising of the Scottish Jacobites in favor of the son of James II., and afterward by wars with Spain, undertaken first in conjunction with Holland and France (the Triple Alliance of 1717), afterward in addition with Austria (the Quadruple Alliance of 1718), with the view of checking the schemes of the Spanish minister Alberoni. George I. was plain and simple in his taste and appearance; he possessed much natural prudence and good sense, and his management of his Germain dominions, to which he showed more attachment than to his English dominions, was able. See Coxe, 'Life of Walpole' (1808); Wright, 'England Under the House of Hanover' (1848); Thackeray, 'The Four Georges' (1860).

George II. (George Augustus), king of Great Britain, son of George I.: b. Hanover 10 Nov. 1683; d. London 25 Oct. 1760. He married in 1705 Wilhelmina Carolina of Brandenburg-Anspach. In 1708, then only electoral prince of Hanover, he distinguished himself under the command of Marlborough. He came to England with his father at the accession of the latter, and was created Prince of Wales. He was made regent during the king's visit to the continent in 1716, but a political difference ensuing, he lived some time estranged from the court. This breach was finally accommodated, and in 1727 he succeeded to the throne. He inherited in full force the predilection of George I. for Germany; and the same system of politics and the same ministers continued to govern the nation after his accession as before it. In the earlier part of his reign, during the greater part of the ministry of Walpole, the neutrality of England was preserved during the wars on the continent. In 1739 the depredations committed by the Spaniards in America on the commerce of England led to war, which brought about the resignation of Walpole in 1742. England next took part in the war of the Austrian Succession, in which George II. himself shared, being present at the battle of Dettingen, in 1743. His reign is also memorable on account of the second Jacobite rising in Scotland in 1745–6, headed by Prince Charles Edward. In 1755 the disputes between Great Britain and France in relation to their respective boundaries in Canada produced hostilities in that country, and an open war between the two nations the following year. The events of this war, in which the principal powers of Europe became engaged, raised Great Britain, under the able auspices of Pitt (first earl of Chatham), to the pinnacle of power. George II. was a prince of very moderate abilities, parsimonious, and wholly regardless of science or literature; hasty and obstinate, but honest and open in his disposition. His queen, the cultivated and well-informed Caroline, acquired a great ascendency over him, which did not, however, prevent some of the irregular attachments so common with royalty. See Hervey, 'Memoirs of the Reign of George II.' (1854); Walpole, 'Memoirs of the Last Ten Years of the Reign of George II.' (1822–46); Schmucker, 'History of the Four Georges' (1860); Thackeray, 'The Four Georges' (1860); Jesse, 'Memoirs of the Court of England from the Revolution of 1688 to the Death of George II.' (1843).

George III., king of Great Britain: b. London 4 June 1738; d. Windsor 29 Jan. 1820. He was the eldest son of Frederick, Prince of Wales, by the Princess Augusta of Saxe-Gotha. On the death of his father in 1751, his education was entrusted to the Earl of Harcourt and the Bishop of Norwich; but the formation of his opinions and character seems to have been materially influenced by the maternal ascendency of the princess dowager, who was principally guided by the counsels of the Earl of Bute. George III., who had been previously created Prince of Wales, ascended the throne on the demise of his grandfather, George II., being then in his 23d year. In the following year he married the Princess Charlotte Sophia of Mecklenburg-Strelitz, a union which in its result operated materially on the domestic character of this reign. In 1763 the Seven Years' war was concluded by the Peace of Paris under the ministry of Lord Bute. In 1764 Mr. George Grenville, who had become premier by the retirement of the Earl of Bute, began those measures in relation to the American colonies, the consequences of which proved so momentous; and the Stamp Act was passed the following year. About the same time, in consequence of some appearances of the mental derangement of the king, a bill was passed to enable his majesty to appoint the queen, or any of the royal family residing in England, guardian to his successor, and regent of the kingdom. In 1766 the Rockingham administration repealed the American Stamp Act; at the same time passing a declaratory act asserting the right of taxing the colonies. The Rockingham cabinet was dissolved 30 July 1766, and succeeded by one formed by Pitt, now earl of Chatham. In 1768 Lord Chatham, disgusted with the conduct of his colleagues, resigned the privy-seal, and was succeeded by Lord Bristol. The same year was distinguished by the return of John Wilkes for Middlesex, and the popular tumults attendant upon his imprisonment and outlawry. In 1773 the discontents in America burst into an open flame, and a royal message, in the commencement of the session of 1774, called on Parliament to maintain the English supremacy. Notwithstanding the subsequent loss of an empire, George III., by the steadiness with which he put down the coalition administration, acquired a degree of popularity which never afterward entirely deserted him. The smooth course of the early years of the administration of Pitt materially added to this disposition, which exhibited itself very strongly when the constitutional malady of the king again displayed itself in 1789, and still more upon his subsequent recovery. In reference to the French Revolution, and the important contests which arose out of it, it is sufficient to remark that George III. zealously coincided in the policy adopted by his administration. A similar observation will apply to the domestic, and Irish and Indian policy of the Pitt cabinet; as also to the transactions connected with the Irish rebellion. George III. was immovable in his opposition to the demands of the Irish Catholics, and, seconded by the influence of the Church and the popular feeling, was enabled to eject the Fox and Grenville administration, which succeeded on the death of Pitt. The proceedings of the Perceval administration, until the final retirement of the king in 1810, need not be detailed here; while the insanity of the monarch renders the interval which elapsed from his retirement to his death a blank in his biography. George III. possessed personal courage and steadiness of character in a high degree. Of a plain, sound, but not enlarged understanding, he acted upon his convictions with sincerity. His tastes and amusements were plain and practical. Literature and the fine arts engrossed but a small share of his attention, and hunting, agriculture, mechanical contrivances, and domestic intercourse, seem to have chiefly occupied his leisure. Religious, moral, and temperate, the decorum of his private life was always exemplary. His deportment as a father and a husband, according strictly with the national notions of propriety, rendered him and the queen a constant theme of praise; and the throne was regarded as a pattern in respect to the conjugal duties. See Walpole, 'Memoirs of the Reign of George III.' (1894); Massey, 'History of England During the Reign of George III.' (1855).

George IV. (George Augustus Frederick), king of England: b. London 12 Aug. 1762; d. Windsor 26 June 1830. He was the son of George III. and the Princess Charlotte of Mecklenburg-Strelitz. His dissipated life, his extravagance, his supposed marriage with a Roman Catholic, Mrs. Fitzherbert, and his connection with the most prominent members of the Opposition, alienated from him the affection of his father and the esteem of the nation. In 1795 he consented, on condition of the payment of his debts, to marry the Princess Caroline of Brunswick, but he soon began to treat her with neglect, and after the birth of their daughter, Charlotte Augusta, abandoned her. (See Caroline Amelia Elizabeth.) On 3 Feb. 1811, he was appointed regent, with limited powers, on account of the king being attacked the previous year by a repetition of the mental malady to which he was subject. The Whigs, his former friends, now hoped to come into office, but the prince showed a sudden change of sentiments, and maintained the Perceval ministry in power. The distress caused by the interruption of the demand for manufactures, and the high price of the means of subsistence after the general peace of 1815, occasioned great discontent among the people, and the violent measures adopted by the government increased the unpopularity of the regent, upon whose life an attempt was made in 1817 when he was going to open the session of Parliament. In 1820 he became king, on the death of George III. In February 1827, Canning became head of the government. The most important event after his attaining the throne was the passing of the Catholic Emancipation Act, by the Wellington ministry, in 1829. George IV. left no descendants, his only daughter, the Princess Charlotte, wife of Leopold of Saxe-Coburg, having died childless in 1817. He was therefore succeeded by his brother William, Duke of Clarence (William IV.). See McCarthey, 'History of the Four Georges and of William IV.' (1884–1901); Thackeray, 'The Four Georges' (1860); Cooly, 'Life of George IV.' (1830); Lady Bury, 'Diary of the Times of George IV.' (1838).

George I., king of Greece, with the title, King of the Hellenes: b. Copenhagen 24 Dec. 1845. He was second son of the king of Denmark. In 1863 he was elected king by the Greek National Assembly. In 1867 he married the Princess Olga, a niece of the Russian czar. His conduct as a constitutional monarch has been always correct and regular, and he won the popular sympathies by the efforts he made on behalf of the expansion of Greek nationality. His children have been bred in the Greek faith.

George V., king of Hanover: b. Berlin 27 May 1819; d. 12 June 1878. He was son of Ernest Augustus. He ascended the throne of Hanover in 1851; in the war between Prussia and Austria in 1866 took side with the latter, and in the same year was removed by Prussia, which annexed the kingdom on 20 September. As ex-king he assumed the titles of Duke of Cumberland and Teviotdale (Great Britain) and Earl of Armagh (Ireland).

George II., duke of Saxe-Meiningen: b. Meiningen 2 April 1826. He was educated at Bonn, received the commission of major in the Prussian cuirassier-guards, succeeded to power upon the abdication of Duke Bernhard, his father, in 1866, and served in the Franco-German war as Prussian general of infantry. Assisted by the manager Cronegk he did much to improve the artistic presentation of German drama.

George, prince of Denmark: b. 1653; d. 1708. He was son of King Frederick III., and husband of Queen Anne of England. He sided with William of Orange in the Revolution of 1688, and received the title of Duke of Cumberland. Later he became grand-admiral. From his favorite exclamation he was jocosely known as *Est-il-possible*.

George, Greek prince, 2d son of George I., king of the Hellenes: b. Corfu, Ionian Islands, 25 June 1869. He was appointed lieutenant in the Greek navy 19 July 1889. While traveling in Japan, in 1891, with his cousin, the grand-duke (afterward Nicholas II.) of Russia, he rescued the latter from death at the hands of a religious fanatic. He was appointed high commissioner in Crete in December 1898.

George, duke of Clarence, and brother of Edward IV., king of England; d. 1478. He espoused the cause of Henry VI. and his queen, Margaret of Anjou, against his brother and sovereign. Some years afterward he was accused of having sought the hand of Mary, duchess of Burgundy. He subsequently married a daughter of the Earl of Warwick (the "kingmaker"), and joined him in his revolt against the royal authority. Being taken prisoner, he was condemned to death. The unfortunate prince, being allowed to choose the mode of his death, is said to have drowned himself in a butt of Malmsey wine.

George, Ernest, English architect: b. London 13 June 1839. He studied at the Royal Academy and received the queen's gold medal of the Royal Institute of British Architects in 1896. He has conducted extensive restorations, etc., at Welbeck Abbey and has built various country-seats and churches in Devon, Hertfordshire, and other parts of England.

George, Henry, American political economist: b. Philadelphia 2 Sept. 1839; d. New York 29 Oct. 1897. He made his way to California as a sailor in 1858, and worked there as a printer for several years, until he became a reporter for the San Francisco *Times,* and in 1867 the editor of the same paper. In 1871 he published 'Our Land and Land Policy' in which he advocated the single tax theory, later developed more fully in 'Progress and Poverty' (1879). In this latter work, he not only explained his policy of land taxation (see SINGLE TAX), but also attacked the doctrine of Malthus (q.v.), and the "wages fund" theory, advancing the theory that the wages of labor are paid out of the value that the laborer creates, not from a "fund" of capital. The book did not at once attract much attention, and was first widely noticed in England; later attaining great popularity in this country. George visited England in 1880–1, and on his return settled in New York, where he devoted his time to writing, and agitation and organization for the single tax movement. In 1886 he was nominated for mayor of New York by the United Labor party, but was defeated, though receiving over 67,000 votes. In 1897 he was again nominated for mayor and took an active part in the campaign, but died before election day. His works, besides those already mentioned, include: 'The Irish Land Question;' 'Social Problems' (1883); 'Property in Land;' 'The Condition of Labor;' 'Protection or Free Trade' (1886.

George, Hereford B., English writer: b. Bath, Somerset, 1838. He was educated at Winchester and Oxford, was called to the Bar in 1864 but returned to Oxford in 1867, and was tutor at New College, Oxford, till 1891. He has published: 'The Oberland and Its Glaciers;' 'Genealogical Tales Illustrative of Modern History;' 'Battles of English History;' 'Napoleon's Invasion of Russia;' 'The Relations of Geography and History;' etc.

George, James Zachariah, American politician: b. Monroe County, Ga., 20 Oct. 1826; d. Mississippi City, Miss., 14 Aug. 1897. He fought in the ranks in the Mexican war, afterward studied law, became brigadier-general in the Confederate army during the Civil War, and in 1879–81 was chief justice of the supreme court of Mississippi. In 1880 he was elected to the United States Senate as a Democrat, and in 1886 and 1892 was re-elected. As a jurist he aided in drafting the present State Constitution of Mississippi, and in the Senate he was well known as an orator.

George, William Reuben, American philanthropist: b. West Dryden, N. Y., 4 June 1866. From 1880 he was in business employment in New York. His study of conditions among poor children resulted in the formation of the George Junior Republic (q.v.), of which he became director.

George Eliot. See ELIOT, GEORGE.

George Sand. See SAND, GEORGE.

George Junior Republic, the community established (1895) near Freeville, N. Y., by W. R. George (q.v.) as a method of reform in the treatment of dependent and delinquent children. The organization is that of a miniature republic, with a constitution and machinery of government based on that of the United States. Originally the founder was president with other adults in the more important posts, but from 1896 all offices have been held by citizens. Each citizen may work for the founder or for other citizens who contract for labor. All purchase is made by the Republic's aluminum coin, later redeemed by United States currency. School is held, and farming, carpentry, printing, care of the establishment, dressmaking, domestic service, and cookery are the other activities followed. The entrance age is from 12 to 18.

George, Lake, in the eastern part of the State of New York, is one of the most beautiful, noted, and picturesque lakes in the world. It is fed mostly by ice cold springs, there being less than half a dozen living streams flowing into it. Its outlet is Lake Champlain in the Saint Lawrence river basin. It is the headwaters of one of the most noted of the Saint Lawrence valleys. It narrows at its outlet and the waters enter Lake Champlain by a short creek, which has a descent of about 230 feet in a mile with a series of cascades and an abrupt fall of 30 feet at Ticonderoga. Its length is about 36 miles, and it is 346 feet above the sea, and at its headwaters it is 247 feet above Lake Champlain.

In 1609 Champlain sailed up the lake which bears his name, and Indians told him of the beautiful water called Andiatarocti (Place Where the Lake Contracts) but there is no record that he ever saw Lake George. Father Jogues, a Jesuit missionary, first saw the lake on 29 May 1646, and because it was the eve of Corpus Christi he called it Lac du St. Sacrament, or Lake of the Blessed Sacrament, a name which it retained until it was changed by Gen. William Johnson, 28 Aug. 1755, and given that of Lake George, after George II. The name "Horicon" given it by Cooper, is an historical fraud, the creation of the novelist's brain.

This lake is on the direct route of travel which was used in the early days of exploration and colonization in journeying to and from Canada and New York. It was on the Great War Trail of the Nations, and was in turn under the control of the French, the English, and the Colonists, while our country was in its formative stage. During the French and Indian War, forts were built at Carillon (Ticonderoga) by the French, and at the head of Lake George (Fort William Henry, Fort George, and Fort Gage) by the English. It has been the scene of numerous bloody contests, between the whites and the Indians, the French of Canada and the English of the colonies. The encounter known as the "Battle of Lake George" occurred 8 Sept. 1755, between the French and Algonquins under Baron Dieskau, and the English and Iroquois under Sir William Johnson, with an Indian chief, King Hendrick, in charge of the Indians. A monument commemorative of this battle was unveiled at Lake George 8 Sept. 1903. It consists of heroic figures of Sir William Johnson and Chief Hendrick, designed by Albert Weinert. The State of New York has purchased here a large tract of land, containing the battlegrounds and Fort George, the reservation being known as "Battle Park." A few miles to the south King Hendrick fell, while a monument marks the spot where Col. Ephriam

Williams, founder of Williams College, met his death. Among the more important were the siege by Montcalm, capture and massacre at Fort William Henry 9 Aug. 1757; the gathering of Lord Abercrombie's great army, its defeat, and death of Lord Howe at Ticonderoga, 5-8 July 1758; the building of Fort George, advance down the lake and capture of Fort Ticonderoga by Lord Amherst, July 1759; capture of Fort Ticonderoga by Ethan Allen, May 1775; removal of guns and stores over the lake, winter of 1775-76 to Boston by Col. Henry Knox; and occupancy by American forces, spring 1776, followed by devastating smallpox epidemic; seizure by General Burgoyne, summer 1777; unsuccessful attack on Diamond Island by Americans under Colonel Brown on English forces, 22 Sept. 1777; capture of Fort George by Major Christopher Carlton (English) Oct. 1780; visit of General Washington and staff, July 1783.

The State has bountifully stocked its waters with fish. Deer, black bear, rabbits, partridges, foxes, minks, and rattlesnakes are to be found among its mountains, and ducks, eagles, gulls, and all kinds of wild birds fly above its waters. The lake is surrounded by mountains, the most striking of which are Prospect (1,800 ft.), Buck (2,000 ft.), Tongue, with its succession of mounts, Erebus, Shelving Rock, Black (2,315 ft.), Anthony's Nose, named after Anthony Wayne, and Rogers' Slide, after the fabled exploit of Rogers the Ranger, in 1757-58.

Lake George has more than 200 islands, among the largest of which are Long and Big Burnt Islands; Dome Island is the highest, Green Island is the most beautiful, and Diamond the most celebrated historically and sentimentally; Tea — so-called from "a tea house" erected there in 1828; Recluse and Floating Battery, occupied by Abercrombie 1758; Fourteen Mile, used by Burgoyne's forces for camping purposes; Harbor Islands, scene of a bloody conflict 25 July 1757 between French and Indians and English; and Prisoners', at foot of lake, used by the French as a place of confinement for captives. "The Narrows," half way down, are narro passages in the lake, filled with large and small islands, known generally as the "Hundred Islands."

There are many indentations in the lake line, some forming large bays. The best known are Dunham's, Kattskill, Bolton, Northwest, in itself a considerable lake; Fourteen Mile, and Paradise, the most beautiful bay in the world. The lake is well served by three fine steamers run in connection with the D. & H. Railroad and Champlain Transportation Line. The principal villages on the lake are — Lake George, at the head, located in the town of Caldwell (pop. [1900] 534); Bolton Landing, and Hague, near which are the Dixon graphit mines, the largest of their kind in existence. The ruins of Fort Ticonderoga (q.v.) are not far from the foot of the lake. Geologically, Lake George is thought to be a formation of the glacial age. To the mineralogical expert specimens of value are readily accessible in the surrounding mountains. Garnets, resinites, cocolite, pyroxene, sphene, graphite, and tourmaline are found at Rogers' Slide; feldspar, hermatite at or near Anthony's Nose; while the beach sands contain powdered garnet, amethyst, crystal quartz, magnetic sand, and epidote; on Diamond Island are found quartz crystals; gold in nonpaying quantities has also been discovered.

James A. Holden.

George, Order of St. See Garter, Order of the; Orders (Royal): *Russia, Bavaria, Hanover, Sicily, Great Britain.*

Georgetown, capital of British Guiana, situated on the eastern side of the Demarara River, at its mouth, with the Caribbean Sea for a second frontage. The city covers an area of 1,200 acres. Nearly every building is isolated from its neighbor and surrounded by palms, shrubs, or forest trees. The streets cross each other at right angles; those which run north and south in some cases have long canals in the centre, beyond which are the roadways — the width of such streets being more than 100 feet. On Main (or High) street are situated the town-hall, Victoria law courts, police magistrate's office, Colonial Bank, Presbyterian Church, Portuguese Roman Catholic Church, and the Methodist Church. The public buildings, where the Court of Policy sits, and the Anglican Cathedral are also in this section. Another fine street is the Brick Dam, the two rows of houses in which constituted the entire town of Stabroek before the colony was captured by the British. The finest building in the colony, the Roman Catholic Cathedral, stands a short distance east of this street. The Royal Mail Company, with its fortnightly mail service, makes the port of Georgetown a terminus; boats of the French Compagnie Generale Transatlantique call monthly on the way to Cayenne; the Dutch Mail does the same when going to Surinam; and steamers of a Canadian line also call every fourth week. Vessels drawing more than 20 feet cannot cross the bar at the mouth of the river, and those of even lighter draught are obliged to wait for high water. A line of steamers subsidized by the government makes daily trips from Georgetown to Essequebo; three times a week a steamer runs to Berbice; twice a week up the Demarara and Berbice rivers; and there is fortnightly communication by boat with Morawhanna, the capital of the northwestern district. A railway connects Georgetown with Mahaica, on the east coast. The West India & Panama Telegraph Company also puts the city and colony in communication with other countries. There are good streetcar and telephone services. The city water, brought from creeks 20 miles distant through the Lamah Canal, is chiefly valuable in case of fire; it is not sufficiently pure for household use. The city is lighted by gas and electricity. Municipal affairs are managed by a mayor and town council. The value of real property is nearly $8,000,000; the portion held by Europeans and creoles (other than Portuguese) being valued at $4,611,575; the portion held by Portuguese at $1,938,370; by East Indians, $101,930; and by Chinese, $45,750. The tax-rate is usually 2 per cent per annum on the appraised value of private property. There is a well-equipped and trained fire brigade. Among the important institutions are the Royal Agricultural and Commercial Society, which has a library of over 17,000 volumes, and maintains reading-rooms, etc.; the Institute of Mines and Forests, and the Chamber of Commerce. Of the newspapers, one is issued daily, and a number weekly, bi-weekly or tri-weekly. The port is regarded as healthy. There were two or three severe attacks of yellow fever half a century ago; but since that time the drainage has been improved, and the neighborhood of the wharves kept clean, and during the past 50 years only one serious outbreak has occurred. The number of inhabitants is given as 53,176. (See GUIANA, BRITISH.) Consult Rodway, 'Handbook of British Guiana.'

MARRION WILCOX,
Authority on Latin-America.

Georgetown, Col., a town and the county-seat of Clear Creek County; situated at an altitude of 8,475 feet, in a picturesque valley in the heart of the Rocky Mountains, 52 miles west of Denver on Clear Creek and the Colorado & Southern railway. It is the centre of an important silver district, and has also important gold-mining interests. There are several public parks, and gas, water, and electric-light plants. Pop. (1900) 1,418.

Georgetown, Del., a town and the county-seat of Sussex County, 40 miles south by east of Dover; on the Philadelphia, Wilmington & Baltimore railway. It is situated in an agricultural section. The chief interest is the canning industry. Pop. (1890) 1,353; (1900) 1,658.

Georgetown, D. C., at one time a town in the District of Columbia; now included within the limits of Washington (q.v.), and sometimes called West Washington. It was at the head of Potomac navigation, and the port of entry for the District of Columbia.

Georgetown, Ky., a city and the county-seat of Scott County, 12 miles north of Lexington and 20 miles east of Frankfort; on the Frankfort & C., the Cincinnati, N. O. & T. P., and the Louisville S. R.R.'s. It is in the heart of the "blue grass" region, and the centre of an important stock-raising and agricultural district. Flouring-mills, brick-works, and other industries are also located here. Georgetown College (q.v.) is here situated. The "Royal Spring," which rises in the centre of Georgetown and furnishes about 200,000 gallons of water per hour, supplies the municipal water plant and affords the power for the street railway, an ice plant, a flour mill, and other establishments. Georgetown was settled in 1776, incorporated in 1790, and received its charter in 1894. The government is administered by a mayor, chosen for four years, and municipal council, elected on a general ticket. Pop. (1900) 3,823.

Georgetown, Ohio, a village and the county-seat of Brown County, 42 miles east by south of Cincinnati and 7 miles north of the Ohio River; on White Oak Creek and the Cincinnati, Georgetown & Portsmouth railway. It is the centre of an agricultural region, the growing of tobacco being an especially important industry. There are also some manufactures, and blue limestone is quarried in the vicinity. Pop. (1900) 1,529.

Georgetown, Ontario, a town of Halton County, 25 miles west of Toronto; on Credit River and the Grand Trunk railway. The water-power is excellent. There are paper-mills, knitting-machine manufactories, and knitting and woolen factories. Pop. (1901) 1,313.

Gorgetown, P. E. I., town and port on the eastern coast; by rail 39 miles east of Charlottetown. It is the chief winter port of the island. Pop. about 1,500.

Georgetown, S. C., a city and the county-seat of Georgetown County, about 55 miles northeast of Charleston; at the head of Winyah Bay and on the Georgetown & Western railway. It is a port of entry and a seaport of considerable importance, being the central market for an excellent agricultural region whose rivers, with a total navigable distance of 1,000 miles, empty into Winyah Bay. There are exports of rice, pine lumber, turpentine, fish, cotton, shingles, and other commodities. Georgetown was first settled about 1700 and was incorporated in 1805. The Marquis de Lafayette landed here at the beginning of his first visit to the United States (1784). The government is by a mayor, biennially elected, and a municipal council, chosen at large. Pop. (1900) 4,138.

Georgetown, Tex., a city and the county-seat of Williamson County, 30 miles north of Austin; on the San Gabriel River and a branch of the International & Great Northern railway. The surrounding region is an agricultural one. Georgetown has cotton-gins, cottonseed-oil mills, and planing-mills, and manufactories of plows, ice, harness, and woodwork. Here are located mineral springs whose waters are similar to those of the well-known springs at Karlsbad, Germany. Georgetown is also the seat of Southwestern University, an institution of the Methodist Episcopal Church, South, founded in 1873. It was settled in 1854, incorporated in 1874, and is governed by a mayor and council, biennially chosen. Pop. (1900) 2,790.

Georgetown College, Ky., a coeducational institution in Georgetown, founded in 1829 under the auspices of the Baptist Church; reported at the close of 1900: Professors and instructors, 19; students, 360; volumes in the library, 12,000; productive funds, $235,000; grounds and buildings valued at $194,000; income, $23,500; number of graduates, 580.

Georgetown University, D. C., an institution of higher education, under the direction of the Roman Catholic Church. The plan of the institution was undertaken as early as 1785 by the Rev. John Carroll, later first archbishop of Baltimore. In 1786 the corporation of clergymen in the chapter held at Whitemarsh, Md., adopted a series of resolutions directing the establishment of the institution and the erection of its first building. The year 1789 is generally considered the year of the foundation of the university, though students were not received until 1791. Upon the reorganization of the Society of Jesus in Maryland in 1805, the Georgetown College, as it was then called, was transferred to that society, under whose direction it still remains. In 1815 the university was empowered by act of Congress to confer any degree in the arts, sciences, and liberal professions which are conferred in other colleges and universities, and, in 1833, the Holy See empowered the university to confer, in the name of the Church, degrees in philosophy and theology. The university is composed of the college; the school of medicine, organized in 1851 and including since 1901 a school of dentistry;

and the school of law, organized in 1870. The college comprises three distinct departments, the graduate school, the undergraduate department, and the astronomical observatory. A preparatory department is also connected with the university. The teaching of the university is guided by the principles of the Ratio Studiorum, formulated by the Jesuit order, and a strict standard of scholarship is maintained. The facilities of the university include the Coleman Museum of Natural History, the Beauchamp Hughes Art Cabinet, and the Riggs Memorial Library. In 1904–5 there were reported a faculty of 140 and a student enrolment of 544.

George Washington University, The (formerly Columbian), a non-sectarian university with graduate departments for post-graduate and professional studies, and colleges conducting undergraduate, technical, and specialized work, located in Washington, D. C.; organized by special act of Congress in 1821 and by special amendatory acts of Congress. The University is divided first into departments for graduate work: a department of arts and sciences leading to the masters' degrees and the degree of doctor of philosophy; a department of politics and diplomacy, leading to the degrees of master of diplomacy and doctor of philosophy; a department of medicine comprising a four-year course, leading to the degree of doctor of medicine, and a three-year course leading to the degree of doctor of dental surgery; a department of law and jurisprudence with a three-year course leading to the degree of bachelor of laws, a fourth year additional leading to the degree of master of laws, a graduate course of one year leading to the degree of master of patent law, and a three-year course for graduate students in arts and law, leading to the degree of doctor of jurisprudence; Columbian College for undergraduates with courses leading to the degrees of bachelor of arts and bachelor of science; Washington College of Engineering, with courses for undergraduates leading to the degrees in engineering; and a division of architecture with courses for undergraduates and graduates leading to the degrees in architecture.

By an act of Congress amending the charter, approved 3 March 1905, colleges may be organized under the charter of the University upon independent financial foundations, but educationally a part of the University, for educational work in arts, sciences, liberal and technical knowledge. The University reported (1904–5): professors and instructors, 186; pupils, 1,408.

Otis D. Swett,
Registrar.

Georgia, in Europe (by the Russians called Grusia, by the natives Karthli), formerly a kingdom, but now included in the Russian government of Tiflis and Kutais, though the name is sometimes loosely employed to designate a much larger portion of the territory possessed by Russia south of the Caucasus. Area, in the latter sense, about 34,000 square miles; of Georgia proper, about 15,000 square miles; pop. 2,110,000. The history of the Georgians first becomes trustworthy about the time of Alexander the Great, to whom they became subject. After Alexander's death, in 323 B.C., they gained their independence under Pharnvas. The country was then governed by various dynasties of kings. Christianity was introduced toward the close of the 4th century; soon after the death of Mohammed, numerous followers of his entered the country and compelled the inhabitants to accept Islam. In the 11th century Georgia was twice invaded by the Seljuk Turks, and in the 13th, after widespread devastation, was captured by the Mongols under Timur. The Mongols were expelled in 1403 by George VII. In the 16th and 18th centuries Georgia was harried by the Persians, and at the same time the Turks were continually making encroachments. Aga Mohammed Shah in 1795 razed Tiflis to the ground, the king, Heraclius II., abandoning all resistance and taking refuge in the mountain fastnesses. In 1799 George XIII. formally resigned the crown in favor of the Emperor Paul of Russia, and in 1801 Russia annexed the country. Consult: Brosset, 'Eléments de la Langue Georgienne' (1837); Chubinov, 'Russian-Georgian Dictionary' (1846; new ed. 1886); Leist, 'Georgische Dichter Verdeutscht' (1887); Wardrop, 'The Kingdom of Georgia' (1888). See Georgian.

Georgia, the last settled of the 13 original States of the American Union; bounded on the north by North Carolina and Tennessee, on the northeast by South Carolina, on the east by South Carolina and the Atlantic Ocean, on the south by Florida, and on the west by Alabama; capital, Atlanta; area 59,475 square miles, of which 495 are water. Pop. (1900) 2,216,331, of which the white population numbers 1,181,109 and the colored 1,034,998.

Topography.— The northeastern part of Georgia is traversed by that part of the Appalachian chain of mountains known as the Blue Ridge, which in Georgia has an altitude of from 3,000 to 5,000 feet above sea-level. After running one third the distance across the State, it terminates abruptly, but appears again in short ranges and detached peaks. Northwest Georgia, the limestone region embracing about 3,600 square miles, has an altitude ranging from between 600 and 700 to 2,500 feet above sea-level. About 6,000 square miles of northern Georgia are above the altitude of 1,000 feet. About 20 miles to the west of the Blue Ridge lies the Cohutta Range, a continuation of the range known in Tennessee as the Unaka. The Cohutta has an altitude of 3,000 feet above sea-level with an abrupt escarpment toward the valley of the Oostenaula on the west, and then continues into Alabama in a low elevation called Dugover Mountain. To the northwest are Lookout and Sand Mountain ranges, which with their table-lands constitute a part of the Alleghany range, which, like the Blue Ridge, belongs to the great Appalachian system.

High Point, the loftiest part of Lookout Mountain, has an elevation of 2,408 feet. Its northeastern spur, called Pigeon Mountain, has an elevation of from 1,800 to 2,000 feet above the sea, its highest point rising to 2,331 feet. Another spur of Lookout, called Round Mountain, has an elevation of over 2,200 feet. Taylor's Ridge and its prolongation, called the White Oak Mountains, rise to an elevation of from 1,300 to 1,500 feet above sea-level. A little farther south, Rocky Face Ridge, with an elevation of from 1,500 to 1,700 feet, forms the

eastern watershed of Chickamauga Creek (or river, as it is sometimes called), which flows through the valley at an elevation of 900 feet above the sea. There are several detached peaks, among which the most noted are Pine, Lost, and Kennesaw Mountains, the last named with its double peak rising to the height of 1,809 feet. In De Kalb County, 14 miles east of the city of Atlanta, in a comparatively level country, Stone Mountain, a vast mass of granite, rises to the height of 1,686 feet.

One of the most prominent features of northeast Georgia is the Blue Ridge chain of mountains, already mentioned. Some of the peaks of this chain rise to an elevation of 5,000 feet. The following is a list of the most noted of the mountain peaks of Georgia with their height above the level of the sea: Sitting Bull (middle summit of Nantahela) in Towns County, 5,046 feet; Mona (east summit of Nantahela) 5,039 feet; Enota in Towns County, 4,797 feet; Rabun Bald, in Rabun County, 4,718 feet; Blood, in Union County, 4,468 feet; Tray, in Habersham County, 4,403 feet; Cohutta, in Fannin County, 4,155 feet; Dome, in Towns County, 4,042 feet; Grassy, in Pickens County, 3.290 feet; Tallulah, in Habersham County, 3.172 feet; Yona, in White County, 3,167 feet. In all the mountain section of Georgia are charming valleys abounding in very productive lands. The most noted are Cedar, Texas, Broomtown, and Vann's valleys in northwest Georgia, and Nacoochee (Evening Star) and Santee valleys in the northeast section of the State. Among the interesting features of northwest Georgia are numerous caves. Hardin's Cave, near Kingston, has chambers 20 to 30 feet high. Middle Georgia is the most thickly settled section of the State. With the exception of two mountains, this region varies in altitude from 180 to 500 feet, and in a few instances to 1,000 feet. Lands too steep for the plow are seldom found in middle Georgia.

South Georgia embraces more than half the area of the State and extends from the southern limit of middle Georgia to Florida and the Atlantic coast. Its altitude ranges from 100 to 500 feet. About 3,000 square miles of the coastal region have an elevation of 100 feet.

Rivers.— The drainage system of Georgia comprises nine basins. The Tennessee basin is drained by tributaries of the Tennessee River. The Mobile basin is drained into the Gulf of Mexico by the Coosa and Tallapoosa rivers, and their tributaries. The Apalachicola basin is drained by the Chattahoochee and Flint rivers. These, uniting in the southwestern corner of Georgia, form the Apalachicola River which, flowing through Florida, empties into a bay of the same name, an arm of the Gulf of Mexico. The Altamaha basin is drained by the Oconee and Ocmulgee rivers, which empty into the Altamaha, flowing into the Atlantic Ocean. The Ogeechee basin is drained by the Ogeechee River into the Atlantic Ocean through Ossabaw Sound. The Savannah basin is drained by the Savannah River and its tributaries into the Atlantic Ocean. The Ocklockonee basin is drained by the river of that name into the Gulf of Mexico through Ocklockonee Bay. The Suwanee basin is drained by the river of that name into the Gulf of Mexico. Although the Suwanee runs for the greater part of its course through the State of Florida, it rises in southeast Georgia, and two of its main tributaries, the Allapaha and Withlacoochee rivers, are streams of south-central Georgia. The Satilla and St. Mary's basin is drained by the Satilla and St. Mary's rivers. The Satilla is the more northern and enters the Atlantic through St. Andrew's Sound. The St. Mary's enters the Atlantic Ocean through Cumberland Sound. Between these rivers lies the noted Okefinokee swamp. Its numerous large rivers furnish the State with excellent water transportation. Although the extensive railroad lines have built up in Georgia flourishing cities and towns remote from any water highway, yet those which are upon navigable streams enjoy the advantage of a competing water line. The Savannah is the most important river of Georgia for the reason that over 18 miles of its course is navigable for ocean vessels. The Savannah is navigable for river steamboats to Augusta, 230 miles to the north. The Chattahoochee is navigable for steamboats from Columbus to the Apalachicola and through that stream to the Gulf of Mexico. Through its several steamboat lines Columbus has a considerable river trade. The city of Rome in northwest Georgia has besides its several railroad lines a fine river trade through the Oostanaula and the Coosa. Steamboats carry to Rome the productions of the Coosa valley, lumber, iron, grain, and cotton, and the staple products of the Oostanaula valley. Albany, in southwest Georgia, enjoys an extensive steamboat traffic by the Flint River. The St. Mary's River is navigable for the largest vessels up to and beyond the town of that name, which is nine miles from the ocean. The Satilla and Ogeechee are each navigable for some distance, but their advantages have not been utilized to any considerable extent. Other navigable waters of Georgia are the inlets and sounds, flowing between the mainland and the islands that skirt the coast from the Savannah to the St. Mary's rivers. Through St. Simon's Sound the largest vessels pass up the Turtle River, a short but deep stream, to the city of Brunswick, the second in importance of the ports of Georgia, being, like Savannah, the centre of a fine fruit and trucking section. Every section of Georgia is drained by rivers of considerable size, and is consequently a splendid agricultural country. Its numerous navigable streams, supplementing its great railroad system, conspire to give its people unusual advantages for both internal and foreign commerce.

Climate.— Of nine climate belts in the United States eight are represented in Georgia. The lowest of these eight belts in mean annual temperature is below 40°, the highest between 70° and 75°. The climate of less than 40° mean annual temperature is found only on some of the mountain peaks. On the sides of these mountains below the summit the mean annual temperature is between 40° and 45°, corresponding with upper New England and New York and the mountain region of Virginia. There is a still larger climate zone of between 45° and 50° which corresponds with that to be found in portions of New York, Pennsylvania, and Ohio. The zone of between 50° and 55° embraces a narrow strip which runs northward through North Carolina and Virginia up to New Jersey. The zone between 55° and 60° of mean annual temperature contains an area two or three times as large as all the preceding zones together and, passing through both Carolinas, ends in Virginia. The zone between 60° and 65° embraces nearly all of middle Georgia, corresponding with that of upper Alabama, Mississippi, Louisiana, Texas, West Tennessee, and Arkansas, and extends into Virginia. The mean annual temperatures at some of the important stations in this area are: Rome, 61.9; Gainesville, 61.3; Atlanta, 61.4; Carrollton, 62.; Athens, 63.; Augusta, 64.; LaGrange, 64.1; Thomson, 64.7.

The climate of southern Georgia is between 65° and 70° of mean annual temperature and corresponds with that of southern Texas, Louisiana, Mississippi, and upper Florida. At Macon it is 66.1°; Cuthbert, 68.1; Americus, 68.2; Brunswick, 68.7. Blackshear with 70.2° is the only station touching the zone between 70° and 75°. For the whole State the mean temperature for July is 81.8°. The isothermal line of 80°, July temperature, runs above Augusta and Macon to West Point. Above this line embracing the greater portions of north and middle Georgia the July temperature is between 75° and 80°. Below this line, embracing the greater part of East Georgia and nearly all of southeast and southwest Georgia the July temperature is between 80° and 85°. The climate of Atlanta, situated as it is on a ridge 1,050 feet above sea-level, corresponds with that of Washington, St. Louis, and Louisville, the winters being warmer and the summers cooler. Snow seldom falls in southern Georgia, and then rarely to a depth of more than two inches. In middle Georgia the fall of snow is a little more frequent and to a greater depth, while both its frequency and depth are greatly increased in the mountain region. The annual average rainfall of Georgia is 40.3 inches, the highest being at Rabun Gap, 71.7 inches, the lowest at Swainsboro, 39.4 inches. Atlanta's annual rainfall is 52.12 inches. The average for different sections of the State is: Middle Georgia, 49.7 inches; east Georgia, 41.4 inches, and northwest Georgia, 60.3 inches. The summer rainfall averages: For north Georgia, 13.6 inches; for southwest Georgia, 14.5 inches, and for the entire State, 13.4 inches. The summer rainfall averages at different localities: Rome, 10.2 inches; Atlanta, 10.8 inches; Rabun Gap, 15.4 inches; Americus, 16 inches; Brunswick, 16.6 inches.

Agriculture.— The northwestern section of Georgia presents a great variety of surface and soil. The slopes of the mountains and hills are well suited for the grazing of stock, and abundance of land, either rolling or entirely level in the valleys, is adapted to the raising of vegetables, fruits, corn, wheat, rye, oats, barley, buckwheat, cowpeas, clover, timothy, orchard grass, Bermuda, Johnson, crab, red top, and many other grasses useful for hay and pasturage. Cotton also is a profitable crop as far north as Floyd County, above which very little of this crop is raised. Some of the chief fruits are peaches, apples, pears, cherries, all kinds of berries and grapes of every variety. The forest timbers are oaks of several varieties, pines of two varieties, also the poplar, ash, beech, elm, chestnut, hickory, maple, walnut, iron wood, sugar berry, sycamore, sweet-gum, dogwood, persimmon, sassafras, wild cherry, rosebud, warhoo, cedar, and buckeye. In northeast Georgia but little over 12 per cent of the land is under cultivation, because this part of the State is thinly inhabited; but many of the tillable lands have a very rich, dark red soil. Little Tennessee valley in Rabun County and Nacoochee valley in White County are noted for fertility, bearing all kinds of crops, fruits, and grasses. About 75 per cent of the whole area known as middle Georgia is under cultivation. The central cotton region of the State includes the southern part of middle and large areas of southern Georgia. This region embraces the sand and pine hills belt, the red hills belt, and the yellow loam region. The first of these covers about 3,000 square miles, the other two about 12,000 square miles. Large crops of corn and cotton are raised throughout this area except in the sand hills belt. In the long-leaf pine region there are 17,000 square miles, and here the vast forests of long leaf pine are a great source of wealth to the State. Wherever the timber lands are cleared, they are being put under cultivation. The marls and swamp muck found in this section, when mixed, form a cheap and excellent fertilizer. The pine and palmetto flats around Okefinokee swamp furnish large quantities of long leaf pine, cypress, and saw palmetto, while along the creek-bottom and hummock lands are found these same trees, black-gum, tupelo-gum, titi, and maple. The coast region, about 2,045 square miles, includes the savannas, live-oak lands and islands. The coast lands from the Savannah to the St. Mary's River are noted for magnificent live oaks, also red and water oaks, red cedar, hickory, chinkapin, sassafras, cabbage and blue palmetto. Along the coast lands rice is cultivated, and the Georgia sea-islands produce the larger part of the finest cotton known to commerce. All over middle and southern Georgia grows the sugarcane, richer in saccharine matter than any other known plant from which sugar is extracted.

By reason of its more than 4½° of latitude and different altitudes of its various sections Georgia produces the crops and fruits of every section of the Union, and on its sea islands and extreme southern section of its mainland many of those of the tropics, such as oranges, lemons, bananas, etc. Pomegranates and figs are found all over the State.

The census of 1900 gives the total value of Georgia's agricultural products at $86,345,343. Of this amount $42,534,235 represented the value of the cotton crop, and $17,155,868 that of the corn crop. The sugarcane crop brought $1,690,704; Irish potatoes, $326,853; sweet potatoes, $2,354,390; miscellaneous vegetables, $3,009,306. But in that year both the cotton and corn crops were below normal in Georgia. The value of the peach crop that year was insignificant, because of unfavorable seasons. The normal value of Georgia's corn crop for several years has been in the neighborhood of $19,000,000, and in 1902 her cotton crop brought above $69,000,000, these two crops alone showing a greater value than all her agricultural products combined in the census year. The peach trees in commercial orchards number 16,000,000, of which over half are now in bearing. In a good fruit year the produce of these orchards brings into the State many millions of dollars. In any ordinary year the peach crop of Georgia is worth at least $4,000,000, and in some years it will far exceed those fig-

STATE CAPITOL AT ATLANTA.

ures. Georgia outranks all the States in the number and quality of her watermelons.

Stock raising is very profitable to those who engage in it. In southern Georgia cattle and sheep need very little shelter and for only a few weeks of the winter. The total value of all live stock on farms in 1900, including poultry, was $35,200,507 and the total value of all domestic animals not on farms was estimated at $2,281,059, making in all $37,481,566. The number of specified domestic animals on farms in 1900 was: Dairy cows, 276,024; other neat cattle, 623,467; horses, 127,407; mules and asses, 267,840; sheep (lambs not included), 258,894; swine, 1,424,298. Of poultry there were 4,549,144 chickens, 103,416 turkeys, 208,997 geese, and 64,895 ducks. The total value of all the poultry was $1,458,055. There were 187,919 swarms of bees valued at $242,769.

Geology and Mining.— There are three main geological divisions of Georgia. The Palæozoic in the northwest embraces the counties of Dade, Walker, Catoosa, Whitfield, Chattooga, Floyd, and the greater parts of Murray, Gordon, Bartow, and Polk. Cambrian, Silurian, Devonian, and Carboniferous formations are represented. The rocks are chiefly shales, sandstones, limestone, quartzites and cherts. This is a region of parallel valleys and mountain ridges in which are found valuable deposits of coal, iron, aluminum (or bauxite), manganese, and roofing slate. Hydraulic cement rock is found in large quantities in Bartow County. The crystalline area includes that portion of the State not in the Palæozoic area that runs north of a line extending through Columbus, Macon, Milledgeville, and Augusta. In this area are granites, schists, and gneisses, and in the region which borders both the Palæozoic and crystalline areas are found the marbles for which Georgia is so famous. The marble belt traverses Fannin, Gilmer, Pickens, and Cherokee counties, the most important quarries being in Pickens County. Large quantities of granite and gneiss are found in many localities in the crystalline area.

The gold deposits are found in four belts. The first runs through Rabun, Habersham, White, Lumpkin, Dawson, Forsyth, Cherokee, Cobb, Bartow, Paulding, and Haralson counties. The second belt traverses Rabun, Habersham, Hall, Gwinnett, Forsyth, Milton, De Kalb, and Fulton counties. A third belt traverses Cobb, Paulding, and Carroll counties. A fourth belt goes through Lincoln, Columbia, McDuffie, and Warren counties in the southeast part of the crystalline area. There are some irregular deposits in Towns, Union, Gilmer, Fannin, and Meriwether counties. The iron ores are in the Palæozoic area. The brown iron ores are mined in Bartow, Polk, and Floyd counties. The red iron ores are mined in Walker and Chattooga counties. Ochre occurs in Bartow County, manganese in Bartow and Floyd. The largest bauxite deposits are in Floyd and Bartow counties, but it occurs also in Polk, Walker, and Chattooga counties. Corundum deposits are found in Rabun, Towns, Union, Habersham, Carroll, and Heard counties. Laurel Creek mine in Rabun County near the Carolina line is the largest in Georgia, and one of the most noted in the United States. Pyrite is found in Lumpkin County; copper in Murray and Fannin counties, graphite near Emerson; asbestos in several localities in the crystalline area; talc in Murray, Fannin, and Cherokee; mica in Union and Fannin; barite in Bartow. Of precious stones amethysts are found in Rabun County, a few diamonds in Hall County, some good moonstones in Upson County. Rubies and sapphires of small size have been found in the northeast part of the crystalline area. The coal fields of Georgia are in Dade and Walker counties.

Limestone beds of good quality for both calcimining and building purposes are found in the Palæozoic area and in Hall and Habersham counties in the crystalline area. Limestone for calcimining is also found in different localities in the coastal plain region, which takes in all the southern portion of Georgia. In this region are found marls and phosphates. Through all that part of the State north of the fall line, which runs from Columbus through Macon to Augusta are found clays suitable for the manufacture of common brick and the coarser grades of earthen-ware, while immediately below the fall line in a narrow belt across the State are clays suitable for the manufacture of porcelain, enameled brick, china-ware, terra-cotta, sewer pipes, etc. The annual output of all the mineral products of Georgia is nearly $5,000,000.

Manufactures.— Georgia stands in the front rank of the Southern States in the variety and value of its manufactures and the number of its manufacturing establishments. The total value of all its manufactures by the census of 1900 was $89,789,656. The number of establishments engaged in the manufacture of cotton goods was reported as 68, with 817,345 spindles and 19,398 looms. The capital invested was $24,222,169. But in 1901, after a more searching investigation than ever before in regard to the growth of cotton spinning in the South, the United States Department of Agriculture reported that in 1899 there were 79 mills in operation and that in 1900 the number in operation had increased to 86 with 969,364 spindles. The same report stated that during 1900 there were completed 28 more mills and that the stock had been raised and plans prepared for 13 more. This report agrees very closely with one prepared early in 1901 by the Georgia department of agriculture, which gave a list of the mills by name and showed 111 mills in operation with 1,192,486 spindles and 26,645 looms. In bleached cotton goods Georgia stands fourth in the Union with 24,265,583 square yards. The cotton gins reported in the census of 1900 numbered 4,729 running for four months. Eli Whitney was living in Georgia, when he invented the cotton gin. The cotton oil mills in operation in 1901 numbered 58. They paid above $5,000,000 for cotton seed, which they manufactured into various products, valued at $14,000,000. The fertilizer factories registered with the commissioner of agriculture for the season of 1902 and 1903 numbered 82, many of them being of great capacity and having an immense trade all over the Southern States. In the manufacture of turpentine and rosin Georgia easily leads all the States, exporting in 1900 the vast amount of 14,623,328 gallons of spirits of turpentine and 1,408,928 barrels of turpentine, rosin, and pitch. In 1900 there were 1,254 establishments with a capital of $11,802,716 engaged in the lumber industry. Among the other manufactures the most important are printing establishments, flour and grist mills, woolen mills, furniture factories, ornamental iron works, foundries, blast furnaces, carriage factories, car shops, blacksmithing and wheelwrighting, brick, tile and pottery manufactories, marble and stone works, manufactories of paints, chemicals, ice, electric light plants, carpenter work, canning factories, creameries, and numerous others.

Railroads.— The principal railway lines are the Central of Georgia, 1,302.23 miles; Southern, 919.90 miles; Seaboard Air Line, 648.49 miles; Atlantic Coast Line, 607.70 miles; Georgia Railroad, 302.50 miles. There are many other important railroads in the State whose combined mileage is 2,104.50. The total railroad mileage of the State is 6,035.32. Besides these are numerous electric lines in the cities of the State and their suburbs, connecting them in many instances with neighboring towns.

Finances.— In 1903 the assessed valuation of the State was $467,310,646 and the bonded debt $7,531,500 net. The tax rate was $5.30 per $1,000.

Banks.— There are 39 national banks, with a capital stock of $5,046,000, deposits of about $20,000,000, and reserve of about $9,000,000; 243 other banks with about $10,100,000 capital, and over $30,000,000 deposits.

Education.— In addition to her public school system Georgia has numerous private schools and several noted colleges for both sexes. In the public school system there are 7,700 schools, of which 4,919 are for whites and 2,781 for colored. The total number of teachers is 9,180 of whom 5,997 are white and 3,183 colored. The number of normal trained teachers is 2,238, of whom 1,791 are white and 447 colored. The number of pupils admitted during 1901 were 439,645, of whom there were 258,984 whites and 216,359 colored. The average daily attendance was 159,562 white and 105,826 colored, making a total of 265,388. Among the leading higher institutions of learning are: University of Georgia, Athens; and its branches as follows: North Georgia Agricultural College at Dahlonega, Georgia School of Technology at Atlanta, Georgia Normal and Industrial College (for ladies) in Milledgeville, Georgia State Normal School (for both sexes) at Athens, and the Georgia State Industrial College for Colored Youths, near Savannah; affiliated with the University of Georgia, but not receiving State funds: South Georgia Military and Agricultural College at Thomasville, Middle Georgia Military and Agricultural College at Milledgeville, West Georgia Agricultural and Mechanical College at Hamilton. Other noted colleges are: Emory College, Oxford; Mercer University, Macon; Wesleyan Female College, Macon; Shorter Female College, Rome; Agnes Scott Institute, Decatur; Lucy Cobb Institute, Athens; Southern Female College, College Park (near Atlanta); Southern Female College, La Grange; La Grange Female College, La Grange; Andrew Female College, Cuthbert; Monroe Female College, Forsyth; Young Female College, Thomasville; St. Stanislaus College, near Macon; Young L. Harris Institute, Young Harris; Brenau Female College, Gainesville; Piedmont Institute, Rockmart; South Georgia College, McRae. With the exception of the State Industrial College for colored youths, at College near Savannah, all the above-named institutions are for whites exclusively. For the colored people there are the following institutions: Atlanta University, Clark University, Spellman Seminary, Morris Brown College and Gammon University, all at Atlanta; Payne Institute at Augusta, under the auspices of the Methodist Episcopal Church, South.

The number of pupils enrolled in private schools and colleges is 10,097 whites and 4,877 colored, total 14,974.

Religion.— The Baptists have 368,000 members, 3,586 church buildings, and 76,000 Sunday-school pupils; the Methodists have 272,000 members, 3,205 church buildings, and 117,828 Sunday-school pupils; the Presbyterians have 18,000 members, 327 church buildings, and 12,600 Sunday-school pupils; the Congregationalists have 4,714 members, 65 church buildings, and 4,284 Sunday-school pupils; the Episcopalians have 7,070 members, 137 church buildings, and 4,400 Sunday-school pupils; the Disciples of Christ have 9,805 members, 110 church buildings, and 7,147 Sunday-school pupils; the Roman Catholics have 20,000 church members, 40 church buildings, and 2,500 Sunday-school pupils. The Hebrews in Georgia number about 6,200.

Charitable Institutions.— The principal benevolent institutions of Georgia are: the Orphan House at Bethesda, near Savannah, founded in 1739; the State Lunatic Asylum at Milledgeville; Georgia Institute for the Deaf and Dumb, at Cave Spring; Academy for the Blind at Macon; Female Asylum at Savannah; Augusta Orphan Asylum at Augusta; Orphan Home of the North Georgia Conference of the Methodist Episcopal Church South, at Decatur; Orphan Home of the South Georgia Conference of the Methodist Episcopal Church South, at Macon; Mumford Industrial Home for boys and girls, near Macon; Appleton Orphan Home (Episcopal), Macon; Baptist Orphans' Home, Hapeville, near Atlanta; Hebrew Orphan Home, Atlanta; Abram's Home for widows in Savannah.

State Government.— The State Constitution adopted in 1877 carefully guards the rights of the people and prevents extravagant appropriations by the legislature. The governor is elected for two years and receives a salary of $3,000. The state-house officers are: the attorney-general, comptroller-general, adjutant-general, treasurer, secretary of state, state school commissioner, commissioner of agriculture, state geologist, state librarian, commissioner of pensions, three prison commissioners, and three railroad commissioners. The supreme court consists of one chief justice and five associate justices. There are 24 superior court circuits, each having a judge and solicitor. Georgia is represented in the National Congress by two senators and 11 representatives.

Population and Division.— The population of Georgia at each census is as follows: (1790) 82,548; (1800) 162,686; (1810) 252,433; (1820) 340,985; (1830) 576,823; (1840) 691,392; (1850) 906,185; (1860) 1,057,286; (1870) 1,184,109; (1880) 1,542,180; (1890) 1,837,353; (1900) 2,216,331. The total white population in 1900 was 1,181,109 and the total colored 1,034,998. There were also 204 Chinese, 1 Japanese, and 19 Indians. The foreign-born population numbered 7,603 males and 4,800 females. There are 137 counties in the State.

Of 372 incorporated places in Georgia 40 had a population in 1900 of more than 2,000 and 13 of these had a population in excess of 5,000. Atlanta, the capital, had 89,872; Savannah, the chief seaport, had 54,244; Augusta, the greatest cotton manufacturing city of the South, had 39,441; Macon had 23,272; Columbus, the second great cotton manufacturing city of the South, had 17,614. Other cities of the State having over 5,000 inhabitants in 1900 are: Athens, 10,245; Brunswick, 9,081; Americus, 7,674; Rome, 7,291; Griffin, 6,857; Waycross, 5,919; Valdosta, 5,613; Thomasville, 5,322.

History.— A charter for the establishment of the colony of Georgia was obtained from George II., king of England, in June 1732, by a number of benevolent gentlemen of London, whose design was to found a home for the poor of Great Britain and a place of refuge for the Salzburgen and other persecuted sects of the continent of Europe. The colony was also intended as a military settlement to serve as a barrier against encroachments of the Spaniards upon South Carolina. Gen. James Edward Oglethorpe, a man of great liberality and of marked ability and experience in military affairs, being selected by the trustees as governor, brought over 116 emigrants. Landing at Yamacraw Bluff on 12 Feb. 1733, they laid the foundations of the city of Savannah and colony of Georgia. At first rum and slavery were prohibited, but in 1747 these restrictions were removed. During the 10 years of Oglethorpe's administration many settlers of a very desirable kind were brought into the colony, peace with the Indians was secured by treaties, their lands being in every instance procured by purchase, a formidable Spanish invasion was defeated, John and Charles Wesley and George Whitefield preached to the people and Whitefield founded the Orphan Home at Bethesda a few miles from Savannah. In 1752 the trustees of Georgia surrendered their rights to the crown and in 1754 John Reynolds was appointed governor. At the close of the French and Indian war the boundaries of Georgia, which had embraced a territory between the Savannah and the Altamaha rivers, were extended to the Mississippi on the west, and to latitude 31° and the St. Mary's River on the south. Subsequently they were extended on the south to latitude 30° 21′ 39″. Georgia united with the other colonies in resisting the aggressions of the mother country. On 11 May 1775 Col. Joseph Habersham and Commodore Bowen with 30 volunteers seized the powder magazine at Savannah and secured 13,000 pounds of powder, of which the Georgia authorities sent 5,000 pounds to the Continental army at Boston. In March 1776 the Georgians under Col. McIntosh aided by the Carolinians under Col. Bull burned 3 and disabled 6 out of 11 merchant vessels which under the protection of some British war vessels were endeavoring to carry on trade with some loyalist planters. In April 1776 Georgia instructed her delegates in Congress to vote for independence. The signers of the declaration on the part of Georgia were Button Gwinnett, Lyman Hall, and George Walton. In December 1778 the British captured Savannah and early in 1779 Augusta. But the Carolinians under Andrew Pickens and the Georgians under John Dooly and Elijah Clarke by the victory of Kettle Creek recovered Augusta. Subsequently the British defeated Ashe at Brier Creek and repulsed the combined attack of the Americans under Lincoln and the French under D'Estaing at Savannah. This battle at Savannah was one of the most important conflicts of the Revolution. After the fall of Charleston, S. C., in 1780, the British overran all eastern Georgia. But Col. Elijah Clarke made a desperate effort to retake Augusta. Failing he tried again in 1781 and, by the assistance of Pickens and "Light Horse" Harry Lee, succeeded. Almost the last fight of the Revolution was Wayne's victory over the Indian allies of the British near Savannah, 23 June 1782. On 11 July 1782 Savannah was evacuated by the British and the authority of Georgia was established over all her borders. On 2 Jan. 1788 a convention of delegates from the different counties of the State at Augusta ratified the Constitution of the United States on behalf of Georgia.

In 1802 Georgia ceded to the Federal government all her lands west of the Chattahoochee embracing the greater part of the present States of Alabama and Mississippi. In 1807 Milledgeville became the capital. During the second war with Great Britain 1812–15 the Georgians under Gen. John Floyd gained several battles over the Indians and shared with the Tennesseeans in the decisive victories won over the savages by Gen. Andrew Jackson. In the Mexican war Georgia's sons were distinguished, among whom Col. James S. McIntosh was killed at Molino del Rey and W. H. T. Walker was desperately wounded at Chapultepec.

Georgia seceded from the Union 19 Jan. 1861 and furnished to the Confederate army 94 regiments and 36 battalions, embracing every arm of the service. On Georgia soil were fought the battles of Chickamauga, Ringgold, Resaca, New Hope Church, Kennesaw Mountain, Peach Tree Creek, Atlanta, Jonesboro, Allatoona, and numerous smaller engagements and skirmishes. At the close of the Civil War Georgia resumed her career of enterprise in every industrial line, not waiting even for her re-entrance into the Union, which occurred in 1870. During the Spanish-American war Georgia furnished more volunteers in proportion to population than any other State.

Among prominent Georgia citizens have been Gen. Joseph Wheeler, William H. Crawford, John McPherson Berrien, George M. Troup, George R. Gilmer, Herschel V. Johnson, Howell Cobb, Robert Toombs, Alexander H. Stephens, Joseph E. Brown, John B. Gordon, Alfred H. Colquitt, Benjamin H. Hill, Sidney Lanier, the poet; Dr. J. Crawford Long, the discoverer of anæsthesia; Bishop George F. Pierce, Allen D. Candler.

JOSEPH T. DERRY,
Editor of 'Georgia, Historical and Industrial.'

Georgia, South, an island in the South Atlantic, lat. at its north point, 53° 57′ S.; lon. 38° 13′ W. It is 90 miles long, and has high and rocky coasts, inaccessible from ice during a greater part of the year.

Georgia, Strait of, a large inlet of the North Pacific Ocean, between the continent of North America and Vancouver's Island; about 120 miles in length from north to south; the breadth varies greatly in its different parts, from 6 miles to 20. It communicates with the ocean on the north by Queen Charlotte's Sound, and on the south by the Strait of Juan de Fuca.

Georgia, University of, an important university which is at the head of State education in Georgia. It was chartered in 1785 and is the oldest State university. The charter coordinates primary and secondary schools with the university in the scheme of education by the State. The institution was located at Athens, and began academic work in 1801. This is the parent institution and includes four colleges: (1) Franklin College, the college of the liberal arts; (2) State College of Agriculture and the Mechanic Arts, on the Morrill foundation. (3) Law School. (4) Graduate School. The phrase "University of Georgia" in the wider sense includes the various colleges in different parts of the State which are declared by law to be "parts" of the university. These are: North Georgia Agricultural and Mechanical College, at Dahlonega; Medical College, at Augusta; School of Technology, at Atlanta; Georgia Normal and Industrial College, for women, at Milledgeville; State Normal School, for men and women, at Athens; Industrial College, for negroes, at Savannah. The university, in the collective sense, has (1903) 1,884 students of college grade; 156 in professional schools; 585 in preparatory schools; total, 2,527. The members of the faculties number 160. All these institutions are managed for the most part by local boards or commissions, but legal title and control of all of them is vested in the single Board of Trustees of the university. This is a unique feature of organization of the higher education of the State and differentiates it from the system of any other State. Understood in the narrower sense, the single institution at Athens has 359 students, and its income is $50,000 per annum. Among the alumni of national reputation are Howell Cobb, speaker of the House of Representatives and secretary of the treasury; Alexander H. Stephens, John A. Campbell, justice of the United States Supreme Court; senators Robert Toombs, Benjamin H. Hill, Augustus O. Bacon; Joseph and John LeConte, afterward president and professer in the University of California; Henry Timrod, poet; Henry W. Grady and J. L. M. Curry, diplomat and educator. As the university is a State institution, tuition is free for residents of Georgia in all schools except the professional schools; non-residents pay a small fee.

Georgia Bark, a small tree of the Southern States closely resembling the cinchona or Peruvian bark, and belonging to the natural order *Cinchonaceæ*. It has pretty large white flowers, with longitudinal stripes of rose-color, disposed in beautiful clusters at the extremities of the branches; each flower is accompanied with a floral leaf, bordered with rose-color near the upper margin; the corolla is tubular; the stamens five, with a single style; and the capsule contains two cells and numerous seeds. The wood is soft and is therefore unfit to be used in the arts. The inner bark is extremely bitter, and is employed with success in intermittent fevers.

Georgian Architecture, a neo-classic style of architecture that flourished in England from about 1715 to 1800, during the reigns of the four Georges, from whom it derives its name. It was a union of the Italian and Palladian styles divested of excessive ornamentation, and is to be found throughout the United States in buildings of the Colonial period. Among its prominent exponents were Gibbs, Campbell, Chambers, and Dance; Somerset House, and the church of St. Martin's-in-the-Fields, London, are fine types of the style.

Georgian Bay, Canada, formerly Lake Manitoulin, the northeastern part of Lake Huron, partly separated from the main body of the lake by the peninsula of Cabot's Head and the island of Great Manitoulin, province of Ontario. It is about 120 miles long and 50 broad.

Georgian, or **Ibernian**, or **Grusinian**. The people (about 600,000) who speak the Georgian language call themselves Karthveli, but are also named Grusini, and inhabit the valley of the upper and middle Kur, those of the Rion and Tchoruk, as far as the promontories of the Ararat chain, and north to the Alazan, beyond which their language is mixed with the tongues of Shirvan and Daghestan, as far as the Caspian Sea. Probably descendants of the Colchi and Albani, they were anciently called Iberi, and, according to tradition, are akin to the Armenians, although their language differs from the Haikanian (*Somasi* in Georgian), and is believed by their learned prince Theimuraz to be primitive. Brosset and Voss (1847) place it among the Indo-European languages. It consists of several dialects, namely: The Karthveli or Georgian proper in the centre, the Kakheti and Imerethi next, then the Mingreli and Guri, and more remotely the Suani and the Lazi, which reaches almost to Trebizond. A colony transported into Asterabad in Persia in 1622 is said to speak a purer idiom than any of those now spoken in Georgia. Georgian literature is mostly founded on that of Greece. The Bible was partly translated in the 8th century, finished in the 18th, and splendidly printed at Moscow, Tiflis, and St. Petersburg. Arabic and European works have also been translated into Georgian. We can mention but a few of the many remarkable national works. Among the romances are the following: 'Tariel' (Of the Man in the Tiger Skin), by Skhotta of Rusthvel, a general of the heroic queen Thamar, with a commentary by King Wakhtang VI. (Tiflis 1793); 'Daredjamiani' (Deeds of Amiran, son of Daredjan, a hero of Bagdad), by the courtier Moses of Khoni; 'Visramiani' (Love of the Princess Vis for Prince Ramin), somewhat resembling Rousseau's 'Héloïse'; 'Miriani' (story of the Chinese Princess Miri), imitated from the Persian. These and many others exhibit lively imagination and good taste. The 'Thamariani' is a panegyrical epic on Queen Thamar, by Tchakhakhadze. In poetry, there are versions of lyrical poems from the Greek, etc., by Georgi Aphoni (11th century); a collection of historic odes; there is also a very keen satirical work by Bessarion Gabas Khoili. There are many histories of Georgia, chronicles, biographies, histories of families, monasteries, etc. The drama began to be cultivated at a late period, especially by Prince Eristov. Wakhtang VI. established a printing office at Tiflis. There are also there at present a national theatre and opera house. The 'Aurora,' a periodical established in 1857, and the 'Kavkas,' a Russian newspaper, are published at Tiflis.

Geotropism, jē-ŏt'rō-pĭzm, the influence which causes a tendency in plants and animals to grow toward the centre of the earth; it is defined by Dr. John Coulter as "sensitiveness to gravity." Geotropism in its simplest form, called "positive," causes growth directly downward, as in the tips of roots, which strike straight down into the earth. So strong is this influence upon roots that they will turn from any abnormal position in which they are placed and bend downward until they reach and penetrate the ground,— an adaptation for the preservation of plants against dislodgment by wind or water. The reverse of this is negative geotropism (apogeotropism), the influence which causes parts of plants, particularly stems, to grow *away from* the earth. A demonstration of these opposing influences in regulating plant-growth is found in the fact that when seedlings are caused to revolve continuously and rapidly for a period, their stems point and increase toward the centre of the centrifugal force, while the roots take the opposite line of growth. A third form of the tendency is called "diageotropism," and leads parts subject to its influence, as runners and rhizomes, to grow horizontally; that is, in a direction at right angles to the plane of positive geotropism. This influence is seen in the tendency of branches and foliage to assume a horizontal position. In all these cases, however, the result is modified and complicated by influences of sunlight, moisture, etc., styled heliotropism, hydrotropism, chemotropism, etc. (qq.v.); and sometimes, as in the case of twining plants, it is impossible at present to extricate them and assign to each its part in the result.

Geotropism, or the influence of gravity, has had a great effect, also, upon the forms of animals, especially in determining proportions and strength of parts with reference to weight. Associated with other influences it determines the "instinct" which leads many of the lower forms of life to seek the earth whenever possible, or at the proper time, a striking example of which is found in those caterpillars which, born in tree-tops, migrate to the ground as soon as born or when ready to begin their metamorphoses.

Gephyrea, jĕf-ĭ-rē'a, worms allied to the chætopod annelids, but differing from them in not being segmented, though provided with bristles. The mouth is either surrounded with a circle of tentacles, or is overhung by a large broad "proboscis," which in the European *Bonellia* may be several times as long as the body and forked at the end. The vent is either terminal or situated dorsally on the anterior end of the body. They possess a true blood system similar to that of annelid worms. The young free-swimming larvæ of certain forms (*Echiurus*) are like the Trochophores (see LARVA) of ordinary annelids. The male of *Bonellia* differs remarkably in shape and size from the female, being only 1 millimetre in length, while the female measures 3 inches, with a proboscis from 8 to 12 inches in length. Our most common form is *Phascolosoma*, which is cylindrical, its mouth surrounded with tentacles, the vent opens near the head, it is without bristles, and lives in dead shells, building out the aperture by a conical tube of sand. Its larva is cylindrical, the head small, with a circle of cilia.

Gepidæ, jĕp'ĭ-dē, a people of Gothic origin who settled about the mouth of the Vistula in the 3d century. Before the 5th century they had migrated to the Lower Danube, where they were subjugated by the Huns; but, revolting against Attila's son, they recovered their freedom and established themselves in Dacia. There their power grew so great that they levied tribute from the Byzantine emperors down to Justinian's days. In the end of the 5th century a powerful enemy arose to them in the Ostrogoths; and after them came the Longobards, who, in alliance with the Avars, inflicted a crushing defeat on the Gepidæ in 566. A part of the last named then submitted to the Avars, while a part accompanied the Longobards to Italy. Henceforward they passed out of history.

Gera, gā'rä, Germany, a town in the principality of Reuss-Schleiz, on the right bank of the White Elster, 35 miles from Leipsic. Among the chief buildings are the castle, the old Trinity Church, the town-hall, gymnasia, theatres, library, museum, town-hospital, etc. There are municipal water-works, electric tramways, scientific and artistic societies, etc. Pop. (1901) 45,640.

Gerace, jā-rä'chā, Italy, city in Calabria, on the east slope of the Calabrian Mountains and the shores of the Ionian Sea, 34 miles northeast of Reggio, and 64 miles by rail. It is on the site of the celebrated Greek Colony of Locri Epizephyrii. The cathedral, rebuilt in 1783, is partly of ancient materials. The district produces grapes, oranges, olives, and grain; and coal, iron, and marble are worked in the neighboring mountains. Pop. (1901) 10,595.

Gerah, gē'rä, the smallest piece of Hebrew money, being the 20th part of a shekel, or about 3 cents. Also, in Hebrew weights, a weight corresponding to the coin.

Geraldini, jā-ral-dē'nē, **Allesandro**, the first Roman Catholic Bishop of Santo Domingo: b. in Italy, 1455; d. in Santo Domingo, 1525. He was a soldier, and served in the army of Spain against Portugal, 1475-6, before taking orders. His learning and his friendship with Archbishop Mendoza, of Toledo, procured for him the tutorship of the royal princesses of Castile. He had great influence in the Spanish Court, and is said to have first interested Ferdinand and Isabella in behalf of Columbus. In 1520 he was made Bishop of Santo Domingo, after having held many high places in church and State. His residence and labors in the island, where he spent the remainder of his life, went far toward bringing law and order out of the chaos that followed upon the rule of the Spanish conquerors. His narrative of his journey thither and his description of Santo Domingo, printed in Latin (1631), is of great value and interest. He also wrote a life of Catharine of Aragon in verse.

Gerando, Joseph Marie, zhō-zĕf mä-rē zhā-rŏn-dō, BARON DE, French author: b. Lyons, France, 29 Feb. 1772; d. Paris, 11 Nov. 1842. He became governor of Catalonia in 1812, and was professor of public law in the law faculty of the University of Paris from 1828 to 1842. His works, treating law, philosophy, and other subjects, include: 'Des signes et de l'art de penser' (1800); 'Histoire comparée des systèmes de philosophie' (1803); 'Institutes de droit administratif' (1829); and 'Cours normal des institutions judiciaries' (1839).

Geraniaceæ, jē-rā-nĭ-ā'se-ē, the geranium family, consisting of herbaceous plants or shrubs with opposite or alternate leaves, and white, red, yellow, or purple flowers with five sepals and five petals. Sixteen genera and about 750 species are known. They are found in temperate or hot climates, rarely in the arctic regions. They are often astringent and aromatic, abounding in vegetable oil.

Geran'ium, the typical genus of the *Geraniaceæ* (q.v.), having palmately lobed leaves, regular flowers and a five-lobed ovary, terminated by a long thick beak and five stigmas. On coming to maturity the carpels separate from the base and become resolute or spiral. The spotted crane's-bill (*G. maculatum*) is a very familiar species in the eastern and northern States. The root is astringent and has been used medicinally. The tubers of *G. parviflorum* are eaten in Van Diemen's Land, where it is called the native carrot. Indian geranium is the name given by perfumers to a species of *Andropogon*. The so-called geraniums of gardens are mostly species of *Pelargonium*, and are natives of southern Africa. See CRANE'S-BILL; PELARGONIUM.

Gerard, jē-rärd', **Dorothea**. See LONGARD DE LONGGARDE.

Gerard, Emily. See LASZOWSKI-GERARD.

Gérard, Etienne Maurice, ā-tē-ĕn mō-rēs zhā-rär, French marshal: b. Damvillers, Meuse, France, 4 April 1773; d. Paris 17 April 1852. For his brilliant services at Austerlitz (1805) he was appointed general of brigade; he also took a notable part at Jena (1806), Erfurt (1806), and Wagram (1809). During the Russian campaign of 1812 he rendered conspicuous service at the capture of Smolensk in the battle of Valontina-Gora, and at the passage of the Beresina. In 1831 he commanded the French army sent to the assistance of the Belgians against the Dutch, whom he drove out of Flanders, and 27 Dec. 1832 compelled the citadel of Antwerp to capitulate. After the July revolution of 1830 he was appointed marshal and war minister by Louis Philippe; he was again war minister from July to October in 1834.

Gérard, François Pascal, frän-swä päs-kāl, a French portrait and historical painter: b. of French parentage, Rome, Italy, 11 March 1770; d. Paris 11 Jan. 1837. At 10 he was brought to France, and at 16 became the pupil of David. In 1795 he exhibited 'Belisarius,' which first brought him into notice; shortly afterward he painted 'Psyche receiving the First Kiss from Cupid.' His portrait of Madame Bonaparte in 1799 was the beginning of his career as the "painter of kings." Almost all the royal and other celebrities who visited Paris between 1799 and 1837 were painted by Gérard, who owed his success not alone to his skill as a portraitist, but also to the charm of his manners and conversation. His most celebrated portraits are those of Napoleon in his coronation robes, the Queen of Naples and her children, Talleyrand, Talma, Louis Philippe, and Madame Recamier. The grandest of his works are, however, historical pictures, the 'Battle of Austerlitz' (1810) and the 'Entry of Henry IV. into Paris' (1814). Gérard was appointed first court painter and made baron by Louis XVIII.

Gerard de Nerval, zhā'raar'de-ñar'vaal, the pen-name of GERARD LABRUNIE, a French author: b. Paris 21 May 1808; d. there 25 Jan. 1855. His first book to attract attention was a volume of poems, 'Élégies Nationales.' In 1828 he produced his translation of Goethe's 'Faust,' which brought him the author's personal approval, and which Berlioz (q.v.) used largely as the score for his 'La damnation de Faust.' Gerard also wrote several original plays; was a regular contributor to various periodicals; and published 'Les illumines' and 'Contes et facéties' (1852), and 'Scenes de la vie orientale' (1848–50). While insane he committed suicide. His writings were collected in five volumes in 1868.

Gerard Thom (and variously also TUNC, TUM, or TENQUE), Italian monk, founder of the order of the knights hospitallers of St. John of Jerusalem: b. Amalfi about 1040; d. 1120. In the latter part of the 11th century he first visited Jerusalem, and while there was appointed the superior of a hospice for the convenience of pilgrims, and there he organized the religious order afterward so celebrated, duly recognized by a bull of Pascal II. in 1113.

Gerber, gār'ber, **Ernst Ludwig**, a German musical authority: b. Sondershausen, Germany, 29 Sept. 1746; d. there 30 June 1819. He published 'Historische-biographisches Lexicon der Tonkunstler,' a work which, commenced in 1790, was not completed until 1814.

Gerbers. See GUEBERS.

Gerbert. See SILVESTER II.

Gerda, jĕr'dä, (1) In Scandinavian mythology, wife of Freyr, and daughter of the giant Gymer; she is so beautiful that the brightness of her naked arms illuminates both air and sea. (2) In astronomy, an asteriod, the 122d found; discovered by Peters, 31 July 1872.

Gerez, hā-rēs, **Serra de**, Portugal, a mountain chain which ramifies from the mountains of Asturias and stretches between the basins of the Douro and Minho, from north to south, for about 18 miles. It consists generally of a succession of granite peaks, the loftiest of which, Murro de Burageiro, has a height of 4,296 feet.

Gerfalcon, or **Gyrfalcon**. See JERFALCON.

Gerhard, William Paul, American sanitary engineer: b. Hamburg, Germany, 30 July 1854. He was educated in Germany and came to the United States in 1877. He was chief assistant engineer to Col. George E. Waring (q.v.) at Newport, R. I., 1881 3, and has since practised his profession in New York. He is the author of 'House Drainage and Sanitary Plumbing' (1881, 7th ed. 1897); 'Sanitary House Inspection' (1885); 'The Prevention of Fire' (1886); 'Recent Practices in Sanitary Drainage of Buildings' (1890); 'Disposal of Household Waste' (1890); 'Gas Lighting and Gas Fitting' (1894); 'Theatre Fires and Panics: their Causes and Prevention' (1896); 'Sanitary Engineering' (1898); etc.

Gerhardt, Karl, American sculptor: b. Boston, Mass., 7 Jan. 1853. He studied in Paris and has exhibited in the Paris salon. His works include busts of Gen. U. S. Grant, Henry Ward Beecher, Samuel L. Clemens, etc.; and statues of Nathan Hale, Gen. Israel Putnam in the Connecticut State capitol, etc.

Gerhardt (Fr. zhâ-rär) **Karl Friedrich,** a French chemist: b. Strasburg 21 Aug. 1816; d. there 19 Aug. 1856. He studied chemistry under Liebig at Giessen. In 1838 he went to Paris, where he lectured on chemistry, and there with his friend Cahours he commenced his researches on the essential oils. In 1844 he was appointed professor of chemistry at Montpellier. About this time he published his 'Summary of Organic Chemistry.' In 1848 he resigned the chair and returned to Paris. In 1855 he became professor of chemistry at Strasburg. His ideas and discoveries are embodied in his 'Treatise on Organic Chemistry' (1853-6).

Gerhart, Emanuel Vogel, American German Reformed clergyman: b. Freeburg, Snyder County, Pa., 13 June 1817; d. Lancaster, Pa., 6 May 1904. He entered the ministry in 1842, was president of Tiffin College, Ohio, 1851-5, and of Franklin and Marshall College, Lancaster, Pa., 1855-66; and professor of theology at the theological seminary at Lancaster from 1868. He published: 'Philosophy and Logic'; 'Institutes of the Christian Religion' (1891); etc.

Gerizim, ger'ĭ-zĭm, one of the highest mountains in the central Palestine chain (3,000 feet), separated from Ebal Mountain by a deep narrow valley, in which stands the town of Nâblus. The valley between them is very fertile. Jacob's well stands where the vale joins the plain of Moreh. The Samaritans built a temple on Mount Gerizim as a rival to that of Jerusalem, and organized a rival priesthood; and the Samaritan Pentateuch closed the Decalogue with the injunction, "Thou shalt build a temple on Mount Gerizim, and there only shalt thou worship." And, though the Samaritan temple was destroyed by Hyrcanus about 200 years after, the mountain on which it stood continued to be held sacred by the Samaritans. It was to Mount Gerizim that the "woman of Samaria," referred when she said to our Saviour: "Our fathers worshipped in this mountain, and ye say that in Jerusalem is the place where men ought to worship." See EBAL.

Germ, in medicine, a general term meant to include any microscopical form of life, plant or animal, supposed to have some relation to a disease process. In the earlier history of the study of the germ theory of disease most of these low forms of life were thought to be of animal origin, but in recent years it has become appreciated that both lowly organized plants and animals may cause characteristic forms of disease processes. Thus it is well known that malaria is due to a minute animal, and also that spotted fever, cattle fever, tryponosoma, filariasis result from infection by minute animal parasites, while typhoid fever, pneumonia, cholera infantum, influenza, septicæmia, tuberculosis, and others of the infectious diseases are known to be occasioned by minute forms of plant life, the bacteria. Higher forms of both animal and vegetable parasites are capable of causing characteristic reactions in the human body, as well as in lower animals and also in plants. Man is not the only organism that has diseases. There is no living animal and no living plant that does not have to struggle with either plant or animal parasites or, it may be, both. See BACTERIA; DISEASES, GERM THEORY OF; DISEASES OF PLANTS; PARASITES; PROTOZOA.

Germ-plasm, the peculiar form of protoplasm supposed by some embryologists to constitute the germinative part of the egg; and to contain in each case the qualities peculiar to that organism, and inherited from generation to generation. Compare GEMMULE and see EMBRYOLOGY.

Germ Theory of Diseases. See DISEASES, GERM THEORY OF.

Germain-en-Laye, St. See ST. GERMAIN-EN-LAYE.

German, Edward, English composer: b. Whitchurch, Shropshire, 17 Feb. 1862. He was educated at the Royal Academy of Music and since his graduation in 1887 has conducted at many important English musical festivals. He has been a prolific composer, among his works being the music to Irving's productions of 'Richard III.'; 'Henry VIII.'; 'Much Ado About Nothing,' and 'Romeo and Juliet'; music to 'Nell Gwyn' (1900); 'The Emerald Isle,' with Sullivan (1901); 'Symphonic Poem, Hamlet' (1897); 'Symphonic Suite, The Seasons' (1899); 'Operetta, The Rival Poets' (1901); 'Rhapsody on March Themes' (1902); 'Welch Rhapsody' (1904); 'Just So Song Book' (with Rudyard Kipling); etc., and the operas 'Merrie England' (1902); and 'A Princess of Kensington' (1903).

German Architecture. During the period which elapsed between the withdrawal of the Romans and the reign of Charlemagne Germany seems to have been in such a state of anarchy that no great buildings were or could be undertaken. At all events no trace of any edifice of this age remains, nor even a tolerably distinct tradition of any one being founded by the unsettled barbarian tribes who occupied that country when deprived of the protection of the Roman empire. With the accession of Charlemagne commences a brighter era. He restored the authority of the laws, and encouraged the arts of peace, and founded many noble structures, some of which, in whole or in part remain to the present day. This gleam of tranquil brightness appears to have been more owing to the individual greatness of the sovereign than to the ripeness of the people for more civilized institutions; for on his death they relapsed into confusion and barbarism. From this state the land partially recovered under the first three Ottos, in whose reigns church building seems to have been renewed with some energy. Up till the end of the 12th century the prevalent style of architecture was the Byzantine, the low state of German civilization compelling the employment of Greek or Italian artists. The cathedrals of Spires, Worms, Mainz, Bamberg, Basel, Würzburg, Limburg, Erfurt, Treves, Nuremberg, all conform in their primitive parts to the Byzantine style. But about the 12th century the Gothic began to make its appearance;

from that time the ogival and semicircular arch were both in equal favor.

Toward the close of the following century the Gothic, as a purely German style, replaced those brought from the south. The churches of that period are all of the pure Gothic character. Such were the cathedrals of Meissen and Magdeburg, buildings of a severe and simple taste. This style was succeeded by a second, not less grand, but more ornate and elegant. The Cathedral of Freiburg opened this new era; its front spire, erected in 1272, is the first and finest in the open style, and altogether the church is one of the most perfect monuments of Gothic art. The cathedrals of Cologne and Strasburg were both commenced about the same epoch. The latter edifice has a peculiar interest for the student of art, as in it is plainly marked the progress of architecture from the heavy Lombardo-Byzantine style to the degenerated after-Gothic style. In spite of these traces of bad taste the Strasburg Cathedral was considered in the Middle Ages and at the era of the Renaissance the finest structure in Germany. The Cathedral of Cologne commenced in 1248 was completed in 1863 with the exception of its towers, which were finished in 1880. It is said to be the noblest specimen of Gothic architecture in Europe. Another *chef d'œuvre* of German art is the Church of St. Stephen at Vienna, commenced about the middle of the 12th century. It is regarded as the last expression of the pure Gothic style. Among the other noble churches of this epoch may be mentioned those of St. Lawrence and of St. Sebald, the latter remarkable for its Gothic general plan with Arabic ornamentation; that of St. Mary in the same town, by Georg and Fritz Ruprecht; St. Catharine's of Oppenheim, the Cathedral of Goslar, St. Mary's of Königsberg, etc. The 14th and 15th centuries witnessed the erection of the magnificent Cathedral of Ulm, commenced under the direction of Matthias von Ensingen, and continued by Boblinger and Engelberger; the Cathedral of Augsberg; the beautiful church of Landshut; that of Esslingen, renowned for its elegance; that of Dunkelsbühl, by Nicholas Eseller; St. Giles' of Prague, constructed by Peter von Arler and Matthias von Arras; St. Mary's of Würtzburg, the cathedrals of Innspruck, Salzburg, Bremen, Dantzig, Constance, Berne, Zürich, Lausanne, etc. Among the most remarkable monasteries must be classed those of St. Gall, Fulda, Lindau, Lorsch, Treves, Hildesheim, St. Blaise in the Black Forest, Einsiedeln in Switzerland, etc.

Civil architecture took its rise shortly after ecclesiastical. After the towns had succeeded in securing their freedom and become prosperous, they first erected a church to their patron saint, and then constructed handsome council halls, bridges, quays, custom-houses, immense warehouses, hospitals, etc. All these edifices are characterized by their simple and elegant forms, appropriate to the uses for which they were intended. The public buildings of Dresden and Mainz, are among the most celebrated specimens. About the beginning of the 15th century the pure Gothic art commenced to decline. The sanguinary religious wars of Bohemia destroyed the unity of belief, and diminished the spirit of enthusiasm which had led to lavish expenditure in the interest of the Church. From that time new ecclesiastical structures were not only not undertaken, but those partially built were for long left unfinished. The war of the Hussites, and the Reformation inaugurated by Luther, were fatal to the magnificent old Gothic style. About this time the revival of art in Italy was making itself felt, and Germany, in consequence of her relations with that country, adopted in some measure the ideas of the Italian architectural school; and though in the churches several of the ancient forms were adhered to, the new style soon gained complete possession of the field. As instances of a compromise between the two styles we may cite the Jesuits' church at Munich; the town hall and the tower at Perlach; the churches of St. Charles and St. Peter at Vienna (the last-mentioned on the plan of St. Peter's at Rome).

This style, characterized by its intricacy of outline and prodigality in ornamentation, prevailed up till the end of the 18th century, when three eminent men, Raphael Mengs, Winckelmann, and Lessing, opened their campaign in favor of purer and more dignified forms. Weinbrenner, an architect of Baden, animated by their spirit, lent his powerful aid, and became the head of a school which, in spite of its imitation of classical antiquity, has given Germany a host of learned and enlightened architects: Hansen, who found a sphere of activity in Hamburg and Denmark; Fischer, who planned the Munich theatre, and others. After them the school (called the archæological and æsthetical) was represented by Klenze. This architect, in the many edifices erected from his designs at Munich, has shown a wide and profound knowledge of the various styles of architecture. The Glyptothek is Ionian in style; the royal palaces, Florentine; the Church of All Saints is Byzantine; several details of the Pinakothek are borrowed from the Vatican; and in the Valhalla of Ratisbon he has imitated the rude Cyclopean walls. His royal patron, Louis of Bavaria, who merits the title of regenerator of the arts, employed many other famous architects, such as Gästner, Ohlmüller, Liebland, Pertsch, and Probst, and had the honor of leaving to his country a city of palaces. The king of Prussia followed his example to some extent, and his architect Schinkel planned many of the best edifices in Berlin and the provinces. Among his principal works in the capital are the royal palace, the museum, the theatre, the conservatory, etc. Knoblauch is a more recent architect, who erected some fine buildings in Berlin; while Semper is equally distinguished for edifices erected in Zürich, Dresden, and Vienna.

German Art. See GERMANY—HISTORY OF GERMAN PAINTING AND SCULPTURE.

German Baptist Brethren (in their own name simply "Brethren"; by outsiders often called Dunkers or Dunkards, German *Tunkers* or "dippers" as immersion Baptists), a flourishing sect of German origin, but now existent chiefly in the United States, with some congregations in Europe, re-founded by missions, located chiefly from Pennsylvania to Virginia, in the central West from Ohio to the Rockies, and in North Dakota. At the end of 1902 they numbered 1,101 congregations, 3,001 ministers, and 115,194 members, mostly farmers. They support seven colleges,—Elizabethtown and Huntingdon, Pa.; Uniontown, Md.; Bridgewater, Va.; Mount Morris, Ill.; Manchester, Ind., and McPherson, Kan.; missions in France and Switzerland, Scandinavia, Asia Minor, and India, with a mission endowment fund of over $250,000; and a publishing house at Elgin, Ill., which issues their organ, the 'Gospel Messenger.' There are other papers in their interest.

The sect was the product of the great outburst of religious zeal and mysticism in the German Lutheran Church near the end of the 17th century; it was almost identical with the Mennonites (q.v.) in all except insistence on immersion, which they perform face forward and "trine" (once at the mention of each name in the Trinity). It began with Alexander Mack a miller of Schwarzenau on the Eder, in the little principality of Wittgenstein west of Hesse-Cassel. Wittgenstein was a curious nest of zealots, mystics, hermits, etc.; and in 1708 Mack baptized eight like-minded companions in the Eder. The sect—whose vital principle, like that of the Quakers and Mennonites, was rejection of creeds and reliance on the "inner light," abhorrence of war, litigation, oaths, and sumptuous living, and return to primitive simplicity and the Golden Rule—grew rapidly; but the authorities forbade the public baptisms, and they withdrew to Crefeld beyond the Rhine, another great home of dissent. Here they were unmolested; but the skeptical mockery of outsiders was more dangerous to their steadfastness than persecution, and in 1719 part of the band came to Pennsylvania and settled among the Mennonites near Germantown, founding a "prayer-house" in 1823. The rest followed by 1729. Thence they pushed south and west. One of them was Christopher Saur, whose German press, established 1638, printed the first—long first—European Bible in America.

The stories of their communism and celibacy, marriage only within the sect, and other antisocial practices or tenets, are fictions; perhaps originally confounding them with Conrad Beissel, a zealot who lived with the early Brethren in Pennsylvania for a while, but broke with them and set up a monastic community. But to retain apostolic simplicity they are obliged, like all such sects, to lay prime stress on separatism of habits and manners; outlawing or reprobating fine dress, lawsuits (choosing referees instead), politics, oaths, secret societies (as oath-bound), intoxicants, and tobacco. Before the close of the 18th century they denounced the slave trade, and prohibited the manufacture, sale, or use of strong drinks. They dislike "hireling" ministers, and most of theirs are unpaid. In doctrine they are simply orthodox Protestants; they accept the Bible as the verbally inspired utterance of God, the Trinity, and reward or punishment in a future life. Grace is free to all; the only requisites are faith, repentance, and baptism (as above), hence the latter is for converted adults only. The Lord's Supper is an evening meal (as originally), preceded by mutual foot-washing (each sex separate), and followed by the right-hand of fellowship and the kiss of peace, and then by communion. Their organization is episcopal, the bishops or elders being elected by the members out of the higher of two grades of ministers, who with the deacons are also elected by the congregations. The latter with the State districts elect delegates (of either sex) to an annual conference, which is the binding legislative and executive authority on a two-thirds vote.

The sect had the curious and unique fortune in the early eighties of having one party secede from it, as too progressive, and the other as not progressive enough. The Old Order Brethren objected to its humanitarian, missionary, and Sunday-school activities; the Progressive Brethren to the rules of dress and other conservative decisions of the conference. The Old Order numbering in 1902 80 congregations, 140 ministers, and about 4,000 members, publish a newspaper, the 'Vindicator,' to oppose education, missions, Sunday-schools, and revivals. The Progressives had 145 congregations, 231 ministers, and 13,000 members, and are increasing at the expense of the "Conservatives," or mother body. They support a college and publishing house at Ashland, Ohio, and issue an organ, the 'Evangelist.' A small body of seventh-day German Baptists, with five churches and some 200 members, is usually included among the Brethren, and its tenets often absurdly accredited to them; but it is a separate church, long since parted from the others.

German Catholics, a religious sect which sprang up in Germany about the close of 1844, which rapidly increased during the four or five following years and then as rapidly declined. The immediate cause of the formation of this sect was the exhibition by Arnoldi, bishop of Trèves, of the holy coat preserved in the cathedral of that city and said to be the coat of Christ. The bishop accompanied the exhibition of the holy coat by a promise of plenary indulgence to whoever should make a pilgrimage to Trèves to honor it. The announcement of this proceeding on the part of the bishop of Trèves produced a feeling of general astonishment in Germany and drew from a Silesian priest called J. Ronge, who had already been suspended from his charge on acount of his independent views, a letter protesting against the exhibition of the holy coat and denouncing the projected pilgrimage as idolatry. This letter was published in the 'Sächsische Vaterlandsblätter' on 16 Oct. 1844, and produced an amount of excitement that was quite unanticipated by the writer. Ronge was excommunicated, but this only increased the general enthusiasm in his favor, and when he entered into relations with Czerski, another independent priest who had seceded from the Church, and made along with him an appeal to the lower grades of the clergy to unite in founding a National German Church independent of the Pope and governed by councils and synods, the appeal received a ready answer from a considerable number of those to whom it was addressed. A number of congregations belonging to the new body were formed in the more important towns, especially in Leipsic, under the celebrated Robert Blum, and in Magdeburg under the teacher Kote. In the spring of 1845 there were already about 100. At this time (March 1845) a council was summoned to meet in Leipsic to deliberate on the affairs of the body. Only 20 congregations were represented there, but these nevertheless at once proceeded under the presidency of Prof. Wigard to arrange a system of doctrine and practice which was to form the basis of union for the whole Church. The Bible was recognized as the sole standard of faith, and its interpretation was left to reason, "penetrated and animated" by the Christian idea. Only two sacraments were admitted, baptism and the Lord's Supper. In matters of ritual each congregation was left free to carry into practice its own views. The organization of the new Church was almost the same as that of the Presbyterian dissenting churches of Scotland. Each congregation was to choose its own pastor and elders. Affairs of a general interest were intrusted to the management of a general council to meet every five years, but the decisions of this council were to be ratified by a majority of the congregations before they became valid. The confession of sins, the hierarchy of the clergy, and the celibacy of the priests were abolished and the authority of the Pope was not recognized. On the subject of purgatory nothing was declared either for or against it. The constitution of the new Church was thus a Protestant one, but in some respects the German Catholics went even further than the majority of Protestants in a liberal direction, inasmuch as they claimed for all, complete religious liberty and declared their religion to be capable of development and modification with the progress of the human mind.

The Church established on this basis had at first, as has already been stated, great success. The most eminent men of the liberal party regarded the movement with sympathy, or at least with interest. Gervinus expressed his belief that great benefits might result from it. Many Protestants, dissatisfied with the subjection of their religion to state supervision, joined the body, which, at the end of 1845, counted 298 congregations. But it was not long before the spirit of opposition began to show itself. The majority of the governments in Germany at the instigation both of the Protestant and the Roman Catholic clergy began to use repressive measures against the new body. Prussia contented itself with regulating the exercise of their worship; but some of the other states went farther. At Baden the adherents of the sect were deprived of their political rights. Austria took the course of banishing them from her dominions. But persecution from without did less hurt than the divisions within the body. Almost immediately after the meeting of the council at Leipsic a congregation had been formed at Berlin which refused to abide by its decisions. Czerski and Ronge, the two originators of the sect, became the leaders of two opposing parties within it, one of which, that headed by Czerski, clung to the traditions and doctrines of the Roman Catholic Church, rejecting only the supremacy of the Pope and the union between Church and State; while the other sought for more freedom, converted religion into a sort of popular philosophy and began to mix up with it questions of politics, exhibiting strong democratic tendencies. These were most plainly manifested during the revolutionary epoch of 1848. The schism between the two parties was then complete. One section of the congregations of German Catholics professed to have only religious ends in view, while another section openly pronounced itself in favor of socialistic principles.

From the year 1850, however, there were several attempts to re-establish the unity of the body. An effort was made to reintroduce harmony by widening the basis of union. Instead of founding a religion, a council held at Gotha in June 1850, proposed the formation of a religious association or confederation into which all free Protestant and even Jewish congregations were to be admitted. Legislation in the different states had become more tolerant and the carrying out of the scheme of the council of Gotha seemed to be at least practicable. But the result proved otherwise. The association consisted of too heterogeneous elements. While some of the members receding further and further from orthodoxy proclaimed simple deism as their religion and abolished baptism and the Lord's Supper, others on the contrary lost themselves in an exaggerated mysticism. According to the most recent statistics there are still about 100 congregations of German Catholics in Germany; but their numbers only amounted to about 6,200 in 1895.

German East Africa, the largest German colonial possession, extending from lat. 1° to about 11° 41′ S., and from lon. 29° to 40° 40′ E. It has a coast line of 620 miles, and lies between British East Africa, Indian Ocean, Portuguese East Africa, Rhodesia, Congo Free State, and the British Sudan. The area is 384,000 square miles. The German empire is represented by an imperial governor, who appoints a council of five in each of nine communes. There is a military force of 232 Germans and 2,000 natives. The region produces almost every kind of tropical fruit, fibres, sugar, tea, etc. In 1901 over 1,600 tons of copra were exported. The chief seaports are: Dar-es-Salaam (pop. 13,000); Bagamoyo (pop. 14,000); Saadani, Pangani, Kilwa (pop. 10,000 each), and several smaller towns. A railroad from Tanga is open for traffic to Muhesa and Korogme, 54 miles. There are nine telegraph stations in the coast towns. The trade is chiefly with Zanzibar and Germany. Pop. (1901) 6,750,000 natives, 15,347 foreigners, mostly Arabs, Syrians, and Loanese. See GERMANY—THE COLONIES.

German Empire. See GERMANY.

German Evangelical Protestant Church, in the United States, a religious body, liberal in doctrinal belief, having no confession of faith. Its ministers are associated in district unions. There are 52 churches having a membership of 36,156.

German Evangelical Synod of North America, a religious body, accepting the symbolical books of the Lutheran and Reformed churches, representing in the United States the State Church of Prussia, which is a union of the Lutheran and Reformed bodies. It celebrated, 12 Oct. 1890, the semi-centennial anniversary of its organization in the United States. In 1900 there were 909 ministers, 1,129 churches, and 203,574 members.

German Ivy *(Gynasys cordifolia or Senecio scandens)*, a creeping plant of the *Com-*

positæ family, with fleshy light-green leaves. It is commonly grown as a house plant.

German Language and Literature. See GERMANY—HISTORY OF LANGUAGE; HISTORY OF LITERATURE.

German Measles. This disease is acute, very contagious, and of unknown causation. It differs from measles in the mildness of its onset and symptoms, in the quicker appearance of the rash after the first signs of illness, and the more rose-red tint of the developed rash. It is distinguished from scarlet fever by its mildness of onset, the patchy character of the rash, without diffuse redness, and the shorter duration. The disease develops in 10 or 12 days after exposure, lasts about 3 to 5 days, and is followed by a moderate branny desquamation. Complicating bronchitis, pneumonia, gastro-intestinal catarrhs, and kidney disturbance may occur, but are infrequent.

German Ocean. See NORTH SEA.

German Silver, a white alloy for tableware, consisting of nickel, copper and zinc in various proportions. The best quality consists of four parts copper, two parts nickel, and two parts zinc, but this quality is the most difficult to work. For some purposes the proportion of copper is slightly increased, and for articles which are to be cast instead of stamped or hammered about 2 per cent of lead is added. To make a good malleable alloy, the three metals of which it is composed should all be of the best quality. It is harder and tougher than brass, and takes a fine polish. In color it is sufficiently near silver to make it valuable for plating with that metal. This, together with its hardness in resisting wear, has caused a great demand for German silver for certain wares made in Birmingham and Sheffield.

Spoons and forks of this alloy are made in immense numbers. Such articles as salvers, dish-covers, jugs, teapots and the like are also largely made of it, but these objects, or at least some of them, are still more largely made of a greatly inferior alloy, because much softer. German silver has a coppery odor and is readily attacked by acid liquids, such as vinegar, which coat it with verdigris. Spoons and forks made of this alloy should therefore either be plated with silver or carefully kept clean. Of late years, through care in preparing a suitable alloy, large objects, such as the bodies of jugs and coffee-pots, can be formed of sheet German silver by "spinning" it on the lathe, instead of by stamping or by the slow process of hammering. Formerly it was only a soft alloy that could be so treated. For some time past there has been a tendency to substitute for electroplate—that is, German silver plated with real silver—white alloys having nickel for their basis. These, however, are but varieties of German silver known under different names, such as silveroid, argentoid, navoline, and nickeline. Some of them contain small quantities of tin, cadmium, and other metals. Mountings for ship-cabins, bar-fixtures, forks and spoons, and other similar articles have been manufactured on a considerable scale from these new alloys. See ELECTROPLATE; METALS.

German Southwest Africa, a German protectorate in West Africa, coast extending from Cape Frio to Walfisch Bay, inland to lon. 20° E.; area, estimated, 322,450 square miles. Coast infertile and desolate; inland are richer tracts. Damaraland is the name of the north district, Namaqualand and Luderitzland lying to the south. Damaraland is occupied by the Southwest African Company, an Anglo-German syndicate, which was formed in London in 1892, and obtained from Berlin a concession to search for and work the minerals of the district, including the copper mines of Otavi, but outside of the district worked and occupied by the German Southwestern Africa Colonial Company, which district consists chiefly of the coast lands. The German government, owing to complaints that too great favor had been shown to the Anglo-German Company, decided to give preference to German settlers, and to reserve certain parts of the country for them for 10 years. The country is apparently rich in copper and in agricultural resources, though undeveloped. The seat of administration is at Great Windhoek, 170 miles inland from Walfisch Bay. The German government decided in 1897 to commence the building of a railway from the coast to the interior. Pop. (1900) 221,000. See GERMANY—THE COLONIES.

German Theology. See GERMANY—HISTORY OF RELIGION.

Germander, jĕr-man'dĕr (*Teucrium*, a large and widely distributed genus of labiate herbs, of which all the European species are of old medicinal repute on account of their aromatic bitter and stomachic properties. The species are numerous. The wall germander or true germander (*T. chamædrys*), often found on ruined walls, has probably been introduced from Europe. Wood germander or wood sage (*T. scorodonia*) is a very common British plant, in dry bushy or rocky places. It is very bitter and slightly aromatic. It is used in the Island of Jersey as a substitute for hops. Water germander (*T. scordium*), in wet meadows, has a smell like garlic. Cat or sea thyme (*T. marum*), of southern Europe, like catmint and valerian root, has great attractiveness for cats. It is still sometimes used in the preparation of sneezing powders. The American species (*T. canadense*) is also known as wood sage.

Germa'nia, a country of ancient Europe See GERMANY.

German'icus Caesar, Roman general: b. 15 B.C.; d. Epidaphnæ, near Antioch, 9 Oct. 19 A.D. He was the son of Nero Claudius Drusus, and of Antonia, daughter of Mark Antony and niece of Augustus. By desire of Augustus he was adopted in the year 4 A.D. by Tiberius, whom he accompanied in the war against the Pannonians, Dalmatians, and Germans. In the year 12 he was consul, and next year was appointed to the command of the eight legions on the Rhine. He was at Lugdunum Batavorum when news came of the death of the Emperor Augustus and of the mutiny for more pay and shorter service among the soldiers in Germany and Illyricum. Germanicus hastened to the camp and quelled the tumult by his personal popularity; and at once led his soldiers against the enemy. Crossing the Rhine below Wesel, he attacked and routed the Marsi, and next year marched to meet the redoubtable Arminius (q.v.), the conqueror of Varus and his legionaries, whose bones had lain unburied for six years in the Teutoburg Forest. With solemn rites his soldiers buried these sad relics of disaster, then advanced against the foe, who, retiring into a difficult country, managed to save himself, and was not subdued till the year after, when Germanicus again carried a part of his army up the Ems in ships, crossed to the Weser, and completely overthrew Arminius in two desperate battles. Tiberius, jealous of the glory and popularity of Germanicus, recalled him from Germany in the year 17, and sent him to settle affairs in the East, at the same time appointing as viceroy of Syria, in order secretly to counteract him, the haughty and envious Cn. Calpurnius Piso. Germanicus died, probably by poison. His wife, Agrippina, and two of her sons were put to death by order of Tiberius; the third son, Caligula, was spared. Of the three daughters who survived their father, Agrippina was as noted for vice as her mother for virtue.

Germanium, jer-mā'nĭ-um, a metallic chemical element discovered in 1886 by Dr. Winkler in a silver ore (argyrodite); symbol, Ge; atomic weight, 72.3. It has a melting-point about 1,650° F. (900° C.); is oxidized when heated in air; crystallizes in octahedra; has a perfectly metallic lustre, and is of a grayish-white color. As gallium had been named from France, the new metal was named after Germany. Fifteen years before its discovery its existence was prophesied by Mendeleeff as required to fill the gap in the periodic table between silicon and tin.

Germans in the United States, The. See GERMANY—THE GERMANS IN THE UNITED STATES.

Germantown, Pa., a former village, since 1854 the 22d ward of Philadelphia. Considerable historical interest is attached to the place. It was settled by the Germans, under a grant from William Penn, in 1684, and on 4 Oct. 1777 a battle took place between the armies under Washington and the English under Howe. See GERMANTOWN, BATTLE OF.

Germantown, Battle of, 4 Oct. 1777. Howe having captured Philadelphia, stationed his army across the Germantown road north of the city and east of the Schuylkill: the left wing with its supports on the river, the right "in the air" to the east. He shortly detached part of it to reduce the forts which blocked the Delaware below the city; and Washington planned the capture of the weakened army, starting after dark on the evening of 3 October. His right under Sullivan and accompanied by himself, with six brigades, was to move down the main street and crush the British left; the Pennsylvania militia to march along the river and take it in flank; the left under Greene was to divide, three brigades under himself taking the British right in front and flank, while two others were to move to the east and come up in its rear. This would drive it back upon the left and both on the river, and it was hoped would compel surrender. A mile or so north of the British centre on Mount Airy, were a battalion of light infantry and a battery; in a field just left was a regiment under Col. Musgrave; a little south on the main road was the massive stone house of former Chief Justice Chew. At sunrise a heavy fog came up and left all darker than ever. The British advance bodies were overwhelmed by the Americans, and the battery captured; but Musgrave took shelter in Chew's house, and after an unsuccessful attempt at breaching it with the light guns, the Americans left a brigade to besiege it and pushed on. Despite this delay and the warning to the British, both their wings soon began to give way before the American onset. But in the fog, the heavy firing at Chew's house drew Gen. Stephen with his brigade, on Greene's right, too far west, thinking the main fight was there; and Wayne on Sullivan's left had turned considerably east and came in front of Stephen, who took him for the enemy and attacked him in the rear. Wayne's men were driven against the next left of Sullivan's remaining brigades, a panic started, and a general retreat began. The British took the offensive, and reinforced by Cornwallis from Philadelphia, pressed the Americans hard; but the latter soon regained composure and retired in good order, though one regiment of Greene's was surrounded and captured. The Americans, however, brought away several captured cannon, and all their own and their wounded. Their loss in killed and wounded was 673, the British 535. Stephen was accused of having drunk too much on the night march, court-martialed, and dismissed from the army. Despite the failure of the plan, the ultimate results were very great. The audacity of the Americans in attacking the British so soon after the defeat of the Brandywine, and the fighting qualities displayed, were a large factor in determining the French alliance.

DEPARTMENT OF

GERMAN HISTORY AND DEVELOPMENT.

GERMANY:

HISTORY AND MODERN DEVELOPMENT.

1. **Germany.**—*Geography* — Germany, or the German Empire (Deutsches Reich, emperor Deutscher Kaiser, 208,830 square miles), the third in size of the European states and the most central of the powers of Europe, covers the territory between the Alps and the North and Baltic Seas, between 56° and 47½° N. and 6° and 23° E. It is bounded, E. by Russia, S.E. and S. by Austria and Switzerland, W. by France, Luxemburg, Belgium, and the Netherlands, N. by Denmark.

Physiographically, the German territory consists of three main divisions: The Alpine region, the "Mittelgebirge" (Central Ranges), and the North German Lowland.

The highest elevations are in the South, where the Northern Limestone Alps enter on Bavarian territory (Zugspitz, 9,660 feet). At their base a plateau covered with glacial drift, about 2,000 feet high, interspersed with many lakes (Bodensee, Starnberger, Chiemsee) stretches north as far as the Danube, drained by the tributaries of this river which bounds it along a large fault line.

The Mittelgebirge is an old mountainous country of Appalachian type, whose ranges are controlled by two directions of tectonic movements: The Rhenish, running S.W.-N.E., and the Hercynian System, running S.E.-N.W. To the former belong (see map), beginning in the South: The Swabian Jura, Erzgebirge, Black Forest-Odenwald-Spessart, Taunus, Westerwald on the right, and Vogesen-Hardt, Hunsrück, and Eifel, left of the Rhine; to the latter: the Bohemian Forest, Thuringian Forest, Teutoburger Forest, the Weser mountains, and Sudeten; the horseshoe-shape of the Fichtelgebirge and the parallelogram of the Harz present a combination of the two. Intersecting each other in many places, these ranges produce a chessboard-like dissection of the country which has not been without influence on the political dissection of central Germany into many small states.

The North is a large lowland, narrow at the West and widening toward the East where it joins the great Russian lowland. It is dissected by two heights of land extending, respectively, from Silesia along the middle course of the Elbe and across that river between the lower courses of Elbe and Weser to the North Sea, and from Eastern Prussia along the Baltic coast into Slesvig-Holstein. The latter culminates near Dantzig in the Turmberg (1,000 ft.) and is dotted with innumerable lakes ("Seenplatten" of Prussia, Pomerania, and Mecklenburg); the former consists mostly of glacial sands (Flaming, Lüneburger Heide) and is of little interest economically or scenically.

Rivers.— The courses of the rivers are adjusted to these topographic conditions flowing partly in one, partly in the other, direction. Thus the Rhine flows first N.N.E., then W.S.W., then N.W. The Danube, first, N.E. and then S.E.; the rivers of the lowland; Weser, Elbe, Oder, alternate between a more westerly or northwesterly direction where they follow the general slope of the Hercynian system predominating in the East, and a northerly course where they cut through the heights of land. The Main is perhaps the best illustration of the complicated topography of central Western Germany; Neckar, Moselle, and Lahn dissect, the former, the terraced country east of the Black Forest; the latter two, the old peneplain through which the lower Rhine has cut its gorge. The largest tributaries of the lowland rivers on the right repeat the zigzag of the main watercourses so exactly that they almost establish connections between the corresponding reaches of the latter: Weser-Aller-Elbe, Elbe-Havel-Spree-Oder, Oder-Warthe-Netze-Vistula. An extensive canal system utilizes these conditions for commercial purposes, thus reconstructing the watercourses of the glacial period when at different stages of the advance and retreat of the ice sheet the waters collected at its southern margin and flowed westward or northwestward along it to join the ocean in the present lower courses of the Weser and Elbe. The tributaries on the left generally continue the S.-N. reaches of the main rivers, and during the eastward expansion of the nation often gained strategic importance, such as the Saale-Elbe line in the struggles with the Slavs. The Vistula belongs to Germany only in its lower course; E. of it the Pregel and Memel are coastal rivers of great commercial importance; so is the Ems in the extreme northwest; the Eider in Slesvig, by means of a small canal, once connected the Baltic with the North Sea until it was superseded by the large Kaiser Wilhelm canal. Of the large rivers the Rhine is the only one which, owing to its Alpine origin, affords good shipping all the year round. The others generally suffer from lack of water during the dry season, and only by extensive river regulation has it been possible to satisfy the needs of modern river transportation.

Harbors.—The seaports suffer from similar disadvantages. The Baltic has good river harbors (Königsberg, Dantzig, Stettin) or fiords (Kiel), but their location on an inland sea, though recently improved through the Kaiser Wilhelm canal, puts them at disadvantage. Those on the open North Sea have to combat with the dangers of shallow water on a sinking coast ("Watten"), and Hamburg and Bremen owe their importance more to the energy of their merchants than to natural advantages. Wilhelmshafen, the naval port on the Jade bay, is an entirely artificial creation. The chain of

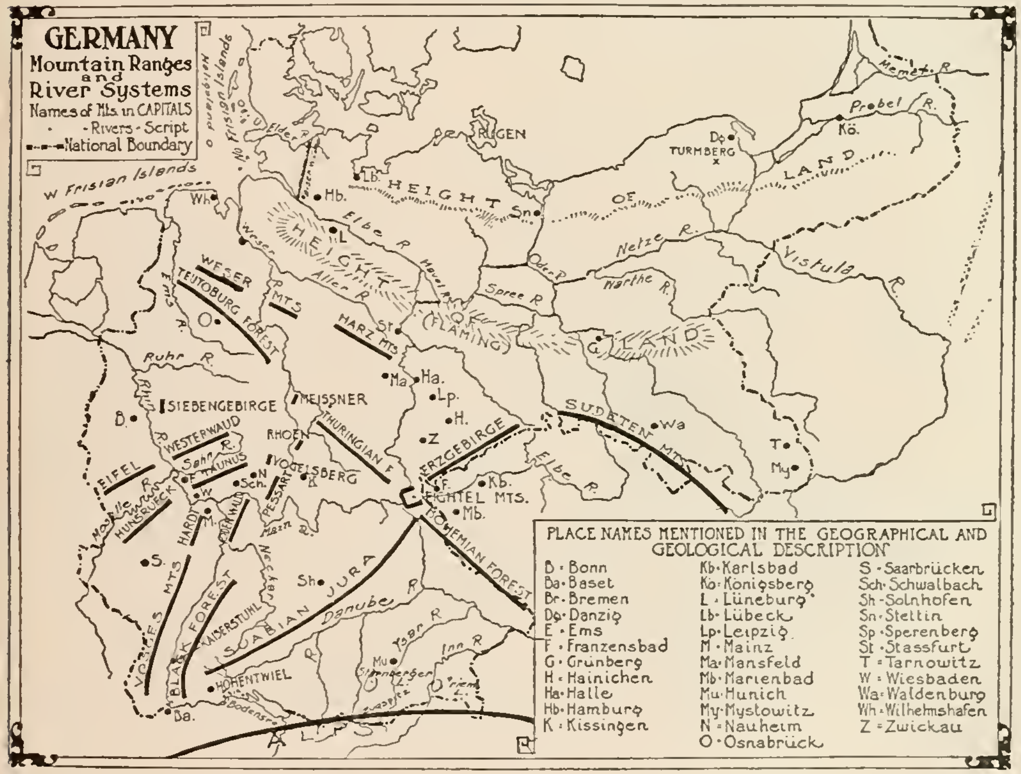
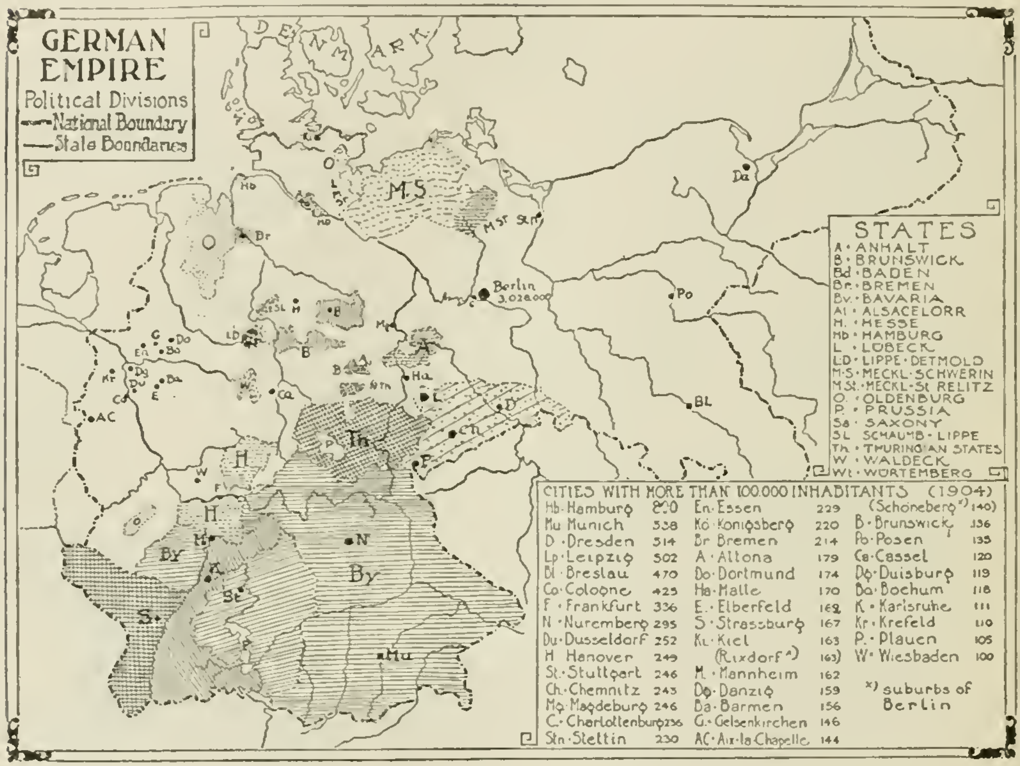
the Frisian Islands represents the old coastline, Heligoland being the only genuine island in that region. On the Baltic coast, Rügen is the largest and most picturesque of the German islands.

Climate.— Being open to the mild westerly winds, Germany has a milder climate than would be expected from its latitude. There is little difference between the North and South, as in the latter higher elevation counterbalances the southerly location. The mean annual of Hamburg is 48° F., of Leipzig, 47°; of Munich, 45°. A greater contrast exists between the East and West, the lowland sharing already the continental climate of Russia with colder winters and warmer summers. The latter allow the vine to reach here its most northerly location on the earth, at Grüneberg on the Oder, in lat. 52° N. The valley of the upper Rhine is the only part of Germany where low elevation and low latitude are combined: here we find, therefore, the warmest parts of the empire, where Indian corn is cultivated and chestnut forests abound.



States.— Politically, the German empire is a union of 26 states under the leadership of an emperor. Twenty-two are monarchies: four kingdoms (Prussia, Bavaria, Saxony, Württemberg), six grand-duchies (Baden, Hesse-Darmstadt, Oldenburg, Saxe-Weimer-Eisenach, Mecklenburg-Schwerin, Mecklenburg-Strelitz), five duchies (Anhalt, Saxe-Altenburg, Saxe-Meiningen, Saxe-Coburg-Gotha, Brunswick), seven principalities (Waldeck, two Schwartzburg, two Lippe, two Reuss), each under its own king, grand-duke, duke, or prince, and with an upper and lower house (except Mecklenburg which has not yet a constitution); besides these there are three republics: Hamburg, Bremen, and Lübeck, the old Hansa towns with their territories, and one "Reichsland" (imperial territory): Alsace-Lorraine, regained from France in 1871, and, for lack of a hereditary prince, placed directly under the imperial government, with a governor appointed by the emperor. Prussia alone occupies about two thirds of the whole empire, practically all of northern Germany, with exception of a few of the smaller states interspersed between her provinces. Since 1871 the king of Prussia holds the office of German Emperor, made hereditary in the Hohenzollern dynasty, and Berlin thus is the seat of both the Prussian and the federal government. The latter consists of the emperor and two houses, similar to the state governments, but the members of the lower house are elected by direct and secret vote, while the modes of the state elections are quite intricate. The upper houses of the states and the empire consist of representatives of the governments.

Population.— Exclusive of Berlin, Germany had, in 1905, 40 cities with over 100,000 inhabitants, mostly industrial centres and state capitals (see map). The majority of the population (60,000,000) are of Germanic origin, especially in the older countries west of the Saale-Elbe line. East of this line lives a more colonial race, with a large admixture of slavic blood. Among and beyond them there are 3,000,000 Poles in the formerly Polish provinces of Prussia; in the East 140,000 Masurians, 106,000 Lithuanians, 100,000 Cassubians; on the upper Spree 90,000 Wends; 220,000 French in Alsace-Lorraine; 11,000 Walloons along the Belgian, and 140,000 Danes near the Danish line. Although no more than one tenth of the whole population, these foreign elements are not insignificant because most of them have their mother country back of them, and the problem is still more complicated by the overlapping of the German race into foreign territory on the N. E., S. E., and S.



Geology.—The oldest parts of Germany, geologically, are the metamorphic rocks of the Bohemian Forest-Erzgebirge-Sudeten region, the Thuringian and Black Forests, the Vosges, etc. Of paleozoic rocks, Algonkian and Cambrian schists and quartzites occur in the S. W. Erzgebirge (Vogtland), the S.E. Thuringian Forest (Frankenwald), and Eichtelgebirge. Silurian schists, limestones, and sandstones occur above them in these three ranges, and the eastern Sudeten, while the Rhenish Slate Mountains (Eifel), are the classical locality of the German Devonian, and the Harz includes portions of all paleozoic formations. Igneous rocks (diabases) and mineral veins intersect them.

Between the lower and upper Carboniferous this whole area of paleozoic rocks was folded into a mountain system of Alpine height, extending from Belgium to the Sudeten ("Variscian Mountains" of Suess, or Paleozoic Alps). Eruptions of volcanic matter accompanied the mountain making forming the granite massifs of the Erzgebirge, Black Forest, etc. In the valleys between the ranges and in the low country at their base the deposition of the carboniferous formation took place. The German Carboniferous belongs to the terrestrial facies of the period, the lower part (Culm) being shales and sandstones of litoral origin with occasional coal seams (Hainichen, Saxony); the upper includes the productive coal fields. They extend with little interruption from Belgium along the northern slope of the Rhenish Devonian into Westphalia (Ruhr Basin), and with the fields around Saarbrücken farther south, in Saxony (Zwickau), and Silesia (Waldenburg, Myslowitz), are the most important sources of coal supply in central Europe.

The Permain consists of two epochs: Rotliegendes and Zechstein. During the Rotliegende the area remained land, the Paleozoic Alps were worn down to Mittelgebirg heights,

and their deposits filled the depressions with sands and conglomerates of a reddish color; hence the name. Occasionally coal beds occur between them. Volcanic activity continued in some places (porphyrites and pitchstones of Saxony). In the Zechstein epoch the ocean advanced again, leaving its deposits on the northern edge of the Mittelgebirge, especially around the Harz and in northern Thuringa. Among them are the famous copper-bearing shales of Mansfeld, the Zechstein proper (shallow water limestone), and the immense salt beds of the upper Zechstein epoch (Stassfurt, Sperenberg) with their large supplies of gypsum and «araum» salts.

The Triassic period consisted of three epochs in Germany. In the first a shallow sea covered especially western Germany, forming the reddish sandstones (Buntsandstein) which cover miles and miles from Basel to Osnabrück, the W. slope of the Eifel, the region around Tarnowitz in Silesia, and form the cliffs of Heligoland. This sea deepened in the second epoch producing a shell limestone (Muschelkalk), but in the third (Keuper, pron. coiper) was cut off from the main ocean and formed gay colored marls and sandstones with occasional coal seams. (Lettenkohle). The uppermost stage of the Keuper, the Rhaetic, shows the beginning of another transgression of the ocean, that of the Jurassic period.

About the Alpine facies of the Triassic, see ALPS.

The Jurassic ocean overflooded all of central Europe, with only the tops of the mountains standing out as isles. It reached a great deal higher up on their sides than its present distribution would indicate, since the highest deposits were probably eroded in subsequent periods. At present we find its deposits in South Germany on both slopes of the Black Forest and Vosges, and especially in the range of the Swabian-Franconian Jura, where the lithographic stones of Solnhofen belong to its upper epoch. It also occurs in the N. foothills of the Mittelgebirge, near the Elbe in Saxony, in Silesia, and evidently underlies the whole lowland, cropping out frequently from under the younger deposits.

Likewise a zone of Cretaceous hills skirts the northern border of the Jurassic ranges, with many isolated occurrences in the lowland. The second part of the Cretaceous again witnessed a large advance of the ocean, its deposits often lying on rocks several periods older in places which had never been submerged since; on archaic and paleozoic rocks in Saxony, on Carboniferous in Westphalia, etc. The white chalk cliffs of Rügen, and the Pläner sandstone of Saxon Switzerland are the best known examples of German Cretaceous.

The Tertiary was again a period of great geological disturbances: Mountain folding, volcanic eruptions, and changes of shore-lines. During the Eocene, almost all Germany was land; but in the Oligocene a shallow sea extended over the lowland as far as Bonn, Leipzig, and Silesia. Local oscillations favored the formation of coal beds, to which soft coal measures (Halle and Leipzig) owe their origin. From the South the sea entered the rift valley formed by the breaking in two of the Black Forest-Vosges massif, the present Upper Rhine Valley. Toward the end of the Miocene, the folding of the Alps began and gradually shut off this bay from the ocean; it became brackish and finally a freshwater lake drained by the later Rhine (Mainzer Becken). All through the Mittelgebirg region, volcanic eruptions accompanied these tectonic processes; the volcanoes and volcanic rocks of the Eifel, Siebengebirge, Westerwald, Vogelsgebirge, Meissner, Rhön, northern Bohemia, and the eastern Sudeten, together with the hot springs which have created a belt of famous watering places along this line (Ems, Schwalbach, Wiesbaden, Nauheim, Kissingen, Franzensbad, Karlsbad, Marienbad, etc.), in the South the Kaiserstuhl, the Hegau volcanoes (Hohentwiel) and those of the Suabian Jura date from this period. During the Pliocene practically the whole of Germany was land again, and ready for the invasion of the Pleistocene ice sheet.

In the Pleistocene six glacial and five interglacial stages have been distinguished of which, however, only the second (the Kansan of America) and third (corresponding to the Wisconsin) deserve special mention. At the time of its largest extension the Scandinavian glacier reached the northern foot of the Mittelgebirge from the lower Rhine southeastward into Silesia. The terminal moraines are well developed along this line and the whole lowland is covered with till and strewn with erratic boulders. Another inland glacier stretched northward from the Alps, covering the Bavarian plateau with its moraine material. The Black and Bohemian Forests and the Sudeten (Riesengebirge) had local glaciers of smaller size.

Palæontology.—The geological description indicates the old faunas and floras. Special mention deserve:

Devonian: Eifel limestones: Brachiopods, crinoids, corals.

The Rotliegende of Chemnitz: cycads, conifers, especially treeferns; of the Saar valley and the Plauen Grund (Dresden): Stegocephales (larvæ and adults).

Zechstein shales of Mansfeld: Ganoid fishes.

Buntsandstein rocks have few fossils but contain footprints of various animals (Thuringia, Franconia).

Muschelkalk limestone (Thuringia, Württemberg) are packed full with fossils, few species, many specimens: molluscs, besides brachiopods, ammonites, crinoids. Terebratula vulgaris is very common, the stalks of Encrinus form whole beds. Ceratites nodosus, practically confined to Germany, is common everywhere.

Keuper sandstones of Württemberg: well-preserved amphibia and reptilia; gigantic Mastodonsaurus, Capitosaurus; huge Belodon, Zanclodon. Famous is a slab with 24 specimens of Aëtosaurus (Stuttgart Museum).

The Jurassic rocks, especially of Swabia and Franconia, show a marvelous wealth of beautifully preserved fossils of all kinds: sponges, corals, jelly-fish, sea-urchins, crinoids, brachiopods, molluscs (ammonites and belemnites especially), crustaceans, insects, many fishes (ganoids especially), and above all the reptiles: Ichthyosaurus, Plesiosaurus, Teleosaurus, the Pterosaures, the unique Campsognathus, finally the two specimens of Archæopteryx so far known. Holzmaden (Württemberg), Solnhofen and Eichstätt (Bavaria) are the famous localities. The finds fill the collections of Banz, Stuttgart, Munich, Berlin. Tübingen has a slab (15x24 feet) with 24 Pentacrinus (some measure three feet across).

The flora of the Wealden formation (N.W. Germany) looks like jurassic.

Suddenly the dicotyledons appear in the upper Cretaceous beds.

The Tertiary climate was warm, the flora had a tropical or subtropical character. During the Oligocæne epoch corals could grow. The dense forests and swamps resembled those of Florida and Louisiana of to-day, although plants of a former more Indo-Australian flora survived: Conifers (sequoias, cypresses), evergreen oaks, gardenias, fig trees, cinnamon trees, palms, magnolias, laurels, but also poplars, alders. Several oscillations during the Oligocæne and Miocæne favored the formation of extensive soft coal measures. The amber (E. Prussia), the fossil resin of pines and especially one spruce (Picea Engleri) contains a rich insect fauna related to those of N. America and E. Asia of to-day.

The Miocæne flora much resembled the modern N. American and Japanese floras: sequoias, bamboo, palms, laurels, camphor, and cinnamon trees, fig trees, evergreen oaks, chestnuts, magnolias, myrtles, acacias, mimosas; but also poplars, maples, elms, walnuts, hazel nuts, willows, birches. The fauna likewise shows many specimens found now only in warm countries: elephants, Mastodon, Dinotherium, Rhinoceros, Hippopotamus, tapirs, antilopes, monkeys, together with wild boars, deer, large and small carnivores, and the ancestral forms of the horse.

In the Pliocæne epoch the climate became temperate, animals and plants resembled those of modern N. America.

The ice masses of the Pleistocæne advanced and many animals and plants were exterminated, some, however, adapted themselves. The narrow belt finally left between the northern and southern ice sheets had an arctic fauna and flora that had come in from the north. The glacial and interglacial periods caused plants and animals to migrate back and forth. Survivors of the Tertiary were: Hippopotamus, hairy elephants, the mammoth, hairy rhinocerosses; arctic forms: the musk-ox, reindeer, lemming; others: horses, deer, fallow deer, elks, the aurochs, the urus, wild boars, bears, tigers, hyenas. The ice retreated, a wide plateauland or rolling country was exposed. Animals and plants found to-day in the steppe of S.E. Russia and S.W. Siberia came in and mixed with the others: jerboas, bobacs, marmots, altaic gophers, voles, calling-hares, ermines, the Saiga antilope, wild horses, bustards.

Many arctic animals and plants could not stand the change and followed the retreating ice northward or climbed the mountains. Thus the fauna and flora of the Alps and many lower mountains (Schneekoppe, Brocken) contain arctic specimens.

Soon a denser covering with vegetation developed, immigrations from all sides occurred, a new fauna and flora resulted. Lack of connection with a region where the old Tertiary forms had survived prevented restocking. Thus we find fewer species and less variety than in N. America or E. Asia, and only the Tertiary forms of the three countries are much alike.

Old Germania was moist and cool, had extensive swamps and perhaps 75 per cent of her area covered with dense forests.

Flora.— The flora is that common to northern Europe. Germany lies entirely within the northern forest zone of phytogeography and is pre-eminently a wooded country. Even to-day forests abound (26 per cent of the area; France, 16 per cent; Great Britain, 3 per cent). Man has taken care of the woods, dried out or drained swamps, regulated rivers, planted fields, and thus caused great changes. Little "primeval forest" is left. (N. and N.E., Bohemian Forest.)

The flora comprises about 2,200 phanerogames, 60 vascular cryptogames; 6 coniferous forest trees: fir, spruce, pine, larch, juniper, yew, 40 deciduous forest trees, 20 shrubs.

An alpine flora (one third of the alpine plants) is found in the Bavarian Alps and spreads along the rivers onto the high plateau. The Sudeten mountains (with some arctic forms missing in the Alps) and the tops of other high mountains (Brocken) are isolated centres of alpine plants.

The southern mountainous region (so-called Hercynic flora) is characterized by the fir (Abies alba) and shows a varied flora, the valleys having the Baltic, the mountain slopes a subalpine character. Vine culture is possible only here.

The Baltic flora occupies the northern lowland.

The forest line on the mountain slopes is at about 4,000 feet (Brocken, 3,400; Vosges, 4,264). Above is a zone of trailing trees and shrubs up to about 4,500 feet: Mountain pine (*Pinus montana*), dwarfed willows and junipers, rhododendron (in the Alps); above this the true alpine region with its peculiar flora. The highest peaks have only cryptogames (lichens, mosses). The alpine region in Bavaria begins at 5,500 feet, spruces go up to 5,900, larch trees to 6,200. Generally, heights above 3,500 feet are unfavorable to tree growth and covered with grasses and often heather. In the Alps the region above timber-line is pasture with many flowers (gentians). Many species which are missing in the arctics probably represent alpine plants of the Tertiary (Edelweiss).

The deciduous forests are diminished by secular changes (natural rotation?): the spruce *(Picea excelsa)* is everywhere gaining ground at the expense of the red beech which, as is almost certain, once crowded out oaks, pines, and birches (known to have happened in Denmark). In W. Prussia pines replace oaks and birches.

To-day, deciduous forests occupy only the lower mountain slopes, above are coniferous forests. The Spessart only has retained its old oak and beech forest to the top. The large Buntsandstein area in S. W. Germany not good for agriculture supports magnificent forests.

The pine is typical for the northern lowlands and forms forests even on the sand plains. The spruce has spread from the south all over the country. The larch forms groves in the Alps but is not confined to them. The Swiss Stonepine (*Pinus cembra*) occurs in a few places in the Bavarian Alps. The yew once common has almost disappeared and is found only in E. and W. Prussia, and occasionally in the mountains. The juniper is a tall tree in the E., smaller and rarer in the W., missing in E. Friesland; a shrub in the mountains and in the heath.

Deciduous forests are usually mixed, beech forests, however, common. The northern limit for the beech is south of Königsberg. In the N. the oak is most characteristic (two kinds); it is the national tree celebrated by songs, poems, and myths. Maples, elms, hornbeams, birches, ashes, mountain-ashes, poplars, aspens, wild apples and pears, hawthornes, service trees form the mixed forests which contain no trees with showy flowers, except wild fruit trees, have little underbrush and no climbing vines, except hop, clematis, and ivy. The autumn coloration is not remarkable. The beauty of the mountain forests lies in the mixture of light deciduous and dark coniferous woods, interspersed here and there with meadows or heath patches.

The linden marks former Slavic regions. The chestnut (Mediterranean flora) thrives along the Rhine. The evergreen holly (Mediterranean) is confined to W. Germany. The evergreen box avoids the cold east.

Introduced trees: American horsechestnuts quite common, especially in the cities; American locust trees belong to the flora now and form woods in Anhalt; Oriental cherries, plums, prunes, apricots; and walnut trees are common fruit trees. Along the highways tall Lombardy poplars are seen, but also apple, cherry, and plum trees.

Meadows occupy marshy districts along the shores, and together with woods, the flood plains of rivers, and form patches in the mountains and in the Alps. They are a dense growth of grasses (20–30 species) intermingled with a great variety of flowering herbs (meadow saffrons in the fall); natural or cultivated, always indicating moist soil.

On sandy soil birches and pines may grow or the heath develops (heather and vaccinium) (N.W. Germany, tops of mountains, high plateaus of S. Germany).

Bogs and swamps cover large areas of the lowland and of the southern plateaus. They are the coldest parts of the country and retain arctic plants. Rushes, sedges, reeds, sphagnum mosses and the insectivorous sundew, Utricularia, and Pinguicula form their flora.

Along the shores a salt flora develops with fleshy leaves and stalks. It is occasionally found inland (near Halle).

Sand dunes have special grasses and thistles.

Elodea canadensis introduced in female plants only has multiplied so that it often blocks navigation in rivers and canals.

Red poppies, blue bachelors' buttons, and purple corncockles adorn the grain fields. Many plants, especially weeds, are spread by man, railways, and modern traffic, and foreign plants are mixed in with the native flora.

Difference in climate: fruit trees bloom in Memel about four weeks later than on the Rhine.

Fauna.— Old Germania had a rich woodland fauna. Directly and indirectly man has caused many changes. Many animals were exterminated, others were too much disturbed in their habits and disappeared. The creation by farming of an artificial steppe («Kultursteppe») invited others. Some were protected, other useful or injurious ones introduced.

Mammals.— The urus became extinct probably in the 17th century. The last bison (aurochs) was killed in E. Prussia in 1755. The elk is now confined to a few preserves in E. Prussia. Wild boars much reduced in number survive only by protection. Bears have not been seen since 1835 (Bavaria). The wolf is now only found along the western mountainous border and in the large eastern forests. The lynx, common in the 17th century, seems to have disappeared (last ones: Harz mountains, 1818; E. Prussia, 1861; Wollin, 1875). Wild cats are scarce. The beaver has narrowed down its habitat to a few quiet places (Elbe near Dessau). The black rat (*Mus rattus*) which spread during the 12th century (from Asia?) is crowded out by the brown rat (*Mus decumanus*) which migrated in from Asia in the 17th century.

The snowhare in the Alps is an arctic relic. The hare, the most popular game, has many enemies, but is still common (game laws). Rabbits have been introduced and occasionally run wild. They are bred here and there, but are not popular.

Red deer are the pride of the woods, the ambition of the huntsmen, the subject of songs and poems. They and the smaller roe deer give the best venison (game laws.) The fallow deer introduced in the 16th century, is usually kept in game parks.

Other mammals are: fox, two martens, fitchet, ermine, weasel, otter, badger, a mink called «Nörz» (*Putorius lutreolus*, very rare in N.E. Germany, reaching here its western limit of distribution); the insectivores: hedgehog, mole, six shrews; the souslik (western limit in Silesia), the hamster (a steppe form which is comfortable in the fields).

The mammalian fauna comprises about 65 species, 16 per cent. of the mammals of the paræartic region.

The *avifauna* has about 225 species. The many singing birds and water-birds are characteristic. Among the former are: finches, bullfinches, skylarks, nightingales, thrushes, orioles; among the latter: rails, coots, cranes, herons, bitterns, storks, the spoonbill, swans, geese, brants, many ducks, mergansers, pelicans (very rare), cormorants, many gulls, sternas, greebes and loons, auks, murres. Flamingoes (Mediterranean) have been met with on the Rhine.

The cuckoo (nesting parasitism like the American cowbird) is the only member of a family of about 200 mostly tropical species.

The lammergeier, the largest bird-of-prey of the old world, seems now exterminated in the German Alps. Three of the Mediterranean vultures occur rarely. The golden eagle has become very scarce, the imperial eagle sometimes penetrates in Germany. The osprey is common, the sea-eagle is found. Gledes, sparrowhawks, hawks, kites, buzzards, falcons are the birds-of-prey. The capercailzie and the heathgrouse are interesting (game laws). The large bustard, a steppe animal, is found especially in Saxony.

Many birds of passage breed in Germany and leave in the fall; northern birds spend the winter and go north in spring. From the E. birds of the Pontic fauna often penetrate into Germany, sometimes repeatedly until they establish themselves as new members of the fauna. Pallas' sandgrouse (Syrrhaptes paradoxus) has several times arrived in large flocks. The large bustard, some larks, quail and partridges, the house-sparrow seem to have come in that way, and like the "Kultursteppe." The small bustard, the bee-eater (Merops), still breed in S. and E. Europe but penetrate occasionally in Germany. They may be about to immigrate. The S.W. gate into the Rhine valley is often used by Mediterranean birds.

In autumn most of the migrating birds fly to the Rhine valley and then south to the Rhône. On Heligoland where many migrating birds take a little rest 396 different species have been observed. The black guillemot breeds here.

Thirteen *Reptiles* belong to the fauna. One tortoise occurs in ponds east of the Elbe. Three lizards (including the blindworm), the ringed snake, and the poisonous adder are common, the smooth snake is common in certain regions. Other lizards and snakes reach the S.W. so that here all twelve of them occur; among them is the venomous asp (Metz) and the deadly ammodyte viper.

The *Amphibia* have twelve batrachians and six urodeles. The nurse-frog and the Swiss newt reach into the Rhine valley, the black salamander is alpine.

A great variety of freshwater *fishes* (64 species) is characteristic, and is due to the double drainage Atlantic and Pontic). Smelt, salmon, eel, sturgeon are missing in the Danube, hucho, Acipenser ruthenus in the Rhine. The alpine lakes and those of the N. E. have many specific fishes, especially Salmonides which have become landlocked. The most important food-fishes are perch, pike-perch, carp, dace, roach, tench, bream, pike, eel, lamprey; those of the German seas: mackerel, cod, halibut, plaice, flounder, sole, herring, sprat. The piscifauna is diminishing as the industrial development progresses (withdrawal and pollution of the waters.)

The land and fresh water *molluscs* number 240, the genus Helix alone 40. Helix pomatia is the edible snail (snail farms in Swabia). The pearl mussel occurs in some districts. The Pontic Dreissena polymorpha has spread by migration and transportation through vessels into the larger rivers and is now spreading into their tributaries.

Marine food mussels are: the edible mussel, scallops, oyster (Ostrea edulis, an expensive luxury). Oyster beds are confined to the North Sea.

The *insect* fauna is numerous (6,000 beetles, 3,500 butterflies and moths), many are injurious, many useful. Immigrations can be traced from the S.W. and the E. (Praying mantis (Rhine), Cicada orni (S. W.), death's head moth, Sphinx nerii, migratory locusts). The potato beetle has appeared here and there, the American Phylloxera has done enormous damage.

The great many Carabidæ are characteristic. The cockchafer (periodicity four years) is a serious pest. The gypsy moth (E. and Bavaria), the processionary moths (N.W. and N.E.) are others.

Of the *Crustaceans* the common crayfish is widespread and a much-relished titbit.

We can distinguish three faunal districts: (1) the alpine region (chamois, snowhare, marmot, snowgrouse, chough, many insects and molluscs); (2) the mountainous regions with a western and eastern section; (3) the lowlands again with a western and eastern section.

2. Germany — Political History. The place of origin of the Germans is doubtful, and even the theory, based on similarities of language, that they formed part of one great Indo-European race is no longer tenable. One race may readily impose its language on another, as the Germans on their Slavic neighbors.

Quite early we find German tribes in conflict with the Romans. Marius (in 101–2 B. C.) gained victories over bands of Cimbrians and Teutons that had penetrated to Provence and Northern Italy. Cæsar, after a struggle with the German Ariovistus, established the Rhine as a Roman boundary. Augustus undertook an invasion of Germany and his stepsons, Tiberius and Drusus — also, later, the son of Drusus, Germanicus — penetrated far into the land and built camps and fortifications, of which the remains are still to be seen. But the Cheruscan Arminius (or Hermann) at the head of a coalition of tribes defeated the Roman general Varus in the Teutoburg Forest (9 A. D.) and liberated Germany. Augustus began the *Limes* or great fortified wall which, under his successors, was extended across the whole frontier. The Germans were not always unfriendly and a considerable trade sprang up.

From being, in the days of Tacitus, a great number of semi-nomad tribes, the Germans coalesced into larger bodies called "stems" or "nations," among which the chief were the Goths, Vandals, Saxons, Burgundians, and Franks (q.v.). The Goths were the first to accept Christianity — in the Arian form, indeed, — and were represented by their own bishop at the council of Nicea. Throughout the 3d and 4th centuries the Germans made themselves more and more felt in the affairs of the Roman Empire, and thousands were allowed to settle on Roman soil. The advent of the wild hordes of the Huns (q.v.), who first crossed the Volga about 375 A. D., started the "wandering of the nations" and brought about the disintegration of the Western Empire and the rise of new kingdoms. Of these the only one that proved permanent was the kingdom of the Franks. Its survival is ascribed to the facts that it never lost touch with Germany, and that it adopted the Roman Catholic form of Christianity, thus finding support in the clergy of its conquered provinces.

Under the Merovingian Clovis and his sons an end was put to the remnant of Roman rule in Gaul. Provinces were wrested from the Visigoths (q.v.) to the south; while, to the east the Allemanians (q.v.) and Burgundians (q.v.) were subjugated. Though the race of the Merovingians (q.v.) steadily degenerated, the affairs of the new kingdom were well administered by the chief officials, the mayors of the palace, who contrived to make their own position hereditary and who handled the kings like puppets. Several mayors in turn distinguished themselves by quelling revolts, but the most brilliant achievement of all was the driving back of the Saracens by Charles Martel (q.v.). The battle near Poictiers (732 A. D.) was one of the world's great combats. The Saracen war is notable, too, as marking the beginning of the feudal system (q.v.). The first fiefs were lands of the Church, confiscated and parceled out by Charles Martel with the understanding that the persons thus favored should provide themselves with horses and perform military service.

Pepin, son of Charles Martel, put an end to the fiction of Merovingian kingship (752 A. D.) by imprisoning the last of the line and causing himself to be proclaimed king. This he did with the sanction of Pope Zacchary, who declared the Frankish crown hereditary, anointed Pepin's sons, and pronounced a curse on those who should choose a king from any other line. Charles, known as "the great," then brought the work of consolidating the kingdom to its culmination. He conquered the last free German tribes, notably the Saxons, with whom he warred for 30 years. He interfered in Italy, overthrowing the Lombard kingdom, and he conquered the wild Avars in the present Austria. He came forward as the champion of Pope Leo III, who had traveled to Germany to ask aid against a faction of the Romans. Charles conducted a sort of trial over the Pope's enemies, finally banishing them from Rome. Leo, in return, surprised Charles as he knelt in Saint Peter's by crowning him as successor to the old Roman emperors (800 A. D.). Charles, who had already subdivided the greater party of Germany into administrative districts, now centralized the government still more by requiring a new oath of allegiance and by sending out envoys with power to examine into the actions of all officials. It was a flourishing period not only politically, but also in learning, literature, and art. Unfortunately Charles's son, Louis the Pious, proved unequal to the task of governing. He allowed the clergy to override him and did humiliating penance for alleged faults; he quarreled with his sons about their rights to the succession and became involved in civil war, which kept up after his death and only ended with the treaty of Verdun, in 843. (See PEACE TREATIES.) This treaty divided civilized Europe into three parts, one nearly corresponding to modern France, another to modern Germany, and the third being a strip between the other two, extending from the North Sea far down into Italy. After the death of Lothar and of one of the latter's sons this middle strip (Alsace Lorraine) was divided between Germany and France (Treaty of Mersen, (q. v.) 870), but remained a bone of contention down to our own day. Lothar's other son retained Italy.

From 885 to 888 the dominions of Charles the Great were reunited under his great grandson, Charles the Fat. Unable to cope with the invading Norsemen Charles the Fat was deposed and five independent kingdoms arose: Germany, France, Italy, Upper and Lower Burgundy. Germany itself narrowly escaped further subdivision, but the danger was averted by the election of Conrad of Franconia, chosen possibly because he was related to the Carolingian house. So slight was the political cohesion that Conrad went to war with the heads of each of the great duchies in turn — Lorraine, Saxony, Swabia, and Bavaria — and that he felt compelled on his deathbed to urge the election of Henry of Saxony simply because that prince had been the most powerful of his opponents and could, it was hoped, hold the discordant elements together. It was a good choice. Henry proved a great organizer, training an army, building fortresses, and overcoming the wild Hungarians and other Slavic tribes. He left Germany so consolidated that, at the coronation of his son and successor, Otto I, the heads of the duchies — Lorraine, Franconia, Swabia, and Bavaria — did feudal, almost menial, service as cup-bearer, steward, chamberlain, and marshal. Later, indeed, Otto had to put down rebellions on the part of all these dukes, and he came to rely on the ecclesiastical princes as the staunchest supporters of his throne. He inaugurated the policy, which proved unfortunate in the end, of endowing the clergy with great landed possessions. The benefit to him was that at every vacancy, as the bishops had no lawful descendants, these lands reverted to the crown and could again be used to reward faithful service. Grants made to the nobles, on the contrary, came to be looked upon as hereditary family possessions, which, being let out in return for feudal service, assured the owners of large bands of faithful retainers. These local powers, especially the great dukes, were very often arrayed against the crown.

Otto kept not merely the German, but also the Roman, church in subjection. Drawn into Italian affairs by an appeal from the heiress to that kingdom, he put her enemies to flight, married the heiress, Adelaide, and himself assumed the titles of "King of the Lombards" and "King of the Italians." He restored the empire of Charlemagne with the title of "Holy Roman Empire of the German Nation," and, for misconduct, deposed the very Pope (John XII) who had crowned him emperor. Unfortunately these Italian interests drew Otto's successors away from their duties as German rulers. Again and again, with German armies, they descended upon Italy; each felt it a vital necessity to be crowned with the imperial crown at Rome. One consequence of their repeated absences was the loss of the supremacy over the Slavic nations on the German borders.

Otto's ecclesiastical policy was imitated by his son and grandson and led to a gigantic conflict with the papacy. It was a question, ultimately, as to who should control the elections of the German bishops. If the Pope, then he had simply to adjudge the rich German sees to his partisans; the emperor lost the supporters of his throne and the lands might practically as well have belonged outright to Rome. It seemed a life and death struggle, which accounts for its long continuance and for the venom displayed on both sides. There were wonderfully dramatic moments, like the penance at Canossa of Henry IV (1077), who amid winter snows appeared barefoot on three successive days before the Tuscan castle in which sat Pope Gregory VII, refusing him absolution, or the capture, in Rome itself, by Henry V, of Pope Paschal II and all his cardinals. This so-called investiture quarrel ended in 1122 with the Concordat of Worms, a compromise by which there were to be two investitures, one with the temporal estates by the emperors, the other with the spiritual power by the Pope. It had taken 50 years to arrive at this simple solution of the matter. See INVESTITURE.

New conflicts with the papacy broke out under succeeding rulers. Frederick Barbarossa warred for years with the semi-independent Lombard cities which were upheld by Pope Alexander III. Defeated at Legnano (1176) he was obliged to conclude the Peace of Venice with the Pope (1177), and that of Constance (1183) with the Lombard Cities. See PEACE TREATIES.

The fact that Barbarossa's son, Henry VI, acquired Sicily by marriage, made the enmity of the Popes and the emperors implacable. The papal possessions seemed to be held in a vice. It was this jealousy and fear that led to the papal determination to destroy the house of Hohenstaufen, root and branch. Other pretexts were never wanting. Frederick II was placed under the papal ban for delaying to accomplish his crusading vow, and again for starting when forbidden. Crusades were preached against the emperor himself, who retaliated by capturing a whole ship-load of prelates on their way to a council at Rome. It was a Titan struggle, the Sicilian kingdom being always the real bone of contention. The papacy conquered, with the aid of Charles of Anjou, who was promised the rule over Sicily. The last scion of the Hohenstaufen line, after losing the battle of Tagliacozzo (1268), was beheaded in the market-place at Naples.

Meanwhile the continued absence of the lawful rulers from Germany, and also the gifts of land and of privileges with which they had tried to win the support of the German nobles in the Italian campaigns, had led to the rise of many small and almost independent states. Frederick Barbarossa had still been strong enough to put down his most powerful vassal, Henry the Lion, and divide up his lands. Frederick II's death (1250) brought anarchy; and when, after an interregnum, Rudolph of Hapsburg was made king it was practically a confederation over which he ruled.

Yet, strange to say, the age of the Hohenstaufens marks a great advance in civilization and well-being. It was the age of the crusades (q.v.) and of chivalry (q.v.), an age that marked an era in commerce, in learning and literature, and in luxurious living. It is from this time that some of the great cathedrals date. Germany's boundaries, too, were pushed to the east and north by colonization and occasionally by war.

The 14th and 15th century kings left little impression on the history of Germany. They were men of no great force and they advocated no great principle. Henry VII and Louis of Bavaria renewed the old struggles in Italy but with no lasting results. The quarrel of Louis with Pope John XXII, indeed, is memorable for the literary productions that it called forth. The success of the *Defensor Pacis* of Marsilius of Padua was phenomenal. Never had the papacy been so assailed.

Charles IV was a man of no high aims, and his reign is chiefly remarkable for his promulgation of the so-called Golden Bull (q.v.) in favor of the seven electors. The earlier kings of Germany had been chosen by the whole body of the princes. At the election of Rudolph of Hapsburg, however, seven,— the three archbishops (Mainz, Treves, and Cologne) and the dukes of Saxony and Bavaria, the Margrave of Brandenburg, and the Count Palatine — had been especially prominent. Bavaria's vote, indeed, was adjudged later to Bohemia. This electoral college became very powerful, exacting promises from the successful candidates and even deposing an emperor. The Golden Bull (1356) fixed the elaborate ceremonial of elections and the functions, rights, and prerogatives of each of the seven electors. They were accorded almost sovereign rights.

Equally remarkable with the growth of the duchies and electorates was the development of the free towns. We find them banding together into commercial leagues and exercising real political power, such as setting their own king on the throne of Denmark. The Hanseatic League had its own fleet and its settlements in foreign lands. It enjoyed monopolies of trade and built great halls or warehouses that excite admiration to-day.

Another important organization was the Teutonic Order, a band of knights who had undertaken the conversion of wild Prussian tribes and had ended by building up a great state with the Marienburg for its centre. The order became rich and powerful and was visited by the greatest princes. It degenerated at last and became involved in a long war with Poland. By the Peace of Thorn (1466) the part of its territory known as West Prussia passed into Polish hands, while even the portion that was left became a Polish dependency.

Throughout the 15th century the cohesion of the different parts of Germany was slight. The interests of its rulers lay elsewhere: in Hungary, Bohemia, Italy, or Luxemburg. Emperor Wenceslaus was deposed for staying away as much as eight years at a time. Sigismund made his first appearance four years after his election. Frederick III once retired in a fit of anger and did not come near a diet for 27 years. Yet the chief courts of justice followed the king's person! No wonder a secret tribunal, the Veme, could become the chief upholder of law and order and even venture to summon the king himself. Like the Hausa and the Teutonic Order the Veme had its flourishing days and then sank into disrepute; the end of the 15th century marks the decline of all three institutions.

After 1437 Hapsburgs, many of them inefficient, held the imperial throne in almost unbroken succession. After the Councils of Constance and Basel Frederick III, by a concordat or agreement with the Pope, renounced practically all the benefits that Germany had obtained. Frederick is noted for the fact that the great Renaissance movement began under his reign. His son, Maximilian, was a regular product of the Renaissance, versatile, talented, but lacking in balance. Maximilian was personally active in a scientific, literary, and artistic way, and was full of political projects, some of which were almost too wild for belief, aiming as they did at making him world-ruler. He was, for instance, to combine the offices of Pope and emperor in his own person, and to succeed Perkin Warbeck as king of England.

In Maximilian's reign, independent of him yet a product of the Renaissance spirit, falls the beginning of the German Reformation. The invention of printing (about 1450) had provided a channel for the rapid dissemination of ideas, and pungent satires like Erasmus' 'Praise of Folly,' Brant's 'Ship of Fools,' and the anonymous 'Letters of Obscure Men' had mercilessly assailed abuses in the Church. Inflammatory writings of various kinds had made the peasants familiar with the idea of vengeance on the clergy and nobles, in whose favor they were overtaxed; while payments for the support of the papal court at Rome were becoming decidedly unpopular. Altogether, the ground was well prepared when the monk Martin Luther (q.v) launched his demand for a discussion of the matter of papal indulgences, a demand that drew down an avalanche on his own head and that altered the whole course of German history.

Luther had soon found that the indulgence-preacher, Tetzel, was merely the instrument of higher personages and was not altogether to blame for his extravagant utterances. He then joined issue directly with Pope Leo X, who had authorized the indulgences, and with the Archbishop of Mainz, who was to benefit largely by them. Luther's sovereign prince, the elector of Saxony, though a professed Roman Catholic to the end, came forward as the reformer's protector, and Luther, in response to his own demand for a fair hearing, was summoned to meet the Roman cardinal, Cajetanus, at Augsburg. The meeting proved fruitless, as did one with the legate Miltitz, who had been sent to Saxony to bribe the elector with the gift of the golden rose. A disputation with the theologian Eck, at Leipsic (1519), only served to clarify Luther's own ideas and to widen the breach with Rome. In three great writings he attacked the Pope and the doctrines of the Church, drawing down upon himself the papal ban. But the bull of excommunication was publicly burnt by Luther at Wittenberg. The new emperor, Charles V, felt compelled, by a recent agreement with his princes not to condemn any one unheard, to summon Luther to his first German diet (Worms, 1521). By this time, if we can believe the Roman legate himself, nine-tenths of the German people were more or less in favor of Luther. Crowds gathered all along his route. His final word at Worms was: "I neither can nor will recant anything, for it is neither safe nor right to act against one's conscience. God help me. Amen." He left as a convicted heretic, an edict signed by a majority of the princes declaring him in the ban of the empire. His life was in danger, but by order of the friendly elector of Saxony he was attacked by seeming brigands and spirited away to the Wartburg, where he employed his time in preparing a translation of the Bible. Germany meanwhile was in a ferment and the number of polemical publications became enormous. Luther himself, by 1523, had published a hundred writings. Radical elements, men who claimed to be following Luther's own teachings, soon caused disturbances and drew him from his seclusion. His successful effort at restoring order in Wittenberg was one of the causes that prevented his arrest. His rôle in the great peasant revolt that broke out in 1524 was not so admirable. His incendiary eloquence had been taken by the masses as an invitation to iconoclasm. Discontent against the nobles, fanned by long oppression, had blazed up fiercely and 300,000 peasants rose in revolt, sacking castles and monasteries in all directions. Luther preached against them as "brands of hell," and urged every man to strike them dead. The revolt was quelled and horrible vengeance taken, but Luther, naturally, lost many adherents, and the course of the reformation was changed. Reliance had now to be placed on the princes rather than on the people. The Edict of Worms was never carried out, though still considered in force as late as 1530. Charles V was hampered by political considerations and by his wars with Francis of France and the Pope. His enmity to the latter once led him to remark that "Martin Luther might, after all, prove a useful man." Luther was able at his leisure to organize his new church; and the diet of Spires, in 1526, unanimously passed a decree which practically allowed the Lutherian princes to conduct the religious affairs of their lands as pleased themselves.

The reversal of this decree, in 1529, by a simple majority vote, drew forth the "Protest" from which the "Protestant" party takes its name. Charles V had meanwhile gained the advantage both of the papacy and of France (treaties of Cambray and Barcelona) and his adherents were feeling very aggressive. They wished to force the issue, and they succeeded. The "Protest" was a technical one against the right of the diet to reverse the former unanimous edict. Charles himself earnestly sought to bring the schism to a peaceful end. He invited discussion and summoned conferences, acting not at all like the tyrant that many writers have made him out. He staved off war for 17 years, and then entered into it more on political than on religious grounds. Several Protestant princes fought on his side. This war with the Smalkald League, of which Elector John Frederick of Saxony and Margrave Philip of Hesse were heads, ended in the defeat and capture of those princes and in their long captivity. The electoral dignity in Saxony passed to the other branch of the house, the head of which, Maurice, had helped the emperor. But Maurice in turn, dissatisfied because Charles did not fully keep his promises, and alarmed at the emperor's attempt to have his son, Philip II of Spain, declared successor to the throne, headed a revolt which reduced Charles to great straits. A temporary peace was concluded at Passau (1552), but the final settlement was delayed by the disunity of the Protestant princes, the Margrave of Culmbach and Maurice of Saxony fighting on opposite sides. Maurice was killed at Sievershausen (1553).

Finally at Augsburg (1555) a general peace was concluded between the Protestant and Catholic princes; but by Ferdinand, not by Charles V — the latter preferring to abdicate rather than to make the needed concessions. The basis of the peace was free choice on the part of each lord of the land of the form of faith to be tolerated. There were, unfortunately, ambiguous clauses that led to later conflicts.

For the next 20 years Protestantism had the upper hand; but while the Roman Catholic party was strengthening itself by internal reforms, the Protestants, through dogmatic disputes, were becoming greatly weakened. Saxony (Lutheran) and the Palatinate (Calvinist) allowed their private enmities to ruin their cause as a whole. The Jesuits, marvelously trained for such work, made it their chief purpose to combat Protestantism. They secured the majority of votes in one bishopric after another, and even in the imperial diets and in the law courts.

A revolt of the Bohemians (Protestant) against the house of Hapsburg precipitated a European war. The acceptance of the Bohemian crown by Frederick V of the Palatinate was a challenge on political as well as on religious grounds: for the other German states could never suffer one of their number to hold two of the seven electoral votes. The Pope, the king of Spain, the elector of Bavaria, even the Protestant elector of Saxony rallied to the Hapsburgs. Frederick proved but a winter king and, before a year was over, was decisively defeated on the White Hill near Prague. New allies came to the fore in time: Bethlen Gabor, prince of Transylvania; Mansfeld, the Savoy condottiere; Christian of Brunswick; the margrave of Baden Durlach, and, last but not least (1530), Gustavus Adolphus of Sweden. The emperor, Ferdinand II, would have succumbed to Gustavus Adolphus, who won a great victory at Breitenfeld and made a triumphal progress as far as Nuremberg, had he not, by enormous concessions, succeeded in inducing the mysterious Wallenstein, who was living in forced retirement, to re-enter his service. Wallenstein, endowed with dictatorial, almost royal rights, raised a huge army, compelled Gustavus Adolphus to withdraw from Nuremberg, and, finally, engaged him in a battle at Lutzau, near Leipsic, that cost the Swedish conqueror his life. Later, indeed, doubts arose in many quarters as to Wallenstein's ultimate purpose. As far as we can judge now, it was to dictate a peace to Germany even at the risk of having to intimidate the emperor. Just at what stage his dealings with the Swedes and Saxons became treasonable is hard to establish, but treasonable they were at the last. An order was given for his arrest, living or dead; and some of his own officers joined in a deliberate plot to kill him. His room was invaded, he himself stabbed in the breast (1634).

The war now entered a new phase. It was no longer merely a question of religious interests, for Catholic France joined in on the side of the Protestants. The struggle finally became one merely for compensation and costs. For four years it went on simultaneously with peace negotiations (at Osnabruck and Munster in Westphalia) which ended in an agreement as to mutual religious toleration and in a readjustment of the map of Europe. Unfortunately the boundary between Germany and France was established by an ambiguous formula and, later, led again to war (1688–97).

The most important development in the period following on the peace of Westphalia was the rise of the Brandenburg-Prussian monarchy. See Prussia. After the Great Elector (1640–1688) had consolidated his possessions, his son, Frederick III, was allowed to assume the royal title as compensation for aid furnished the Hapsburg emperor in the Spanish Succession War. The Spanish throne, vacant by the death of the childless Carlos II, was claimed by Emperor Leopold for his son Charles (VI), and by Louis XIV for his grandson, the duc d'Anjou. Against Louis XIV was arrayed the grand alliance, consisting of England, Holland, Austria, and the majority of the German states. With Louis were the electors of Cologne and of Bavaria. The war, which lasted 13 years, showed an almost unbroken series of victories — Blenheim, Turin, Ramilies, Malplaquet, and others — for the Grand Alliance. Yet by the treaty of Baden (1714) the German states gained absolutely nothing, England and Austria having already secured their own advantages by the treaties of Utrecht and Rastadt.

Meanwhile in Prussia (see Prussia) the first king, Frederick I, had been succeeded by the great organizer, Frederick William I, who remodeled the administration, brought the army to the highest pitch of efficiency, and placed the finances on a good basis. It was these reforms that enabled Frederick the Great to play a commanding rôle in European history. Scarcely had Frederick come to the throne (1740) when he made a descent on the Austrian province of Silesia, advancing old claims of his house, not altogether unwarranted, to a portion of the territory. Received with open arms by the inhabitants of Breslau, who had chafed under the Austrian rule, he won the battles of Mollwitz and Chotusitz, and compelled the Archduchess Maria Theresa to conclude the Peace of Breslau (1742) which left Silesia in his hands. Austria and England continued the war with France. Austria's growing strength and prestige, and especially the fact that, in 1744, she concluded a treaty with Saxony, determined Frederick to re-enter the arena. He did so ostensibly in support of the new emperor, Charles VII of Bavaria, the only man not a Hapsburg chosen to that position in 300 years. In the Bohemian campaign of 1745 Frederick suffered severe reverses, but at Hohenfriedberg, at Sohr, and at Kesselsdorf he gained important victories and was able to obtain at Dresden the same terms as in the Peace of Breslau, compelling Saxony, besides, to pay an indemnity. Charles VII having died, Maria Theresa's husband was now elected emperor, and took the name of Francis I.

Eleven years later Frederick, learning through secret channels that Maria Theresa, the Czarina Elizabeth, and Augustus of Saxony-Poland were plotting the dismemberment of Prussia, concluded the Convention of Westminster with England and prepared for a new war (1756). France, where Madame de Pompadour was now all powerful, joined the two empresses. Madame de Pompadour boasted that the Treaty of Versailles (May, 1750) was her work. It was followed by a second, offensive, treaty signed at the same place. See Peace Treaties. The odds against Frederick in this Seven Years War were very great, for though England sent him money and though she maintained an army of Hanoverians, she sent him no direct reinforcements. The allied forces often outnumbered his own by two and three to one, yet in the teeth of such superiority he gained some of his most splendid victories: Rossbach, Leuthen, Zorndorf, Liegnitz, and Torgau. There came a time, indeed, when even victories were of small avail, for there was no way of filling the ranks. The death of the Czarina Elizabeth (1762) did more for Frederick than many battles and even neutralized the effect of the desertion of England, which country, under the new Bute ministry, suddenly left him in the lurch and tried to compel him to make peace. The new Czar, Peter the Third, became Frederick's ally but was deposed before his troops could be of much assistance. France, however, had also withdrawn from the struggle and concluded the preliminary Peace of Fontainbleau with England. Maria Theresa saw the helplessness of continuing alone the task she had been unable to accomplish when aided by powerful allies, and sent an envoy to treat for peace. After seven weeks of negotiation an agreement was signed at the castle of Hubertsburg (1763) which in every respect was a return to the condition of things before the war.

Later Maria Theresa and her son, the Emperor Joseph, joined with Frederick and with Catherine of Russia in dismembering Poland — a step which the demoralization of the Poles invited if it did not excuse. Though Frederick the Great's share was but one-third the size of that of either of his allies, it was doubtless of greater proportionate value, as it comprised West Prussia, the land that had once belonged to the Teutonic Order, and rounded out his domains. Austria and Prussia once more went to war (1778–9), this time with regard to the Bavarian succession, claimed by Joseph. The acquisition of a German electorate would have assured the preponderance of Austria in all the affairs of the empire and would have been a fatal blow to Prussia. Frederick and his brother Henry took the field in person, but no battle of importance took place and the war was stopped by the intervention of France and Russia. Frederick devoted his last years to organizing a league of German princes for mutual protection against Austria. It was a powerful weapon, for three of the members were electors and might readily be in a position to frustrate the choice of a Hapsburg as emperor.

Frederick's policy of opposing Austria with the aid of other German states was not carried further by his successor, Frederick William II. Indeed the latter sided with Austria in an attempt to intimidate the French revolutionists, and joined with the Emperor Leopold II in the declaration of Pillnitz (1792). Frederick William himself took the field. The blatant manifesto of his chief commander, the Duke of Brunswick, roused the French to fury and encouraged them to win the battles of Valmy and Jemmappes (1792).

Frederick William's attention was diverted from France by further partitions of Poland (1793 and 1795) which gave him a vast territory; but the new provinces were badly administered and proved a source of weakness rather than of strength. Prussia had greatly lost her prestige even before Frederick William consented to the disgraceful Peace of Basel (1795), which secretly bound Prussia to non-interference even though France should annex the left bank of the Rhine. Austria was left to continue alone the struggle that had been begun in common, but in 1797 concluded the Treaty of Campo Formio, which contained secret clauses about the left bank of the Rhine similar to those signed by Prussia.

The Holy Roman Empire, as it was still called, was in an incredible state of disintegration. At the Congress of Rastadt (1798) the French envoys openly came out with their demand for Rhenish territory, and the dispossessed princes clamored for compensation elsewhere in Germany. A witty publicist thereupon drew up the last will and testament of the old empire. Austria renewed the war, indeed, but was defeated at Marengo and Hohenlinden and, by the Peace of Lunéville (1801), was obliged to take active part in the dismemberment of Germany. An executive council of the Diet, called the Imperial Deputation, passed a decree (1803) which practically annihilated more than 200 German states and divided up 50,000 square miles of territory. The compensations were arbitrarily apportioned so as to serve French interests, Napoleon Bonaparte's idea being to strengthen the South German states and create a "Third Germany" to be under his own influence. He treated Germany as conquered territory, sending his troops to occupy Hanover, carrying off and putting to death the duke of Enghien, who thought himself safe on Baden soil, and causing a bookseller of Nuremberg to be shot for selling a harmless publication which bewailed the general state of affairs.

The murder of the duke of Enghien was one of the occurrences that roused Alexander of Russia to form a third coalition which was joined by Austria and England, but not by Prussia. The Napoleonic victories at Ulm and Austerlitz (1804) routed this coalition, and by the Peace of Pressburg (1805) Austria was divested of 28,000 square miles of territory and 3,500,000 inhabitants; while Würtemberg and Bavaria, which had aided Napoleon, were raised to the dignity of kingdoms. They formed the nucleus of the Rhine Confederation, which now formally repudiated the jurisdiction of the Holy Roman Empire. This caused Francis I to abdicate the throne (1806), though he had carefully provided for the future, in 1804, by having the Hapsburg possessions declared an empire by themselves.

Prussia was now goaded into war with Napoleon by violation of her territory and by double-dealing with regard to Hanover. But never had a seemingly strong state shown more abject weakness; never was military organization more faulty. The defeats of Jena and Auerstädt (1806) were overwhelming and the fortresses with which the land was studded fell like houses of cards. A brief rally at Eylau, where the Prussians were joined by Russian forces, was followed by the defeat of Friedland which frightened Alexander into signing a truce. By the Treaty of Tilsit (1807), Prussia was humbled in the dust and was shorn of half of her provinces. They went to form the kingdoms of Westphalia for Jerome Bonaparte, and the duchy of Warsaw for the king of Saxony.

Then began a time of moral and physical regeneration. In every department arose earnest workers: Stein and Hardenberg, Scharnhorst and Gneisenau, Jahn and Arndt, Fichte and Schleiermacher. Austria, too, arose from her lethargy, but struck her blow at Napoleon too soon and collapsed after Wagram (1809). Napoleon made Prussia join him in his invasion of Russia, but his disasters gave the Prussians their longed-for opportunity. General Yorck, in command of a Prussian auxiliary force, renounced his allegiance to France, and even the phlegmatic Frederick William III was finally carried away. Landwehr and Landsturm were called out; England, Russia, and Austria came to Prussia's aid and the war of liberation began (1813). Napoleon returned from Paris with a new army and gained the battles of Lützen and Bautzen. But Blücher showed indomitable energy. After a series of defeats and one more victory Napoleon was penned in in Leipsic, and only escaped after an ultra-bloody three days' battle. He was eventually followed into France and was forced to surrender. His return from Elba and his defeat at Waterloo are too familiar to be more than mentioned. See WATERLOO, BATTLE OF.

The Congress of Vienna left Germany in a very unsatisfactory condition, as a loose confederation with Austria at the head, and with a Diet that was to meet at Frankfort. There was no central army, no treasury. The only means of coercion was federal execution, the deputing of one state to punish another.

The policy of the reactionary Austrian minister, Metternich, dominated the next 30 years. He made it his life-work to prevent the German states from introducing constitutional government. He saw conspiracies everywhere and became the bitter enemy of the Burschenschaften and Turnvereine, comparatively innocent student organizations which held meetings, like the Wartburg and Hambach festivals (1817 and 1832), where there were inflammatory demonstrations. The murder of the Russian agent Kotzebue by the Jena student Karl Sand enabled Metternich to thoroughly frighten Russia and Prussia, which had formed with Austrian a "Holy Alliance." Draconian decrees were passed, and a sort of revolutionary inquisition was established at Mainz (1819). The Burschenschaften were dissolved, but the discontent of the students simmered on until 1848.

The hope of Germany, as we know now, lay in the supremacy of the strongest state. It was a great step forward when, between 1828 and 1842, Prussia managed to enroll in her Customs Union all the other German states except Austria. Commercial hegemony then paved the way for political leadership. One deterrent was the imperviousness of the Prussian king to liberal ideas Frederick William IV steadfastly refused to give his subjects a written constitution, though at times using language that implied sympathy with the popular demands. In 1848 the happenings in France unchained the spirit of revolt all over Germany. There were bloody uprisings in Berlin and Vienna, and a national parliament met at Frankfort. The crown of a new empire was offered to Frederick William IV, but he spurned it as a crown plucked from the gutter and reeking like carrion. He got the better of the Prussian revolutionary parliament, but felt obliged to grant a constitution which, as he wrote to a friend, was liberal enough to make his own stomach ache. It is the constitution still in vogue in Prussia. The Frankfort parliament was finally dispersed by force of arms, and Prussia endeavored to form a "Union" of which she should be head (1849). At Olmutz (1850), at the peremptory summons of Austria, she desisted, and consented to a simple restoration of the old confederation, with its diet, as before, at Frankfort. To this diet the Prussian delegate was Otto von Bismarck who, for 10 years, made it his special task to combat Austrian pretensions. Later he attacked the problem by strengthening the Prussian state, being called by King William to be prime minister, and so put through a great increase in the Prussian army. This was done by technically unconstitutional means and in the teeth of violent opposition from the parliament, which was not appeased until the utility of the new measures had been proved beyond a doubt in the victories over Denmark (1864) and over Austria (1866). The Danish war had been undertaken in common with Austria because of Danish efforts to incorporate the province of Schleswig-Holstein; the conflict with Austria had arisen with regard to the disposal of the spoils. Austria, supported by the minor German states, had threatened federal execution. Prussia had accepted the challenge and declared her intention of founding a new confederation which the other states were to be compelled to join. After the swift overthrow of Saxony, Hesse, Hanover, and Nassau, and after the great victory over Austria at Königgratz, this plan was easily put into execution. Prussia became the head of the North German Confederation, from which Austria was excluded. By the mediation of the French emperor, Napoleon III, it was stipulated that the South German states might form their own organization, which they never did. Prussia was allowed to annex much of her conquered territory.

Napoleon's own prestige demanded that France, too, should have some annexations to show. He begged for the Rhenish provinces, he tried to buy Luxemburg. But Bismarck was inexorable. Hatred of Prussia became a dominant passion with the French, and when, in 1870, a pretext was found in the candidacy of a Hohenzollern to the vacant throne of Spain, the nation rushed joyously into war. When the candidacy was withdrawn the chamber sent an insulting demand that the king of Prussia should promise that it should never be renewed. Bismarck's publication of a terse version of the incident aroused intense excitement in Germany; but it was the French who began hostilities. Their total want of preparation and the wonderful organization of the Germans, for which Moltke was largely responsible, brought about the long series of French defeats and resulted in the capture of the two main armies, as well as of the emperor's own person (Metz and Sedan). After the successful siege of Paris the war closed with the treaty of Frankfort (May 10, 1871). Already on 18 January, by invitation of all the states, King William of Prussia had assumed the crown as German emperor.

3. **Germany—Political History (from 1871-1906).** The date of birth of the new German Empire, 18 Jan. 1871, marks the successful termination of the efforts of the German people, continued ever since the downfall of Napoleon, to reconstruct national unity; it marks also the beginning, for this Empire, of an era of deliberate consolidation within, as well as of a gradual, since 1890 however, more vigorous, expansion, less territorially than industrially, commercially, and culturally, into nearly every part of the globe. None of the other great powers has enjoyed, during the 35 years past, the blessing of a more peaceful development. During this period the population of the Empire increased from 1870–1890 by 8½ millions (from 41 to 49½ millions) and, in a much higher ratio, from 1890–1906 (January) by 11½ millions (from 49½ to 61 millions). From an inferior position the Empire rose to be second only to the United States in the production of iron and steel, second only to England in merchant marine tonnage and foreign commerce, and holds undisputed first rank in the excellence of ocean steamship building, in war materials, and first rank in volume also of the output of chemicals, of sugar, of printed books and music. Nor have the higher cultural affairs been allowed to lag behind in development: Germany still leads the world in the provision for and organization as well as the methods of learned and scientific research, in university and general school organization, in the cultivation of art and music. Since the country is not favored by great natural resources, it is obvious that man's will and intellect have overcome difficulties, triumphed over the material forces, and made the most of the situation. It is also evident that it required unusual wisdom and conscious effort in the policy of the nation, domestic as well as foreign, to bring about and safeguard this extraordinary development. The lack of perspective, of course, does not permit of a definitive estimate of this period, yet a review of it, in its more important aspects, clearly reveals the outlines of the main currents of historical development. Two periods are easily discerned; the one from 1870 to the resignation or dismissal from office of the first imperial chancellor in 1890; it is dominated by the personality and the leadership of him whose creation the new body politic may be said to be, Bismarck (q. v.). The second period, still in process, succeeds the first; it is outspokenly characterized by Emperor William the Second's (q. v.) personality. These two men are both leaders and types (the most pronounced, naturally) of the minds and men ruling and shaping modern Germany, they embody her spirit and energy much beyond the average measure. The men of the first, the Bismarckian, period quite logically entered upon the task of consolidating, and filling out, within the outer framework of the national structure. Germany, it was obvious, would have to be maintained principally, according to old political wisdom, by what had built her up, her military organization, defensive as well as offensive. The nation realized this fully, in fact nowhere is the army such a popular and, in the best sense, a democratic institution as with the Germans. The development of the army, in numbers, efficiency, technique, and organization, has been the paramount national concern, uniting, with the exception of the Socialists, all parties, north and south, Prussians and Bavarians, and the rest. When, in 1886, a great portion of the Liberals blunderingly opposed, for party reasons, measures calculated to increase the efficiency of the army organization, an appeal to the people in the new elections swept the extreme Liberalists into impotence. Pacificist arguments have evidenced no influence with a people so exposed, naturally, to foreign invasion.

Federal legislation covers a vastly greater area in the German Empire than in the United States. The execution of the Federal laws, however, is, different from the United States, entrusted to the judges of the States. Only the Imperial Supreme Court (Reichsgericht) at Leipzig, strictly speaking, is composed of Federal judges appointed by the emperor on nomination by the Federal Council (Bundesrat). German institutions resemble French ones in the fact of a stricter separation of administrative and of legal functions; they resemble Anglo-Saxon ones in the application of self-government principles. So, e. g., the 'Landgemeindeordnung,' an act of 1891 organizing rural communities in Prussia, is a continuation of the policy of administrative decentralization so successfully inaugurated by Stein in the Städteordnung. Gradually the legislative jurisdiction of the Empire was extended, after the Reichstag, in 1873, on an original motion by the National Liberal Lasker, had adopted the constitutional principle of Federal competency in all matters of legislation. Criminal and civil procedure were made uniform for the Empire and a uniform system of courts was established. Furthermore, a series of laws regulating and meeting new conditions in the rapid economic development of the country were framed and enacted as Federal laws, acts concerning trade organization, banking, merchant marine, patents, etc.

The adoption of the criminal and the commercial codes, the acts regulating citizenship, copyright, etc., mark important steps in the unification and consolidation of the German States. The culmination of this process was the introduction, as the result of many years of juristic codification, of the Imperial Civil Code ('Bürgerliches Gesetzbuch), in 1900. Roman civil and the territorial laws are thereby superseded by a law of distinctly more Germanic character. A unique legislative development is contained in the body of laws relating to workingmen and their conditions enacted since 1883 (Sozialgesetzgebung); partly as the result of the spread of socialistic agitation among industrial workingmen, an agitation which led, indirectly, to several attempts to assassinate Emperor William I. (in 1878 and in 1883), partly in recognition of the obligation of state and society to protect and assist the economically weak in their struggle for existence. Besides these labor laws, e. g., protecting children and women, and establishing courts for settling minor industrial disputes, a series of insurance and pension laws for the laboring classes came into existence, insuring (in 1900) about nine millions of working people against sickness, 17 millions against industrial accidents, and securing for 13 millions pensions in case of permanent infirmity, and at the age of 70. In the same year the Empire's and the employers' share in the payment of premiums amounted together to 200 millions of marks. An Imperial Insurance Office (Reichsversichrungsamt) and numerous branch offices carry on the immense executive business of this legislation. It is true the Socialist vote, in spite of all that, has steadily increased, numbering, in 1903, more than three millions, but it is also true that the intransigent radical character of the movement is slowly but surely decreasing.

It is evident that Bismarck (cf. his 'Memoirs') was to some extent influenced, if not carried away, by doctrines of Liberalism, when he entered into the conflict with the Catholic Church (Kulturkampf). Since the Vatican Council had adopted the dogma of papal infallibility, Liberals and Liberal Catholics (these latter ones headed by the learned Bavarian Ignaz Döllinger) had been thrown into a state of uneasiness, since, by origin and application, the dogma was clearly anti-German and obviating German political consolidation. It is a fact, however, that principally these hierarchical tendencies urged Bismarck to the direct attack on the Church by a number of restrictive and disciplinary laws (Maigesetze) excluding the Jesuits and similar congregations from Germany, and pronouncing a number of principles of State authority over ecclesiastic affairs. By combining the Catholics with the separatist and anti-imperial tendencies of the Guelphs, Poles, Alsatians, and part of the Bavarians, the Center Party, in consequence of these laws, was organized, principally by Windthorst (q.v.) into the strongest party of opposition to the imperial and consolidating policy of Bismarck. When, in 1878, Leo XIII. succeeded Pius IX., and William I. feared for a dangerous loss of religious spirit among his Catholic subjects, peace between State and Church was obtained by compromises and gradual abolition of the most offensive and disquieting church laws. Yet the State retained a number of valuable conquests, e. g., relating to so-called mixed marriages, school supervision, etc., and succeeded in strengthening materially the patriotic devotion of Catholics to the Empire and its future, and weakening the fierceness of partisan strife which was the curse of German political life for centuries. But if we believe with Treitschke that men make history, too much importance can hardly be given to the uplifting and unifying effect of those personalities with whose names the founding of the Empire is associated, Moltke, Roon, and more than these, William I. and Bismarck

William I. and Bismarck.— William I., king and emperor, through his very personality, gave the Germans, in an age of liberal and republican tendencies, a new and genuine love and respect for monarchial institutions, which, since his death, have been rather strengthened by domestic and foreign experiences. This strong and dignified man was again, in the fullest sense, what his ancestor, Frederick the Great, had been, but on a firmer, a nonautocratic basis, the first servant of the State. A modern German writer calls him a patriarchal educator of the German people, "a plain German, honest, sincere, just, benevolent, sensible, unselfish, God-fearing. In him was embodied heroic gallantry, a strongly national and lofty sense of honor, faithful and laborious fulfillment of duty in the service of his country." And yet the greatest has not been told without an appreciation of his unusual ability to select and his loyalty toward the great men, whom he was blessed to encounter in his life, especially toward the greatest of them all, Bismarck. He, in a higher sense even than Luther or Frederick the Great, will stand in German history as the national hero, the representative German, to speak with Carlyle and Emerson. He united where Luther was forced to disunite, and he embodied, in his person and his works, both the conservative and the liberal elements, the traditional and the modern views, from the harmonious union of which emanates that healthful realism or practical idealism that makes nations prosper. Bismarck, more than any other German, has won for the Germans a national consciousness and pride which with other nations are a long inheritance. The verdict of the great conductor, von Bülow, that Beethoven's 'Eroica' had at last found its hero in the welder of German national existence is accepted as the verdict of his people. The sculptor Lederer, in the colossal statue of Bismarck erected by the city-republic of Hamburg to its friend and benefactor, represents him as a modern and idealized Roland, in whom the mediæval Hansa towns personified their civic liberties and independence. So the people's imagination, like the artist's, is simplifying the character of the first chancellor into an heroic type of colossal outline: the creator as well as the conservator and guardian spirit of his nation's greatness and might. Bismarck was, unlike Napoleon, a religious man; he felt himself to be a soldier of God in the service of his king and his people. His loyalty toward his monarch springs from this source, also his keen appreciation and respect for the subtler feelings of his people, which the political doctrinaire never takes into account. He never interfered with these feelings needlessly, that is, unless a higher duty, the ideal of national unity and power, was involved. His critics, incompetent ones, who have no sympathy with his soul nor his ideals, see him merely as the man of blood and iron, who, however, was possessed of the tenderest feelings toward his wife and family, and whose heart beat with horror and was full of responsibility at the thought of war and its effects. The Napoleonic "hybris" which trampled underfoot everything in the way of its self-aggrandizement was not in Bismarck. While Napoleon's work was shattered, most of it, Bismarck's will stand as long as true patriotism shapes the destiny of his creation.

Bismarck opposed unnecessary centralization and red tape; the smaller States in the federation and their rulers could rely on him as their stanchest friend as long as they were loyally and actively engaged in the affairs of the whole empire. Unlike Napoleon, after the state of saturation, on national lines, was reached with the foundation of the Empire, he never conspired to annex, or force into the federation against their will, smaller States, like Belgium, Holland, Switzerland. He resisted also all agitation for a similar union of German Austria to the Empire. His whole life was spent in uniting and consolidating the unity of his people. Even when grudgingly aloof from the affairs of state after his dismissal, he advised and cautioned his nation from the fullness of his experience. In his memoirs he left the Germans a treasure of history and political wisdom in classical German. The sociologist and sometime Austrian minister, Albert Schäffle, speaks in his memoirs of a meeting with Bismarck who consulted him regarding the plans of the workingman's insurance laws, as follows: «The most interesting feature of this interview I feel to be the perception, how Bismarck took in at a glance, with the intuition of a genius, the situation and all its circumstances, even the remotest, bearing on the immediate success, nor did he neglect those facts that at present seemed to be irrelevant but were bound to be of importance later on. Then I understood the secret of his great success and of his power, but also the reason for his many changes of tactics and temporary retreats in his political career.»

Bismarck succeeded, after 1871, in preserving the peace for the Empire. Twice the country was on the brink of war with France, in 1875 and in 1887 (Boulanger); both times his calm conduct and his firmness in carrying through defensive measures, averted the war. When Russia, in 1879, after her diplomatic defeat at the Berlin peace congress, in her Balkan policy, threatened an alliance with France, he entered with Austria into the «Zweibund,» which became the «Dreibund» by Italy entering the alliance in 1883. Especially the relations of the Empire to Austria have become more and more friendly and close, from geographical, racial, and economic reasons. Bismarck had worked toward this ever since 1866 with steadfastness and clearness of vision. The recent troubles of Russia with its resulting new grouping of powers still leaves the German Empire in i. itary predominance on the Continent, even without Italy staying in the triple alliance.

When William the Second succeeded his unfortunate father in 1888 it soon became apparent that he, as Bismarck had prophesied, would be his own chancellor. It was the temperament and the whole high-strung individuality of the young ruler that made impossible the co-operation of two so masterful minds. Yet, with some oscillations due to the nervousness besetting public life after this sudden change, the traditional policy within and without was carried on on Bismarckian lines. In foreign relations William II. continued to cultivate the friendship and close defensive alliance with Austria-Hungary. He succeeded also in changing the attitude of the influential Danish court and of the Danish nation into one of friendliness, and with singular tenacity he gained friendship and influence with the Sultan for a far-sighted policy of cultural expansion in Asia Minor, Mesopotamia, and Syria. The military equipment of the nation was constantly developed. The success, since, of the Turkish, Chilean, and Japanese pupils of Prussian drill and strategy, has given abundant proof of its efficiency and up-to-dateness.

But the young emperor, and the younger generations with him, could not nor would content themselves with simply preserving what their ancestors had won for them; they pushed since 1890 with business energy into what is known as «Weltpolitik.» In the struggle for existence the fittest, nation or individual, will survive. The German nation holding such a high and unique rank among peoples, a model and a prototype for other civilized peoples, is determined to take its share of the white man's burden so-called, and to play its melody in the symphony of human culture in every part of the globe. Its paramount position in some of the highest concerns, its efficiency, honesty, and energy are so many valuable assets also of humanity, for the loss of which the world would be greatly impoverished. This is the spirit agitating young Germany and its emperor and leading them on to their destiny.

There can be no doubt that since William II.'s accession Germany's progress has been phenomenal, and it is also probable that with Bismarck's influence still omnipotent this progress would not have been so great. What was the immediate occasion, not though the cause, of Bismarck's resignation, the conflict of opinion about the policy to be pursued in regard to the Socialists, demonstrated the young emperor to have definite ideas of his own. The law against the Socialists was, in spite of Bismarck's wish, not renewed. There is no discrimination, any more, under the law, against Social Democrats. The wisdom of this measure will be appreciated only in times to come, since the numerical development of the Socialist party seems, at present, to speak against it. More immediately successful were the emperor's efforts to win over the Catholic Germans for a vigorous and patriotic participation in the national affairs. In this connection may be mentioned the extremely intimate relations the emperor entertains with Cardinal Prince Bishop Kopp and Cardinal Archbishop Fischer, of Breslau and Cologne, respectively. In fact, it may be said that the emperor's fervent patriotism, his optimism and energy, his Americanism one might say in this respect, has done immeasurable good in neutralizing that sectional strife and the spirit of partisanship so dear to the German heart. Whether Conservative or

Liberal, Catholic or Protestant, Jew or Gentile, all are carried along by their sovereign's lofty idealism, his sense of impartiality, that makes only one supreme demand: unflinching, active devotion to the nation's greatness.

There is no real break in the Bismarckian tradition of economic policy. Bismarck, at first rather favorable to free trade, for reasons of industrial development as well as for financial or fiscal purposes entered, in 1879, on a protective policy extending to grain, wood, iron, wine, tobacco, coal oil, coffee, etc. Under William II. this policy was continued but, since 1893, partly neutralized by a system of reciprocity treaties which favored especially the exporting industries. The farming interests of the nation (*Agrariertum*) were aroused by these, however, and the urgent necessity of protecting the bone and sinew of the population, the source of its military and, indirectly, also its industrial strength, its farmers, finally culminated in an elaborate revision of the tariff, prepared with extreme care and scientific acumen in the new *Zolltarif* of 1904. No doubt that this new tariff which raises the duties especially on food stuffs of every description, but also on industrial products, was brought about by the agrarian movement and by the protective tariff legislation of the United States with its almost prohibitive duties. The German tariff, though, provides for differential duties on the basis of which a number of countries (Russia, Austria, Sweden, etc.) have already come to trade arrangements with the Empire, thereby assuring a steady advance in the enormous export trade of Germany.

Gradually, although reluctantly, Bismarck had yielded, from 1884 on, to the increasing demands of the commercial interests of Germany for the acquisition of colonies. German Southwest Africa, German East Africa, Kamerun, Togo, German New Guinea, the Bismarck, and some smaller archipelagoes were acquired up to 1890. Part of East Africa (Zanzibar, Uganda, Witu) were exchanged in 1890 for Helgoland, an inadequate compensation for Germany. Since them most of the Samoa Islands have become German territory, in 1898 and in 1899 the Caroline Islands were bought from Spain in the great liquidation of her colonial possessions. Also in 1898 Kiautschou was leased from the Chinese government to serve as a German Hongkong for trade development with China. Coercive actions had to be undertaken, e. g., against Hayti and Venezuela in 1902, the latter in concert with Italy and England. The last few years in German South Africa necessitated elaborate measures for putting down the Herero rebellion, but this brought about also a renewed interest in the development of the only German colony fit for permanent settlement of white people.

While all these measures and events were, to some extent, prepared and initiated by Bismarck, there are yet two problems to be mentioned, which owe to William II. most of their solution so far attained, namely, the reform of the higher (secondary) school system in Prussia and the development of the German navy to such adequate proportions as befit Germany's position as the second country in foreign trade and in ocean transportation and the third as a colonial power. Both questions are, not directly but indirectly, related to another.

The school system of Prussia (the other States do not differ materially) has demonstrated its supremacy for the training of scholars of all sorts, of experts in every science, of officers, military and civil, of engineers and merchants, to a degree that admits of no questioning of its results. But, so it seems to the emperor and many others, its success in making its pupils for all intents and purposes good Germans, wherever they might be, and to fill them with the pride of a nation which yields to none in patriotism and devotion to its own highest interests, is more than doubtful. The deplorable and, from the German point of view, indecent and degrading easiness with which Germans renounce allegiance to their people and its political and cultural mission, clearly points to a defect in the schools. The demand is that they have to be national throughout, while preserving their excellent facilities for training along special lines. This nationalizing of the schools, i. e., to require from them what the American school system is doing so successfully for its own purposes, is carried into the lower schools (*Volksschule*) with no great difficulty. But in the higher schools the obstinacy of pedagogues only reluctantly yields to the pressure of the emperor who in this undoubtedly represents the best interests of the country. Especially the so-called humanistic schools (Gymnasien) gave little assurance of the recognition of German, German literature, and German history as the studies of paramount importance and interest for all German schools, higher and lower. A conference called together and addressed in this sense by the emperor in 1890 led to a compromise which preserved, practically, all the privileges of the Gymnasium while at the same time endangering its efficiency for mental training so well established. A second conference resulted in what must be considered a satisfactory arrangement. It was admitted that the principal aim of the higher schools must be to educate young Germans able to cope with the questions and conditions confronting them, not young Romans or young Greeks, if the latter were at all possible. Each of the three forms of higher schools (Gymnasium, with Greek and Latin, Realggymnasium with Latin, modern languages, and mathematics, Oberrealschulen with modern languages, mathematics, and the sciences as central studies of mind discipline) grant the same privileges as to admission to the universities. A wholesome competition of the three kinds of schools may now be expected. It is quite in consonance with this policy that the emperor endeavored to raise the standing, in the social estimation, of the men of practical affairs, business, industries, technology, to the level of military or civil officers or professional men. The great technical universities (Polytechniken) were given the privilege of granting degrees of Doctor of Engineering and they are also represented now in the Upper House of the Prussian Diet. Prussia in this set the pace for the other German States.

The German navy as it is to-day, by no means the largest, but perhaps one of the most efficient, modern, and well equipped for naval warfare, is almost exclusively the work of William II.'s initiative and untiring agitation. The nation, at first, was quite unwilling to enter on a scheme of extensive naval construction. Grad-

WILLIAM II., EMPEROR OF GERMANY,
IN ADMIRAL'S UNIFORM.

ually only the enthusiasm of the young men was able to win over the cautious older generations. Recent developments, though, beginning with the Spanish war of the United States, the Boer war, and most of all the Japanese-Russian sea-fights, have brought about the determination of the German nation to build a navy so strong as to be independent of any one's good will and mercy in the protection of its own interests, colonial and commercial. The recent Delcassé incident with its revelations has confirmed this determination. Immediately after the Moroccan difficulties had disclosed the intentions of England and France against Germany, the Reichstag, for the first time in its history, voted unanimously and without much debate the adoption of the naval budget of the government. William II. has his nation, the socialistic iconoclasts excepted, behind him in this greatest national problem.

William II. has been conspicuous before the eyes of the entire world ever since he came to the throne in 1888, a comparatively young man of 29, and the world is not likely to lose its interest in his personality. It has been emphasized how intimately he is identified with the great immanent tendencies at work in the German nation. As President Roosevelt may be called a type, not the only one, but the most characteristic of the modern American generation, of the American young man, so William II. is typical and characteristic of the modern German. From this fact comes the best assurance of historical eminence, which, otherwise, in the case of a living person, would be nothing but vague calculation, which might or might not come true. But William II. leads his nation, heads it, directs it, as a born leader, as the first and most loyal patriot, the most indefatigable worker for Germany's future. His civil governor, Professor Hinzpeter, observed in the boy and youth an extraordinary and strongly marked individuality, a masterful, sovereign character in the true sense of the word, in whom conservative and progressive elements and inclinations were indissolubly blended. Never, though, has he overstepped the privileges given him by the constitution, which cannot be said of all the rulers of to-day, but these privileges, great as they are, he has made use of and uses to their very limits. He holds office, he rules and reigns by what appears to him as a divine commission. His deep religiosity, so tolerant toward every form of belief, his avowed Christianity, makes him conceive of his duties as a ruler such as perhaps no other living sovereign or president. In one of his speeches (he is perhaps the greatest living impromptu orator on serious matters) he expressed himself thus as to his duties: «The royal office with its burden of duties, its never-ending, ever-enduring cares and labors, with its awful responsibility toward the Creator alone, wherefrom no man, no minister, no house of representatives, no people can relieve the sovereign.»

There is in this monarch a most remarkable mixture, or better an harmonious amalgamation, for there is no split in his character, of romantic and idealistic ingredients with the most modern ones of a nervous energy, a strong optimism, and a bent toward an active, strenuous life, devoted to practical realistic ends. In this he represents, like Bismarck, the extreme counterpart of that contemplative, pedantic type of Germans so prevalent and so efficient in its way since the great cultural renaissance after 1700. His range of interests, his information on many subjects, is truly astonishing, his mental alertness likewise, and all who have had the opportunity to speak and come into personal touch with him testify to his unusual personal magnetism, which overpowers even his severe critics. This man, who is the very incarnation of royal demeanor and dignity at all official occasions, delights in good fellowship when he is not under functional restrictions. In spite of impetuousness, and what sometimes seems to be an erratic nervousness, every close observer sees in him a singular steadfastness and tenacity in pursuing his political ends. What some critics, German ones especially, have called his «Zickzackkurs,» has never dimmed his vision of nor changed his resolution to obtain his final aim. Aside from his religiousness and his pious devotion to the spirit of his ancestry one must mention also his pure and happy family life among his conservative traits that go far in explaining the health and vigor of this truly strenuous life.

A few words remain to be said about the development of political doctrine in this period. Heinrich von Treitschke is the great and passionate political writer of the constructive period of the Empire, of the Bismarckian era; next to him in importance is Gustav Freytag. They cannot be identified with any party platform, the former being more conservative, the latter more liberal in his fundamental views. Among the present political writers are found Franz Mehring, the Socialist, and Maximilian Harden, essentially a negative mind and critic, a professional «kicker.» Among the constructive critics we find conspicuous Hans Delbrück, professor of history in Berlin University, Carl Jentsch, a former priest, and Friedrich Naumann, formerly a Protestant minister. The Pangermans (Alldeutsche) represent what in English-speaking countries are the Pan-Anglo-Saxon world saviors.

Bibliography.— Detailed references on German history for this period are found in Dahlmann-Waitz, 'Quellenkunde der deutschen Geschichte,' 7th edition by Erich Brandenburg (Leipzig, 1905–06) and in *Jahresberichte der Geschichtswissenschaft,* im Auftrage der historischen Gesellschaft zu Berlin hersg. v. Ernst Berner. Reliable literature on the subject in English there is none, since Ernest B. Henderson's excellent 'Short History of Germany' closes with the foundation of the new Empire, and since the works of Wolf von Schierbrand are written with a resentful bias. (See his 'Germany; the Welding of a World Power,' New York, 1902.) Some of the more important German books are Georg Kaufmann, 'Politische Geschichte Deutschlands im 19. Jahrhundert.' (Berlin, 1900); Bruno Gebhardt, 'Deutsche Geschischte im 19. Jahrhundert' (Berlin, 1898–99); Theobald Ziegler, 'Die geistigen und sozialen Strömungen des 19. Jahrhunderts' (Berlin, 1899); Karl Lamprecht, 'Zur jüngsten deutschen Vergangenheit' (3 supplementary volumes to his 'Deutsche Geschichte' (Berlin, 1902–04); Heinrich von Treitschke, several volumes of his essays and 'Reichstagsreden,' and his 'Politik' (ed. Max Cornicelius, Leipzig, 1899–1901); Otto von Bis-

marck, 'Politische Reden,' Gesamtausgabe by Horst Kohl, 'Gedanken und Erinnerungen' (2 vols. Stuttgart, 1896), 'Anhang' (supplements to the preceding, 2 vols. Stuttgart, 1901); W. G. Taylor, 'Bismarck, or the Typical German' (Amer. Hist. Ass. Papers, vol. 5); Werner Sombart, 'Sozialismus und soziale Bewegungen im 19. Jahrhundert' (Jena, 1901); Friedrich Naumann, 'Demokratie und Kaisertum, Handbuch für innere Politik' (Berlin, 1906); Paul Liman, 'Der Kaiser, ein Charakterbild Wilhelms II.' (Berlin, 1905); Reden und Erlasse, Briefe und Telegramme Kaiser Wilhelms II.' (ed. A. O. Klaussmann, Leipzig, 1902); translations thereof by L. Elkind (New York, 1904), by W. v. Schierbrand (New York, 1903); G. Hinzpeter, 'Kaiser Wilhelm II.' (Bielefeld, 1888).

KARL DETLEV JESSEN,
Professor of German Literature, Bryn Mawr College.

Germany, Rulers, Emperors, and Kings of. Up to the treaty of Verdun (843 A.D.) we can not speak of a king or emperor of Germany. Charlemagne was "King of the Franks" and "Emperor of the Romans." But as he was the first to unite all the elements that later made up Germany, he rightly heads our list.

NAME	Dynasty	Date of Reign
Charles the Great or Charlemagne	Carolingian	768–814
Louis the Pious (emperor)	Carolingian	814–840
Lothair (emperor)	Carolingian	840–843
Louis the German (first real king of Germany)	Carolingian	843–876
Charles III. the Fat (king and emperor)	Carolingian	876–888
Arnulf (king and emperor)	Carolingian (illegitimate)	887–899
Louis the Child	Carolingian (illegitimate)	899–911
Conrad I	Franconian	911–918
Henry I. the Fowler	Saxony	919–936
Otto I. the Great	Saxony	936–973
Otto II	Saxony	973–983
Otto III	Saxony	983–1002
Henry II. the Holy	Saxony	1002–1024
Conrad II. the Salian	Franconian	1024–1039
Henry III	Franconian	1039–1056
Henry IV. (whose reign was interrupted by the four following)	Franconian	1056–1106
Rudolph of Swabia	....	1077–1081
Herman of Luxemburg	....	1081–1087
Conrad (son of Henry IV.)	....	1093–1098
Henry (son of Henry IV.)	....	1105–1106
Henry V. (same as above)	Franconian	1106–1125
Lothair the Saxon	Saxony	1125–1137
Conrad III	Hohenstaufen	1138–1152
Frederick I. Barbarossa	Hohenstaufen	1152–1190
Henry VI	Hohenstaufen	1190–1197
Philip of Swabia / Otto IV. } Jointly	Hohenstaufen	1197–1208
Otto IV. (alone)	Guelph	
Frederick II. (whose reign was interrupted by the following)	Hohenstaufen	1208–1215
	....	1215–1250
Henry (Landgrave of Thuringia) merely nominal	....	1246–1247
William of Holland (chosen by the ecclesiastical electors merely nominal	....	1247–1256
Richard, Duke of Cornwall, England, merely nominal	....	1257–1272
Alphonso of Castile, merely nominal*	....	....
Rudolph	Hapsburg	1273–1291
Adolphus	Nassau	1292–1298
Albert I. of Austria	Hapsburg	1298–1308
Henry VII	Luxemburg	1308–1313
Louis IV. } Were contenders.	Bavaria	1314–1447
Frederick the Fair } Were contenders.	Austria	1314–1330
Charles IV	Luxemburg	1347–1378
Gunther, Count of Schwarzburg (rival king)	....	1349
Wencelaus (deposed)	Luxemburg	1378–1410
Rupert, Count Palatine	Bavaria	1400–1410
Sigismund of Brandenburg	Luxemburg	1410–1437
Jobst of Moravia (pretender)	....	1410–1411
Albert II	House of Austria Hapsburg	1437–1439
Frederick III	Hapsburg	1440–1493
Maximilian I	Hapsburg	1493–1519
Charles V.	Hapsburg	1520–1556
Ferdinand I	Hapsburg	1556–1564
Maximilian II	Hapsburg	1564–1576
Rudolph II	Hapsburg	1576–1612
Matthias	Hapsburg	1612–1619
Ferdinand II	Hapsburg	1619–1637
Ferdinand III	Hapsburg	1637–1658
Leopold I	Hapsburg	1658–1705
Joseph I	Hapsburg	1705–1711
Charles VI	Hapsburg	1711–1740
Charles VII	Bavaria	1742–1745
Francis I	Hapsb'g-Lorraine	1745–1765
Joseph II	Hapsb'g-Lorraine	1765–1790
Leopold II	Hapsb'g-Lorraine	1790–1792
Francis II	Hapsb'g-Lorraine	1792–1806
William I**	Hohenzollern	1871–1888
Frederick	Hohenzollern	1888
William II	Hohenzollern	1888–

* The period from 1250 to 1272 is generally called an interregnum.

** Between the end of the "Holy Roman Empire" (1806) and the beginning of the new German empire (1871) fall the German Confederation (1815–1866) and the North German Confederation (1867–1871).

4. Germany — History of the German Language. The Modern German Language, as written, spoken on the stage and also, with certain provincial variations, in the ordinary intercourse of the educated classes of the German Empire and of parts of Austria and Switzerland, is a literary language which has arisen by a process of selection and refinement from the popular dialects formerly used in their respective territories and preserved even now in the natural speech of the uneducated and, to some extent, in dialectic literature. At the beginning of historical tradition these dialects, in their entirety, had certain important characteristics which justify their classification under the common head of German. They were distinguished from, though closely related to, the Frisian and the Anglo-Saxon, and together with them they constituted the West Germanic branch of the Germanic family of languages, the other branches of which were the East Germanic, comprising Gothic, Vandalian, Burgundian, and the North Germanic, or Scandinavian, comprising Swedish, Danish, Norwegian, Icelandic. From the beginning, two main groups may be distinguished: High German and Low German, the former spoken in the hilly and mountainous midland and South, the latter in the low and level North. High German differs from Low German and from all the other Germanic dialects chiefly by the so-called High German shifting of consonants, which probably took place between A.D. 500 and 700. By this process original *d* changed to *t;* original *t*, initial and after consonants (or doubled) to *z* or *tz* (pronounced *ts*), after vowels to a sound similar to *s*, which much later became identical with *s;* original *p*, initial and after consonants (or doubled), to *pf*, after vowels to *ff*, *f;* original *k*, initial and after consonants (or doubled) in the extreme South only, to *kch*, later *ch*, after vowels to *ch*. A similar change, sometimes classified here, original *th* to *d*, began much later, but spread over the entire High and Low German territory. In consequence of these changes High German differs in its consonants more widely from Modern English than do the Low German dialects. Examples:

English.	Low German	High German.
day	*dag*	*tag*
tide	*tid*	*zeit*
plant	*plante*	*pflanze*
water	*water*	*wasser*
pipe	*pipe*	*pfeife*
corn	*korn*	(*chorn*, *Alemannian*)
make	*maken*	*machen*
that	*dat*	*das*

One of the chief divisions of Low German, Low Franconian, gradually separated from the other German dialects and developed a literary language of its own, which in its modern form is called Dutch or Hollandish. Hence «Low German» is sometimes used in the more restricted sense excluding Low Franconian. The dialects thus designated were for a long time used extensively for literary purposes, but gradually High German gained ground, and by the end of the 16th century Low German had almost ceased to be written, the people of the North adopted the common High German literary language for all higher purposes, and the use of the Low German dialects, in their modern form also called Plattdeutsch, was restricted to more intimate intercourse and to consciously dialectic literature. The modern literary language has drawn upon Low German for contributions to its vocabulary, notably terms relating to the sea, navigation, and transmarine commerce, but in the main it is based upon High German dialects. The latter form two groups: Middle German and Upper German. Middle German comprises Franconian (not including the Low Franconian mentioned above) and Thuringian, Upper Saxon, and Silesian. Upper German comprises Alemannian with its subdivisions Swiss and Swabian, and Bavarian, which includes Austrian.

At first all the dialects ranked practically alike, every writer using the speech of his own region. There was, indeed, at first no name of national significance applied to the whole group of dialects; the word *deutsch*, which later came to mean «German,» denoted originally "popular," and was used mainly of the language of the people as distinguished from Latin, which was the language of church, school, and, to some extent, of government. This indicates the beginning of a struggle for pre-eminence between German and Latin which continued for many centuries and which may be characterized by a few especially important facts and dates. Religious writings in poetry and prose are found in German as early as the 8th century, but for a long time the majority of them continued in Latin. About 1230 we find the first code of laws in German, the Low German Sachsenspiegel, also the first history in German, a chronicle of the world (in Low German), and the first legal documents; but for many years afterward Latin continued to be used alongside of the vernacular for all such purposes. The Reformation gave a great impetus to the use of German for all literary purposes, but even in 1570 70 per cent of all the books printed in Germany were in Latin, and as late as 1691 more than 50 per cent. In the winter of 1687-1688 Christian Thomasius gave at Leipzig the first lectures in German in any German university. Even works of poetry were up to the 17th century mostly in Latin. By the end of the 18th century the use of Latin had become generally limited to a few branches of learning, chiefly philology and jurisprudence.

It is customary to divide the history of the German language in three periods. The first of these, from the beginnings to about 1150 (Old High German, Old Low German), was characterized by full inflectional and derivative suffixes, showing a great variety of vowels: *singan*, *singu*, *singit*, *sungun*, *sungīn*, *gasungan*, *salbōta*, *lebēta*, *zunga*, *zungūn*, *guotēr*, *guotaz*, etc. From the beginning a tendency to weaken these endings is noticeable and by the end of the period their vowels had, with slight exceptions, been reduced to the indifferent *e:* *singen*, *singe*, *singet*, *sungen*, *süngen*, *gesungen*, *salbete*, *lebete*, *zunge*, *zungen*, *guoter*, *guotez*, etc. Another important change affected the stem vowels, namely, vowel assimilation or "Umlaut:" when the suffix contained an *i* or *j*, *a* changed to *e*, e. g. *gust*, pl. *gesti* (later *geste*, now written *Gäste*); *ū* changed to *ü* (written *iu*), e. g. *hūt* (now *Haut*), pl. *hūti*, *hiute* (now *Häute*); *uo* changed to *üe*, e. g. *vuoz* (now *Fuss*), pl. *vuozi*, *vüeze* (now *Füsse*), etc. The change from *a* to *e* took place in the 8th century; the others do not appear in writing until the end of the period. The period was further characterized by crudity of vocabulary and of syntax, the latter due chiefly to the fact that the grammatical means of subordination, viz. relatives, conjunctions, and a characteristic word order, while already in existence, were not yet fully developed. Translations from Latin clearly show the inadequacy of the language to render easily sentences of complex periodic structure. During the period also a considerable number of words were adopted from the Latin. The oldest stratum of these was due to the first contact with the Romans, from whom the Germans learned some of the fundamental arts of civilization. Hence terms referring to commercial intercourse like *Pfund* (Lat. *pondo*), *Münze* (Lat. *moneta*), *Strasse* (Lat. [via] strata), *Zoll* (Lat. teloneum, Low Lat. *toloneum*), *Meile* (Lat. *milia* [*passuum*]), etc.; the names for the months, *Januar*, *Februar*, *März*, etc., which supplanted the native *Wintermonat*, *Hornung*, *Lenzmonat*, etc.; terms relating to building, *Mauer* (Lat. *murus*), *Pfeiler* (Late Lat. *pilarius*), *Keller* (Late Lat. *cellarium*), *Kammer* (Lat. *camera*), *Ziegel* (Lat. *tegula*), etc.; terms of agriculture, horticulture, and especially viniculture, *Pflanze* (Lat. *planta*), *Sichel* (Lat. *secula*), *Pflaume* (Lat. *prunum*), *Wein* (Lat. *vinum*), *Winzer* (Lat. *vinitor*), *Essig* (Lat. *acetum*), etc.; terms relating to cookery and eating, *Koch* (Lat. *coquus*), *Schüssel* (Lat. *scutella*), *Tisch* (Lat. *discus*), *Kessel* (Lat. *catinus*), *Becken* (Low Latin *bac-*

cinus), Kohl (Lat *caulis*), *Pfeffer* (Lat. piper), etc. The second stratum includes the terms relating to the Christian church, the oldest of them of Greek origin, e. g. *Kirche* (Gr. *kyriake*), *Pfaffe* (Gr. papas), the majority from the Latin, e. g. *Messe* (Lat. *missa*), *Kreuz* (Lat. *crucem*), *predigen* (Lat. *praedicare*), *kasteien* (Lat. *castigare*), etc.; also terms relating to school and the art of writing, e. g. *Schule* (Lat. *schola*), *Tinte* (Lat. *tincta*), etc. Sometimes Latin influence is seen in the make-up of a compound of native elements, e. g. in *Gevatter* = Lat. *compater*, *Gewissen* = Lat. *conscientia*. Most of the words of these oldest strata have been thoroughly assimilated in form and meaning, and few have ever been given up again.

The second period, from about 1150 to about 1500 (Middle High German, Middle Low German), was characterized by smoothness and melody of sounds, simplicity of grammatical forms, flexibility and variety of construction, and great richness of vocabulary. This was particularly true of the language of Middle High German poetry during the 13th Century, which was not inferior to any medieval language as a means of poetic expression. It showed in all parts of the High German territory such a uniform poetic diction and technique, that scholars for some time assumed for this period the existence of a common literary language ranking above the dialects. This is now generally regarded as overstating the case; the poets traveling much from place to place probably learned to avoid words of distinctly local color and range, but in regard to pronunciation greater variety must have prevailed than the unreliable spelling of later manuscripts and the uniformized spelling of modern text editions suggest. The language of the prose literature of the time, homilies, chronicles, philosophical works, shared in this improvement over that of the preceding period. If the impetus given to literature by the Crusades, by the bloom of chivalry, and by other contemporary events and conditions had continued, it is likely that a common literary language ranking superior to the dialects would before long have developed; but the impetus was of short duration and in the middle of the 14th century we find, together with the decay of chivalry and literature, a rapid deterioration of the language and a great increase of dialect differences. For this reason the time from about 1350 to about 1500 is sometimes reckoned as a transition period. The contact with French knighthood during the Crusades and the predominating social and literary influence of the French during the whole period of chivalry led to the introduction of many French words. Some of them, being technical terms, were given up again with the things they represented; others are still in common use, e. g. *Abenteuer* (Fr. *aventure*), *Lanze* (Fr. *lance*), *Palast* (Fr. *palais*), *prüfen* (Old Fr. *pruef*), *preisen* (Fr. *priser*). German thus gained even two important and prolific suffixes: the Old French verbs in *-ier* (Modern Fr. *-er*) were adopted with the infinitive form *-ieren*, e. g. *parlieren* (Old Fr. *parlier*, Modern Fr. *parler*), and this suffix then spread to other verbs of foreign and later to such of native origin, e. g. *komponieren* (Lat. *componere*), *halbieren*, *irrlichtelieren*; the French suffix *-ie* (Lat. *-ia*), Middle High German *-ie*, gave by regular phonetic change Modern German *-ei*, e. g. *Melodei* (but also, under a re-assertion of French influence, *Melodie*), hence *Büberei*, *Druckerei*, etc.

The third period, from about 1500 to the present day (New High German, New Low German), is characterized by the creation of a common literary language and its superimposition upon the dialects. The latter continued to develop and diverge, and an inhabitant of the extreme South would now probably find it difficult, if not impossible, to communicate with one from the North if each could understand only his own dialect. The common language was composed of elements contributed by the dialects, but its spread was not brought about by the assimilation of dialects, but by the substitution of the common language for the dialects for one purpose after another, by one class of the people after another, in one region after another. The beginnings of this common language may be traced back to the middle of the 14th century, by which time German had generally taken the place of Latin in public documents. From 1347 for almost a hundred years the chancery of the Empire was located at Prague, in the borderland between Upper and Middle Germany. The documents issued from here were written in a language in which Bavarian-Austrian and Upper Saxon elements were blended, which was comparatively readily understood in other parts of the country, and which the chanceries of the various German states found therefore easy to imitate. The chancery of the Elector of Saxony was among the first to approximate to the language of the Imperial chancery; others followed and thus a larger and larger part of the country came to make use of a comparatively uniform language for the business of government. The extension of the use of this common language to general literature and finally to all the higher forms of intercourse was largely due to the enormous popularity and deep influence of Luther's writings. The great reformer deliberately and avowedly chose as his medium the language of the Saxon chancery, and he was therefore not, as he has been often called, the creator of the modern German literary language; but while his standard served him well enough in matters of linguistic form, the chancery language, owing to the limited range of subjects treated in public documents, could offer him little help as regards words and idioms. Luther had a remarkable natural command of language, but he also proceeded with the utmost care and spared no pains to learn from the mouths of the people and through his correspondence with men in all parts of the country the most widely understood and yet vigorous and effective forms of expression. Thus the form as well as the substance of Luther's numerous writings caused them to find a ready reception and enormous sale throughout the country, and his prominence in the most important affairs and the most stirring events of the period gave a peculiar authority to the form of his utterances.

The principal formal characteristics of the new common language were as follows:

(1) The diphthongs *uo*, *üe*, and *ie* of the Middle High German are regularly contracted into *ū*, *ü*, and *ī* (the latter continuing, however, to be spelt *ie*): *guot*, *güete*, *liebe* became *gūt*, *güte*,

lībe (spelt *liebe*). This change was originally a Middle German characteristic.

(2) The long vowels *ī, ū, and ü* (spelt *iu*) of the Middle High German are regularly diphthongized into *ai* (written *ei*), *au*, and *oi* (spelt *eu*): *mīn* and *hūs* became *main* (spelt *mein*) and *haus* (the English *mine* and *house* have gone through similar changes), and *hüte* (spelt *hiute*) became *hoite* (spelt *heute*). This change was originally a Bavarian-Austrian characteristic.

(3) The diphthongs *ei* and *ou* are regularly changed to *ai* (continuing, however, to be spelt *ei*) and *au*: *kein* and *boum* became *kain* (spelt *kein*) and *baum*. This was also first a Bavarian-Austrian characteristic.

(4) In the combinations *sb, sm-, sn- sw-, sp-, st-*, the initial sound has regularly changed to the sound represented now by *sch*, though in the last two combinations *s* continues to be written: Middle High German *slange, smelzen, snīden, swimmen, sprechen, sterne* appear as *schlange, schmelzen, schneiden, schwimmen, schprechen* (written *sprechen*), *schtern* (written *stern*).

(5) A later change, which came about during the period itself, consists in the lengthening of most short stem vowels in open syllables; by analogy many in closed syllables have followed suit. New High German *sā-gen, fāh-ren, nēh-men, Vā-ter, Hōf, Wēg*, etc., had originally short stem vowels. On the other hand many originally long vowels and diphthongs followed by more than one consonant have been shortened, hence, *brachte, Mutter, Jammer*.

(6) By the end of the 17th century the old differences between the stem vowels of the preterit singular and preterit plural of strong verbs had been wiped out: *sang-sungen* had become *sang-sangen*; the only exception remaining is *ward-wurden*.

(7) The influence of Latin exercised through the traditions of the chancery language on the one hand, and through the clerical and humanistic training of Luther and his followers on the other, resulted in a cumbersome and greatly involved sentence structure, from which Luther's style in his most popular works, notably his translation of the Bible, is happily free, but which in the writings of others, notably in more or less technical works, has been carried to such excess that it has seriously interfered with the acquisition and spread of the German language among foreigners, and only in modern times has the style of the best writers become reasonably free from this defect. The influence of Latin showed itself further in the vocabulary, not only in the borrowing of Latin terms, but also, as in the first period, in the coining of German compounds on Latin models. During the 17th century, chiefly as a result of the Thirty Years' War, the language became so corrupt with Latin and French words that it was scarcely recognizable. A reaction, however, set in, societies were formed by scholars, writers, and patrons of letters for the purification and refinement of the language, and these conscious efforts for improvement have continued with more or less persistence to the present time, so that the language of the best writers of our day is freer from unnecessary foreign words than that of Lessing, Goethe, and Schiller. Indeed Modern German is, especially compared with English, a very homogeneous language, which shows itself not only in the small number of foreign words, but also in the thoroughness with which most of these have been naturalized in pronunciation and inflection.

In spite of the great influence of Luther and other favorable circumstances it must not be supposed that the introduction of the new literary language did not meet with more or less conscious and unconscious resistance. The South was slower than the North to accept it: being largely catholic, it looked askance at the « Lutheran » language. The political independence of the Swiss made them ambitious to raise their native Alemannian to the position of a literary language. Not until the middle of the 18th century had all resistance practically ceased, and the German-speaking countries possessed and were conscious of possessing a common literary language. The provincial characteristics which still remain, especially in Austria and Switzerland, are slight in comparison with the unity that has been attained. Moreover the common language has not only supplanted the dialects in literature, government, school, and church, but also in the ordinary intercourse at least of the educated; on the other hand it is still constantly drawing upon the dialects to replenish and rejuvenate its stock of words.

5. **Germany — History of Literature.** German literature which, as far as its documents are preserved, extends over a period of 15 centuries, may be considered in more than one way a history of the very soul of the German people, reflecting its ideals and innermost aspirations in the productions of the poets and writers of the various centuries, and showing at the same time the development and growth of these ideals and aspirations in their influence upon the people as a whole. « Literature,» says Goethe, «is the fragment of all fragments, the least of what happened and was spoken was put in writing, and of that which was written the least has been preserved.»

There are many reasons for assuming the existence of a richly developed poetry among the Germanic tribes long before we meet any records of it in writing. The nature of this poetry was, without question, that of the poetic productions of most primitive peoples, inasmuch as it originated with their religious cults, their festivities and games, and showed the elements of lyric, epic, and dramatic poetry in their original combination. With this opinion accord the accounts given by Tacitus of old Germanic poetry, according to which its character was partly religious, partly heroic. Later sources assure us of the existence of nuptial poems, funeral hymns, love-songs, and dramatic plays. There was scarcely a manifestation of old Germanic life which was not accompanied and permeated by poetry. But with the exceptions of a number of charms and incantations, such as the *Merseburger Zaubersprüche*, little of this oldest poetry has been handed down to us. Its metrical form was the alliterative verse, as is shown not only by these charms, but also by numerous ancient riddles, proverbs, and the richly developed gnomology of the various Germanic tribes.

The alliterative verse, whose origin was presumably contemporary with the development of the Germanic word-accent, was the metrical form also of the old heroic poetry that flourished chiefly during the time of the migrations, the truly heroic period in the history of the Germanic tribes. The heroic song was cultivated by a special class of rhapsodists whom we find mentioned among the Goths, the Franconians, the Anglo-Saxons, etc. Their lays are almost entirely lost to us, but from the Beowulf and the later Nibelungenlied and the Gudrun, all of which originated among these rhapsodists, we may still form an idea of the greatness of their poetic productions. A fragmentary relic of this early period, though not recorded in writing until about 800, is the *Hildebrandslied*, the highly dramatic account in alliterative verse of the fight between Hildebrand and Hadubrand, father and son.

The chief reason why so much of the oldest German poetry was lost or suppressed must be ascribed to the Church. The introduction of Christianity in Germany meant the decline of popular national poetry as well as the rise of new ideals resulting from the acquaintance with Christian religious life and ancient civilization. Unfortunately it was not the civilization of classic antiquity, but that of the decaying Roman empire with which the youthful German people were brought into contact.

The earliest German written literature was produced by the clergy, and its chief character, therefore, is learned and religious. As the oldest document of this kind may be mentioned the translation of the Bible into the Gothic language by Wulfila (✝ 381), of which, however, only fragments are preserved. They are of the greatest value not only from a linguistic point of view, but also as a document of the intellectual character of the Goths, whose name quite unjustly became synonymous with "barbarous."

Among the earliest products of Christian poetry in Germany may be mentioned the 'Heliand,' an epic poem in alliterative verse of the 9th century, possessing considerable literary merit in its representation of the story of Christ as the story of a powerful Germanic king. The Heliand was written in Old Saxon, a dialect agreeing in its consonant system with English and Dutch, but differing from Old High German, which was destined to form the basis of the future literary language of Germany. It was due chiefly to the patriotic efforts of Charlemagne, who collected the old Germanic heroic songs and began the writing of a German grammar, that a certain unity in the literary use of the various Old High German dialects was attempted even at this early period, the Franconian dialect attaining, of course, a certain preponderance in this literary language.

Of less poetic value than the Heliand, though displaying the marks of serious literary industry and patriotic sentiment, is the 'Evangelienbuch' by Otfried (ca. 868), a monk in the monastery of Weissenburg. He was the first to employ the rhyme in his work; the structure of his lines still show, however, the rhythmic characteristics of the old alliterative verse.

Otfried's complaint in the Latin dedication of his book to Archbishop Liutbert about the lack of grammatical rules in his mother tongue makes it quite evident that even then a chasm existed between clerical learning and native German speech and poetry. The learned disregard for the poetry of the people, the opposition between artificial and popular poetry, seems to have continued during the 10th and part of the 11th centuries, although in the monastery of St. Gall we find a laudable exception. Here lived the greatest of the early German grammarians, Notker (✝ 1022), and here the monk Ekkehard I (✝ 973) turned into Latin hexameters one of the famous old Germanic hero-songs, the song of 'Walther and Hildegunde.'

Popular German poetry did, however, not cease to exist during this period; it was cultivated by the Spielleute or traveling minstrels, a class of poets less dignified than the old German rhapsodists, but equally influential. They were the first to seize upon a subject-matter which a period, fond of fabulous tales of adventure, as was the age of the Crusades produced in great abundance. Thus a number of epic poems originated of which the charming 'König Rother' is the most important. In the meantime the clergy, who always had a strong antipathy against the minstrels and the worldly spirit of their poetry, turned their literary efforts also in the direction of the epic, choosing their subjects partly from the stories of the Bible, partly from history. But the exclusive literary predominance of the clergy soon had to make room for chivalry which gradually assumed the leadership in matters of literature.

The conditions from which chivalrous society developed in Germany during the 12th century were essentially the same as in England and France. Hence the similarity, too, of ideals: chivalrous valor and virtues, culminating in the "service of ladies." But although we are still able to follow the paths by which these ideals entered Germany from France, their literary expression in Germany is not merely imitative of French models. It is an acknowledged fact that the great German court epics of Hartmann von der Aue ('Erec,' 'Gregorius,' 'Iwein'), of Gottfried von Strassburg ('Tristan und Isolde'), and, above all, of Wolfram von Eschenbach ('Parzival,' 'Willehalm,' 'Titurel') are more than mere translations from the original French versions of these tales, most of which belong to the Arthur legend. In Wolfram von Eschenbach's mind the story of the Holy Grail assumed, in fact, a depth of feeling and thought which makes his 'Parzival' one of the greatest poems of the Middle Ages. The same is true of the 'Minnesong.' This may be seen especially in the songs of Walther von der Vogelweide, one of the greatest lyrists of all times, who proclaimed the divine mission of the poet both in the social and political spheres of human affairs. The beauty and grace of his 'Minnesongs' (love-poems), and the depth and power of thought, the humor and the patriotic and religious pathos of his 'Sprüche' (didactic poems) were admired long after the dissociation and decline of the court-society had taken place as the result of economic conditions no less than of inherent elements of unnatural and immoral artificiality.

By introducing into his poetry the healthy sentiment of the folksong Walther von der Vogelweide attempted to stem the degeneration of the Minnesong into artificial unnaturalness, against which the women of the time themselves seem to have occasionally protested. A similar patriotic protest against the popularity in fashionable court circles of Franco-Celtic literary models and subjects seems to have led to the final shaping into epic-poems of the old Germanic hero-legends such as underlie the 'Nibelungenlied,' the 'Gudrun,' and a number of minor poems. Though disguised in these epics as ladies and knights of the 13th century, the characters of the old hero-legend still disclose their original gigantic proportions, and the force of their passions, the grandeur of their struggles, and the primitive depth and simplicity of their feelings contrast strongly with the fantastic picture of court-life portrayed in the contemporary court-epics.

The period of classical productions during the latter part of the 12th and the beginning of the 13th centuries was followed by a period of poetic dearth in which great literary activity was, however, not wanting. The place of the chivalrous Minnesingers is taken by the so-called Mastersingers, mostly honorable citizens and tradesmen, fond of cultivating the didactic, the mystic, and abstruse in their songs. A similar decline we notice in epic literature. At the same time we may, however, observe the beginnings of new forms of literary expression, such as prose, the drama, and folk-song, all of which were developed especially during the 15th and 16th centuries.

During the classical period of Middle High German literature a general uniformity in the language of poetry had been sought and, to a certain degree, attained by the best writers. It was essential that a like uniformity, displacing the various dialects, should be established for the literary use of German prose which, from the 13th century on, had been employed more and more in sermons, mystical writings, and in chronicles. According to the testimony of Luther (1483–1546) he found the form of German prose, which became so powerful an instrument in his hands, in the language used by the imperial Saxon chanceries. It was Luther's genius and great personality which assured this Saxon dialect the future literary predominance over the other High German dialects. For the language of his classical translation of the Bible and his powerful church-hymns soon became the authority for the grammarians and the best writers.

The origin of the German drama must be traced to the simple dramatic representations, given by the Church at Easter, Christmas, etc., the old Germanic plays having gradually died out. How popular these performances soon became may be seen from the great number of Easter, Christmas, and Passion plays, of Carnival plays and farces which have come down to us. It is the dramatic form gradually developed in these plays which we find also in the dramas of Hans Sachs, the foremost German dramatist and mastersinger of the 16th century. An enthusiastic admirer of Luther and his work, Hans Sachs (1494–1576) did inestimable service to the cause of Reformation by popularizing its ethical ideas in his numerous dramas, farces, and poems.

The most perfect poetic productions of the 15th and 16th centuries are, however, the 'Volkslieder' (folksongs), the direct and artless expression in verse of inimitable beauty and simplicity of the very soul of the people, who were then still feeling and thinking as a whole, and were as yet undivided into the learned and the unlearned. The discovery later by Herder of the truth, the ethical force, and the beauty in which human nature reveals itself in these songs, contributed greatly to the rejuvenation of German life and literature during the 18th century and afterward.

Great as the influence of the Renaissance was on the intellectual life of Germany during the 16th century, the indebtedness to this influence of the really great writers, of men like Luther, Hans Sachs, and even Johann Fischart, was after all comparatively small. The attempt to reform German literature after the model of the ancients was, however, made during the 17th century by Martin Opitz (1597–1639). The principal features of this attempt the effects of which are noticeable even in the classical literature of the 18th century, were the breaking with the life and the literary traditions of the past, and the beginning of an entirely new literary development. While in matters of metrics Opitz's reform was fully justified, this reform meant, nevertheless, mere imitation and the introduction of a literature of the learned for the learned. The people as a whole were forgotten, if not disregarded; the writing of poetry became, as with the Neo-Latinists of the 16th century, a conscious labor, the result of reasoning and calculation instead of the product of the free play of inspired imagination.

Neither Opitz nor his more gifted immediate followers produced poetry of more than ordinary value. In their endeavor to surpass the former and by their imitation of contemporary Italian and Spanish models the writers of the next generation, known as the Second Silesian School, ended in bombast and filthy sensuality. Much of the pitiable condition into which German literature fell during the 17th century was, of course, due also to the degenerating effects upon the intellectual, political, and social life of Germany produced by the Thirty Years' War.

It was due to the efforts of numerous noble and patriotic men during the 18th century that German literature as well as German life underwent a great regeneration. The rejuvenation of the German nation and of mankind in general was, in fact, the ultimate aim in the efforts of all the great thinkers and poets of this period, and nowhere can we follow this process better than in their writings.

Long before Rousseau's panacea, "back to nature," became the watchword in literature, we notice in these writings the endeavor to find, independently of the ancients, nature, truth, and reality. Poets like A. von Haller (1708–77) and F. von Hagedorn (1708–54) discover the rich inner world of man as the only great object of poetry. And in C. F. Gellert (1715-69) the preclassic period produced a writer of extraordinary popularity. A harmonious personality who discarded traditional learning, he exerted a liberating influence on his time by poinging to the human heart as the source of true life.

Hand in hand with these attempts of the poets proceeds the work of criticism in ascertaining the nature of the beautiful and thereby the nature of what constitutes true humanity. It is characteristic of German poetry since Opitz that the creative activity of the poets is accompanied by a conscious reflection concerning the nature of poetry: thus it came about that Lessing, Herder, Schiller, and Goethe were also great critics.

The discovery by the Swiss critics, Bodmer and Breitinger, of the imagination as the true source of poetry prepared the way for the first great poet of this period, F. G. Klopstock (1724-1803). The influence which the latter, through his 'Messias' and his 'Oden' exerted upon the intellectual, the moral, and the political life of his people was extraordinary. In him the old Germanic conception of the poet seemed revived; he regarded his calling as that of a priest and a prophet, and his highest ideal was that of true humanity.

Yet Klopstock's principal work, the 'Messias,' was, with regard to the subject-matter and its treatment, a mistake. It was the task of Lessing (1729-81) to establish the laws of poetry, particularly those of the epic and of the drama. This he did in the 'Laokoön' and in the 'Hamburgische Dramaturgie.' A fearless critic and searcher for truth, he was also the first great German dramatist of this period The characters of his famous plays, *Minna von Barnhelm* and *Emilia Galotti*, breathe real life, embodying at the same time the poet's new and manly conception of human life. And through his theological writings, his 'Erziehung des Menschengeschlechts,' and his drama 'Nathan der Weise,' he exerted a reformatory influence not only upon theology, but also upon the religious life and conduct of his country.

In Lessing's path as a critic followed J. G. Herder (1744-1803), one of the most remarkable geniuses of this period. Correcting and supplementing Lessing's discoveries in his early writings, Herder soon became a critical pathfinder who pointed out with prophetic instinct the course which the intellectual development of Germany was to take. To him is due above all the momentous discovery of the true nature of popular poetry and, moreover, a conception of history such as no previous historian had thought of.

With Herder began the so-called "Storm and Stress" period, the revolution in German intellectual life, whose ultimate aim it was to break with previous traditions and to attempt the regeneration of human nature, the beginning of a new life from the innate eternal sources of the soul. The result of this remarkable movement was the classical German literature of the 18th century, the chief representatives of which are Goethe (1749-1832) and Schiller (1759-1805). Goethe's earliest works ('Götz von Berlichingen,' 'Werther,' his early lyric poetry and the oldest scenes of 'Faust') as well as Schiller's first dramas ('Die Räuber,' 'Fiesco,' 'Kabale und Liebe') show us the spirit of the literary revolution in its whole force and depth. In the works of the mature period of both poets, with Goethe's 'Iphigenie,' 'Tasso,' 'Hermann und Dorothea,' 'Wilhelm Meister,' etc., and with Schiller's 'Don Carlos,' 'Wallenstein,' 'Wilhelm Tell,' and his æsthetic essays, German literature reaches its highest perfection both as to form and contents. It is the ideal of humanity which lives in the best works of these poets and lends them an imperishable charm. Poetry is no longer an imitation of the ancients, but the highest human creative power which, independent of science and religion, strives to solve the riddle of the world and of man. In the creation of this new ideal of humanity the example of the ancients was, no doubt, most helpful, but it was, after all, essentially a product of the German mind, to which the great thinkers, Kant, Fichte, Schelling, and Hegel contributed their share also.

That this fact was gradually recognized, and that, in place of the abstract cosmopolitanism to which Goethe and Schiller inclined, the conception of nationality was established, was due to the Romantic School, which, in the main, was a continuation of the Storm and Stress period, particularly of Herder's ideas and discoveries. Although the members of this school (A. W. Schlegel, Fr. Schlegel, L. Tieck, and Novalis) were lacking as poets, in plastic creative power, frequently losing themselves in fantastic dreams, their influence upon art, music, science, and even on politics and religious life was extraordinarily great. To them belongs the credit of having discovered the beauty and greatness of Germanic antiquity, the investigation of which was undertaken by the Brothers Grimm, by Ludwig Uhland, and many of their successors. At the same time the political humiliation of Germany by Napoleon I. had no small effect upon the awakening of national consciousness, as is clearly shown by the patriotic poetry of E. M. Arndt, Th. Körner, M. von Schenkendorf, Fr. Rückert, and others who roused the nation from its political lethargy and despair.

The wars of liberation were followed by a period of political stagnation during which the contradiction between the ideal world that had been created by the poets and thinkers and the wretched reality of the social and political conditions was felt most keenly. Against these conditions, which also form the background in the work of the great humorist, Jean Paul Richter, arose, at the beginning of the third decade of the 19th century, a group of writers called Young Germany. Its leaders, L. Wienbarg, H. Heine and Karl Gutzkow were arrayed chiefly against the spirit of degenerate romanticism, claiming at the same time greater political freedom and the concession of the principle of realism in literature. The political struggles which, during the subsequent decade, completely occupied German intellectual life are reflected also in the patriotic poetry of the time. Inspired by Goethe's lyrics and the revived folksong, lyric poetry had flourished greatly in Germany. Its chief representatives were L. Uhland, Ed. Mörike, H. Heine, N. Lenau, and Jos. von Eichendorff. Several of these masters, like Uhland and Heine, now took a hand in the political movement, and the younger poets like

F. Freiligrath, H. von Fallersleben, G. Herwegh, Em. Geibel, and others joined their ranks.

The disappointment following the failure of the national hopes after 1848 had to affect literature also. There was, to be sure, during this period no lack of eminent talent — I only mention the dramatists, Fr. Hebbel and Otto Ludwig, the novelists, V. Scheffel, G. Freytag, G. Keller, and Paul Heyse, and the lyric poet, E. Geibel — but poetry had ceased to play the leading rôle in the intellectual life of Germany. Music, the plastic arts, and especially the natural sciences had taken its place. Even the great events which finally led to the unification of Germany did not bring with them the expected revival of poetry, but rather a visible decline.

Dissatisfied with this state of affairs, and influenced by foreign authors, such as Zola and Ibsen, a group of young men attempted in the early eighties to reform German literature along the lines of realism and to win back for it its lost prestige in the estimation of the nation. Much in this movement was abstract theorizing and fruitless æsthetic experimentation by men whom Goethe would have called "forced talents." But the interest of the nation in contemporary literature has been reawakened by gifted writers like D. von Liliencron, H. Sudermann, G. Hauptmann, Ricarda Huch, Clara Viebig, and others, and to-day an industrious activity prevails especially in the fields of the drama and the novel. The crude and sometimes revolting realism of the early productions of this recent literary movement has been followed by a return to the ideal dreamland of romanticism, and many are the signs that Germany is about to enter upon a new great era of national literature.

6. Germany — History of Science and Philosophy. The German nation has often been called a people of "thinkers." That had perhaps in the past sometimes a slighting implication, as if the Germans lived in a world of dreams and were unfit for success in the practical world of reality; only the last decades have removed completely such a tacit meaning, since the German Empire has proved itself not less strong in its achievements in commerce and industry and politics than in the fields of science and scholarship. Yet, on the whole, it was at all times a sincere acknowledgment of that German contribution to the progress of human civilisation which has been most original and most lasting. German earnestness and thoroughness, German love of truth and of freedom, have blended, at least since the days of Leibnitz, into a productiveness of knowledge which is not paralleled in the world.

1. The most valuable contribution of the earliest times was the historiography done in the German cloisters. Their "annals" were faithful work and Einhardt's 'Life of Charlemagne' (written 820) is a noble piece of history writing. But the scholarly thought was still essentially imitative. When in the 9th century the Benedictine Rhabanus Maurus in the cloisters of Fulda wrote his encyclopedia 'De Universo,' in 20 books, setting forth the status of German knowledge in the time of Charlemagne, it was on the whole a repetition of that which Isidor of Sevilla had brought together in the 7th century. All thought about nature was controlled by the ancients. And when in the 11th century a new European movement of thought was growing, the great scholastic effort to harmonize belief and reason, France, Italy, and England gave the signal. Yet Germans as, for instance, Hugo, Count of Blankenburg, took an important part, and Albert von Ballstädt, called Albertus Magnus (1193–1280), was one of the deepest and most brilliant scholastic thinkers, whose knowledge of natural science, too, was far superior to his age. Theologians and philosophers of repute, like Thomas von Strassburg, followed in the 14th century, and certainly no thinker of the 15th century equalled the cardinal Nicolaus von Cusa (1401–1461), who combined scholasticism and Platonism, mathematics and theology. In the meantime Germany had founded its famous seats of higher learning, the universities, which have been always at the same time schools for the professional training of clergymen, teachers, doctors and lawyers and centres of productive scholarship. (See GERMANY, UNIVERSITY SYSTEM IN.) Through the 13th century the university of Paris was the point of crystallisation for scholasticism; in 1348 the first German university was founded in Prague, soon after that the university of Vienna, and Western Germany followed immediately with Heidelberg (1385) and Cologne (1388). The political disturbances in Boehmen brought about a secession in Prague, and its emigrating scholars founded the university of Leipzig (1409). These new centres of scholarly influence increased the independence of German scholasticism of the dogmas of Paris, and in the declining period of mediæval thought the German systems of nominalistic philosophy played an important rôle.

The opposition to the hairsplitting rationalism of scholastic thought came from two movements which better expressed the German instincts: mysticism (q.v.) and humanism (q.v.). Mystical speculation became influential from the beginning of the 14th century; in an immediate personal unity with God there was sought a deeper knowledge than that of church and university. Meister Eckhart's pantheistic mysticism, a Christian neoplatonism, stands with such daring independence against the doctrines of the hierarchy that it must be acknowledged as the first original German philosophy, in spite of its unsystematic character. The mystical schools develop themselves, especially in the western Germany, through the 15th and 16th centuries and emphasize now the theological interests or even the practical religion (Thomas à Kempis, 'Imitation of Christ'), now the naturalistic interests. The mystical study of nature was most strongly influenced by the physician Paracelsus (1493–1541). His aim was a fundamental reform of medicine, which had still the stamp of Galen and Avicenna. But to understand man's body the microcosmos must be understood as image of the macrocosmos and thus natural science, astronomy, and theology become the basis of medicine. His numerous writings influenced, through all Europe, medicine, alchemy, and theosophy. The last great mystic was Jacob Boehme (1575–1624), whose speculations concerning God's relation to the world and its evils became influential through the following centuries.

Far more systematic and scholarly was the opposition which arose against scholasticism from the humanistic side. The European renaissance which flourished from the 14th to the 16th century found nowhere a more enthusiastic echo than in Germany. The best minds entered into its service and here, too, the movement took a threefold form: it created the historical æsthetic interest in the literary treasures of classical antiquity, it opened the eyes to nature, and it liberated from the mediæval onesidedness of christianized Aristotelianism. The time thus demanded philology, natural science, and independent philosophy. The great philological movement was carried by Germans like Johann Wessel, Rudolph Agricola, Johann Reuchlin (1455–1521), whose handbooks and editions stimulated the study of Latin and Greek throughout Germany, and who at the same time inaugurated the study of the Hebrew language in Western Europe; Erasmus of Rotterdam (1457–1537), the most eminent scholar and the most witty writer of his time, who published the first edition of the Greek New Testament, and whose writings fill 24 folio volumes; and above all the "teacher of Germany," Philipp Melanchthon (1497–1560). Famous as theologian and diplomatist, he desired to be in first line philologist and expounder of the classics. For 40 years he taught in Wittenberg. His 'Loci Communes' appeared in 60 editions during his lifetime.

The return to nature and the striving for scientific knowledge is expressed in great scholars like the mathematicians and astronomers Nicholas von Cusa, Georg Peurbach, Regiomontanus (1436–1476), famous for his 'Ephemerides ab Anno'; Martin Stöfler, and epoch-making Copernicus (1472–1543), whose discovery that the planets moved around the sun was worked out in 'De Orbium Celestium Revolutionibus.' The movement culminated in Johann Keppler (1571–1630), who discovered that the planetary orbits are elliptic and that the squares of the periods of revolution of any two planets are to each other as the cubes of their mean distances from the sun.

Humanism thus brought to Germany ample results in the fields of philology and natural science, but seemed without such results in that field in which the other countries gained most by the renaissance: philosophy. The German philosophical humanistic reaction against mediævalism (q.v.) and scholasticism (q.v.) was inhibited by the religious movement which absorbed Germany's metaphysical energies — Protestantism (q.v.). The Protestant religion, no doubt, ultimately reinforces knowledge and scholarship. Its appeal to the sources, its attack on authority, liberates the spirit of criticism and research. The great progress of Germany's scholarship in all fields in the 19th century is markedly the work of the Protestant parts of Germany and, in a much less degree, of the Catholic regions. German philosophy, more than any other branch of knowledge, shows this Protestant character from Leibnitz to Kant and Fichte and Hegel. But in the days of the new awaking, when Italy and France and Holland and England produced great philosophical systems, Protestantism necessarily inhibited the metaphysical movement in Germany.

Scholasticism had been a union of church theology with rationalistic philosophy, an effort to bring the religious belief into harmony with reason. The Reformation agreed, of course, with the new humanistic antagonism against those scholastic systems, but not in the interest of an independent philosophy, rather in the interest of an independent theology — independent alike of the church and of abstract logic, faithful only to the individual religious instinct and to the revelation of the Scriptures. Martin Luther, with his mystical tendency, had no sympathy with the logical definitions of human thought and no trust in the power of merely human intellect. The humanists who in the first decades of the 16th century defeated the scholastic world and who fought for literary-æsthetic ideals and platonistic philosophy, soon felt that the Lutheran movement was unfriendly to the cherished arguments. It is true, Zwingli stood nearer to philosophy, and Melanchthon became a most influential teacher of philosophical doctrines; his philosophical writings, not only the commentaries to ancient philosophers, remained the best books of Protestant Germany for a century. Yet Melanchthon, too, was more original as theologian than as philosopher. The theological discussions filled the time and reached the masses, and the humanistic movement, which fascinated the few, was necessarily the loser in Germany. The increase of religious strife was accompanied by a decrease in independent interests of thought throughout the land. The lowest point was reached when the Thirty Years' War destroyed the power and prosperity of the commonwealth; the moral and intellectual energies of Germany seemed paralyzed and German universities and German scholarly interest had never so little dignity and authority in the world as through the first two-thirds of the 17th century. Naturalists and philosophers like J. E. Sturm or Joachim Jungius stood under the influence of the great French thinkers, and even the famous jurist Samuel Pufendorf (1632–1694), the first German teacher of natural law, is under foreign leadership. Indeed, the neighboring countries had incomparably better conditions for scholarly activity than the devastated land of Germany, and while they did their utmost to reinforce the spirit of productive scholarship through the founding of academies and the high social position of the scholars, Germany had no academies and no protectors of knowledge; university life itself became vulgar and barbaric.

The new spirit had thus to come from foreign lands. The French language and literature and philosophy entered at first the courts of Germany and soon after its universities; the humanistic neo-classical interests were replaced by the more "modern" efforts which had been developing in the neighboring country since the days of Descartes. The universal thinker who stands at the threshold of a new and better time is Leibnitz.

2. Gottfried Wilhelm von Leibnitz (1646–1716), a man of the great world, brought German thought in contact with the advanced scientific spirit of France, Holland, and England. Through his influence the Berlin Academy was founded in 1700 with the aim to create a place for the real advancement of knowledge at a time when the universities felt, on the whole, satisfied with handing down the scholarly traditions. He created the most elegant instrument of natural science: the differential calculus, which he published (1684) in his essay 'Nova methodus pro maximis et minimis.' But still more important was his metaphysical system. It shared with Descartes and Spinoza the rationalistic belief in the power of transcending experience through reason, but Descartes' sharp separation of mind and body and Spinoza's monism were left behind by Leibnitz's 'monadology.' His monads, held together by pre-established harmony, represent a continuous series of simple substances which are without windows, each containing the whole world as perceptions, but each apperceiving only a varying part of them. His system fulfills in an original way the purpose of every great philosophy: to justify and to harmonize both the causal, mechanical, and the teleological idealistic knowledge of the time. And thus Germany had finally, as the last of the European nations, a real philosopher who was to introduce the enlightenment of the 18th century.

While Leibnitz brought the modern interests to the German courts and academies, the universities, too, reflected the progressive time. Halle, founded in 1694, and Göttingen, founded in 1737, became the new centres of an activity which had no sympathy with the doctrines of authority, either the theological ones of the church or the classicistic ones of the humanists. An independent free thought, working with mathematics and logic and empirical observation, was the demand of the time in every field. The jurist Thomasius (1655–1728) became the leader of the academic movement of protest against all narrowness and prejudice, fighting alike against the mediæval methods of legal and equivocal prosecution, against the superstitions of orthodox theology, and against the artificiality of classical learning. He was the first to emancipate German university instruction from the traditional Latin and to publish a literary critical magazine in the German language. After conflicts with Leipzig he became one of the founders of Halle, and his spirit of modern intellectualistic enlightenment came to be characteristic of the place. To be sure, on theological grounds the opposition against orthodoxy did not move so much toward theoretical rationalism, but took at first the turn toward practical religiosity. The great pietistic anticlerical movement which Spener (1635–1705) started, influenced by English puritanism, was continued in Halle by Francke (1663–1727), to whom true Christianity was not an object of science but a living duty; and yet even the insistence on the Bible as the only true source of religion meant here, as two centuries before in Luther, in first line not a binding of the free intellect, but a liberalizing and modernizing opposition against the orthodox spirit of the past. The full development of theological criticism in Halle belongs rather to the influence of Semler (1725–1791), whose historical interpretations of the Bible open the way for the new rationalistic theology.

The most influential separation from church authority, however, on all fields of human thought came through Halle's fertile philosopher, Christian Wolff (1679–1754. His system was no great original construction — it was essentially Leibnizian philosophy — but it gained its new strength and power by being really a system. Dogmatic rationalism herein reached its most self-conscious expression and Wolff's didactic treatment of ontology, cosmology, psychology, theology, ethics, economics, and politics soon penetrated the whole protestant scholarship of Germany. Theology and metaphysics, morality and jurisprudence had to become "natural" and "rational"; the ideals of mathematical knowledge and social happiness determined the whole period. The Leibnitz-Wolffian movement was not without opponents like Crusius and Rüdiger, and yet the adherents carried the day. Among Wolff's pupils, besides interesting philosophers like Bilfinger and Lambert, Baumgarten (1714–1762) must be mentioned as the founder of German "æsthetics," a name which he invented. The scholarly rationalistic philosophy yielded quickly to its natural tendency to subserve the practical purposes of human virtue and happiness, to be reached by the emancipation of the individual from every authority but its own reason, and with this practical aim came the tendency to popularisation. It was a movement to which Frederick the Great lent himself from the Prussian throne, and authors like Moses Mendelssohn and Reimarus, Nicolai and Engel, Tetens and Moritz spread it throughout Germany. Here also is the place for the important scholarly writings of the poet Lessing (1729–1781), who stimulated theoretical æsthetics as well as philosophy of religion and philosophy of history.

While thus the new philosophical and theological spirit of the 18th century radiated from Halle, it was the university of Göttingen in which the new scientific and philological impulses started, till finally the light came from Königsberg. In Göttingen taught the next to Linnaeus most eminent biologist of the time, Albrecht von Haller (1708–1777), famous for his botanical books, but still more influential by his medical studies. He introduced the physiological experiment, and his demonstrations of what he called sensibility and irritability of nerves and muscles, became the starting point for biological theories which controlled the medical discussions of Europe down to the time of cellular pathology. Among those who took part in these physiological, pathological, and therapeutical controversies of the 18th century Frank, Weikard, Röschlaub, Pfaff, and others belong to Germany; and especially the group of those who defended that branch of Haller's system which had found its development in France under the name of vitalism: Blumenbach, Reil, and Hufeland. Blumenbach (1752–1840) who interprets the organic world by his "nisus formativus," became the founder of anthropology: the doctrine of the five human races is his. He was also the first to lecture on comparative anatomy. Reil considers life as a galvanic process, and with Hufeland the doctrine of animalism becomes practical medicine. Side branches of this vitalistic movement are mesmerism and homœopathy, whose founders, Mesmer (1734–1815) and Hahnemann (1755–1843), are German physicians.

While biological studies flourished in Göttingen through Haller and Blumenbach, mathematical and physcial, historical, juristic, and philological scholarship also found there the most brilliant representation. Lichtenberg (1741–1799) had there his model laboratory for physics and his theories of electricty became victorious. Tobias Mayer (1723–1762) worked out there his famous catalogue of zodiacal stars and Kaestner (1719–1800) attracted the mathematicians. All three stand as foremost representatives of the inorganic sciences of the time; yet Euler (1707–1783), whom Frederick the Great called to Berlin, was perhaps more original in his numerous works dealing with mechanics and dioptrics, integral calculus and astronomy. Chemistry which began to demolish the old phlogiston theory was largely enriched by the comprehensive analyses of Scheele (1742–1786), by Klaproth and others, and Richter (1762–1807) became the founder of chemical stoechiometry.

The classical philology of the 18th century also took, in Germany, a new turn. It was the time of the great literary movement in which every mind was directed toward the beauty of art. The new aim for the student of antiquity was to join the interest in classical fine arts with the interest in the writings and to approach the literature of antiquity with the attitude of æsthetic appreciation. Gesner (1691–1761) had revived the Greek studies throughout Germany; his Göttingen successor, Heyne (1729–1812), who edited Virgil, Homer, and Pindar, and explained Greek mythology, did much to give classical studies the æsthetic interest. The whole revival was known as the neohumanistic movement. The greatest exponent was Heyne's pupil, F. A. Wolf (1759–1817), whose 'Prolegomena in Homerum' were epoch-making. With Wolf, the one-sided æsthetic attitude goes over into an enthusiastic interest for the whole of Greek life, its religion and art, its politics and history. The study of antiquity became for him a system of twenty-four different disciplines.

3. While thus the spirit of enlightenment in philosophy and natural sciences, in jurisprudence and theology, and the æsthetic spirit in literature, history, and philology gave interest and value to the intellectual life of Germany, the greatest emanation of the German genius had prepared itself. In the year 1781 appeared the first of the three great critiques of Immanuel Kant (1724–1804). Kant's critique of pure reason, critique of practical reason and critique of judgment, represent the most essential progress of human thought since Plato and Aristotle. The preceding rationalism which sought knowledge of metaphysical reality through reason, and the preceding empiricism which sought knowledge from the impressions on the senses, were equally superseded by Kant's "criticism," which proves that knowledge does not mean a reproduction of an independent reality, but a reconstruction of objective data by the subjective categories of perception and understanding. Knowledge is thus not concerned with a metaphysical reality; but we belong to the world of reality as free subjects of will who are determined not by the causality of phenomena, but by duties. This gigantic reorganization of human knowledge and morality inspired the leaders of German culture; in Schiller it came into live contact with the great literary movement of Germany.

In the philosophical discussion of Kantian philosophy Jacobi, Beck, Maimon, Reinhold, Fries, represent most different attitudes, yet none of them suggests real progress. But Kant's system demanded further development; the subjective factor of his system was not really connected with the objective factor. The genius of Fichte (1762–1814) created a system whose ethical idealism made the object itself dependent upon the will-act of the subject, while Herbart (1776–1841) moved in the opposite direction, developing out of Kant's objective factor a realistic system which gave impulses to modern psychology. Directly from Kant, too, is derived Schopenhauer's (1788–1860) voluntaristic system of pessimism, which combines Kant's doctrine of the categories with Platonism and Buddhism. Schleiermacher (1768–1834) finally seeks to harmonize the ideal and the real factor in the interest of ethics and religion. It was Fichte's system which showed the direction for the further movement. The life of nature had been neglected in Kant and Fichte; as soon as it becomes a factor in philosophic thought, ethical idealism turns into the objective idealism of Schelling (1775–1854), and ultimately into the absolute idealism of Hegel (1770–1831), which understands nature and mind as the logically necessary expression of the Absolute. At every stage idealism exercised influence on the intellectual life of the time. From Fichte started the ethical regeneration of Prussia, expressed in the foundation of the university of Berlin (1810), and the romantic movement of Schlegel and Novalis. Schelling, on the other hand, influenced most deeply the naturalists, men like Oken, Oersted, Carus, Ness von Esenbeck, and many others who brought natural science itself under the categories of Schelling's system of identity, but philosophers like Krause and Solger also followed him. The strongest philosophical influence, however, resulted from the Hegelian system which, at about 1830, entirely controlled the academic philosophy of Prussia. But the triumph of Hegelianism meant an overtension of purely speculative thought, the maximum distance of theoretical and metaphysical construction from the facts of observation. This neglect of experience demanded a necessary reaction against speculation; the breakdown of metaphysical onesidedness was disastrous. In the fourth decade of the 19th century the defeat of philosophy seemed complete and it meant the triumph of natural science as against metaphysics, of analysis as against synthesis, of realism and materialism as against idealism, of technique as against art, of specialisation as against generalisation. This naturalistic reaction filled the larger part of the 19th century in all civilized countries and brought to them the manifold discoveries and inventions which seem most characteristic of the time. Only at the end of the 19th century does the pendulum seem to begin again its backward swing with a new awaking of the idealistic spirit and deeper philosophical interests as reaction against the philosophical superficiality and incoherency of mere specialistic science.

4. In every new phase of this 19th century movement German scholars have taken the leadership. The deep philosophical longing of the German soul had created the unique movement which led from Kant to Hegel, but when the opposite tendency of the newer time demanded the patient work of the specialist, it was the world-known German thoroughness which won the laurels for the German laboratory experiment and naturalistic research and historical investigation.

Of course this specializing work had not waited for the downfall of philosophy; it took its rise in the work which we traced through the period of enlightenment in the 18th century. And further, the emphasis on specialisation does not mean that the scientific life of Germany lacks in the 19th century great central figures, scholars with broad synthetic energy: the geographer Alexander von Humboldt, the physicist Helmholtz, the pathologist Virchow, the historians Ranke and Mommsen, are certainly not specialists in the narrow sense of the word. A short survey of the different fields indicates the abundance of brilliant thinkers who were grouped about such leaders. We may begin with mathematics and the inorganic natural sciences, then turn to the organic sciences and medicine, then to the historical and philological, economical and juristic, finally to the theological and philosophical fields.

For mathematics the first place belongs to Gauss (1777–1855) and after him the chief advance came through Jacobi, Dirichlet, Riemann, Kronecker, Weierstrass and others; yet the mathematical achievements were always blending with the works of physicists and astronomers — as not a small part of the mathematical progress belongs to naturalists like Kirchhoff, Helmholtz, Encke, Clausius, etc.

Gauss gave the strongest theoretical impulse also to astronomy, while Bessel (1784–1846) may be considered the founder of the practical astronomy of the century. Most influential for the theory were Hansen and Encke and their followers, Bruhns, Argelander, Brünnow, Auwers, etc. Here belongs also as a special triumph of German thought, the discovery of spectral analysis by Kirchoff and Bunsen, applied by Zöllner and others.

In physics the turning point of the century lies at its middle when Helmholtz (1821–1894) and independently R. Mayer (1841–1878) formulated the law of the conservation of energy. In the first half of the century the best work in physics was done outside of Germany; among the Germans excelled Ohm (1787–1854) with his fundamental theories of galvanism; the brothers Weber, Poggendorff, Lenz, belong to the same period. The influence of Helmholz is felt not only in the theory of energy, but in the whole field of mechanics, optics, and acoustics, besides physiology and psychology. The next and last climax is reached by Hertz through his study of the propagation of electric waves. Important too are the thermodynamics of Clausius, the electrolytic work of Hittorf, and most recently the discoveries of Röntgen concerning cathode rays.

In chemistry the decisive step was the foundation of a chemical university laboratory in Giessen by Justus Liebig (1803–1873), the greatest chemist of his time, who revolutionized organic chemistry and whose researches became invaluable for agriculture, pharmacy, the preparation of food, etc. Out of his school came influential chemists of all nationalities; in Germany itself especially, Kekule, Hofmann, Fehling, Kopp, Bayer, V. Meyer. Other centres of chemical ideas were the laboratories of Wöhler in Göttingen, of Bunsen in Heidelberg, of Mitscherlich and Rose in Berlin. The theory of atomistic combination was furthered by the antagonists Kekule and Kolbe, stereochemistry by Wislicenus and von Meyer, inorganic analysis by Wöhler, Winkler, Kirchoff, Bunsen, whose epoch-making spectral analysis has been mentioned before. The first organic synthesis is the famous work of Wöhler in 1829. It opened the long series of synthetic successes of which not a few became technically important, as those of Fettig, Gräbe, Hofmann, Fischer. Practical gain also to pharmacy came directly from German chemistry; chlorohydrate and chloroform, salicyl and antipyrin, etc., are products of German laboratories. The incomparable position of German chemical industry is the immediate outcome of the wonderful development of chemical science in German universities and technological institutes.

The independent growth of physical chemistry prepared by Kopp, Bunsen, Wiedemann, became most significant in recent times through Ostwald, Van't Hoff, Nernst, etc. Mineralogy and crystallography connects its development in Germany in first line with the name of C. S. Weiss in Berlin, Neumann in Königsberg, Hessel in Marburg, Rose in Berlin, von Rath in Bonn, Zirkel in Leipzig, etc.

Geology became a science in Germany through A. G. Werner, in Freiberg, at the beginning of the century, and L. v. Buch developed the doctrine of the slow upheaval of continents; his geological map of Germany appeared in 1824. But greater was their pupil, Alexander von Humboldt (1769–1859), the most comprehensive German naturalist of his time. His studies in South and Central America and in Asia, his incomparable richness of observation in all fields of descriptive science, his unifying apperception of nature, as expressed in his 'Kosmos,' make him the most imposing and most sympathetic figure in the German science of the first half of the last century.

Inasmuch as Humboldt's geography was essentially physical, it seemed opposed to the historical-geographical interest. A synthesis of both tendencies characterises the work of Carl Ritter (1779–1859), whom his time considered the founder of scientific geography. His contributions to theoretical geography found a brilliant continuation through Peschel, Kiepert, Gerland, Ratzel, and others. In the meantime, practical geography was stimulated by Richthofen, Peschuel-Lösche, etc. Well known are the maps of Petermann, Perthes, etc.

Geography may connect the inorganic with the organic world. To begin with botany, the first decades of the last century belonged to plant anatomy; the highest point was reached by H. v. Mohl. Then came, about 1840, the turn to the genetic study, and the development of plant histology. The epoch-making discoveries of Schleiden (1804-1881) and of Nägeli showed the way. The morphologic work, partly with histological, partly with phylogenetic interest, was continued by Schwann, Hofmeister, Pringsheim, DeBary, Strasburger, Solms, etc. The fundaments of plant physiology were laid by Julius Sachs, whose 'Experimental Physiology of Plants' appeared 1865. Pfeffer, Klebs, Stahl, etc., followed.

In zoölogy the century began with systematic interests, but turned soon to morphological ones and came on this path to the brilliant achievements connected with the names of Köllicker and Siebold, Ehrenberg and Max Schultze, Leydig, Leuckart, and Hertwig. The leader in comparative anatomy, which started in Germany with Meckel, the "German Curvier," was Gegenbaur; the prophet of Darwinism became Haeckel, and the most influential critics of Darwinism, Wagner and Weismann.

The progress of human anatomy links itself partly with the same names which became influential in Zoölogy; at the middle of the century the anatomists Henle, Hyrtl, Baer, and Köllicker stand as the acknowledged leaders. His, Hertwig, Roux, and Waldeyer represent the later decades. Yet, it is characteristic for the German mind, that its most brilliant achievements belonged to physiology rather than to anatomy. No field, indeed, has greater names than physiology, with Joh. v. Müller and Helmholtz. Rudolphi and Burdach, whose large physiology appeared 1832, made physiology at home in Germany, and soon came the master, Johannes v. Müller (1801-1858). His influence — it is said that he wrote 16,000 printed pages — was deeply felt throughout physiology, embryology, anatomy, and zoölogy; most popular is, perhaps, his doctrine of the specific energy of the senses. Among his many important pupils none was greater than H. v. Helmholtz (1821-1894), whose invention of the ophthalmoscope (1851) created the new ophthalmology. His physiological optics and his book on tone sensations are still authoritative to-day. Dubois-Reymond's investigations of electrophysiological phenomena, Ludwig's analysis of the functions of the heart opened new ways also, and so did Voit, Pettenkofer, Hering, Brücke, Pflüger, etc., in various directions.

In the development of pathology the central figure is Rudolf Virchow (1821-1902), whose cellular pathology revolutionized the theory of disease and led it to the heights of modern histology. His pupils, Cohnheim and Recklinghausen, continued his proof that the organic laws working in disease are identical with those of the normal organism. A new movement came in with bacteriology; the discovery of the tubercle bacillus (1882) through R. Koch and his investigations of anthrax, turned his attention from the diseased cell to the microscopical causes of the diseases. From bacteriology pathology finally turned to chemistry, studying the substances produced by the diseased tissues. This led to the theory of antitoxins and to Behring's discovery of the antitoxin treatment of diphtheria. Practical medicine was in the meantime led by men like Frerichs and Erb, Langenbeck and Billroth, Graefe and Griesinger.

5. In the world of mental sciences it is philology whose specialistic ramification in the 19th century is similar to the work of the naturalists. The classical philologians led the way, and the grammatical scholar Hermann deepened the linguistic interest in the classical authors; his opponents, Boeck, Welcker, O. Müller, and others stood for the wider view of F. A. Wolf, taking philology in its fullest meaning. Zeller, Niebuhr, Droysen, Mommsen, Curtius gave new life to the thought and politics of the old nations, and Lachmann, Haupt, Ritschl and others interpreted their authors.

Germanic philology is entirely a product of the 19th century. The romanticists, Schlegel and Tieck, stimulated interest in it, but it became a real branch of scholarship through Lachmann, Benecke, and especially the brothers Jacob Grimm (1785-1863) and Wilhelm Grimm (1786-1859), whose studies in the history of the German language and literature became of paramount importance. As to other languages German scholarship has con-[illegible]uted much to Romanic, English, Slavic, but most of all to Oriental philology in the widest sense of the word, and through Bopp, Pott, Benfey, W. v. Humboldt, Schleicher, etc., is the comparative science of language essentially a German creation.

History, too, took the stamp of the specializing scholarship of the century. An overwhelming mass of material has been gathered by the research of the German historical schools. Typical are the 'Monumenta Germaniæ historica.' But the pride of this field of German scholarship is the noble line of great historical writers. Niebuhr (1776-1831) gave to the world a perfect reconstruction of early Roman history, and Mommsen (1817-1903) equally eminent as historian, jurist, and philologist, gave in his Roman history the German masterpiece of classical history writing. Yet the greatest figure of this group was Leopold Ranke (1795-1886), whose works deal with the popes, with Prussia, England, France, especially in the 16th and 17th centuries, and in the last years of his life with world history; they are famous alike for their style and composition, for their richness of material, and for their objective presentation. Schlosser and Gervinus went their own way; Sybel and Waitz, Giesebrecht and Treitschke, however, were deeply under Ranke's influence.

The economic life of the social community was seen at the beginning of the century through the eyes of France and England. The abstract theory of economy with its individualistic tendency controlled the first decades; of this the work of Rau is typical. With the year 1840 begins the growing reaction. The historical relativistic view is developed by Roscher, Kries, and others, and List, in his National System, Rodbertus, in his Social Letters, Marx, in his Kapital, led the attack of collectivism against the abstract individualistic theory. Brentano, Knapp, and Schmoller turned the attention to the objective history of economic conditions.

The legal life of the community and the theory of law was the object of not less intense discussion. Among the leaders of the century Savigny, Windscheid, and Jhering may be mentioned for Roman Law, Eichhorn and Grimm for German Law, Mohl and Bluntschli for State Law, Feuerbach and Mittermaier for Criminal Law, Thibaut and Dernburg for Private Law, etc.

In the field of religion the naturalistic tendency of this post-idealistic period demanded, first of all, historical criticism, and yet positive theology was not idle. In the study of the Old Testament most fundamental research work was done by Hengstenberg, Delitzch, and Hofmann; in the study of the New Testament by F. C. Baur, the founder of the school of Tübingen, D. F. Strauss, and in sharp contrast to them, Ritschl and Weizsäcker; in the study of church history by Planck, Neander, Ritschl, and Harnack; in the study of Systematic Theology by Schleiermacher, Rothe, Lipsius, Nitzsch, Ritschl.

And finally, philosophy. The period which we have just characterized by the abundance of its specializing work began with the downfall of Hegelianism. The age became indifferent to real philosophy and substituted either an uncritical materialism with Büchner, Vogt, or the history of philosophy which naturally became the domain of Hegelians like Erdmann, Kuno Fischer, etc., or developed a specialistic study of empirical psychology. In the latter field Germany founded, through Fechner and Wundt, the new science of experimental psychology. In the last two decades of the century new interest in real philosophy has set in, partly in the midst of the special sciences, as mathematics, physics, history, etc., where a disappointment in mere fact-gathering has everywhere led to the deeper problems of principle, partly in pure philosophy. This new idealistic movement has grown rapidly; logical, ethical, metaphysical, æsthetical discussions come again more and more to the foreground, welcomed by the empirical sciences which held them in contempt for half a century. And thus it can be said that with the beginning of the 20th century the anti-idealistic specialistic movement, which began in the third decade of the last century, has come to an end and a new synthetic idealistic tendency appears to-day throughout German science and thought.

Professor of Psychology, Harvard University.

7. **Germany — History of Painting and Sculpture.** The inward relationship and intimate connection of sculpture and painting in German art render it desirable to treat of their development as a whole. Painting is the more important of the two branches, because of its greater possibilities of expression. Christian art, and especially German art, demands the representation of inward emotion, of individual character, of spiritual aspirations, not the realization of outward beauty, and perfection of form. The aim of German sculpture and painting is, therefore, not so much the perfecting of the typical, as the complete characterization of the individual.

The first beginnings of plastic and painting are to be found in the sphere of ornament. Peculiar patterns formed by ribbons, bands, plaited, twisted and intertwined with fantastic representations of beasts and birds exist in the miniatures of the 7th century and in the decorations of early architecture. These ornaments differ in character according to their locality. Under Charlemagne the first attempt was made to produce a national characteristic style, which was based upon a direct and conscious imitation of late Roman art. Under the Ottoman Empire a second weighty element became the influence of Byzantine models.

In the 9th and 10th centuries bishops and abbots were the chief patrons of art. A large part of the income of the cloisters was devoted to decorative purposes. The monastery of St. Gallen ranked foremost in the number and importance of its illustrators. We hear of various series of rural paintings, but one alone is preserved to us, that of St. George in Oberzell (c. 1000.) The first inspiration to monumental works in plastic was likewise due to the taste and erudition of the church. Bishop Bernward (d. 1023) became the centre of an art movement of enduring value, as is attested by the Bernward's column, the bronze doors, and various other works of the cathedral in Hildesheim. This art, containing strong Byzantine reminiscences, influenced by late Roman models, but transformed by the glowing imagination of the North into a new beauty, was the first flower of the Romanesque period, in which we can generally class all the works of the 11th and 12th centuries in Germany. The oldest work of German easel painting belongs to this period — the wooden Antependium in Soest (1166). The "Hortus Deliciarum," of the Abbess Herrad of Landsperg shows most clearly the progress of painting, which was chiefly developed by the miniaturists. In Schwarzheindorf, in Brauweiler, in Brunswick and in other places cycles of frescoes attest the presence of artists, who with simple means attained inspiring results. The highest expression of the lofty spirit of the Romanesque period is, however, to be found in the sculptures of the 12th and 13th centuries. The Crucifixion in Wechselburg, the choir-reliefs in Halberstadt, the Golden Gate of the cathedral in Freiberg in Saxony, the Apostles of the cathedral in Bamberg, together with the statues of the princely patrons of Naumburg show a truth to nature and a technical mastery of material, an elevation of taste, and an understanding of the possibilities and necessary restraints of sculpture which in such perfection are not again reached by German plastic.

About the middle of the 13th century the Gothic, entering Germany from France, celebrates its triumph over Romanesque ideals. The forms of the figures in sculpture as in painting undergo a gradual change. The statuesque pose, the truthful portraiture of the individual, the large dignified treatment of drapery of the Romanesque period are abandoned. A general type of contrast movements is adopted. The human body is represented in a strongly curved position, the hip bent sidewise, the head drooping, while an extreme delicacy of hands and affected position of the arms is sought for. The peculiarly long, thin proportions of this type are the result of the influence of Gothic architecture, which demanded extraordinary height in its decorative members; the naïve charm of expression is a reflex of the rich, though conventional, poetical, and religious life of the period. The most important plastic works of Gothic Germany are to be found in its cathedrals. First among these is the portal of the minster in Freiburg i. Br. (c. 1270) unsurpassed in feeling and grace in German Gothic. Strassburg, Mayence, Nürnberg, and Brunswick follow with portals and façades covered with a wealth of decorative figures. The subjects are drawn from Biblical legend and scholastic dogma.

In the field of painting the illustration of sacred books and classic poets occupied numberless miniaturists. Repressed by the conditions of Gothic architecture, fresco decoration did not flourish. The leadership fell to easel-painting, and soon wooden altar-pieces of monumental size filled the churches. In the 14th century three cities became the centres of art development, Prag, Nürnberg, and Cologne. History begins now to record the names of individual artists. Under Charles IV Nicolas Wurmser enjoyed great popularity. The Nürnberg local school evinced earnest endeavor to depict nature and to discover the laws of its proper presentation. Foremost in power, however, ranked the school of Cologne. The city was then a centre of the mystical movement of Germany. The religious leaders were full of poetry and of love of the Beautiful. They recommended the use of paintings in the churches as an aid to the devotional spirit. The simple, fervent belief in Madonna and saints which inspired the people finds expression in their altar-pieces of the 14th century, gathered largely to-day in the museum of Cologne. Sunk in revery, or rapt in ecstasy the aerial Gothic figures appeal to us as embodied ideals of the æsthetic and religious spirit of the middle ages. The glowing colors, the gold and the deep blue, are in themselves a symbolism of pure joy. The creations of Meister Wilhelm (Hermann Wynrich) may be regarded as the most finished works in conception and execution of early German painting. A note of such exquisite and unconscious loveliness is not again attained, for no tarrying was possible upon this height. The lyric of the Minnesinger and the piety of the mystic had reached their full artistic expression. About 1400 a new era broke over German art. Not Heaven but earth claimed its interest. A naive realism replaced the dreamy vision of soulful saints. The Gothic type gradually disappears. It is succeeded by a naturalistic tendency bent upon characteristic representation of the individual. In the social life of the nation knighthood yielded to the might of the burghers. A new commerce sprung up in flourishing cities. The spirit of discovery and of invention arose in its power. Thus the beginning of the 15th century became again a period of experiment and of new technical processes. Especially influential in bringing about this change was the great altar of Ghent, which in 1432 made the names of the Flemish painters, Hubert and Jan van Eyck, famous for all time. A practically new technique — the use of oil mixtures — presented itself here, and soon all Europe was engaged in working out new problems of painting. Italy called upon science to aid art, and there the problems of perspective, of anatomy, of composition, and of artistic harmony were systematically solved, so that the artist built his lofty structure upon a sure foundation. Not so in Germany. Individual painters reached here during the first half of the 15th century at times a high degree of excellence, but the works of this period show in general a lack of constructive ability.

Stephan Lochener (d. 1452) in the beginning of his career painted a series of harmoniously beautiful works in the spirit of the early Cologne school, of which the best known is the altar-piece of the cathedral. Later Lochener loses himself in imitation of the Flemish masters, as do the later painters of Cologne, "Master of the Life of Maria," "Master of the Lyversburg Passion," "Master of St. Severin," "Master of Liesborn," and other painters of this school.

Lucas Moser in Swabia and Pfennig in Nürnberg are the most important painters of the South. Their works form a strange contrast to those of the foregoing period in their short, heavy figures and in their genre-like use of the incidents and implements of daily life.

Flemish influence during the 15th century gradually becomes paramount, not only in technique, but also in the type of figure adopted, in costume, landscape, portraiture, composition, and color. Different local schools progress in the knowledge of perspective, anatomy, in the management of drapery, and in atmospheric unity. In Kolmar Kaspar Isenmann (d. 1466) founded a workshop in which was trained the artist who was destined to give to the school of the Upper Rhine a position of leading power, Martin Schongauer (d. 1491). Schongauer's rich phantasy and high artistic talent covered a wide range of subject and technique. His influence upon his time was far-reaching. Especially as an engraver was he an inspiration and a model to his compatriots.

In Ulm, Bartholomäus Zeitblom (c. 1450–1517) took the leading position, through the exceptional restraint and simplicity of his compositions. In the local school of Augsburg the chief place is filled by Hans Holbein the Elder (1460–c. 1524). In his works it is possible to trace the progress made by German art in this period from narrow realism and exaggerated movement to an understanding of the harmony of form and color characteristic of the Renaissance.

Nürnberg continued during the 15th century to be a centre of artistic energy. Hans Pleydenwurff is the first name in a long list of local artists. Pleydenwurff has a talent of superior order and delicate artistic appreciation, but he died young, leaving his workshop to Michael Wolgemut, under whose name many of Pleydenwurff's paintings are known. To Wolgemut (1434–1519) art was a business. A clever artisan and imitator of Rogier von der Weyden, he lacked all deeper feeling and higher imagination. In his works, as well as in numberless other productions of the Nürnberg school, we can best see the subject-matter to which the early artists of the 15th century devoted their attention. Not soulful representations of Madonna and gentle saints, such as are found in the early Cologne school, enthrall the imagination, but the subject of the Passion of Christ, and the sufferings of martyrs, become the theme of their art. The Italians, seeking the highest beauty in subject, as in form, had more and more abandoned the scenes of the passion as their art advanced to its full height. The Germans, on the contrary, found in their representation of the heartrending agony and unbridled cruelty of the Cross an outward expression for their inward religious emotion. The countless crucifixions of this period show an imagination quivering with intensity of feeling, but devoid of artistic balance. With passionate earnestness every detail of distortion, of rude ribaldry, is dwelt upon, while compositional construction and loveliness of form and color are neglected.

If this striving after a delineation of highest tragic was incompatible with æsthetic beauty in painting, how much more was this the case in sculpture. Without regard for the potentialities of representation in stone or wood, the German of this period poured his intense feeling, his love of movement, and of detail into the altar-pieces of the cathedrals. Plastic separates itself gradually from architecture. Shrines, reliefs, statues, monuments, are placed in the churches as entities, not as integral parts of the architecture as heretofore. An earnest study of nature is characteristic of the time, but it lacks the system of a great school, or the inspiration of a great leader. The sculptors in general may be divided into two groups. In northern Germany the centre is again Cologne, whose masters are influenced in plastic, as in painting, by Flemish models. In southern Germany the centre is Nürnberg, where sculpture precedes painting in importance until the end of the century. Michael Wolgemut is the first artist we meet here, in whose busy workshop sculptors, as well as painters, were employed. From primitive beginnings an art is developed which shows increasing mastery over technique and a clearer understanding of the problems of plastic. Humanistic studies and classic models gradually influence artists as well as scholars. When we think upon the sculpture of the developed Renaissance, we see that a change of view and of purpose has taken place. Perfection of form and harmony of composition are sought. The individual and the momentary are changed into the typical and the enduring. Three artists stand out in prominence, all in Nürnberg; the one, a carver of wood; the second, a cutter of stone; the third, a founder of bronze — Veit Stoss, Adam Krafft, and Peter Vischer.

Of the woodcarver, Veit Stoss (c. 1440–1533), the best known work is the "Angel's Greeting" in the St. Lawrence Church of Nürnberg, the most attractive is the statue attributed to him of a full length Mater Dolorosa in the Germanic Museum. This figure in its grace and beauty of pose, its simple treatment of drapery, and its sincerity of feeling justly ranks among the best statues of German art.

Adam Krafft (c. 1450–1507) is chiefly known through his representations in sandstone of the "Seven Stations" recorded by holy legend as the scenes of Christ's journey from the house of Pilate to Golgotha. These realistic sculptures in high relief show the costume and countenance of Nürnberg burghers; the composition is clear and admirable.

Neither Stoss nor Krafft, however, attained that perfected excellence of style which is found in the works of Peter Vischer (c. 1450–1529). As Dürer is the first representative of German Renaissance in painting, so Vischer must be regarded as its highest expression in sculpture. The influence of Italian art is powerful with him, and his inspiration is drawn largely from an enthusiastic study of the antique, though he never for a moment loses his own individuality. Vischer's masterpiece is the tomb of St. Sebaldus in the church dedicated to that saint, a bronze work of mixed Gothic and Renaissance features, which on account of its originality of conception and artistic perfection of detail has become the pride of Nürnberg. Totally different in character, it is comparable in beauty to Ghiberti's "Gates of Paradise," the much prized jewel of Renaissance sculpture in Italy.

Vischer's sons and pupils continued his workshop, but toward the middle of the 16th century the deterioration of the commerce and power of Nürnberg closed the door of the famous foundry, which for nearly 100 years had furnished the best bronze reliefs, grave tablets, shrines, and statues of German Renaissance sculpture.

Outside of Nürnberg we find only the sculptors of Lower Franken, in and near Würzburg, of importance. The "Master of the Creglinger Altar" and Tillmann Riemenschneider (1460–1531) are the two names worthy of especial note. The latter's masterpiece is the celebrated tomb of Emperor Henry II. and his wife Kunigunde in the cathedral of Bamberg.

The representatives of the Swabian school of this period are Jörg Syrlin and Friedrich Herlen. In northern Germany the development of woodcarving culminated in the richly-decorated altar of Hans Brüggermann (1515), now in the cathedral of Schleswig.

In Tyrol we find a sculptor, who, although near to the Italian boundary, nevertheless shows himself a northerner in form and feeling. Michael Pacher (d. 1498) owes his refined taste and his monumental composition to his contact with Italy, his wealth of fanciful detail and his treatment of drapery to his native surroundings.

In remaining Germany exist numberless altar-pieces and statues by unknown or unimportant masters. These altar-pieces are usually divided into various compartments, and, almost without exception, are richly colored and gilded.

It was no mere chance that in painting, as in sculpture, Nürnberg produced the first great artist who united theory and practice to a noble whole. The city had been for generations the chief centre of artistic movement and interest. In Albrecht Dürer we find the full and complete expression of the spirit of German Humanism, which was ethical as well as æsthetic in its nature. His works are mirrors of universal personality. In him took place that transfiguration of art which stamps its creations with living truth and gives to them enduring value.

Albrecht Dürer (1471–1528) was the third among eighteen children. He entered the workshop of his father, a skillful goldsmith, to learn his trade, but was sent later (1486) as a pupil to some unknown painter in the workshop of Michael Wolgemut. Dürer's portrait by his own hand at 13 years in Vienna shows the early talent of the boy. In 1490 he started on the usual pilgrimage of young German artists to distant centres of art, and visited Kolmar, where he came under the influence of Schongauer, then Augsburg, Basel, and Italy. In 1494 after his return to Nürnberg he was married to Agnes Fry. He enjoyed the protection and friendship of the learned young patrician, Willibald Pirkheimer, through whose influence he entered the circle of the humanists where his mind was stirred by contact with such men as Erasmus von Rotterdam and Reuchlin. In 1506 Durer made a second journey to Italy, where he spent a year, devoting himself especially to Venice. In 1520-'21 he undertook a lengthy visit to the Netherlands. On the 6th of April 1528 Dürer died in Nurnberg, the scene of his life labors. In the open square which bears his name, the city erected in 1840 a bronze statue by Rauch to his memory. In the quiet cemetery of the Johannis church lies, as the inscription says, "That part of him which is mortal."

Dürer's genius belongs to the highest class. He far surpasses in range of imagination, in depth of feeling, in understanding of nature, and in artistic power of presentation any of his compatriots. His productiveness was especially great in the field of engraving. His wood cuts and engravings stand unsurpassed. Among the most important wood cuts are The Revelation of John, The Small Passion, The Large Passion, The Life of Mary, and Maximilian's Gate of Honor, the largest existing wood cut. For the Emperor Maximilian were also made the celebrated 'Triumphal Chariot' and the illustrations of The Prayer Book.

Dürer's best known engravings are: Melancholy, St. Jerome, Adam and Eve. As a painter Dürer produced portraits which belong to the world's masterpieces. Among many of great value those of the Nürnberg Senator Muffel, and of Hieronymus Holzschuher, both in the Berlin museum, take the highest rank.

Among Dürer's numerous religious paintings: 'The Trinity' in Vienna, 'Christ on the Cross' in Dresden, must be especially mentioned, while the crowning masterpiece of his art is to be found in the 'Four Apostles' in Munich, a work unparalleled in the history of German painting for monumental greatness and truth to nature.

Dürer's writings as well as his creations with the brush were epoch-making. His works were translated into Latin and most of the modern languages. The most important among them is the treatise 'Concerning Human Proportions.'

An artist of Dürer's genius necessarily had a powerful influence upon the further development of his country. His wood cuts and engravings carried the knowledge of his great spirit into the most distant provinces. The later painters of the Nürnberg school according to their own greater or less pronounced individuality followed in his foot-steps. Among Dürer's own pupils his brother Hans Dürer (1490-1538) deserves mention, also Hans Schaüfelein (c. 1840-1540), Hans von Kulmbach (1475-1522). Among the younger generation of his followers Georg Penz (c. 1500-1550) and the two brothers, Hans Sebald Beham (1500-1550) and Barthel Beham (1502-1540) were, like Dürer himself, enthusiastic supporters of the Reformation.

In the district of the Upper Rhine a school of painters, whose chief representative is Matthias Grünewald, preserved an element of independence. Grünewald's (c. 1479-1525) importance lies in the artistic means which he employed to give his paintings life and beauty. He was, in contrast with his contemporaries, a colorist. Effects of light and harmony of color formed his ideal. He seemed a German forerunner of the light and shadow painters of Holland. In spite of a naturalism which depicts every revolting detail of a crucifixion, Grünewald has been named the "German Correggio." To him belongs by right the fame of first arranging his compositions with regard to value of mass and poetry of light.

Grünewald's influence is seen most clearly in the works of Hans Baldung Grien (c. 1475-1545) who combines coloristic aims with a baroque imitation of Dürer's forms.

Albrecht Altdorfer (c. 1475-1538) is also a product of the art of Durer and Grünewald, but a painter of decided individuality who developed in his landscapes and atmospheric quality which gives to them great charm.

To this period belongs Hans Burgkmair (1473-1531) who endeavored to transform the circumscribed naturalism of the 15th century into greater nobility of form through the use of Italian types. Burgkmair was followed by Christoph Amberger (c. 1500-1561) by Martin Schaffner (t. 1541) and Berhard Strigel (c. 1460-1528), who excelled especially as portraitists.

In Augsburg, the centre of riches and culture, was born Hans Holbein the younger (1497-1543), that painter, who, together with Dürer, stands in the foremost rank of Renaissance art. Holbein's first instruction was received from his father in his native city. Later he was occupied in Basel as well as in Augsburg. When the storm of fanaticism against art broke during the Reformation, Holbein turned his attention to England and in 1526 visited that country for the first time. In 1538 he became the court painter to Henry the VIII and in this position fell a victim to the pest in November 1543.

Holbein possessed a remarkable sharpness of eye for every detail of nature, a boldness of drawing comparable to that of Mantegna, an exquisitely fine sense of modelling, and a greatness of conception classical in its spirit. As a colorist he is unequalled in German art. Holbein's Madonna of the Bürgermeister Meyer now in Darmstadt (an excellent Dutch copy of the 17th century exists in the gallery of Dresden) is to German art that which the Sistine Madonna of Raphael is to Italian painting, the culmination of a long period of artistic evolution.

A long list of portraits by the hand of Holbein vie with one another in excellence, none however surpassing that of the Ambassadors in London. To estimate correctly the greatness of Holbein's genius, a careful study must be made not only of his paintings, but also of his engravings and wood cuts. The deep earnestness of his nature and his fiery religious zeal speak from his illustrations of the Bible, his representations of daily life and above all in his celebrated series of the Dance of Death.

The remaining painters of this period were scarcely more than imitators, or clever artisans. In Saxony, however, a school of influence was founded by Lucas Cranach the elder (1472-1553), whose name became for a time almost as popular as those of the great artists of southern Germany. As a landscape painter and harmonious colorist, Cranach deserves a high rank, but he soon became affected in his types and sterile in his compositions, losing himself in countless soulless repetitions.

With the masterpieces of Dürer and Holbein the development of German art had reached its height. In their works we find that ripe union of nature and style which is the secret of classical epochs. The period of fruition, however, was not in proportion to the slow ripening of German art. Scarcely had it reached its full power when the signs of decay imposed from without became apparent. The art of Italy gave to the great masters of Germany inspiration, and helped them to develop their own ideals. To their immediate followers it became a law foreign to their nature. They began to use forms which they did not feel. Virtuosity soon replaced living art.

Upon the great period of Dürer and Holbein followed a weakening and lassitude of artistic power, which lasted nearly 200 years. The later 16th and the early 17th century were filled by poor productions in imitation of Italian art, later in imitation of Flemish models. The only real artist whom Germany produced at this time was Adam Elsheimer (1578–1620), who created a new form of landscape, in which the human figure became an integral part of the compositional whole.

In the 18th century there are likewise but few names of especial note. Denner (1685–1749), a portraitist, depicted the human face with the exaggerated detail of a microscopic vision. Chodoviecki (1726–1801) paints the life of the burgher. Anton Graff (1736–1813) possesses in portraiture excellent technique. Architectural scenes, animal hunts, still life were copied from Flemish models. Academic barrenness paralyzed inner life.

Sculpture shared the general downfall. The Thirty Years War destroyed the seeds from which new life might have sprung. From the end of the 16th century until the last decade of the 17th foreign sculptors were almost exclusively employed. Superficial beauty and emptiness of form replace healthy naturalism. At the beginning of the 18th century single cities produce some good works of home talent. As the best of these is to be regarded the bronze statue of the great Kurfürst in Berlin by Andreas Schlüter (1664–1714), the foremost representative of German baroque. In southern Germany Georg Raphael Donner (1692–1741), in contrast with Schlüter, devotes himself to a study of the antique, striving after simplicity of composition and form, as is shown in his celebrated fountain in Vienna. A return to nature is sought by the Berlin sculptor Johann Gottfried Schadow (1764–1850), whose worthy followers are Christian Rauch (1777–1857) and Ernst Rietschel (1804–1861).

Winckelmann's History of Antique Art in 1764 created a new artistic enthusiasm in the minds of Germany. His followers hoped for a new birth of art through contact with and appreciation of the art of Greece. When Goethe in theory and practice lent his influence to this teaching, the supremacy of antique ideals became settled. Raphael Mengs (1728–1779) adopted the principles propounded by Winckelmann as his guide and became the founder of German classicism. Although his perfectly formed figures possess no inner life, Mengs was in his own time looked upon as a new Raphael. Angelica Kauffmann (1741–1807) painted allegorical and historical scenes of merit as well as portraits of sentimental charm. Carstens (1754–1798) may be regarded as an artist who possessed not only the form but also much of the spirit of the classical models he followed. In Peter Cornelius (1783–1867) we greet a powerful artist of this period, burning with energy and ideality, his hand trained, his eye set on mighty deeds. The figures, however, which crowd his frescoes, have no root in the soil from which they spring. His compositions are the result of abstract theories, so that his true greatness makes shipwreck on the dangerous shoals of imitation. Of lesser talent but similar aims are Wilhelm von Kaulbach (1805–1874) and Julius Schnorr von Carolsfeld (1794–1872).

With the beginning of the 19th century a group of artists, preserving each his own individuality and technique, found their way again to the thoughts and hearts of the people. The principal names among these are Moriz von Schwind (1804–1871), Ludwig Richter (1803–1884) and Adolf Menzel (1815–1904). Schwind is the pleasant narrator of German fairy tales. Richter the illustrator of the homely, hearty scenes of everyday life, while Menzel is the enduring naturalist, historian of national aims and deeds, a painter and especially a draughtsman of great power. Anselm Feuerbach (1829–1880) sought to unite romantic ideals with classic form. To Hans Makart (1840–1884) a brilliant colorist and pupil of Piloty's, the world appeared as a theatrical scene of bright draperies and gay personages. Landscape painting rose to a high degree of excellence through the painters Friedrich Preller (1804–1878), Karl F. Lessing (1808–1880), and the brothers Andreas and Oswald Achenbach.

With these artists of note are associated in the second half of the century the painters of religious scenes and of genre, Knaus, Vautier, Defregger, Edward von Gebhard, Gabriel Max, Piglheim, and Fritz von Uhde.

At the close of the 19th century three names stand out in prominence — Lenbach, Thoma, and Böcklin. Franz von Lenbach (1836–1905) is the leader among portraitists and a colorist of power. Hans Thoma (b. 1839) depicts in simple truthfulness the German peasant and repeats in poetical landscapes the scenes of his native land. In Arnold Böcklin (1827–1901) the naturalistic pantheism of the Greeks is born again. He gives us a new world of satyrs, fauns, nymphs, and nereids. He experiments in new technical methods and invents new tones of vivid color. As a landscape painter he possesses the charm of composer of melodious music.

In this morning of the 20th century, individual artists are following individual paths. Adolf Hildebrand (b. 1047) in sculpture possesses in his best works simple greatness and pure beauty. Volkmann follows his lead. In contrast to Hildebrand is the sculptor Reinhold Begas (b. 1831), who relies for his effect upon a modern baroque splendor. In painting and in sculpture Max Klinger (b. 1857) stands forth as an artist of power, while a large group of painters, prominent among whom are Kalckreuth and Max Liebermann, devote themselves to the development of the aims of the French impressionist school. According to the talent and insight of the artist we find the individual striving after the accurate delineation of actual things, after sound portraiture, above all after the subtle effects of light and shade in landscape. As these aims have their root in an appreciation of nature and a reverence for her harmonious laws we may hope that the new century in Germany will be rich in artistic expression of its inward vision.

8. Germany — History of German Music. The chief epochs in the history of German music are these,— sacred, polyphonic music, and its culmination in the works of Bach and Handel; the birth and development of modern instrumental forms; the German romantic opera,— von Weber; the German Lied; the Romantic School, Schumann, Liszt; the Music dramas of Wagner; modern tendencies as found in the works of Strauss and others.

The first promising epoch in the development of German music was the Reformation. In that period of storm and stress, of burning questions and of intense longing for religious and social independence, sacred music, that expression of man's belief in the Eternal, was cultivated with the greatest fervor. The music which was the natural outcome of such conditions was of far-reaching influence, especially upon the great vocal and instrumental compositions of Sebastian Bach (q.v.).

Martin Luther, the leader of the movement, was not a composer of chorals or hymn-tunes, as is often supposed, but a writer of the words of hymns to which he and others set traditional melodies taken from the rich stores of religious folk songs then extant. Luther's distinct contribution to the musical life of the time was (1) his writing of about 30 hymns which, deeply imbued with patriotic and moral feeling, spoke directly to the heart of the German people, and (2) his associating with him the best musicians of the period to collect and write chorals suited to his words. Of these the most famous were Johann Walther and Ludwig Senfl.

In 1524 there was published in Wittenberg Walther's choral-book with a preface by Luther. The melody of 'Ein Feste Burg,' which Frederick the Great called "God Almighty's grenadier march," has exercised a powerful influence throughout the course of German music, as may be seen from the prominent part it bears in the works of Bach, Mendelssohn (Reformation Symphony) Meyerbeer (Huguenots) and finally in Wagner who uses its strains in the 'Kaiser-March' to typify the military triumphs of united Germany.

The first representative composer, often spoken of as "the father of German music"— whose works clearly foreshadowed two of the important directions of modern art,— was Heinrich Schütz (q.v.). He was born in 1585, just a century before Bach, and died in 1672, while he was court director of music at Dresden. Quite early in life he came under the stimulating influence of the Venetian school as a pupil of the famous Giovanni Gabrieli. Schütz, as the composer of the first German opera 'Daphne,' is the progenitor of the line which includes Gluck, Mozart, von Weber and Wagner. Schütz's real importance however centres in his sacred compositions, the 'Resurrection,' the 'Seven Last Words' and the four settings of the Passion. In these works, in which a sacred story in dramatic form is told without the aid of scenery or action, Schutz was the real founder of German Oratorio, and in his power of vivid, dramatic characterization anticipated some of the essential features in the Passions and Oratorios of Bach and Handel. In Schutz we also see traces of that Teutonic power of introspection and deep thought which prevented German Oratorio from yielding to the baleful theatrical influence of Italian music, and which, exercised by the great composers of the following century, led to such triumphant achievements in German Art. The prime of Schütz's life unfortunately coincided with the Thirty-years War (1618–1648)— that time of devastation and horror which diverted all men from the peaceful cultivation of either Art or Literature.

On the other hand this period of ferment and of the breaking up of established routine had a stimulating effect upon German music in that composers were brought into closer touch with men and ideas from other nations. German artistic development had suffered from too much isolation, but henceforth, by reason of this intermingling of continental peoples, music began to speak a more universal language. This change is strikingly typified in the Instrumental Suite which was a somewhat loosely connected series of national dances — as may be seen from the names of the principal numbers, Allemande (Germany), Couraunte or Corrente (France or Italy), Sarabande (Spain), Bourée and Gavotte (both French), and Jig (English).

Prior to the complete development of the Sonata and Rondo forms in the time of Haydn, the Suite was about the only instrumental form (with the exception of the Fugue), which made any pretence to artistic organization, and was the favorite form in the clavichord compositions of Bach, Handel, and contemporary composers.

The real supremacy of German music dates from the 18th century, for at that time began the careers of Bach and Handel (qq.v.), both born in the year 1685.

Handel was undoubtedly a man of great force of character and of quick comprehensive intellect; in whatever he undertook, as composer, impresario, or chapel-master, he succeeded through sheer force of will and personal magnetism. His purely musical gifts, great as they were, often seem the least of his powers. His varied career affords a striking contrast to the simple life of Sebastian Bach, who spent his days in a rather obscure part of Germany, was practically unknown, and certainly unappreciated outside his native land, and began to receive due recognition only about a century after his death.

Handel's early studies were made in Italy and in his 47 operas he stood forth as the finest representative up to that time of the flowing Italian vocal style. These operas, although now entirely obsolete on account of their weak, meaningless libretti and lack of dramatic unity, yet contain some of Handel's finest songs, and as a song-writer his power is undoubted.

Handel's fame to-day rests almost entirely upon his Oratorios, among which may be mentioned 'Israel in Egypt,' 'Sampson,' 'Judas Maccabaeus' and the 'Messiah.' His vast number of other instrumental and vocal works on account of their old-fashioned, conventional idiom, and their somewhat monotonous harmonic scheme, are fast becoming obsolete. In the Oratorios, although they contain many arias noted for pathos and beauty of expression, the choruses are the portions in which Handel's distinctive power is chiefly shown. His vocal solos are too often of stereotyped design and defaced by meaningless roulades — a survival of the vain-glorious operatic style of the period. As a chorus-writer, Handel is supreme in the history of music. He was a great impressionist and for dramatic effect, for majesty and dignity of utterance in dealing with large masses of voices, has never been surpassed. Early in middle life Handel became a naturalized Englishman, wrote his most famous works to English words, with special reference to English religious feeling, and so his influence there has at times amounted almost to idolatry. Upon other nations, France, Italy, and Germany, Handel's influence has been much less and is weakening year by year.

If human greatness is to be measured by a constantly growing concensus of approval, Bach was in some ways the greatest musician who ever lived. He is practically the founder of modern music, and his influence is supreme in such different composers as Beethoven, Schumann, Chopin, and Wagner (qq.v.). In wealth of harmonic resource Bach was at least a century ahead of his time, and only recently have the inexhaustible vitality and suggestiveness of his works been fully appreciated. Bach's power is shown in three important branches of composition — as a choral-writer, as an organ-composer, and as the precursor of the important modern developments in pianoforte style and pianoforte playing. Bach's great choral-works are the two settings of the 'Passion according to Saint Matthew' and 'Saint John,' the 'B minor Mass,' the 'Christmas Oratorio,' and innumerable church cantatas. Words are entirely inadequate to describe the sublimity and pathos of these stupendous cathedrals in tone. In the words of Schumann "music owes almost as great a debt to Bach as religion owes to its Founder."

To the general public Bach is best known by his organ-compositions, Preludes, Fugues, Toccatas, Fantasies, Choral-Preludes, etc., and as an organ composer no one can even be mentioned in the same class. These works are all remarkable for their variety of construction, for their free, untrammeled use of every possible contrapuntal device, and notwithstanding their intricacy, for the complete subordination of mere learning to the needs of a personal expression of mood. Bach's most important work for clavier — the prototype of our modern pianoforte — is the 'Well-tempered Clavichord.' This work, in substance a set of 48 Preludes and Fugues (in all the major and minor keys), took its name from the new system of tuning, largely originated and sanctioned by Bach, by which all keys became of equal importance, and modulation was made possible into remote tonalities. The 'Well-tempered Clavichord,' often called the musician's Bible, represents not only the essence of Bach's genius, but contains within it the seeds of the whole growth of music since that day. In strong distinction to the somewhat local influence of Handel, the leading composers of every nation, Italy, France, Germany, America, etc., have taken Bach as their model and have stated unmistakably that they have based their work on his. Other notable compositions of Bach are the French and English Suites, the Chromatic Fantasie and Fugue and the Two and Three-Voiced Inventions. Mention should be made of the Orchestral Suite in D, of the Sonatas for Violin and 'Cello, and of the celebrated Chaconne for violin solo.

Between the culmination of the vocal style of Bach and Handel and the development of modern instrumental music there was an interregnum, a period of overlapping tendencies, and of experimentation as to what the course of music should be.

Sebastian Bach himself said in the latter part of his life that musical taste had altered wonderfully and that the old music no longer sounded good to the ear.

Among many worthy names, two are of real prominence. Gluck (q.v.), (1714–1787), will always be honored as the first reformer of the opera, and although his best works, 'Iphigenia in Aulis' and 'Iphigenia in Tauris' were written to French libretti and brought out in Paris, the peculiarly Teutonic characteristics of the man, his sincerity, his courage and unerring instinct for dramatic truth were the animating causes of his reforms. To carry them out Gluck needed all the strong physical and mental qualities which came to him from his peasant ancestry. Italian opera as he found it was an artificial and undignified form of art, in complete subservience to the capricious whims of singers and the vitiated taste of ignorant patrons. Gluck's title to fame is the fact that in such circumstances he set himself resolutely to express himself in his music, and to make it manly and sincere. His dramatic creed is expressed in the famous preface to 'Alceste.' One of his chief canons was to make the music subordinate to the spirit of the words,— a principle sometimes carried so far as to make the music lacking in beauty for its own sake.

Gluck is rightly regarded as the father of modern opera; his theories and reforms have had great influence upon all opera composers, notably upon Wagner, and his works are the earliest which hold the stage to this day. He was great both in impassioned and pathetic melody and his dramatic use of the chorus is unsurpassed. He was also the first to anticipate in many ways the organization of our modern orchestra.

Emmanuel Bach (q.v.) (1714–1788), third son of the great Sebastian, the forerunner of Haydn and Mozart, is important for his contribution to the development of instrumental form, especially in music for the clavier. In fact many of his first movements all but reach the completely organized Sonata Form as found in Haydn. He was also an important factor in settling the most effective manner of writing for the clavier, *i. e.*, solo-melodies lightly accompanied, brilliant passage-work, etc., instead of the old polyphonic style on a vocal basis. His celebrated treatise on 'The true art of playing the Clavier' contains the principles which have since been developed by Clementi, Cramer, and others into the pianoforte style of our own time.

Haydn (q.v.), (1732 .) is called the Father of the Symphony and the String Quartet, and the term, though a slight exaggeration, is well deserved, for he summed up and amplified the tentative efforts of the many instrumental composers of the period. Born at Rohrau in Austria, near the Hungarian frontier, his peasant origin and his life-long contact with the common people and with rural life must be kept in mind in estimating his music. Much light has been shed upon the causes of Haydn's peculiar genius by the researches of a Croatian scholar, Dr. Kuhac, who has shown conclusively that Haydn was of Croatian stock. The evident and pervasive signs in Haydn's music of light gypsy dance rhythms and of folk-songs are thus accounted for. His earlier years were of intense hardship and his musical education due almost entirely to his own efforts. Finally he came in 1761 under the patronage of the Esterhazy family in Hungary — a post held uninterruptedly for 30 years, in which Haydn's status was typical of the musical patronage in vogue at that epoch. The most prominent external events of Haydn's life were the two visits to London in 1791 and 1794 at the invitation of the violinist Salomon. For these occasions were composed the 12 "Salomon Symphonies" which include Haydn's best work — the 'Surprise,' the 'Oxford,' etc. Haydn received the degree of Doctor of Music at Oxford and also became acquainted with the vocal style of Handel, which influenced him in the composition of the 'Creation' and the 'Seasons,' those remarkable works of his old age. Haydn, a distinctly uneducated man, but one of great musical concentration, was just suited to organize the tunes and rhythms of the people into coherent forms of art. In movements in the so-called Sonata Form his establishment of the second theme and free treatment of thematic development were organic changes of the greatest moment. To the old three-movement Sonata or Symphony with its mechanical contrast of fast, slow, fast, Haydn added the Minuet, in which his fondness for light graceful rhythms and spirit of playful humor found free scope. The modern String Quartet owes almost more to Haydn than the Symphony. His String Quartets contain his most vital and lasting work and show his inexhaustibly fertile invention in varied rhythms and in the individualizing of the instruments. Haydn's music is noted for its cheerfulness and dainty grace, and though it seldom rises to a high level of dignity, bids fair to be immortal as a genuine expression of the optimistic sunny temperament of the man.

Mozart (q.v.), (1756–1791), a most prolific genius, worked in every form of musical art known to his time; his significance however (from the standpoint of historical development) lies in his symphonies, his string quartets and allied forms, and most of all in his operas. Born at Salzburg, the son of Leopold Mozart, a famous violin teacher, the first 25 years of his life were chiefly spent in professional tours. His marvellous precocity both as composer and executant is well known. In 1772 he became music director at Salzburg, but unable to endure the galling system of patronage went in 1781 to Vienna, where he continued to pour forth masterpieces until his tragic death, largely brought on by poverty and hardship. He was buried in a pauper's grave. Mozart is the supreme example in history of the inborn spontaneous musical temperament, and his wonderful gifts were supplemented by a perfect mastery of the technique of his day. In some ways his music is more Italian than Teutonic, and though often limited in depth of expression, is perfect in its beauty of melodic outline, in its fineness of detail and in its serene purity of sound. His works are a complete embodiment of abstract classic beauty in distinction to the arbitrary self-expression of the Romantic composers.

Mozart's first string quartets (1782) were dedicated to Haydn, who greatly improved his own symphonic style by a study of Mozart's three great symphonies, all written in 1788. His pianoforte Sonatas, owing to the limitations of the instruments of that time, are often superficial, but in his compositions for pianoforte and orchestra he is virtually the founder of the modern pianoforte concerto.

Mozart's most vital influence is felt in his operas. In no way a reformer like Gluck, he accepted the existing Italian models, but through sheer power of musical beauty and wonderful dramatic characterization he created the greatest operatic works of his century, which to-day are still full of life. The most important are 'Don Giovanni,' 'Figaro' and 'Cosi fan Tutte.' The operas written to German words, including 'Die Entfhrung aus dem Serail' and 'Die Zauberflöte' are of historic interest from their connection with the German Singspiel and as forerunners of the romantic opera of the following century.

Beethoven's (q.v.), (1770–1827) historic relationship is akin to that of Bach in that he concentrated all forms of expression then extant, and also foreshadowed many of the important developments still to come. His artistic growth is to be studied in relation to his times. His life coincided with the French Revolution, with the American War of Independence, and the German struggle for National Unity; the most prominent single note in his music, the free expression of individualism, is a definite result of the spirit of emancipation so prevalent in both literature and political life, and shows Beethoven's intense susceptibility to all the contemporary currents of thought. With him music ceases to be merely an art depending for its effect upon fineness of workmanship; it becomes a language capable of expressing the deepest emotions of the composer and voicing the joys and sorrows of humanity. Beethoven, of mixed ancestry, was born at Bonn but spent the chief part of his life in Vienna and the neighborhood. His study characteristics of body and mind may be traced to his Dutch grandfather while his intensely emotional and romantic nature came from the German blood on the maternal side.

Beethoven's greatness depends on the perfect equipoise found in his works of the intellectual and emotional elements. His symphonies and sonates embody the most carefully planned musical architecture and yet are so surcharged with emotion that our deepest feelings are touched. In him the principle of thematic development reached its climax; entire movements were founded on some striking motive, *e. g.*, the opening movements of the 'Heroic' and the 5th symphonies. This method of construction, by which instrumental music was freed from its former diffuseness, has had great influence on all modern composers.

Beethoven's sketch books illustrate his method of work; we see how an idea springing from an emotional source was worked over, changed, and improved, until it could stand forth as a perfect expression of musical thought. This concentration is shown by the fact that, although an unceasing worker for 37 years, he produced but 133 works, in contrast to the many hundreds of Haydn and Mozart which are largely in the same style.

Beethoven in variety of conception ranks with Shakespeare. Each of his nine Symphonies is unique, differing from any one of the others. He also first revealed the possibilities of humor in music as distinct from the light wit and playfulness of Haydn, and in many of his works substituted for the Minuet a movement to which he gave the name "Scheroz." His nature had a vein of brusquerie and irony and this may be seen manifested in such movements as the Scherzi of the 3d and 5th Symphonies and in the Finale of the 8th.

Great advance in the art of orchestration is due to Beethoven; he studied the expressive qualities of each instrument and first showed the entire capabilities of the horns, clarinets, kettledrums, contrabass, and bassons. His imagination was distinctly orchestral, even when he was composing for the pianoforte. In Beethoven's works we see striking anticipations of modern "programmistic" tendencies, witness the frequent titles, *e. g.*, the 'Heroic' and 'Pastoral' symphonies, the Overtures to 'Coriolanus' and 'Egmont'; the sonata called 'Adieu, Absence and Return'. He said himself that he generally composed with some poetic thought in mind, and his music is often symbolic of mental states. His favorite name was "Ton Dichter". Since his day there has been a growing tendency to bring instrumental music into closer touch with external poetic thoughts. Beethoven, though not highly educated in the modern sense, was of a powerful, comprehensive intellect. His disposition, a strange mixture of contradictory traits, was at bottom warm-hearted and loyal. His character was one of perfect honor. Although thrown back on himself by his deafness which began in his thirtieth year his music never became morbid, but continued to sound the notes of sublimity and spiritual exaltation. He would not allow "destiny to drag him down", kept a firm grasp on his lofty ideals, the love of liberty, the brotherhood of man, and expressed them in immortal music in his 'Heroic' symphony and in the Choral symphony, the last movement of which is based on Schiller's 'Ode to Joy'. Beethoven is the central figure in the development of music. His supreme power is manifested in his influence over all the composers of the 19th century as indicated in their works and recorded eulogies.

During the latter part of Beethoven's life, *i. e.*, the first quarter of the 19th century, there were going on two most important movements in German music, the creation of a distinctly German opera, and the establishment of the German Lied. The former is chiefly due to the genius of von Weber (q.v) (1786–1826), the latter to that of Franz Schubert (q.v.) (1797–1828). Both these achievements had their birth in the war of liberation waged in art and literature against the long domination of French and Italian standards. Weber did not create the German romantic opera *de novo*. Its origin was in the Singspiel, a light piece with plot and characters drawn from native sources, copiously supplied with incidental music often based on folk songs. Fairy tales and local legends were also much used. Closely connected with this operatic movement was the Romantic school of poetry founded about 1800. Breaking away from classic themes the Romanticists found their inspiration in the German world about them, the mystery of the forest, the charm of out-of-door peasant life, etc., and upon such themes and other fantastic subjects suggested by his glowing imagination, Weber built his dramatic works. His first success was gained during the Napoleonic invasion by some spirited settings of Körner's war songs 'Lyer und Schwert'. His great operatic triumphs began with 'Der Freischutz' in 1821, that most German of operas, the mere name of which affords a clue to the wealth of color and fancy displayed in the descriptive music.

Weber's wounderful power of characterization was unique at the time, and has by no means lost its telling force to-day. He was completely saturated with the romantic spirit and entered in his works all the realms of fancy thrown open by the poets. Thus in 'Euryanthe' we are taken back to the Middle Ages, and the days of Chivalry, in 'Oberon', brought out in London in 1826, we hear "the horns of Elfland faintly blowing." Weber was also of considerable influence in his pianoforte compositions, as a forerunner of the "brilliant" school of Liszt (q.v.), and others.

Spohr (q.v.) deserves passing notice as an associate with Weber in the romantic movement in opera, and as one of the great violinists of his day. Although essentially a classicist, Spohr often gave titles to his instrumental works. They are lacking, however, in real poetic vitality, and so are seldom heard to-day.

Schubert (q.v.), the inheritor of Mozart and Beethoven, the last of the purely classic school, notwithstanding the many interesting phases of his genius, must be treated here as the founder of the German Lied (see LIED), the first of the great group of Song Composers which includes Schumann, Franz, Brahms, and Richard Strauss. Schubert, whose highest gift was that of expressive melody, with an imagination keenly susceptible to poetic suggestion, lived at just the right epoch to take full advantage of the wealth of German lyric poetry which was one of the results of the romantic movement. The difference between the Lied and other earlier forms of solo song, aria, etc, is that no longer the music itself is the chief element, but the word-text. Instead of setting several stanzas to the same simple tune the composer endeavors by continuous musical development to suggest every sentiment and mood of the poem. Imagination is made submissive to the suggestiveness of the poet. The music exists not independently, but as a means of carrying the essence of the poem to the soul of the hearer. Words and music are blended in a composite form of art, which is always enhanced by suggestive pianoforte accompaniment. In the union of these three factors Schubert was supreme. With few exceptions he always selected poems of intrinsic merit, *e. g.*, by Goethe, Schiller, Shakespeare, Klopstock, Müller, and Heine; of unsurpassed power as a melodist, he followed each varying sentiment of the words in the most subtle manner, and although recent composers have enlarged the scope of the piano accompaniment, he first revealed its possibilities. In illustration of the last point we may cite the accompaniment to 'Der Erlkönig' and 'Auf dem Wasser zu singen'. Schubert's genius for instrumental music was continually growing; indeed it was his intention to devote himself to orchestral music. His early tragic death cut short these fair prospects, but we have a priceless legacy in the great symphonies — the 'Unfinished' and the one in C major — and in the Chamber music — notably the Quartet in D minor. These are inferior to the best works of Beethoven only in a certain lack of organic concentrated treatment; in warmth of melody, in wealth of tonal effect, and in boldness of modulation they have seldom been surpassed. Schubert's short characteristic pieces for pianoforte, such as the 'Impromptus', 'Moments Musicales', Waltzes, etc., are unique in style and of great interest in that they opened the way for the short lyric forms in modern literature. Witness the pianoforte compositions of Schumann, Mendelssohn, Grieg, and Brahms.

In 1830, two years after the death of Schubert, began the career of Schumann (born in 1810), the most prominent — together with his great contemporary, Berlioz (q.v.) — of the romantic composers in the realm of instrumental music. In Schumann we have a unique personality, intensely subjective and of deep poetic feeling — "the greatest musical thinker since Beethoven" according to Liszt. Manifesting very early a strong love for the imaginative poets of the period, notably Jean Paul Richter (q.v.), Schumann definitely moulded his music in accord with poetic ideas, and with his great literary gifts, became the formulator of the romantic idea in the entire musical thought of the time. Up to 1840 Schumann's chief work was his pianoforte compositions. These although in small form, from the novelty of their style, and their exquisite fancy, began a new epoch in pianoforte music. These pieces all have titles. 'Papillons', 'Nachtstücke', 'Fantasiestücke', etc., and indicate with delicate touches of romanticism the moods which the music is to symbolize. In his larger pianoforte works, the two Sonatas, the Fantasie in C and the Etudes symphonique, the defects as well as the merits of the school are apparent Together with a wealth of invention there is often a lack of balance and unity. The romanticist always teems with emotion; whether he succeeds in impressing this on the hearer by means of music is quite another question.

In 1840, the year of Schumann's marriage with Clara Wieck, most of his wonderful songs were composed. In some ways these surpass even Schubert, especially in delicate treatment of subtle shades of meaning in the poems and in variety of piano accompaniment. Many of his most inspired songs are set to poems by Heine. In his four Symphonies, Schumann was of unequal power, and opinions vary as to their permanent worth. There is no doubt of the warmth and variety of the original ideas, but sustained development is often lacking and the orchestration leaves much to be desired. By far the strongest of the symphonies is the second in C major in which the Adagio with its poignant pathos reaches a high point of emotional expression. The fourth symphony is noteworthy for experiments in a more plastic treatment of the conventional symphonic form. Schumann's vocal works, though unequal, contain much fine inspiration — the most sustained is 'Manfred'. Schumann's literary labors in founding 'Die neue Zeitschrift für musik' in 1834 must not be overlooked. His critical writings with those of Berlioz and List have revolutionized musical taste and established new ideals.

Mendelssohn (q.v.) (1809–1847), Schumann's contemporary, although classed with the German school from the style of his works is, strictly speaking, outside the Teutonic line, as he was of Jewish extraction on both sides.

Franz Liszt (q.v.) (1811–1886), although likewise not of pure Teutonic blood—his father was a Hungarian — is of far greater importance, not only for his intrinsic powers as composer and pianist, but for the stimulating influence he has had upon the musical culture of the day. Any sketch of Liszt must be inadequate, and is to be supplemented by reference to the vast amount of biographic and critical literature connected with him and his tendencies. He is one of the compelling forces in music of our times. The greatest pianist the world has ever seen, the modern school of pianoforte playing is largely derived from him. In his pianoforte compositions many new elements were introduced in rhythm, harmony, freedom of form, and pure pianistic effect. In many of these pieces a strong Hungarian, gypsy element is found. In his orchestral works Liszt is a firm adherent of the programme school, agreeing with Berlioz as to the descriptive value of music. His two great symphonies, the 'Faust' and the 'Dante' are unique works in their subtle musical characterization and in their beauty of orchestral tone-painting. In the 'Symphonic Poem' an entirely new form was contributed, one which has had far-reaching consequences not yet exhausted. A symphonic poem is a work in a single movement in which the classic sonata form is abjured and the entire structure and style of treatment are made subservient to the guiding spirit of the poetic subject. Of these works the most famous are 'Orpheus', 'Tasso', 'Mazeppa', and 'Les Preludes'. Liszt was also a prolific vocal composer and his Masses and Oratorios of 'Saint Elizabeth' and 'Christus' contain many noble thoughts. His solo songs are of rare distinction. Liszt's rank as a composer is still hotly debated and cannot yet be settled. His influence was certainly many-sided, as composer, critic, conductor, and teacher. From the loftiness of his ideals and the generosity of his character he has done an inestimable service in raising the standard of music in the eyes of the world. His championship of the dramatic reforms of Wagner is an inspiring chapter in the annals of art.

The comparative youth of modern music and likewise its continuity of development is strikingly shown by the fact that the birth of Wagner in 1813 is within four years of the death of Hayden in 1809. The mere name of Wagner provokes a wide range of discussion, but though to the specialist he may be of interest as a philosopher, a writer on æsthetics, and a sociologist, by the general public he is admired as the founder of the music-drama, and as a mighty musician. Considerable harm, in fact, has been done to Wagner's music by the metaphsical speculation in which his rabid admirers have tried to submerge it. "I require nothing from the public" writes Wagner to Liszt "but healthy senses and a human heart". Surely he may be taken at his own word in an estimate of his works. Wagner's reforms may be briefly summarized as follows: (1) to make the opera a serious and uplifting form of art instead of a mere passing amusement; (2) to treat in his dramas subjects which had moral and intellectual value; and (3) to combine all the factors, poetry, music, action, and scenery into a homogeneous means of direct influence upon the emotion and intellect of the hearer. Wonderful as was Wagner's growth in originality, his early works show distinctly derivative influence. Brought up in the shadow of the theatre, his inborn dramatic instinct was strengthened by an early acquaintance with the works of Shakespeare, Goethe, and Schiller, while on the musical side he became familiar with the operas of von Weber and the instrumental works of Beethoven, many of which he had copied out in score before his eighteenth year. The real Wagner begins with 'Der Fliegende Holländer.' In this, notwithstanding traces of French and Italian influence, the effort toward dramatic and musical unity is apparent. 'Tannhäuser' and 'Lohengrin' are transitional works in which we find certain survivals of conventional opera, together with prophecies of the highly developed, later style.

In his mature works, 'Der Ring,' 'Tristan,' 'Die Meistersinger,' and 'Parsifal,' traditional forms, the aria, the set chorus, etc., are entirely renounced, and the growth and form of the music are derived from the spirit of the text. Richly accompanied recitative makes up the body of the work. The melody is composed poetically and, to use Wagner's term, is "endless," running sometimes through a whole act without a break. The expansion of the descriptive powers of the orchestra reached a climax in Wagner. His power as a musical scene-painter is incontestible. Building on the work of von Weber, Berlioz, Meyerbeer, and Liszt, he evolved an entirely new orchestra boundless in wealth of tone-color and in power of emotional appeal. In fact, the chief beauty is often in the instrumental part and the vocal melody is at times rather crudely plastered upon this. As a discoverer of new harmonic effects and as a contrapuntist, Wagner ranks with Bach and Beethoven.

One of Wagner's organic changes was the use of "Leading Motives." These are not mere musical labels with fantastic names — this conception is due to the misguided Wagner commentators,— but musical epitomes of the chief characters and the important objects in the drama, *e. g.*, 'Wotan,' the 'Sword,' 'Fire,' etc. By their use the music though plastic becomes highly organic. Wagner himself says it is the thematic development of Beethoven expanded and used for dramatic purposes.

Not the least feature in Wagner's operas are the scenic effects. He revolutionized the art of stage mounting. Such scenes as the Grail Castle in Parsifal and the final scene of 'Die Walküre' have never been surpassed. Wagner's pen as a literary man was ever busy. His writings are collected in 10 large volumes. The essays 'On the Art of Conducting' and on the Symphonies of Beethoven are noteworthy.

The position of Brahms (q.v.) (1833–1897), in modern music is remarkable in that by temperament standing apart from two of the main tendencies of the times, the operatic and the programistic, he made free use of the polyphony of Bach and the classic forms of Beethoven to voice his own individual message. A man of singularly deep and simple human feeling,— what strikes us most in his music is its emotional wholesomeness. Never morbid, hysterical, or theatric, Brahms' compositions in their broad impersonality make the impression of a work of nature. With the exceptions just noted, Brahms has worked in every field of modern art. His pianoforte music, with its complexity of rhythm and its subtle harmonic tissue, is distinctive and novel. His songs in their consumate blending of poetic sentiment and musical expression are the most perfect since Schumann. The chamber-works for strings alone or for various combinations of instruments contain some of the noblest thoughts ever uttered in that form. Brahms' four symphonies are comparable with those of Beethoven in their variety and latent strength. Each has its own peculiar atmosphere; Brahms has not written *one* symphony in *four* parts. His 'German Requiem' is one of the grandest compositions of modern times.

Debate is still going on as to the final position of Brahms. To some he seems austere, lacking in emotional warmth; to others he represents all that is truest in music. He is certainly one of the few since Beethoven to sound the note of sublimity. His musice is Miltonic in its dignity and repose. Such qualities may well be considered lasting in music.

Since Wagner and Brahms the German school has been most prolific. Among others, Wolff, Schilling, Hüber, Mahler, Humperdink, Weingartner, and Reger (qq.v), are prominent.

Most important of all however is Richard Strauss (q.v.) (1864), who has carried the programme method to undreamed-of lengths. In technical resource Strauss is undoubtedly the greatest master of the orchestra who has yet appeared. In his great symphonic poems 'Don Juan,' 'Tod und Verklarung,' 'Also sprach Zarathustra,' and others, by utilizing and expounding the discoveries of Berlioz, Liszt, and Wagner, he has produced orchestral effects of brilliance and sonority which are unparalled. Strauss is also a composer of prodigious contrapuntal skill, and his works are marvels of musical architecture. In fact so audacious is the use he makes of his descriptive and realistic powers that music seems to be changing its entire nature. The controversy rages about him and his tendencies as violently as in former times about Wagner. It would be premature to forecast Strauss' permanent rank. Whatever else he has done he has weakened the former assertion that music has no power of definite portrayal. So wonderful are his effects of musical symbolism, that music just stops short of being articulate. Such vast works as 'Ein Heldenleben' and 'Don Quixote' have emanated from the most daring musical imagination of our time, and embody tendencies which cannot be ignored. Music no longer exists primarily for its own sake, but as a means of descriptive expression for whatever philosophic or psychologic scheme the composer may have in mind. Strauss has also written in the smaller forms with distinct success, piano pieces, chamber music, etc. His songs are in direct contrast to the complexity of his orchestral works and abound in simple and yet characteristic melody. Strauss' three operas, 'Guntram,' 'Feuersnoth,' and 'Salomé,' are laid out on the broadest lines of any since Wagner.

A closing word must be said about the great array of critics, biographers, historians, and teachers which Germany has produced. Such men as Jahn, Spita, Pohl, and Chrysander in their well-known biographies; Ehlert, Hanslick, and Ambros as critics; Haupt, Jadassohn, Rheinberger, and Riemann as theorists and teachers have had world-wide influence and are largely responsible for the fact that Germany is still the chief centre of a comprehensive musical activity.

Assistant Professor of Music, Harvard University.

9. Germany—History of German Religion. The earliest religious ideas and forms of worship among the ancient Germans have been the object of scientific study since the epoch-making work of Jakob Grimm (q.v.) (d. 1863), but so far without such generally accepted results as give confidence in their correctness and completeness. The Germans appear to have shared the religious conceptions of the great "Indo-European" family, to which, in the absence of entire certainty as to their origin, we continue to assign them. Their religion thus presents, at the time when they first enter into the field of historical inquiry, the aspect of a well-developed mythology.

Beginning presumably with a simple reverence and dread for the beneficial and harmful forces of outward Nature, they had advanced with a more highly developed social organization to a more elaborate system of personal deities. Three central ideas seem to have been common to the several tribal groups into which the people thought of themselves as divided. The god of War (Thiu, Thiwas), the god of the Storm (Wotan, Odin), and a goddess of Fertility (Freya) appear in a variety of forms and have their history of local adherence, of diffusion, and of adoption. These figures are distinct enough to have left their names on days of the week and to have attracted the attention of Roman observers. In the descriptions of Cæsar and Tacitus they appear respectively as Mars, Hercules, and Isis, so that we may be quite sure that at the beginning of our era these principal figures had taken on a fairly definite shape. They were accompanied by a world of secondary mythological creations, spirits of the air, the forest, and the stream, giants, dwarfs, and other half-human personalities. Later, and especially among the Teutons of the far north, there was added the conception of a cosmos created out of nothing, and, as the climax of the system, appears another equally vivid notion of an ultimate cataclysm in which gods and universe alike shall be overwhelmed.

In their dealings with the unseen powers the Germans seem not to have evolved or needed any formal ritual in the hands of an organized, mediatorial priesthood. The chiefs of the family or the tribe performed the necessary sacrifices by which the favor of the gods was propitated or their wrath averted. No theology or speculative development of these original simple ideas was ever reached. The whole system bears the marks of a fresh, vigorous, and spontaneous expression of intimacy between conquering freemen and the divine governance under which they lived. The conflicts of the gods, their spacious repose in Walhalla, reflect the ideals of a race which from our earliest glimpses of it appears in a slow but steady movement upward toward higher levels of social, economic, and spiritual experience.

Thus equipped the Germanic peoples enter upon their fateful contact with the Romans. In the course of this contact, whether in the form of Roman military or commercial visits to them, or in their own military service in the Roman armies, they may have undergone a species of religious disintegration such as often accompanies profound changes of national experience. The ancient gods of the tribe could not long maintain their hold on the affections of a people whose tribal life was shattered to its foundations by the manifold reactions of the Roman culture. It was probably this weakening of the ancient ties of religion that combined with the more obvious political motives to bring about the transition to Christianity.

It is an undoubted fact that all those German tribes which left their ancient homes beyond the Rhine and the Danube and moved in mass southward and westward on to the lands of Rome had already at the time of this occupation become converted to the religion of Christ. The process of this conversion is, however, almost entirely obscure. Among the Greek and Roman populations Christianity had made its way for three centuries, wholly by the method of individual conviction, and even during the 4th century, after the weight of imperial pressure had been added, the same process had gone on. Christianity had made its appeal to these highly developed peoples as a system of thought and as a rule of life. To the uncultured and intellectually undisciplined Germans such an appeal seems obviously impossible. They encountered Christianity long after it had entered upon its institutional stage. They met it as one of those governmental agencies by which Rome seemed to have grown great, and adopted it as a new means of greatness for themselves. Once adopted they clung to it with unshaken loyalty and gradually came to understand its spirit. Further these same peoples,— the migrating tribes in stricter sense, including the Visigoths, Ostrogoths, Burgundians, Vandals, and Lombards — were all converted to the Arian form of Christianity, that form which was condemned by the first General Council at Nicæa (325), but which continued during the next two centuries, under various disguises, to maintain a powerful hold on Eastern speculative thought. Attempts have been made to show that this doctrinal divergence of the Germans is to be accounted for by some spiritual affinity between their mental attitude and that of the Arian agencies through which they received the new faith. It does not, however, seem likely that it is to be explained on any intellectual grounds whatever. Their conversion took place mainly from the East at a time when Arianism was dominant at Constantinople, and it was altogether in accord with their stage of religious culture that they should take what was offered them without nice discrimination. Later, long after their settlement in their respective homes on Roman soil, such of these tribes as survived changed their form of Christianity to that which had then, under the leadership of the bishops of Rome, come to be dominant in the western world. But one really striking figure emerges out of the obscurity of this period, that of Ulfila the Visigoth, whose translation of the Hebrew and Christian Scriptures from Greek into a written Gothic language which he himself invented for the purpose remains the most important document of the conversion, precious alike to the theologian and the philologist. A copy written in silver letters upon purple parchment and known as the "Silver Codex" is in the library of the University at Upsala, Sweden.

Quite similar in motive and process, but infinitely different in result, is the conversion of those Germanic peoples which did not abandon their ancient homes, but remaining rooted there sent out branches to overspread the more or less Romanised lands of Gaul and Britain. The Anglo-Saxons, coming over into England from about 450 onward and striking upon a Christianized Keltic population not greatly superior to them in culture, early developed a race antagonism which prevented any effective reaction upon themselves. It was not until the close of the 6th century that they were visited by missionaries sent out directly from Rome by Pope Gregory I and converted to Christianity under the Roman form. Their attitude toward it seems to have been the same as that of their brethren of the lower Danube two centuries before. They accepted it at the bidding of chieftains who saw in it a means of sharing in the larger life represented to them by the name of Rome. A generation later Anglo-Saxon Christianity was undoubtedly promoted by Keltic missionary activity in the North. The Anglo-Saxons appear to have been quite uninfluenced by their Teutonic neighbors and kinsfolk across the Channel, the Franks, whose conversion had taken place almost a century before.

The elements of the story in the case of the Franks are again much the same: a heathen king (Clovis) married to a Christian Germanic wife, to whom freedom of worship has been guaranteed, a series of persuasions all based on the superiority of Christianity as a working religion and finally a dramatic event, the victory of the Frankish host over a heathen enemy, and then a tribal conversion with wholesale baptism. In the account of these events wholesale baptism. In the account of this event written a hundred years later by the bishop Gregory of Tours, the gods of Clovis are described in Roman terms, as Jupiter, Hercules, etc., so completely had the sense of distinction among heathen religious systems disappeared from the Christian consciousness.

The decisive incident in these two northern conversions was that they were made into the fellowship of the Roman Catholic Church and thus determined for the future the religious allegiance of those two Gemanic races which were destined to survive or to incorporate the rest. In the furious struggles for power among the Merovingian successors of Clovis, the Church appears as the one civilizing and humanizing agency in a society that seems to be on the verge of complete disintegration. Yet even its influence was fitful and ineffective. The Roman bishopric, involved in a life and death struggle with German Arian invaders and with the revived activity of the Eastern Empire in Italy, was unable to offer to the West the unifying force it needed. The great efforts of Gregory I in this direction do not seem to have had permanent results in placing the church of Gaul on a solid basis. It was reserved for the newly established power of the Carolingian *Majors Domus*, especially the sons of Charles Martel, about the middle of the 8th century, to reorganize the Frankish Church on the two-fold foundation of national control and papal supervision.

This alliance of the Frankish state with the Roman power was strengthened by the effective work of the Anglo-Saxon Winfried, who under his Latinized name of Boniface became the active agent of both in the definite establishment of the Roman church system in Germany. He was made first Archbishop of Mainz and was the founder of the monastery of Fulda in Hessen, long to be the most important outpost of Franco-Roman Christianity toward the still heathen Saxons and Frisians lying in the vast lowlands of the North from Rhine to Elbe.

The contemporary accounts of the long conflict in Charlemagne with the Saxons shows them at practically the same stage of civilization as were their kinsfolk in the narrative of Tacitus 700 years earlier. Still almost untouched by Roman influences, they resisted with heroic courage every attempt to impose upon them Frankish supremacy and Roman religion. Their final defea and incorporation into the political scheme of Charlemagne was by far the most important contribution yet made toward the upbuilding of a distinctively German Christianity. So complete was this process of assimilation that when, about a hundred years later, one of their own historians tells the story of their conquest, the tribal point of view is almost wholly forgotten in the pride of the writer over the delivery of his people from the bonds of a degrading superstition. Episcopal centres were established at Minden, Paderborn, Verden, Bremen, Osnabrück, and Halberstadt, and were henceforth maintained as bulwarks of the Church against the still rampant heathenism of Scandinavia and of the Slavic peoples beyond the Elbe. From an early day the bishoprics of Germany shared with other landholding interests the character of territorial lordships, closely identified with the soil, loyal to the vast Roman ecclesiastical system of which they formed a noteworthy part, but primarily German in character and sentiment. In the struggles for power in the 9th century among the local chiefs the support of the great bishops was indispensable, and they come out in the 10th century firmly established as the equals of the highest among the lay lords, and even superior to many of these in the wide range of their influence and the security of their landed revenues.

With the definite organization of Feudalism (q.v.), after the break-up of the Carolingian system they enter into the scheme of this newly-constructed society as in some ways its most important units. Their selection is so largely influenced by the kings, whenever these chance to be men of weight, that the bishops come to be thought of as a kind of royal officials, and from this close association with temporal affairs come those often well-founded charges of worldliness which are the moving cause of the clerical reform movement of the 11th century. In this movement for the betterment of society through an increased emphasis on the ascetic life Germany took less active interest than those southern regions, notably of France, in which it originated. German monasticism had from the beginning an eminently practical character. Its work had been largely that of the pioneer in a new country, developing industry by the improvement of the land and cultivating learning in the comparative security of its protected life. On the whole we hear little of the corruption that had often led to serious outbreaks against the monastic system in the South. The leading abbacies in the houses for women as well as for men were often filled by members or intimate connections of the royal families, and such persons, as for example, the abbots of Fulda, Saint Gallen, or Reichenau, take their place alongside the bishops as feudal princes. Also their appointments, like those of the bishops, was greatly influenced by the policy of the government.

It is largely this close identification of the higher church offices with the royal power that leads to the most important struggle of the Middle Ages, the Wars of the Investiture (1075–1122). The direct issue in that long conflict was whether the German Church was to continue in its former intimate relation to the German king or was to become, through the process of the papal investiture, subject to a foreign political control. The outcome, as expressed in the Concordat of Worms (1122), was in appearance a compromise based upon a division of the temporal from the spiritual powers of the episcopate; but in reality resolute kings continued afterward, as before, to bring pressure upon the higher clerical appointments. During this period it is the Holy Roman Emperor of the German Nation who stands forth as the spokesman of all temporal powers against the aggressions of his colleague in the administration of the Christian world of the West, the successor of Saint Peter. The conflict is mainly political on both sides, but political ideas were during the strictly mediæval period hopelessly entangled with religious claims. The defeat of the imperial power in its efforts at aggrandizement in Italy was an advantage to the greater clerical powers in Germany as it was also to the territorial lords. From the middle of the 13th to the middle of the 14th century Germany passed through that development of almost independent principalities which was guaranteed by the Golden Bull of 1356. The control over the clergy formerly exercised by the emperor passed thus into the hands of a group of princes with whom the central power of the Church has henceforth to deal. During the Conciliar period (1408–1448) it is they who present schemes of reform for the action of the Councils at Constance and Basel, and who enter into Concordats with the Papacy of the Reaction after 1448, by which it was hoped that the ever-increasing complaints against clerical abuses might forever be laid to rest.

The agitations of the Conciliar period, however, especially in Germany, had driven men into deeper reflection upon the actual sources of authority for religious faith and practice. Three directions of thought were thus stimulated which were to move on side by side into the full current of the Protestant Reformation.

These were the "evangelical," the mystical, and the intellectual. (1) The first of these found its support in the doctrines of Wicliffe in England and Huss in Bohemia in regard to the ultimate authority of Scripture. Whatever in the thought or in the institutions of the Church was not plainly to be discovered in these original documents of Christianity was open to criticism and ought at least to be investigated. If not clearly deducible from Scripture it ought to be reformed. (2) The mystical tendency of German thought was a reaction against the overgrown institutionalism of the later mediæval Church. If it was true that the absolute comprehension of God and the complete identification of the devout soul with Him was possible through a process of individual discipline, then obviously the importance of all ecclesiastical mechanism was proportianately reduced. A formal priesthood might come to be rather an obstacle than an aid to the highest attainment of religious certainty. So also, the most elaborate demonstrations of scholastic ingenuity were made unnecessary by this direct process of spiritual illumination. (3) The purely intellectual element came, in Germany, with the general awakening of the spirit of inquiry in the Revival of Learning. The serious northern mind turned at once away from the frivolities of mere intellectualism to its bearings upon the vital problems of religion. The principle of "common sense" found for the first time its application to religious as to other questions. Especially was this true in the field of textual study and criticism. The German Johann Reuchlin (q.v.) (d. 1522) was the first to break through the barrier of ignorant superstition that had prevented the study of Hebrew. The German Erasmus (q.v.) was the earliest scholar to approach the Greek New Testament in the true scholarly spirit.

On this threefold foundation of scriptural authority, direct spiritual insight, and the right of the human intellect to work out its own conclusions, the German Reformation built up its defense against the institutionalism of the mediæval church system. Its central doctrine, the Justification by Faith, was the expression, crude though it might be, of that harmony between the righteous soul and the order of a divinely governed universe, which had ever been the truest ideal of Christian thought. Its emphasis on the idea of individual sinfulness, exaggerated as it may now seem, was the necessary counterpoise to the equally exaggerated laxness in the existing methods of dealing with this never-ending problem. The outward success of the German Reformation was largely due to the skill with which its leaders, notably Luther (q.v.), succeeded in avoiding the logical extremes of doctrine into which a radical wing under the lead of Thomas Münzer (q.v.) and others sought to force them and also to the clear insight which led them from the first to identify their cause with that of the independent territorial princes. By this eminently conservative and constructive policy they were able to give to their work a distinctively national character, to ensure it against attack from without and thus to make it the starting point for still further advance.

Under the protection and hence to a certain extent under the direction of the several governments Lutheranism acquired during the 16th and 17th centuries a rigidity of form and of doctrine apparently no less dangerous to the free movement of human thought than the system it had supplanted. The doctrine of scriptural authority endangered by an inevitable freedom of interpretation was pushed by one wing to an extreme of literalism which could end only in self-destruction. The doctrine of the "enslaved will," strengthened by the reaction of Calvinistic predestination, was in danger of hardening into an unchristian fatalism. From these dangers Germany was saved by the growth, first, of a healthy, humane spirit, such as had always served to modify the severity of Luther's theology, and, second, of a new philosophy or method of thought, which gave an ever-widening scope to the exercise of plain human reason. Luther himself had indeed laid the foundations deeper and broader than he knew when he had declared that he could be convinced of error only by "Scripture and plain reason." If these two were to have equal rights in determining religious truth it must follow of itself that reason should be applied to the interpretation of Scripture.

This is the special service of Germany in the field of modern religious thought: to have given to the accepted doctrine of Christianity a form that might make it acceptable to the modern world. The key-note is sounded in the writings of Gotthold Ephraim Lessing (q.v.), and this the more clearly because Lessing had no formal system of philosophy to offer, but approached this subject as he did all others from the point of view of the free human spirit working on the divine mysteries in virtue of a divine element within itself. Especially he demanded in religious matters the widest possible use of the critical method, the freest investigation into the original sources, in short, the treatment of the Bible as a collection of literature produced by human means and therefore subject to the same rules of criticism as all other human productions. In so far Lessing stood on the same ground as the English Deists of the previous century and their French followers, Voltaire and the Encyclopedists; but Germany was not ready at once to give up its adherence to formal Christianity. As it had escaped the frivolity of the Renaissance, so it sought to avert the frivolity of "enlightenment." It demanded a principle of thought by which it could reconcile the right of the thinking mind with what seemed to be the essential things in the inherited religious system.

This solution is the special contribution of Immanuel Kant (q.v.) (d. 1804). Others had struggled to find an expression for the idea that our reason may accept anything that is not *above* it, provided only it be not called upon to accept anything that is *contrary* to it. Kant analysed the nature of Reason itself and found a distinction between pure reason which could never penetrate into the supernatural and a "practical" reason to which the absolute moral law is revealed. Through this principle it became possible to give new interpretations to the formal doctrines of Christianity. The intense emphasis thus laid upon the thinking individual as the final authority could not fail, however, to produce in Germany, even among most serious thinkers a growing indifference to the formulas of faith and to the institutions that had come to represent them. Out of this comparative indifference to formal dogmas grew the two directions of religious life and thought which have specially characterized Germany to the present day. Pietism (q.v.), the emphasis upon an overstrict personal morality as the only real condition of religious satisfaction had already found its chief expression at the University of Halle under the teaching of Spener (q.v.) (d. 1705), and Francke (q.v.) (d. 1727). It was profoundly modified by the new philosophic impulse, but it had sunk too deep into the character of the German people to be easily removed. On the other hand Rationalism, the right of the human reason to be heard in every determination of religious truth and in every institution of the religious life was greatly strengthened by the Kantian reconciliation.

Both these directions of thought, Pietism and Naturalism (q.v.), go back in the last analysis to the same principle of the individual as the unit of religious experience and the ultimate authority in matters of faith. German religious thought in the 19th century tried to keep its hold on both these aspects of individualism. In various organizations, notably in the Evangelical Union and the *Protestantenverein* it sought to embody the practical demands for a reformed faith that should not give up the personal and social foundations of the early Reformation. In the successive schools of theological interpretation, the "rational-supernatural" of Schleiermacher and Neander (qq.v.), the "historical" school of Tübingen (q.v.), and the mediatorial school of Ritschl (q.v.), Germany has aimed to keep the balance between the extravagance of modern materialism and a relapse into an official literalism. The problem of the moment in Germany as elsewhere is to bring back a sentiment of religious obligation without sacrificing the gains of modern exact science.

Wynn Professor of Ecclesiastical History, Harvard University.

10. **Germany—The Government.** Germany has a national government only since the establishment of the new empire in the year 1871; for neither the old Holy Roman Empire nor the individual territorial states had a national character. The old empire rested upon the mediæval idea of a Christian *imperium mundi*, as the counterpart of the papal *sacerdotium mundi;* but even in the middle ages the impossibility of realizing this ideal was demonstrated, and the empire fell apart unavoidably into a loose federation of territories that was anything but the political organization of a uniform people. Nor were these territories political units by any means. They were not the organization of natural divisions of the race, of tribes, or districts. On the contrary, they were essentially nothing but enlarged manors, which were sold, mortgaged, divided, and inherited, just like private property. From the manorial rights and prerogatives incident to such a system was gradually developed the conception of "Landeshoheit." When, after the time of the Reformation, the absolute monarchy, which had its most brilliant and perfect development in France, laid hold of almost every country of continental Europe, Germany was without any sort of real state organization; and the existing territorial dominion offered the only opportunity for the establishment of absolute monarchy. In accordance with the need of the times and the prevailing theory of state, these manors were transformed on the model of the absolute monarchy and became substitutes for states. But only in the case of the larger domains was it possible to produce anything like the appearance of actual statehood; and even here there was no national unity of any kind. Such a makeshift of a state was only a complex of many small individual territories which, by inheritance, marriage, purchase, or conquest, had come into the possession of a single dynasty; and its unity consisted merely in the ruler and the dynasty. These facts explain the by far greater individualistic character of the several state monarchies in Germany, as compared with the monarchies of the national Europeon states; likewise the peculiar position which these monarchies still occupy, for historically all of the German dynasties are older than their respective states.

It was this lack of a national government that defeated Germany in the war with France early in the last century. That country, so recently regenerated by the revolution, had a modernized national organization to which disorganized Germany could offer no successful resistance. The result of this conflict was, that the old German Empire, which had in fact already been dead for centuries, was formally dissolved in 1806. But this was not all. At the same time the smallest of the states were abolished, and their total number, which up to this time had been in the hundreds, was reduced to some thirty. These were formally independent states; but almost all of them, mediately or immediately, came under the domination of France, and thus under the influence of modern French legislation. After her terrible defeat, Prussia, the largest of the German states, was reduced to about half her former size and weakened almost to the point of dissolution. Such straightened circumstances compelled the absolute monarchy to attempt a fundamental reform: and it was the purpose of the Stein-Hardenberg measures to modernize legal and social conditions and secure a basis for national government. The reform was begun at the bottom by reviving self-government in the cities, a system that had flourished back in the middle ages but had later been destroyed by the absolute territorial state. Herein lies the far-reaching political significance of the Stein city-ordinance of 1808. It was the plan to reorganize the country parishes on the principle of self-government, as well as the cities; then to organize these into provincial corporations; and finally to unite these larger units under a single government with national representation. However, with the overthrow of Napoleon the necessity for such a complete reform was removed, and these plans were not carried out. Despite solemn promises from the crown, Prussia held fast to absolutism until the year 1848.

On the other hand, the dynasties of the southern German states, after foreign domination had been shaken off and a loose association of German states formed, were willing to adopt a constitutional system in order to retain their independence. The feeling of German nationality developed by the War of Independence undoubtedly threatened the independent existence of the individual states; and, as the best means of averting this danger, the small states formed each a sort of national government of its own, in which the citizens were allowed an active part, thereby encouraging a feeling of attachment to the restricted "Fatherland." Such a narrow patriotism was strengthened by the contrast to the large absolute states, Austria and Prussia, and the alliance which they dominated. Thus, between 1818 and 1820 constitutional government was inaugurated in Bavaria, Baden, Württemberg, and Hessen-Darmstadt, even if parliamentary rights were rather limited. The constitutional movement made farther progress as a result of the July Revolution in France. During the years following 1830 numerous small northern German states received constitutions. However, the decisive victory for constitutionalism was won by the political agitation of 1848, as a result of which Prussia, through the constitutional charter of 31 Jan. 1850, finally took her place among the constitutional states.

Aside from the establishment of constitutionalism in the several states, the goal of the agitation of 1848 had been a national government for the whole of Germany. A direct attempt to secure such national organization, which was made by the first German parliament in Saint Paul's Church, at Frankfort-on-Main, was unsuccessful owing to the unfavorableness of the political situation. However, the kernel of the problem was laid bare; and the view came to be generally accepted that the political union of Germany was possible only with Austria left out, and under the leadership of Prussia. If such a national German state was thinkable only under a constitutional form, then only a constitutional Prussia could be called to the leadership of future Germany. The War of 1866 decided the question of leadership once for all in favor of Prussia; and the overwhelming victory over France resulted in the national organization of Germany under the imperial constitution of 16 April, 1871.

The Imperial Government.—The historical development of the territorial states and their several dynasties accounts for the noteworthy fact, that, even to-day, there is still a dispute in Germany regarding the character of the German Empire. For instance, it is argued that it is the essential nature of a monarchy, at least according to German law, to unite all state power and authority in the monarchy, even though he be limited in the exercise of certain functions, as legislation, by a representative assembly. Since now, according to the imperial constitution, all power and authority has not thus been given to the emperor, it is further argued that he is not the monarch of the empire, and that the empire is not a monarchy. As to what other form of state it is, various answers are given; but all are untenable. In truth, that assumed essential nature of a monarchy is not characteristic of monarchies in general, but only of an absolute monarchy; while every constitutional state is distinguished from the absolute form by the fact, that in the exercise of the highest functions of state, *i. e.*, legislation, several coordinate organs must act together. This applies to the individual states as well as to the empire; and the emperor, as the hereditary head of the empire, does not lose the character of a monarch, nor the empire the character of a monarchy because the emperor is more limited in his functions than are the monarchs of the individual states, and too not only by the Reichstag, but also by the Bundesrat or Federal Council, which represents the individual states as such. That is to say, the German Empire is a monarchy which is limited both federatively and constitutionally. Accordingly, the emperor, the Bundesrat, and the Reichstag are the highest organs of the government. No one of these is appointed by the other: no one is subordinate to the other; no one derives its powers from the other; but all receive their authority immediately from the constitution.

The Kaiser.— The German constitution makes the position of the emperor hereditary and limits the succession to the Prussian dynasty, so that the king of Prussia is at the same time necessarily the head of the empire. The whole organization is built up on this combination of imperial authority with Prussian state authority. While the empire is a federation superior to the individual states, still this peculiar union between Prussia and the empire gives Prussia a certain hegemonial position. But this is merely the political expression of the dynamic fact, that Prussia alone has three-fifths of the territory, as well as of the population, of the German Empire, while the remaining two-fifths is divided among 24 small and medium-sized states. Further, only such a constitutional union of Prussian with imperial authority made it possible to bring Prussia into the federation on a formally equal footing with the smaller states; and, on the other hand, the constitutional position of the emperor is thinkable and possible only if he be at the same time the king of Prussia and able to control the Prussian influence in imperial affairs, and particularly the Prussian votes in the Bundesrat.

The Bundesrat — The Bundesrat is a council composed of plenipotentiaries of the individual German states. Since these states vary so greatly in size and importance, it was impossible to give each and all equal voice in this council; but, on the other side, it was impracticable to make representation in the council strictly proportionate to the size of the states, for then Prussia would always have had a majority of three-fifths, and the supposed cooperation of the other states would have become purely illusory. Since there was no rational criterion at hand, recourse was had to history, and the apportionment of representation in the Plenum of the old German alliance was adopted, making allowance for the states annexed to Prussia in 1866 and granting Bavaria special favors. According to this plan, the 58 votes in the Bundesrat are apportioned as follows: Prussia 17, Bavaria 6, Saxony and Württemberg, 4 each, Baden and Hessia 3 each, Mecklenburg-Schwerin and Brunswick 2 each, and all the other states one vote each. It is not alone in the manner of apportioning the representation that the Bundesrat differs from similar bodies in other federations, as for instance the United States Senate or the Swiss Ständerat, but more particularly in this, that the members, who are appointed by the individual states and are officials of the same, cannot vote according to their own conviction, but must follow binding instructions received from their respective governments. It is not the individual member that votes in the Bundesrat, but the state of Prussia, or Bavaria, as the case may be, that votes through its plenipotentiaries. For this reason the plural votes of a state can only be cast together. The Bundesrat is no house of parliament, and thus no fixed times for meeting. Any state can recall its representatives at any time and replace them with others. Since only the individual states are represented in the Bundesrat, the emperor does not appoint any member, except the president in the person of the imperial chancellor (Reichskanzler).

The Reichstag.— The Reichstag is the parliamentary representation of the German people as a whole. The 307 members are elected by universal and equal suffrage; and the voting is direct and secret. Every German male 25 years old has a vote, and is eligible to election, in so far as he is not under guardianship, or involved in bankruptcy proceedings, or if he has not been supported by public charity in recent years, or if he has not lost the rights of citizenship through sentence in court. When the election-districts for representation in the Reichstag were laid out, it was the intention that a representative should be elected for every 100,000 inhabitants, but that such an election-district should not be formed of parts of different states, and that any state with less than 100,000 inhabitants should still be entitled to a representative. Since, now, the number of these representative districts does not grow with the population, but can be changed only by imperial law, the principle upon which the apportionment of representation was originally based has now, owing to the increase and drift of population, no practical significance. If there were now a representative for every 100,000 inhabitants, instead of having 307 members the Reichstag would have five or six hundred members; and instead of six representatives in the Reichstag, the city of Berlin would now elect 20. It is clear that the maintenance of this old system of representative, or congressional, districts favors greatly the rural population at the expense of the large cities. The Reichstag is elected for five years; but the Bundesrat, with the consent of the emperor, can dissolve this body during a legislative period, whereupon, within a limited period, general elections take place and a new Reichstag is convened. Both the Bundesrat and the Reichstag must be convened at least once a year; though the fact is, that the Bundesrat has come to be a permanent college which takes holidays, to be sure, but has no regular sessions. The members of the Reichstag enjoy the usual parliamentary immunities, but they draw no salary. The sessions of the Reichstag are public; and the speeches made there, as well as truthful reports of the press regarding the same, cannot be made a basis for any prosecution whatever.

The Reichskanzler.— The imperial chancellor, who is appointed and dismissed by the emperor, is not only the president of the Bundesrat, but also the responsible prime minister of the empire; for all official acts of the emperor have to be countersigned by the chancellor, who thereby becomes responsible for the same. The correlative of the responsibility of the chancellor is the non-responsibility of the emperor. But this ministerial responsibility is merely constitutional and formal. The chancellor must account to the Bundesrat and the Reichstag for those acts of the emperor to which he has given validity with his signature; but he cannot be held responsible in the sense that he can be impeached. Originally, the chancellor was the only constitutionally responsible imperial minister; but the impossibility of the responsible conduct of the entire imperial government by one man led to the formation of an imperial ministry with several heads. This was organized on the prefecture, not on the collegial, plan; and the chancellor remained the leader of the government. On the proposal of the chancellor, the emperor appoints for certain branches of the administration secretaries of state and the chiefs of the departments in question (Department of the Interior, Treasury, Department of Justice, Imperial Post Office, Foreign Office, etc.); but these officials are subordinate to the chancellor and merely the responsible representatives of the chancellor in these departments. They can countersign the imperial acts of the emperor; but the chancellor remains their superior and the chief of the entire imperial administration. In his character as president of the Bundesrat the chancellor is also spokesman of the Prussian plenipotentiaries, in so far as he does not have some one to represent him in this function. Further, from the relation between Prussia and the empire, it follows that the imperial chancellor must at the same time be, in fact, the Prussian prime minister. This is not expressly mentioned in the constitution; but the union of empire and kingdom in the sphere of monarchial nonresponsibility must logically have its counterpart in the sphere of constitutional ministerial responsibility, in that the leader of the Prussian administration must at the same time be the head of the imperial administration. Every attempt to separate the two offices has only proved the impossibility of such a thing.

Imperial Legislation.— Imperial laws are passed by a majority vote of both the Bundesrat and the Reichstag. The initiative to legislation may be taken by the individual states in the Bundesrat, or by members of the Reichstag, or — through this is not mentioned in the imperial constitution — by the imperial government, which introduces its bills in the Bundesrat. Bills passed by the Bundesrat are represented before the Reichstag by the Reichskanzler or his deputy, or by members or representatives of the Bundesrat. Laws passed by both Bundesrat and Reichstag must receive the signature of the chancellor and be officially published by the emperor before they can go into effect. The emperor is legally obligated to make such publication, in so far as the law in question is constitutional. The emperor decides the matter of constitutionality; but the chancellor assumes the responsibility. It is possible to change the imperial constitution itself by legislation; but this is difficult, for any constitutional amendment is defeated if it receives 14 adverse votes in the Bundesrat. Since, now, Prussia has 17 votes in the Bundesrat, the emperor in his character as king of Prussia can actually prevent any change whatever in the constitution. (It may be added that the southern German states have reserved certain rights regarding military, postal, and financial affairs, of which they cannot be deprived without their consent.) Further, with the Prussian votes in the Bundesrat, the emperor can prevent any proposed change in the existing laws regulating the army, the navy, the tariff system, and the indirect imperial taxes, so that in fact he can put a veto on any legislation affecting the most important interests of the nation.— The annual imperial budget, which must contain an estimate of all receipts and expenses of the empire, is a matter of imperial legislation; and the empire can negotiate loans only on the basis of similar legislative action.

Imperial Jurisdiction.— As regards the division of authority between the empire and the several states, three spheres of jurisdiction may be distinguished. The sphere of immediate imperial administration comprehends those matters that are not only exclusively regulated by imperial law, but are actually conducted directly by the central government. Here belongs essentially foreign politics, maintenance of embassies, etc. (despite the active and passive diplomatic rights still retained by the individual states out of dynastic considerations); the entire consular system; the navy, colonial affairs, and finances of the empire; the management of the postal and telegraph systems (with the exception of certain rights reserved by Bavaria and Württemberg); and finally, as a matter of fact, the army and military affairs, though the formal rights and regulations here vary somewhat. The second sphere of jurisdiction includes imperial legislation and the inspection of self-government in the individual states. This is the normal form of imperial authority, while the sphere first mentioned is an exception. Here belongs the entire tariff system; the judiciary system, so far as civil, criminal, and procedure law are concerned; the regulation of immigration and citizenship; the banking system; coinage, weights, and measures; control of railway affairs, the press, and of all kinds of unions and organizations. Aside from certain rights reserved by Bavaria, affecting some of these matters, the empire here both makes the laws and sees to it that they are carried out, though the immediate administration of them is left to the several states as self-governing organizations. In case one of the states fails to fulfil the duties thus imposed then sentence can be passed against the said state by the Bundesrat, acting for the empire, and their edict is executed by the emperor. In the whole range of imperial authority the laws of the empire are immediately binding on all citizens, without any regard as to what the laws of the single states may be. State laws that contradict imperial law are *ipso jure* void; for it is a principle that imperial law takes precedence of state law. Finally, the third sphere of jurisdiction is the autonomy of the individual states. The single states as such administer their own affairs and make their own laws (except civil, criminal, and procedure law) without any positive interference from the national government. Negatively, however, the imperial government does interfere, in that it sees to it that the state gevornments do not transcend their authority. Here belongs the constitutional and administrative organization of the states themselves, as well as of their towns, cities, etc.; also taxation, finances, school organization, cultivation of science and art, ecclesiastical affairs, and, in short, everything pertaining to the function of a state which has not already, under the constitution or by special laws based on the same, been turned over to the imperial government. Since the constitution of the empire only determines positively the authority of the empire, but not that of the individual states, the presumption should be in favor of the individual state. In the meanwhile, however, it cannot be denied that, in spite of all opposition, there is a tendency toward a gradual but irresistable extension of imperial authority at the expense of state autonomy.

State Organization.— The empire consists of 25 single states and the province Alsace-Lorraine. Up to the present, the last has not been recognized as a state, but is regarded as an imperial territory. It has no voice in the Bundesrat, but has representation in the Reichstag, of course. At the head of the government is a viceroy, appointed by the emperor, who is supported by a ministry lead by a secretary of state, and by a territorial parliament. Among the individual states the three Hanse cities, Hamburg, Lübeck, and Bremen have a republican constitution: and here the old city-state has been retained in a modified form. The highest organs of government are two coordinated legislative assemblies, the senate which is presided over by the mayor, which is both municipal council and parliament, and elected by the «Bürgerschaft;» and the «Bügerschaft,» elected by the people.

The remaining 22 states are all constitutionally limited monarchies; but it must be added that in two of them, the two grand-duchies of Mecklenburg, the constitution is organized on the old feudal plan, in that their common Landtag, is not composed of representatives elected by the people, but of all the owners of manors entitled to representation, and of representatives of the cities. Otherwise, all the German states have modern constitutions, and, with the exception of the very small states, two legislative chambers. Without exception the upper chambers are mistaken imitations of the English House of Lords, modified by the influence of the French *Charte Constitutionelle*. The most remarkable example of this type is undoubtedly the Prussian Herrenhaus. It consists of hereditary members, and of such as are appointed by the king for life, partly on the recommendation of certain organizations of landowners, and of noble families, as well as of universities and cities. The members of the lower legislative chambers are usually elected by the people, except that occasionally privileged classes for whom there was no room in the upper house are slipped in here. In some states the ruler even appoints popular representatives.

Elections.— Suffrage in the different states is exceedingly varied, being partly direct or indirect, partly secret or public, sometimes on the class-system, sometimes on the census-system. Recently in the southern German states there has been a strong tendency to make the rights of suffrage in state elections conform to the rights obtaining in elections to the Reichstag. The state system in force in Prussia is in sharp contrast to that governing representation in the Reichstag. To be sure, suffrage is universal in Prussia, in that every citizen 24 years old, unless disqualified on the grounds mentioned above, has the active right of suffrage, and the passive right after he has completed his thirtieth year. But suffrage is indirect, since the voters only vote for electors, and these elect the representatives. Further, voting is public, since both the original voters and the electors use no printed ballot, but vote by registration; and, above all, it is unequal. In each of the assembly districts all the voters are divided into three classes, on the basis of the amount of direct taxes they pay. The largest taxpayers, or the voters who pay the first third of the total direct taxes, form the first class; those who pay the second third, the second class; all others, including those who pay no taxes, the third class. Each of these classes elects the same number of electors; then all the electors for a given assembly district, without distinction, together elect the assemblyman. It is clear that the small minority who vote in the first two classes always have a majority of two-thirds in the electoral college; and so the voting-power of the third class becomes illusory. Even if a gradation of political rights on the basis of direct taxation (without regard to the enormous taxes paid indirectly) were a suitable criterion, still this is not by any means consistently carried out by the present election system. As a matter of fact, the retention of the old assembly districts, despite changes in population, makes impossible any relation between taxation and political power. For instance, Berlin pays more than one-seventh of the total direct taxes of Prussia; and yet, of the 433 members of the Prussian Abgeordnetenhaus, only nine are elected from Berlin. Other towns and cities are proportionately poorly represented. Besides, if we will bear in mind the pressure necessarily placed upon the dependent voter by the public ballot, then we see how it is possible for a state election to give results entirely different from those of an election to the Reichstag, and too, even in the same district. For instance, at the last general election of the empire the Social Democrats polled almost a third of the total vote cast; but in the Prussian Abgeordnetenhaus they have not a single representative.

It is a noteworthy political fact, that in the empire, and still more in the individual states, the influence of parliament is less than in other countries enjoying constitutional government. Here the government is not made by a parliamentary majority; and if in important matters it suffers a parliamentary defeat, there is no necessity for the ministry to resign. This state of affairs has often been traced to the antithesis between two political principles, namely, the constitutional system, prevailing in Germany, and the parliamentary system, obtaining in other countries. In truth, however, this distinction is merely one of political development, not of political organization. Despite all the imperfections of the German constitutions, almost all the parliaments have those constitutional rights which would enable them to make their influence effective, just as in other parliamentary countries. Though here the governments never take their origin in the parliaments, but are a band of officials appointed by the sovereign, the explanation of this may be found in the historical development of the states. It is a relic of the feudal system in the territorial states. The lack of political initiative in the German character accounts for the persistence of this system. For this reason, political parties are weak and divided against themselves. The development of large popular parties, able to rule and determined to rule, would be sufficient to develop in every state a real parliamentary government, without the changing of a letter of the existing constitutions; for the difficulty is merely in the political situation, not in the constitutional organization.

Communal Organization.— In the absolute state even local administration was purely a function of the state government. In contrast to this system, the Stein city-ordinance of 1808, mentioned above, has led to the development of communal self-government, though not exactly to the extent that all municipal administration is self-government. Even here the state has retained control of more or less important branches of the local administration, which are either in the hands of state officials, or of local officials treated as state officials. The last is true of the local police in Prussia. In the larger cities they are managed directly by the royal police authorities, but otherwise by the local administrations, acting immediately under directions from the state government. Besides, the entire system of communal self-government is under the inspection of the state. Often the limits of this right of inspection are extended, by law and by constant usage, to such an extent that it is impossible to distinguish mere inspection from actual communal administration by the state authorities. But conditions of municipal government vary in the different states, likewise the organization of parishes, and the relation of towns to country communities, and the rights of suffrage, etc. In this respect there is not even a uniform system within the larger states. For instance, Prussia has seven different city-ordinances and as many systems for the organization of country communities; and similarly in Bavaria municipal rights on one side of the Rhine are different from those on the other side. Under these circumstances it is impossible here to do more than sketch some of the main features.

In the first place, there are two systems of organization. Either all local municipalities have uniform constitutions, or else there are different constitutions for town and country organizations. The first system, developed under French influence, prevails in the west, *i. e.*, in Alsace-Lorraine, the Bavarian Pfalz, the Prussian Rhine province, Hessia, and essentially in Baden, Württemburg, and some Thuringian states. On the other hand, the second system is in force in the remaining Prussian provinces, in Bavaria east of the Rhine, in Saxony, etc. It is exceptional when the distinction between country and town organization is based on area or population. Usually the historical character is decisive. Again, the organization of country parishes in the west is different from that in the east. In the west large organizations are the rule. The villages, which are of themselves well populated, are combined into large communal bodies and include the not very numerous large estates. On the other hand, in the east, where the villages are usually small, every little village forms a separate political corporation; and these weak organizations are naturally unable to absorb the large estates, which are the rule here. Thus, besides the regular rural parishes, there are in eastern Prussia some fifteen or sixteen thousand independent manors, in which the owner unites the rights and duties of a communal organization.

Similarly, there are two different types of city organization: the council-system, on the model of the old German city government; and the mayor-system, developed under the influence of the French administrative organization. In the first there are two coordinated administrative bodies, the town council (Stadtrat Magiprat) and the common council Stadtverordnetenversamlung), or board of aldermen. Here the mayor is essentially only the chairman of the town council. This dualistic system maintains in Prussia, except in the Rhine province, also in Bavaria east of the Rhine, and in Württemberg, Baden, Saxony, etc. The mayor-system exists in the Rhine province, in the Bavarian Pfalz, Hessia, etc. Here there is only one council, the board of aldermen, and the administration is carried on by the mayor, who is at the same time the chairman of the board of aldermen.

The mayor and the members of the town council are partly salaried officials, partly honorary functionaries. As a rule, they are elected, and, too, mostly by the board of aldermen, though according to some laws by the town council and the board of aldermen acting together, or directly by the people. The election is usually for a period of six or twelve years, and sometimes for life; but this last is exceptional. Except in Baden, the election must be confirmed by the state, at least as regards the mayor; and in Prussia, with the exception of Schleswig-Holstein and Frankfort-on-Main, such confirmation is necessary for all members of a town council. The aldermen are elected by the people, partly on the census-system, partly on the three-class system, which here differs somewhat from the class-system of the Prussian state elections. The most important difference is, that here voting is direct, each of the classes voting immediately for the aldermen, and not for electors.

In the large German states the local town and rural municipalities are organized into larger communal units. For instance, in Prussia the districts and provinces are not only state governmental departments, but are also communal self-governing organizations. Such a district has its assembly, elected by the smaller parishes and municipalities and manors thus bound together; and this assembly elects an executive committee, which is at the same time also the board of the state administrations and of the administrative court. Both assembly and executive committees are presided over by the «Landrat,» an official appointed by the state. A province has likewise its assembly, which is elected by the district assemblies. It is the organ of the provincial administration and elects the provincial executive committee and the «Landesdirektor,» or head of the provincial self-government.

The union of these organizations with the system of state administrative and judicial authority is too highly complicated, by far, to be summarized briefly; and, for this very reason, the present condition of affairs cannot be regarded as the final stage of communal development in Germany. Indeed, there is still much work in the future to do, if the principle of local self-government is to be carried out consistently.

11. **Germany — The Political Parties.** Although the German empire is a federation similar to the American union, the political life of these two countries is entirely different. While in the United States there is practically only one system of suffrage, valid alike in all essential respects both for the union and for the individual states, in Germany the voting systems obtaining in the several states are not only different one from the other, but nearly all are fundamentally different from the system that governs representation in the Reichstag. Since the establishment of the new German empire members of the Reichstag have been elected directly by a suffrage that is secret, equal and universal. Every male citizen 25 years old (with only a few excep-

tions as: members of the army and navy, publicly sustained paupers and some others) has a right to vote in an election to the Reichstag. In the individual states of the empire, however, suffrage may be restricted and thus be made unequal; or it may be robbed of secrecy; or it may lose both equality and secrecy. In Prussia, the largest and most important of the German states, voting is done by "classes," there being three grades of voters with unequal voting power. This class-system unites about all the bad qualities of all the bad systems of voting in the world. To show how it works it is only necessary to call attention to the fact that in the Prussian House of Representatives the Social Democrats, by far the largest political party in Prussia, have not a single representative; while in the same body the Conservatives number about 150, although at a general election they cannot poll half so many votes in Prussia as the Social Democrats. When, therefore, we speak of the strength of political parties in Germany, we are limited to representation in the Reichstag and conditions of election to that body.

Some Recent Party Changes.— Since 1890 elections to the Reichstag have taken place every five years, except in cases where that body has been prematurely dissolved. Formerly such general elections occurred every three years. Since the establishment of the German empire elections to the Reichstag have been held in 1871, 1874, 1877, 1878 (on account of a premature dissolution of the body), 1881, 1884, 1887, 1890, 1893 (on account of a premature dissolution of the body), 1898, 1903. During this time various changes have taken place in political parties, both as to organization and designation. Especially within the fold of liberalism have new groupings been frequent. In 1880 the freetraders bolted the Nation Liberal Party and formed the Liberal Union, which in 1884 fused with the so-called Progressive Party. The new organization thus formed took the name German Liberal (deutschfreisinnige) Party; but in 1893 the two elements fell apart again into the Liberal Union (Freisinnige Vereinigung) and the People's Liberal Party (Freisinnige Volkspartei).

Strength of Different Parties in the Reichstag.— The Reichstag is composed of 397 members. The political parties now represented in this body, with the number of members elected by each in 1903, is as follows: Conservatives 52, German Imperialists 20, Antisemitics 11, Farmer's Alliance 7, the Centre 100, Alsacians 9, Danes 1, Poles 16, Guelphs 6, National Liberals 50, Liberal Unionists 10, People's Liberal Party 21, German People's Party 6, Social Democrats 81, independent 7.

Since these numerous parties are more or less closely related, we may, for convenience, group them as follows:

I. *The Conservatives*, including the Conservatives proper, the German Imperialists, the Antisemitics, and the Farmer's Alliance — altogether 90 members.

II. *The Centre*, *i. e.*, the Catholic-Clerical Party, with 100 members; occasionally supported by the Poles, the Alsacians, and a part of the Guelphs.

III. *The Liberals*, including the National Liberals, who are rather conservative and lean toward protection; also the Liberal Unionists, the People's Liberal Party, and the German People's Party — which latter groups represent a more decided liberalism and with greater insistence on free trade. Altogether these related parties control 87 votes.

IV. *The Social Democrats.*— They have 81 members.

Disregarding minor party divisions and taking into consideration only these four larger groups, we see that the strongest of them, the Centre, represents only one-fourth of the Reichstag. Even when supported by the conservative group, with which the Centre has a strong affinity, it cannot control a majority. Again, the Liberals and Social Democrats are equally unable to secure a majority.

The Parties and the Popular Vote.— The relative strength of these parties takes on quite a different aspect when we consider the popular vote, and not merely present representation in the Reichstag. Speaking in round numbers, there were in the empire at the election of 1903 12,500,000 citizens entitled to suffrage, and 9,500,000, or 76 per cent. of them availed themselves of this privilege. Of these 9,500,000 votes 3,000,000 went to social democracy, 2,200,000 to the liberal groups, 1,875,000 to the Centre, and 1,750,000 to the conservative groups. At the elections of 1903, on an average, a representative was elected for every 24,000 votes cast. Therefore it is clear that, on the basis of a popular vote, the conservative groups would be entitled to only 73 members, instead of 90; the Centre to only 78, instead of 100; the Liberals to 92, instead of 87; and the Social Democrats to 125, instead of only 81. Such an apportionment would give the Liberals and Social Democrats, acting together, a considerable majority. In other words, that part of population of the German Empire which gives its support to liberalism and social democracy is in the majority; and any policy which shall express the genuine will of the people must be liberal and democratic.

Despite the fact of universal suffrage, such is the discrepancy between the actual representation in the Reichstag and the will of the majority of the people. This state of affairs is due mostly to the way in which election districts have been laid out and rigidly maintained regardless of variations in population. These districts were fixed when the empire was first established; and they have never been changed. In the past thirty-five years the population of the empire has increased by 20,000,000. These gains have been made in the large cities and industrial districts, *i. e.*, in those quarters where liberalism and democracy find most of their recruits. On the other hand, the population of the rural districts, the main stronghold of the Conservatives and Clericals, has remained practically stable. In this way abnormal conditions have been developed. When these congressional districts were originally marked out it was the intention to have one representative in the Reichstag for every 100,000 inhabitants. That was the law. To-day in the large cities and highly developed industrial parts of the country there are many congressional districts that have several hundred thousand inhabitants each, some of them even passing the half-million mark. This disproportion is augmented by the fact that the population of similar districts in the country falls far short of the required 100,000. If we did not thus take into account the effects of this obsolete system of election districts, our view of political parties and conditions in Germany would be a distorted one indeed.

The Conservative Party.— The Prussian aristocracy, or landed nobility, form the nucleus of the Conservative Party. At the time when Prussia was an agricultural state they gained undisputed sway both in the army and in affairs of state, *i. e.,* in so far as such a thing was possible under an absolute monarchy. Their position at this time is well characterized by the proverb, "Und der König absolut, wenn er unsern Willen tut." Since then Prussia has secured a constitution and a degree of representative government: and under her guidance the German Empire has come into being. From a simple agricultural state Prussia has gradually developed into a powerful industrial state; and her exports now encircle the globe. Under these changed conditions the Prussian landed nobility have continued to assert their claims to political leadership, but naturally they have had to seek new means of defending them. Their chiefest care has been to maintain their favored position at the court, in the army and in the civil government. But they soon saw that, under a system of universal suffrage in the empire, they would have to form a political party that would find support among the populace.

Thus, under the leadership of the Prussian aristocracy, the Conservative Party was gradually developed — a party that has stood sponsor for every reactionary movement, both in the empire and in the individual states. In the internal development of the empire liberalism has been the potent and deciding factor. It had removed many obstacles to economic progress, disposing once for all with the restraints thrown around emigration and industrial freedom; and, in general, it had wiped out much of the hide bound conservatism that had been accumulating for centuries. Thus free play was given to industry, intelligence, technical skill and talent for organization. Competition became vital and strenuous. Since all these changes took place in a comparatively short time, such elements of the population as were unable to adjust themselves to the new conditions had to suffer. Just as is the case with every reform, many were dissatisfied. Now, to marshal these discontented elements against the reformers, *i. e.,* the Liberals, and arouse in them enthusiasm for the "good old times" — that was to be the work of the Conservative Party. They went to the farmers and bailed them with the tale of woe that agriculture was suffering, and that there should be a high protective tariff on all farm products. They went to the mechanics who were suffering under industrial competition and made them believe that unrestricted competition was to blame for all their troubles. Further, the anti-semitic sentiment was used to incite the people against the stock-exchange, that modern machine of commerce. In short, wherever there was an opportunity to enlist a discontented element of society, this was done; and the malcontents were promptly promised legal redress. In this way a conservative party was gradually formed of heterogeneous elements which, in fact, were anything else but conservative. At the same time, this Prussian aristocracy was endeavoring to keep in closest touch with the crown, the court and the government, and to influence legislation in a manner calculated to better the condition of large landowners. The Conservative Party has been the principal support of the Agrarian Protective Tariff System, which, since 1879, has been the focus of all political conflict in Germany.

The Centre, or Catholic Party.— In all essential respects the aims of the Centre, as a political party, coincide with the interests of the Roman Catholic Church. This party sprang up in the early seventies of the past century as a result of the so-called culture-conflict (Kulturkampf) that Bismarck and the Liberals waged against the Ultramontanes. With the new dogma of Infallibility this extreme Catholic party had taken on a more dangerous character. Bismarck withdrew his opposition toward the end of the seventies, when he needed the support of the Centre in order to carry through his protective tariff program. Since then the Centre has made secure its position in the Reichstag and has exerted an uninterrupted influence on legislation in the German Empire. It holds the balance of power in the legislative assembly and for years has nominated the President of the Reichstag.

The composition of this party is by no means homogeneous. Here we find feudal landlords with strong conservative tendencies pulling shoulder to shoulder with unintelligent mechanics, democratic chaplains and day-laborers for whom the Catholic Church is still the supreme authority. Clerical discipline encompasses and binds together all these heterogeneous elements. Even to-day the traditions of the culture-conflict play a considerable part in this party; and the demand that the Catholics be allowed equal rights with the Protestants is still heard, although the Catholics have long been political *enfants gâtés.*

The policy of the Centre is in perfect accord with its heterogeneous composition. For instance, to appease the Agrarians, it will favor the Agrarian protective tariff, and even demand a protective tariff on food-products; or, in order to hold its laboring contingent, it will propose legislation in the interest of the day-laborer; or, again, to keep the hard-pressed mechanic in a good humor, it will support the demands of compulsory guilds. It is the champion of every political attempt to restrain and limit artistic freedom in literature and the fine arts; and, finally, its chief concern is the enlargement of the influence of the Catholic Church, in opposition to the temporal power of the state.

Minor Parties Related to the Centre.— Following close in the train of the Centre are: (1) the *Poles, i. e.*, Catholic Prussians of Polish nationality who oppose with might and main the Germanizing of their country, and yet, as true Catholics, are closely related to the Centre; (2) the *Alsacians*, likewise Catholics principally, who have not yet become completely reconciled to the annexation of Alsace-Lorraine in 1871, but are becoming more and more friendly toward Germany since the violent outbreak against the clericals in France — especially as the relations between the Vatican and the German government continue to become more cordial. The Centre is also on friendly terms with, (3) the *Guelphs*, those Hanoverians who have not yet become reconciled to the annexation of Hanover in 1867.

The Liberals.— The Liberals and the Social Democrats represent modern industrial Germany, the former chiefly from the point of view of the employer, the latter chiefly from the point of view of the workman. The stock-exchange, and the banking, commercial, manufacturing and shipping interests form the main support of liberalism. Besides, there are the "Intellectuals" of science and invention; and, under the secret ballot, a considerable part of the lower classes and many of the minor government employes vote the liberal ticket. The higher up in the social scale these elements of the population may be, the more they are inclined toward a moderate degree of liberalism, such as that represented by the National Liberals. They have in many respects a leaning to the Conservatives and are willing to make considerable concessions to that party. They will accede to the Agrarian protective tariff; but, in turn, they expect the Conservatives to defend the large industrial interests against labor unions and help in the development of syndicates, trusts and similar organizations of promoters. The other liberal parties mentioned above represent a more pronounced degree of liberalism. They are free-traders from principle and believe in a constitutional monarchy from which every phase of absolutism has been eliminated.

During the past 25 years a process of differentiation has been especially noticeable in the ranks of liberalism. Less than a generation ago the greater part of the industrial laboring classes and minor official classes were enlisted on the side of liberalism. With the development of social democracy these elements of the population have gradually deserted the liberal banner and joined the more radical party.

The Social Democrats.— The Social Democratic Party was organized in the interest of the proletariat and has appealed to class prejudice as the most effective means of political propaganda. With only 100,000 votes at the first election to the Reichstag in 1871, the Social Democrats polled 3,000,000 votes at the election of 1903. No other political party in Germany can show a growth even approximating this.

In the year 1878 a ban in the nature of a special law was placed on social democracy, making organization and political agitation extremely difficult. More in a spirit of revenge than of reason, to this party had been attributed the two attempts by Hodel and Nobiling on the life of Emperor William I. At the general election of 1881, the first under this new law, the Social Democrats polled only 311,961 votes, *i. e.*, about 125,000 less than at the election of 1878. Since then, however, this restrictive measure has proved extremely effective in establishing and spreading social democracy. At the Reichstag election of 1890, shortly before the repeal of the statute in question, the Social Democrats were able to poll 1,427,000 votes; and since then their numbers have increased by leaps and bounds. Between the elections of 1898 and 1903 they gained 900,000 votes.

The official programme of the Social Democrats is radical in the extreme. It contains an indorsement of "collectivism" and a republican form of government. But in practical politics these radical demands scarcely come into consideration; and the custom of the social democratic members of the Reichstag to reject the entire Reichstag budget has gradually become purely perfunctory. So far as practical legislative work is concerned, the Social Democrats are forced to adopt a liberal policy, preferably with radical tendencies, and join with the Liberals in combating the views of the Clericals and Conservatives. The more progressive Liberals and the Social Democrats are always on the same side whenever any legislative attempt is made to put a high tariff on food-products, or to limit industrial freedom and the rights of the laborer, or to curb freedom of thought and expression, or to restrict the universal suffrage now obtaining in elections to the Reichstag. The Social Democrats have also joined in the defense of the stock-exchange against the attacks of the Clericals and the Conservatives, and have likewise taken part in maintaining the gold standard. And yet this community of interests which is constantly in evidence in practical politics has not been able to effect a closer political union between liberalism and social democracy. These two parties continue to fight one another bitterly, both in the press and at the polls — naturally to the very great satisfaction of their common enemies, the Conservatives and the Clericals, who see in the continued breach between the liberal middle classes and the social democratic working classes the best guarantee for the maintenance of their own political supremacy. For this reason reactionaries of every type are always endeavoring to stir up anew the conflict between the Liberals and the Socialists.

The Political Outlook.— The question, in how far will it be possible in the future to establish a *modus vivendi* between the Liberals and the Social Democrats, is of unusual importance for the entire political development of Germany. In both parties there is no lack of men of insight who recognize the fact that neither liberalism nor social democracy alone is able to secure in Germany a modern progressive policy; and that, therefore, the co-operation of the two parties in Germany is a political necessity, just as it is in France and Belgium. Just as in liberalism there are two elements, one rather conservative, the other more radical, so in social democracy there are two factions. One is concerned primarily with the practical affairs of state; the other, composed of social extremists, is concerned entirely with socialism. These last would like for the party to devote its entire political activity to the exploitation of Marx's theory of "collectivism." This conflict between social theory and the present political needs of the state is always in progress. It will probably continue for many a year; and the reactionaries may count on deriving advantage from it for a long time yet.

However, the general trend of economic development in Germany seems to lead inevitably toward democracy. The yearly increase of population, which is some eight or nine hundred thousand, forces the political centre of gravity more and more toward the commercial and industrial side; and, in time, industrial Germany must mean democratic Germany.

12. **Germany — The Judiciary.** In the organization of justice and administration in Germany the distinction between the two has not been made in such a way that the guardianship of the law, *i. e.*, its application to the fullest extent in a given case, is a function of the courts. On the contrary, the business of the courts was considered to lie solely in the application of private and criminal law, while the decision of all cases in the whole field of public law, and of administrative law in particular, was regarded as a function of the administrative authorities. Such a view owes its origin to the absolute police-state, which it has now outlived; but it still persists. Only in recent decades have some of the German states introduced a special kind of legal proceedings for deciding certain cases of administrative law; but such innovations are as yet in a fragmentary and unsystematic condition. Even to-day the incorrect usage persists of calling only the civil and criminal courts "regular courts," as distinguished from these aforesaid administrative courts. To be sure, the organization and procedure of the so-called regular courts are legally made uniform throughout the empire by the imperial law under which these courts are organized and by uniform civil and criminal codes; while the organization and procedure of the administrative courts are left completely to the autonomy of the individual states.

Regular Courts.— In this sense the "regular courts" are: The county courts, the district state courts, the courts of appeal, and the supreme court of the empire. They are called respectively, Amtsgericht, Landgericht, Oberlandesgericht, and Reichsgericht. Excepting the last, all these courts pertain to the individual states, though their formation and proceedings are unified and determined by imperial law in the above-mentioned manner. The smaller states have courts of appeal in common, while the smallest states have their state courts in common with a neighboring state. The judges in all these county and state courts are appointed for life by the ruler of the state in which the courts are; and members of the Reichsgericht are appointed by the emperor on the recommendation of the Bundesrat, *i.e.*, the Federal Council. They cannot be transferred against their will; and they cannot be removed except by judicial disciplinary proceedings, or by reason of conviction in a criminal court. The qualification for a judgeship is prescribed by imperial law, which requires the study of law for at least three years at a university, and two rigid and comprehensive examinations, between which lies a period of practical experience in judicial work. The district state courts are divided into civil and criminal chambers, composed of three and five members respectively. The courts of appeal fall into civil and criminal senate, each composed of five members. The Reichsgericht is divided into similar senates, each composed of seven members.

Civil Proceedings.— In litigation in private law, where the sum involved does not exceed $75, and in certain specially designated cases, the judge of the county court alone decides the case in the first instance; in all other cases the suit is instituted, in the first instance, in the civil chamber of the state court. Besides, in judicial districts where a large amount of business is done, the state court has a special branch for the disposition of commercial matters. This court is presided over by a regular judge, assisted by two commercial judges. These last are business men, and their office is honorary. The course of appeal is from the county court to the district court, from the district court to the court of appeal; from the court of appeal to the supreme court of the empire for revision. In the larger commercial cities there is also provision for the formation of special courts to try cases growing out of business, commercial, and labor relations. Such courts are composed of employers and employes in equal numbers, and are presided over by some municipal official.

Criminal Proceedings.— For light misdemeanors criminal proceedings begin in the Schöffengericht, or sheriff's court, which is presided over by a judge of the county court, assisted by two magistrates. For more grave offenses the court of first instance is the criminal chamber of the district court; for serious crimes the Schwurgericht, or jury court. This last is composed of three regular judges and twelve jurors, forming two separate colleges, so that jurors only have to decide the question of guilt or innocence. In cases of treason against the emperor and against the empire the Reichsgericht alone has jurisdiction. We see that criminal courts of first instance are organized on three distinct principles. In some of them regular judges and laymen act together, in others they act as two separate units, and in still others the judges act alone. This condition is a result of a compromise that was agreed upon when the imperial statutes regulating the judiciary were passed. The original draft provided for three kinds of sheriff's courts, organized on a unifying principle. At present there is a reform movement in progress, looking toward the establishment of greater unity; but, in so far as such efforts threaten the existence of the jury-courts, they meet strong opposition in the public sentiment. In criminal matters, appeal, properly speaking, can only be taken from the decisions of the sheriff's court, from which the case goes to the criminal chamber of the district court. From the decisions of a district court, as well as from those of a jury court, there is no appeal, the only legal remedy being revision, in some cases by the criminal senate of the court of appeal but usually by the Reichsgericht.

The Public Prosecutor.— Aside from light cases of personal offense, insult, etc., the right to institute proceedings does not rest with the injured party but rests exclusively with the public authorities, or, so to say, with the Staatsanwaltschaft. It is the business of the attorney-general — district attorney, state's attorney, or whatever we may call him — to follow up every crime that comes to his notice; and only in certain light misdemeanors does the prosecution depend upon the will of the injured party. But, on the other hand, if a case is thrown out by the public prosecutor, the aggrieved party can bring about a legal decision on the matter. The qualification of prosecuting attorneys is the same as that of judges; but they are administrative, not judicial, officials. They are appointed by the several state sovereigns, and are subject to the legal regulations of the state administration. For the Reichsgericht also there are similar attorneys-general. They are appointed by the emperor on the recommendation of the Bundesrat, and are subordinate to the imperial chancellor and the imperial department of justice. The prosecuting attorneys also represent the public interest in matrimonial and guardianship litigation.

Attorneys.— The qualification of an attorney or counselor-at-law is likewise the same as that of a judge; though lawyers are by no means officials, but free practitioners. To be sure, in order to practise his profession, he must be enrolled in the list of lawyers at a certain court; but such enrollment cannot be denied any one who has the qualification of a lawyer. Only for the Reichsgericht does the right to practise depend upon the vote of the council, which decides the question whether a need exists, or not. In criminal proceedings every lawyer can represent the defendant in any German court; but in civil proceedings only in the court where he is enrolled. Only in the county court is it unnecessary for the defendant to have a lawyer; in other courts it is compulsory. Distinct from the attorneys are the notaries. These are regular state officials, appointed by the state department of justice, and in most states from the ranks of the lawyers.

Besides the administration of civil and criminal law, a number of matters have been turned over to the courts, which are properly beyond, but are said to fall within the "voluntary," jurisdiction of the courts. They are scarcely legal affairs at all, but rather administrative business. Among such may be mentioned, the control of guardianships, the keeping of the land-register, and the trade-register, and similar things.

Special Courts.— In addition to the general courts there are special courts for certain classes of persons. Particularly to be mentioned are military courts, having jurisdiction in criminal matters. Military persons are not subject to the general criminal justice, but come under special criminal proceedings managed, in the first instance, by the military, by the military supreme, or by the naval courts, and, in the last instance, by the military court of the empire. These courts are composed of officers and military judicial officials; and here particularly the lord of the court, a survival of the Middle Ages, plays an untimely part. Further, the various systems of state laws provide for special civil and criminal proceedings against the members of the state's dynasties, and for civil proceedings even against the ruler himself. For criminal acts, the head of a German state cannot be tried in any court, and so cannot be held responsible.

In the German protectorates there are also special courts, and likewise special consular courts in those foreign localities where Europeans are exempted from local jurisdiction.

Independence of the Judiciary.— The principle of independence in the judiciary is shown not only by the fact that the judge can neither be transferred nor peremptorily dismissed, but also by the fact that the courts render their decisions independently of any higher orders, and are under no authority but that of the law. The pardoning power in cases of criminals belongs to the heads of the individual states and free cities, except for sentences passed by the Reichsgericht; for these the right of pardoning belongs to the emperor.

The Question of Legality.— From the principle that the courts alone have the right to apply law is deduced the further principle that they have to test the legality of laws and ordinances before they apply them. In Prussia, however, there is a constitutional clause against this, which precludes absolutely the possibility of testing the legality of any properly proclaimed statutes, or even of the royal mandates. But whenever a given law violating the basal principles of a legal system has not been expressly sanctioned, there exists the right to test its legality. This is true of the empire and of many states. It must be added that the weight of opinion in Germany is that this right of the courts to test the legality of a law does not, as in the United States, touch the question of the constitutionality of a statute that is formally valid. While in America legislation, justice, and administration are coördinated, and all are subordinate only to the specially organized constitutional law, in Germany constitutional law is not essentially different from ordinary law; and it is under ordinary law that both justice and administration are subordinated.

The Question of Constitutionality.— Accordingly the whole field of constitutional law, properly speaking, is without any secure protection on the side of the courts; for the American institution of impeachment has not yet been developed in Germany. In all the constitutions, of course, the principle of the responsibility of ministries for their acts is expressed, and many individual states have a legal regulation for the indictment of ministers. Charges are preferred by the state legislature, and the case is usually tried by a specially formed state court. But in the empire, as such, and in Prussia the legal regulation for such proceedings is lacking. However, regardless of the question whether such indictments should be brought against ministers, some sort of control by the courts over the constitutionality of laws and the acts of the government is absolutely necessary. The custom, taken from French law, of allowing the Staatsrat, or state council, to decide whether an official shall be prosecuted in the courts, or not, for acts committed in performing the functions of his office, has been done away with for the empire; but in the individual states, under certain circumstances, a similar arrangement has been retained. Prussia and some other states have made use of it. For instance, if civil or criminal charges are preferred against an administrative official for acts done in his official capacity, his superiors can submit to the highest administrative state court, the Oberverwaltungsgericht, the question whether the official has violated his duty or not. If this court decides that the official on trial committed the offensive acts in the performance of his duty the case is brought before the regular courts.

Whether the courts are to be allowed to test the legality of administrative acts, and in what way and to what extent, this is a matter that the imperial laws leave to the legislation of the individual states. As a matter of fact, Prussia, Bavaria, Saxony, Württemberg, Baden, and many small German states have recently undertaken judicial control of administrative jurisdiction. They have organized a so-called "Verwaltungsgerichtsbarkeit;" but the extent to which this has been done is exceedingly varied; and it is exceptional that the principle is expressed, that every infringement on subjective rights by an administrative act is sufficient ground for an indictment. Usually, as in Prussia, the legal method is to enumerate all the possible cases in which such an administrative indictment is admissible. The list generally includes all police dispositions. However, the decision of such cases is never left to the ordinary courts, but to special administrative courts; and these do not belong to the judicial system, but to the administrative system. Usually, in the first instance, the question of administrative jurisdiction is decided by the administrative authorities themselves, but in collegial formation with laymen and in special proceedings similar to civil proceedings. Only in the last instance does the question go to an administrative court formed especially for the cases in hand. In Prussia administrative courts of first and second instance are simply the administrative county and district boards, which are composed partly of regular, paid officials, and partly of honorary elected officials. The court of final appeal is the Oberverwaltungsgericht, which is composed exclusively of members appointed for life by the king. Half of the members must have the qualification of a judge, the other half the usual qualification required for high administrative service. As to independence, this court offers all the guarantees of the highest courts of justice.

In view of the complication of the limits to the competency of law courts on the one side, and administrative authorities and administrative courts on the other, it is clear that disputes over such competency can easily arise. The imperial law states that the courts are to decide upon the competency of himself; but here too it leaves it to state legislation to form, under certain conditions, special courts for deciding such disputes about competency. As in other states, this has happened in Prussia. Here a so-called competence-court, composed of judges and administrative officials, decides such conflicts. This special court is summoned either by the administrative authorities when the matter is pending, or by the disputants, after both the courts and the administrative authorities have declared themselves incompetent. On the other hand, disputes of competence between the administrative courts and administrative authorities are decided once for all by the Oberverwaltungsgericht.

13. **Germany — The Schools.** The history of German schools begins with the time of Charlemagne. True, before his time, the Church had made it its business to provide, in the monasteries, instruction in theology and other subjects for boys intended for the ministry, and later also for the children of especially prominent families; but it was the great emperor who, advised by such scholars as Alkuin, Paulus Diaconus, and Petrus Lombardus, first strove to introduce really popular instruction in Germany and thus lift his subjects to a higher intellectual plane. School-rooms were fitted up in his castles, as well as in the monasteries, where not only his own children and the sons of the highest nobility, but also capable boys of the lower classes were instructed and educated. In the following wars and confusion many of those schools were abandoned, and under the successors of Charlemagne nothing was done for the youth of the common people for centuries, though scions of distinguished families still found in the monastic schools opportunity to learn the three R's and occasionally even Latin. With the rise of the cities after the Crusades and the increased prosperity of the middle classes came naturally a popular desire to better educational conditions. Already before the 14th century German merchants had established secular writing-schools, in which the subjects of instruction were no longer merely those things that the Church was trying to teach to its new recruits, but more particularly penmanship and commercial arithmetic, and such other things as the business world of that time needed to know. After this time the development of

the German school system was stimulated largely by the examples of Holland and Italy, respectively. While the monastic and cathedral schools still remained under the domination of the scholastic spirit, humanism was victorious in the "brotherhood-schools" that were spreading all over lower Germany, modelled after those established in the Netherlands by Geert Groote. The revival of learning in Italy prepared the way for a reorganization of higher instruction in Germany and led to a more thorough study of the classic languages and literatures. Yet, with a few famous exceptions, there was a lack of really capable teachers. Just as in the guilds, there were masters and apprentices among schoolmen; and hundreds of poorly qualified beginners in the profession roved from place to place as traveling scholars, usually taking with them a number of "A B C" words, which they treated brutally enough and often led astray.

The most important educational reform in Germany was effected by Melanchthon (præceptor Germaniæ) and Martin Luther. Supported by Bugenhagen in northern Germany and Johannes Brenz in Würtemberg, these two reformers sought to improve upon earlier attempts at popular education. Both worked for a popular education that should really become general; and they emphasized effectively the legal duty of all parishes to employ the necessary number of qualified teachers. Just as the school-ordinance of Würtemberg, so also those of Brunswick, and the Electorate of Saxony demanded German schools in every village, besides particular schools of five classes in the towns. Continuing the work of the latter, the three ducal schools (Fürstenschulen) at Meissen, Grimma, and Schulpforta took the pupils through a six years' course, thus preparing them for the university. Besides the old monastic schools there were now also Protestant Latin-schools, where philosophy, mathematics, and the elements of Hebrew were taught as well as Latin and Greek; but it must be added that in the lower Latin-schools Latin and religion were for a long time the only subjects taught. Through the efforts of Hieronymus Wolf, Valentin Friedland, of Trotzendorf, and Johannes Sturm — all pupils and followers of Melanchthon — the Latin high schools (often called monastic, public, and ducal schools) were gradually raised to the dignity and significance of those humanistic Gymnasien, which for some centuries formed the chief stepping-stones to the German universities. The Catholic Church unwilling to be outstripped also took up the work of reform and helped to increase the number of country public schools, and also the charity schools in the towns and cities. The Jesuits furnished some excellent teachers for the Catholic portion of the population. Though girls had received instruction in the convents of the Middle Ages, still it remained for the 16th century to give the daughters of the poorer classes opportunity to receive even a modest amount of elementary instruction.

However, in the following cycle humanism was on the wane. In directing attention to the study of nature Bacon and Descartes had proclaimed the rise of new educational ideals, and now Germany again needed new pedagogical guides. These were found in the persons of the school-reformers Ratichius and Comenius. While the latter emphasized the value of observation and practice (übung) and regarded the "realities" as the kernel of scientific education, Ratichius was more practical and directed his efforts toward the introduction of a quick method of learning languages. During their lifetime compulsory education was introduced, at least in some of the smaller principalities. A number of school-ordinances published later show the far-reaching influence of the pedagogy of Comenius, and particularly a gratifying effort to increase more and more the number of subjects taught. The nobility of the 17th century looked upon humanistic learning as the work of a pedant, and blinded by the brilliance of French culture, they established their Ritterakademien, or academies for young noblemen. Of these institutions, which were of rapid growth, a few are still in existence. August Hermann Francke made a name for himself as the creator of the first German orphan-asylum, of the Bürgerschule, and of the high school for girls. He likewise made the first attempt to unite organically the new subjects of instruction with the traditional subject-matter of instruction. Just as Francke had done, the so-called Philanthropists (Basedow, Campe, Salzmann), under the influence of Locke and Rousseau, laid stress on the importance of educating as well as of instructing youth, and prepared a number of good school manuals and reading books. It is to pupils of Francke that Germany is indebted for the first Realschulen, in which the greatest stress was put upon the German language and literature, to the exclusion of Latin and Greek.

Frederick II., of Prussia, saw in the spread of elementary instruction the best means of enlightening his people; but von Zedlitz, his minister of state, also did much to elevate and multiply the Gymnasien. The final examination (Abiturientenexamen), introduced in 1788, made instruction and courses of study more uniform. Freiherr von Stein laid the foundation for the later Ministry of Public Worship and Instruction in Prussia. Examination-ordinances for the pupils of the various schools were either revised or introduced for the first time, likewise for teachers of public and other schools; also a trial-year for teachers was instituted; a normal programme of study was published for the Prussian Gymnasien; and, finally, the value of gymnastic exercises, which had been advocated by Jahn, was recognized in the programmes of public schools.

However, the wonderful educational progress made by Germany along all lines during the first half of the 19th century was due principally to the work of the great pedagogical reformers Pestalozzi, Fröbel, and Herbart. They emphasized the necessity of a natural beginning and the importance of thorough rudimentary instruction; they insisted that education go hand-in-hand with instruction; and they demanded that Forbildungsschulen, or continuation schools, be established, that the trial-schools for teachers be united with the training-colleges, and that methodically arranged school manuals be prepared. Kindergartens, in which play is made an important factor in education and instruction, trace their origin back to Fröbel, while Herbart was the creator of our scientific pedagogy. He brought pedagogy into its natural relation to psychology and ethics and sought to build up instruction in high schools on the same principles as in the public elementary schools (Volksschulen).

The credit for the excellent and generally admired school system of Germany, with the consequent high level of popular education, is not due to such deserving men alone, but also in a large measure to wise legislation, particularly regarding the thorough preparation of teachers and the compulsory attendance of pupils. All children from 6 to 14 years old must receive instruction, at least in the public elementary schools. Here tuition is free, but not so books, tablets, etc.; and every parish or municipality is legally obligated to establish and maintain such schools. Here and there the state renders some assistance, but claims the right to confirm the teachers and supervise the school. The simplest form of such a free school is the village school with only one class, where children of both sexes and of every school-age sit together in one room and are instructed simultaneously by one single teacher. The subjects taught are: Religion, German, Arithmetic, the Realities, Singing, and Gymnastics, besides some instruction in needlework for the girls. In larger communities similar schools have two or three grades instead of only one, and a corresponding number of teachers, under a regularly certificated principal. In towns and cities the boys and girls are separated, there being such free schools for each sex. Since 1 Oct. 1902, such city schools have had eight grades, and in them are taught, in addition to the subjects mentioned above, also Geometry, Geography, and Natural History. The administration of these common schools is in the hands of the city school commissioners, who are elected by the representatives of the citizens. These commissioners elect the superintendents and the principals and teachers of the individual public schools. State supervision of schools, including the one-grade country schools, is carried out by the district superintendent, or by the head of the district government, or, in the last instance, by the royal government.

The intermediate and high schools for boys, as well as similar institutions for girls, serve more general educational purposes, in that here modern languages are added to the curriculum. All teachers employed in the common and intermediate schools must have been prepared in a state training-college for teachers. In Prussia there are usually separate training-colleges for Protestants and Catholics, and all are under the royal provincial school commissions, in which the head of the provincial government in question is the chairman. Every training college is organically united with a one-grade and with a three-grade practice school. The so-called Präparandenanstalt, a preparatory training school, serves as a stepping-stone to the training college. Pupils who have not attended such an institution must pass an entrance examination at the higher institution. The course of study at a training college embraces three years, and tuition is free. In none of these training schools is there co-education, there being separate institutions for males and females. Usually these colleges for teachers are at the same time homes, where the pupils eat and sleep. Pedagogy, Religion, German, and Music play an important part in the course of instruction. For entrance the pupil must have completed his 17th year, but must not be over 24 years old. After three years, the last of which is devoted chiefly to a practical study of methods in teaching, the pupil must pass a final examination, which qualifies provisionally for the work of a teacher. However, the right of permanent employment in the school service is conditioned on another examination, which the young teacher can take only after the lapse of two years, at latest five years. The candidate must then show that he or she is capable of filling a school position permanently. Any one desiring to become a teacher in an intermediate or a high school, or a teacher or principal in a training college, or a school principal or superintendent, must stand special examinations of correspondingly more rigid requirements.

At the beginning of the year 1902 there were 59,364 public elementary schools in Germany, with 146,584 teachers in full employment, and 8,921,440 pupils. In 1901–02 the total expenditure for public elementary instruction was $104,475,000, of which $30,100,000 came from state funds. There was a public elementary school for every 950 inhabitants, with 158 scholars for every 1,000 inhabitants, and 61 scholars pro teacher. There were further 666 private schools of the same grade, with 39,939 scholars. The teachers of all kinds of public schools in Germany are entitled to pensions, and can, for the most part, be dismissed only by a judge's sentence. In the sum mentioned above, as representing the cost of public elementary education in Germany, the expense of general school management, of school inspection, and of training teachers, is not included. The general level of popular education in Germany is favorably characterized by the fact that in October, 1901, the precentage of illiteracy among army recruits was only ½ per cent per 1,000, not taking into account the one-year volunteers, who, as is well known, are admitted only on the basis of a certificate obtained for six years' successful study at a higher institution of learning.

In Prussia there were, in 1902, 12,183 students at the public training colleges. The total expenditure for such institutions in the same year was some $2,375,000, of which about $2,000,000 was paid by the state. Of the 6,103,745 children in Prussia in 1901 subject to compulsory education (age 6 to 14 years), about 93 per cent received instruction in the public elementary schools, 6 per cent in other schools, and only 1 per cent were temporarily excused from school attendance. In 1901 there were in full employment in the Prussian public elementary schools 76,342 male and 13,866 female teachers, besides 131 male and 33,062 female assistants for such special branches as needlework, gymnastics, etc. In 1901 the cost of maintaining such schools in Prussia amounted to some $67,480,000. Of this amount only 31 per cent was covered by the usual school money, the balance being paid by the state, by the municipalities, and by parties obligated to contribute, and in part from the income of school property. In 1901 there were in Prussia 319 public intermediate schools for boys and children of both sexes, where 86,965 pupils received instruction from 2,368 male and 200 regularly employed female teachers. The number of public intermediate schools for girls was 137, with 47,776 pupils, 702 male, and 704 female teachers.

To be distinguished from these last mentioned are the public high schools for girls (Hohere Töchterschulen). Of these schools alone there are in Prussia about 220, with more than 60,000 pupils and about 2,500 teachers, of which there are only about 200 more female than male teachers. It must be remembered that we are speaking here only of state and city schools. Just in this field of female education there are numerous well-attended private institutions; and in these the female teachers are in a large majority. The ordinary public high schools for girls (Höhere Mädchenschulen) have nine grades; and here are taught, besides the general subjects already mentioned, French, English, Mathematics, Physics, and Chemistry. Not infrequently there are training colleges for girls in connection with these high schools, which have a three years' course and prepare teachers for intermediate and high schools for girls. Recently also regular gymnasial courses, with considerable Latin and some Greek, have been opened to girls, either in a private way, or as supplementing the work of some of the more prominent public high schools first mentioned.

The first Realgymnasium for girls was opened in Berlin in 1906. The curriculum is to be the same as that of the intermediate and upper classes of the Realgymnasien for boys, including Latin but not Greek (see below). In January, 1906, Dr. Studt, Minister of Public Worship and Instruction, summoned to Berlin a conference of educators in the interest of the higher education of young women. The body was composed half of male and half of female representatives of education for girls. The resolutions passed by this conference are of great significance for the further development of female education, and especially so the plan to establish colleges (Lyzeen) for girls. These institutions are to include ancient languages in their course of instruction; and the expectation is that they will give young women an equal opportunity with young men to pursue the highest educational ideals.

As regards higher institutions of learning for boys we have, in general, to distinguish between those having a six-years' course and those having a nine-years' course. All presuppose a three-years' elementary course and receive in their lowest class pupils 9 or 10 years old. When a boy has finished a six-years' course and qualified for the next higher class, he then receives a certificate entitling him to fulfill his military obligations as a one-year volunteer. The most popular and by far the most numerous of these six-year public schools are the Realschulen. Besides the usual branches, French is begun in the first year, to which English is added in the fourth, fifth, and sixth years. Other subjects taught are Mathematics, Physics, Chemistry, Biology, etc. The Oberrealschule is just like the Realschule as regards the programme of study, etc., except that here the course is merely extended organically by three years. Latin and Greek are not taught in any of these schools.

The Realgymnasium is a higher institution of learning with a nine-years' course of study. French, English, and Mathematics are the principal subjects of instructions, but heavy emphasis is also put upon Latin. Even in the first year the pupil is drilled eight hours a week in the elements of Latin grammar. A conference of leading German educators, called together by William II. in December, 1890, has proved significant for the later development of the German school-system. Since that time there has been increased interest in the establishment of institutions that take into consideration the individual talents and inclinations of the pupil and make it possible for him to get either an essentially humanistic, or a more realistic education, thus preparing him later to enter one of the learned professions, if he choose, or to pursue some more practical calling. In such reform schools Latin is banished from the lower classes and French begun instead; then in the third year English is taken up, in accordance with the programme suggested by Principal Schlee, of Altona; and not until the fourth year does Latin take its place with the other languages. The Frankfort reform programme, which has been advocated with most success by Karl Reinhardt, is more popular and really of more practical use. It provides for French as the only foreign language during the first three years; then Latin is added, and later, during the last four years, English is added. If for English we substitute Greek in this programme, there we have the curriculum of the so-called reform gymnasium. As a matter of fact, the three lowest classes are the common foundation for the Realschule and Oberrealschule on the one side, and for the Reform realgymnasium and the Reform gymnasium on the other.

In the humanistic Gymnasien of the old style Latin is studied from the first year on, French from the third, and Greek is added in the fourth year. At present these institutions are still in the majority; but the tendency is decidedly to increase the number of «realistic» institutions and reform schools.

The aim of the reforms of the last 15 years, which were initiated by William II., has been to break the monopoly of authority enjoyed by the Gymnasien. As a matter of fact, anyone who has passed the final examination at any higher institution of a nine-years' course, can now enter the university; though matriculates in the theological department who have not studied ancient languages must later take an examination in these subjects. Similarly, graduates of an Oberrealschule who intend to become physicians must learn a certain amount of Latin; and, if they devote themselves to the study of law and statecraft, they must, after a few terms, take an examination in Latin, to show that they are able to study Roman law from the sources. The certificate of graduation from a nine-year institution (Gymnasium, Realgymnasium, Oberrealschule) besides admitting to the universities and the technical Hochschulen, entitles one later to enter upon the career of an officer in the army or navy, or to take the examinations for state service in the departments of forestry, buildings, and mines, or in the higher postal and telegraph service. To enter upon a career in the revenue department it is sufficient to have studied successfully for one year in the upper class (Prima) of a nine-year institution. For admission to the study of dentistry and veterinary science, as well as to employment in the Imperial Bank, the candidate is only required to have passed the examination for promotion to the upper class. The certificate for service as a one-year volunteer, given for six years' successful study at a higher institution, admits to the Hochschule for Agriculture, also to the Academic Hochschulen for music, painting, and sculpture, as well as to the examinations for teachers of gymnastics and drawing at the high schools. On the other hand, the future apothecary must have passed the examination for promotion to the upper class; and, if he was educated at an Oberrealschule, he must have learned privately a sufficient amount of Latin.

It only remains to refer to special schools for the infirm. Germany has long regarded it as the duty of the State to provide education and instruction for children whose bodily infirmities make it impossible for them to attend the regular public schools. In addition to numerous private institutions of a similar nature, there are royal schools for the blind and for deaf-mutes; and in some of the asylums for the insane there are classes for mentally diseased children, in which the wards are chiefly directed in some kind of systematic manual employment. Further, in many municipalities auxiliary schools for weak-minded children have recently been established. Formerly, such children either received no instruction at all, or else they were allowed to attend the ordinary public schools for years to no use, feeling themselves miserable among normal children and simply hindering the regular class instruction.

LEOPOLD BAHLSEN,
Principal of the Realgymnasium at Stralsund.

14. Germany — The University System. The conception of a university is, as part of the German educational system, free from all the difficulties of determination which are involved in the American usage of the word. In the United States the university means sometimes the best equipped colleges as distinguished from the poorer ones; sometimes those institutions which combine colleges and professional schools; yet at the same time many of the smallest and newest schools leading to the bachelor's degree call themselves universities, while the older and better ones keep the traditional name of college. There is thus on the American side no sharp demarcation line, and hundreds of hardly comparable institutions may be called universities. The situation in Germany is in every respect the opposite of this. The German Empire has 21 universities which, at least in theory, all stand on exactly the same level, have uniform entrance conditions and degrees, are sharply and absolutely different from a German school or gymnasium, from the academies and technical schools, and from every American institution: comparable perhaps with the four post-graduate departments plus the junior and senior classes of an institution like Harvard University.

The oldest German universities lie outside of the present German empire, in Austria: Prague was founded in 1348 and soon after, Vienna. In the Germany of to-day none is older than Heidelberg, founded 1385. The others are, in historical order: Leipzig (1409), Rostock (1419), Greifswald (1456), Freiburg (1457), Tübingen (1477), Marburg (1527), Königsberg (1544), Jena (1558), Würzburg (1582), Giessen (1607), Kiel (1665), Halle (1694), Breslau (1702), Göttingen (1737), Erlangen (1743), Münster (1780), Berlin (1809), Bonn (1818), München (1826), Strasshurg (1872). A lively agitation makes it probable that the next university will be founded in Hamburg.

Sixteen universities, some of them of great historical importance, existed for some centuries and disappeared again, as, for instance, Köln (1388–1794), Erfurt (1392–1816), Ingolstadt (1472–1800), Mainz (1477–1798), Wittenberg (1502–1817), Frankfurt a. O. (1506–1810), Helmstädt (1576–1809), Altdorf (1622–1807).

The essential features of these 21 institutions are given in the fact, firstly, that they are State institutions; secondly, that the instruction is adjusted to the professional training of the lawyer, the physician, the minister, the high school teacher, and the scholar; thirdly, that the teachers are appointed for their achievements in productive scholarship; and finally, that the students are left to the complete freedom of independent young scholars. We have to consider carefully the bearing of these four features to understand the meaning of those institutions which have been throughout the whole of the 19th century the chief pride of the German nation, and have secured to German scholarship the acknowledged leadership in the civilized world.

State Institutions.— The German universities are State institutions. While in America the State has organized university life wherever private initiative has been insufficient, giving to the State universities on the whole a supplementary character, inasmuch as all the leading historical universities have been under the control of private corporations, the German nation takes for granted that the higher education is a matter for the State. This administrative dependence upon the State can alone secure the necessary uniformity in the preparation of the State employes, teachers, judges, and so on. And, on the other hand, as the State demands that its employes shall have studied a number of years in German State universities, it would be impossible to develop universities on private foundations. Germany thus represents in this respect the opposite extreme to England, while America takes a middle place. But it is not the Empire which has any control of the universities. The higher education is a function of the particular states. Thus, Berlin is under the control of Prussia; Leipzig, of Saxony; Munich, of Bavaria; Heidelberg, of Baden; and so on. The State appoints the professors, determines their salaries and their functions, and determines the requirements for the State examinations. All the expenses of the university, salaries and pensions, buildings and equipment, figure in the State budget, and are independent of the small fees which the students pay and which go directly to the professors whose lectures they attend. The income of the instructors comes, thus, from two sources: the salary and the fees. In the case of disability of the professor, his whole salary is to be paid until his death; and in every case, the State takes care of the widow and orphans.

The State expenses for the universities have been about 30,000,000 marks for regular yearly expenses and about 6,000,000 marks every year for extraordinary expenses.

The leading personality in the governmental administration of the last two decades has been Dr. Friedrich Althoff, the eminent head of the Prussian University Department; his greatest achievement is the development of the naturalistic laboratories and of the clinical institutions.

This State character of the universities is in no way antagonistic to an extraordinary democratic freedom in these institutions. Their whole organization is in its essentials that of self-governed corporations, with powers in the hand of the professors which in many respects exceed those of the American Faculties and which still show much of their origin in the free medieval institutions of Germany. Fundamental is the right of the Faculties to fill their vacancies by coöptation. Whenever a professorship is to be filled, the Faculty selects three candidates and the government is bound to appoint a professor from among this number. The Faculties, also, choose each year the President, the so-called rector, out of their own number. The teaching staff consists further, not only of full professors and assistant professors, but also of docents (Privatdocenten) who have no salaries, but fees only, and their appointment is absolutely in the hands of the Faculty. In earliest times the universities had even their own courts. This exemption from civil law has been abolished, but some disciplinary rights have still been kept up. Above all, the State has no right to interfere with the teaching of any instructor. No political pressure can be applied, and no professor can be removed from his place against his will. There is no sphere of public activity in the German Empire in which the State control is so little felt as in the university; everything is adjusted to the greatest possible freedom of thought.

Professional Faculties.— The universities are schools for professional training. They stand hereby in sharp contrast to the English and American systems. In America the law schools, medical schools, and partly the divinity schools, stood in old times on a very low level of general education. Practically every one was admitted. And independent of these, the country had its colleges as places of highest education; these were the real universities of the land, with the aim of furnishing the highest liberal education, accessible alike to the future business man and to the professional students. In Germany the situation has been just the opposite of this since the days of the first university in the 14th century. From the beginning, each university has had its four Faculties, and one of them, the Faculty of Arts, the later so-called Philosophical Faculty, was distinctly the preparation for the three upper Faculties of Divinity, Law and Medicine. The Faculty of Arts had not the coördinated character because its professional aim of preparing school teachers had not reached an independent standing, as all teaching was done by the clergy. As soon as lay teachers were demanded, the Faculty of Arts, too, became professional, and the four coördinated Faculties represented the university. Thus none but professional men have a real right to existence in the German University. The strong social effect of this historical development cannot be overlooked; it characterizes the social difference between Germany and the Anglo-Saxon countries. While in America the community of the best educated is represented by the alumni of the colleges, without reference to the question whether the way from the college leads to the court and hospital or to the bank and office, in Germany the circle of the intellectual leaders is confined to the professional men, as they alone have had reason to attend a university. Only the army ranks with them socially, while the representatives of all commercial and industrial activities take a second place, as they have no university education.

In a certain way the Philosophical Faculty is still to-day introductory to the three others. The students of medicine here receive the biological foundation, the students of law and divinity find here the historical, economical and philosophical work. At certain places the Philosophical Faculty itself has been divided into two, a Naturalistic and an Historical Faculty. Everywhere it is at present the most developed one, with the largest number of teachers and students. The most rapid development in the last century belongs to the Medical Faculty, which stood far behind the Law Faculty a hundred years ago, while it has now far surpassed the Law Faculty in the number of teachers, and, for a period of years, even in the number of students.

In every Faculty the foundations of the instruction are historical and theoretical. The Law Faculty, for instance, develops the juristic problems from a systematic point of view and leads up to the existing law through the history of Roman and German law. The practical preparation which the case system of the American law school provides is left in Germany to the so-called Referendarzeit, a period of several years which every young jurist — he may go into the career of the lawyer or of the judge — has to pass in the court for practical training after passing his examinations in the university. Besides the State examinations for all professions, the university offers the Doctor's Degree in Philosophy, Law and Medicine, which in itself gives no right to any appointment or to any professional work, with the exception of the career of the university docent. Yet the Doctor's Degree is taken by most of the professional men too, as it gives by tradition the stamp of real scholarship.

The relations of the different Faculties may be characterized by the following figures. In the year 1900 there were in the Philosophical Faculties 571 full professors, 52 associate professors, 323 assistant professors, 419 Privatdocents, and 12,244 students. In the Protestant Divinity Faculties 110 full professors, 7 associates, 33 assistant professors, 37 docents, 2,352 students. In the Catholic Divinity Faculties 62 professors, 2 associate, 10 assistant professors, 10 docents, 1,546 students. In the Law Faculties 156 professors, 12 associates, 32 assistant professors, 40 docents, 9,250 students. In the Medical Faculties 224 professors, 19 associates, 210 assistant professors, 329 docents, and 7,433 students. To characterize the growth of the Faculties the following figures may be added: In the year 1850 the German universities had 12,246 students (1,615 Evangel. Div., 1,391 Catholic Div., 4,306 Law, 1,932 Medicine, 3,102 Philosophy). In the year 1880, 22,863 students (2,786 Evangel. Div., 706 Catholic Div., 5,297 Law, 4,779 Medicine, 9,295 Philosophy). In the year 1903, 37,677 students (2,197 Evangel. Div., 1,580 Catholic Div., 11,747 Law, 6,948 Medicine, 15,205 Philosophy).

The Teachers.— The teachers of the university are appointed with reference to their achievements in the advancement of knowledge. No one can understand the meaning of the German university who does not acknowledge this principle as the central energy of German academic life. In this respect Germany stands in contrast to both England and France. In England the greatest scholars, from Bacon to Darwin and Spencer, have stood outside the university life, and even the leading professors of Oxford and Cambridge have little to do with the regular teaching, which is in the hands of tutors and fellows. In France the provincial universities are professional schools whose professors are expected to be first of all teachers, while scholarly production is concentrated in the academies of Paris. In Germany alone is a complete unity of academic teacher and productive scholar demanded. It is a rare exception when an important scholar does not become a university teacher in Germany, and every university teacher without exception is expected to have added to the storehouse of the world's knowledge. America comes nearer to this German system than any European country; and yet in every American university productive scholars and reproductive scholars are mixed; the contributions to knowledge still appear as a kind of private undertaking, while the appointment refers to the teacher as teacher. This cannot be otherwise in a country where there is no sharp demarcation line between the small college, which demands school teachers, and the large university from which the mere school work ought to be banished. Germany's power to reserve all university teaching for the productive scholar thus stands in immediate relation to the sharp and uniform demarcation line between all schools, on the one side, and the universities on the other.

This principle involves the most characteristic features of German university teaching. The university lecture is not intended as a reproduction of ready-made knowledge and the imparting of mere information is its least important function. Its essetial trait is rather that which the productive scholar alone can offer, the training in scholarly methods. The Gymnasium teaches facts; the university teaches a critical attitude toward all knowledge. Its vehicles are partly lectures, partly seminary exercises. The lectures are meant to be strictly personal and critical outlooks over a whole field of knowledge, independent of any special textbook. They are not to be substitutes for anything printed at all, but have to find their value in the contact of the student with a personality, acknowledged as an original productive scholar. The German idea is decidedly that the mastery of method which such a teacher has shown in his works will be more helpful and suggestive for the student than any brilliant rendering of second-hand knowledge. The seminaries, which have taken the place of the formal disputations of earlier centuries, lead the most advanced students to make individual efforts toward scholarly production.

This principle gives meaning also to the institution of Privatdocenten. In America the young scholar has to find his academic career mostly by ascending through positions in small colleges without higher university aims, where he finds neither the means nor the time nor the advanced students for higher work. This is necessary as the large universities have merely salaried teachers whose number has, of course, to be adjusted to the demand of the instruction. The result is that the academic career is discouraging for the most vigorous minds, which see before them years of a second-rate activity. In Germany the opposite prevails. There are no limits for the number of teachers of highest class in the university. The docents have no salaries, to be sure; but their right to lecture on any specialty to advanced students is equal to that of any full professor, and no obligations are involved. It is the ideal situation for the young scholar who wants to live in the academic atmosphere from the first and who wants to devote his life to productive scholarship. A remarkable piece of scientific achievement is the only condition for his admission, however large the number of teachers in the same specialty may be. This docent system thus separates the university career from its beginning, from that of the simple teacher; confines it to productive work; and has its external advantage in the fact that out of these docents the universities choose the candidates for vacant professorships. The result is that the finest and most vigorous minds of the country are drawn into this career, and it is this personal factor above all which gives to the German university its superiority. Germany is the only country in which absolutely the best human material of the nation enters into the academic career; and the docent system is the necessary condition for this situation.

The German university has thus no exact equivalent to the American university instructor, as the instructor has a paid position and is appointed with definite obligations as to teaching, while the docent may offer within the limits of his chosen field whatever he likes. The professor extraordinarius corresponds to the American assistant professor; the ordinarius, to the full professor. But it must be understood that in Germany both categories are appointed for life, and that the full professors only constitute the official Faculty in which the administrative duties are settled. Very frequently the title of professor extraordinarius is given to docents after a series of years of valuable work. This is, then, merely a title without any professorial rights. No docent earns by his years of service any right to be advanced to a real professorship, and seniority plays no rôle in the question of advancement. The principle of inbreeding, so habitual in American universities, is strictly avoided in Germany. A constant migration of the professors is the rule, and this migration includes the German universities of Austria and Switzerland too. The Faculty asks merely for the best productive scholars available, and this rejection of all claims resulting from years of service secures the eminent character of the Faculty.

The Students.— The students attend the university for from three to five years for the purpose of being prepared for a profession through a critical scholarly study of its scientific basis. The attitude of the student, at least in theory, corresponds, therefore, to the scholarly character of the Faculty. This is expressed by the scholarly preparation demanded as entrance condition, and is expressed further by the complete freedom of the student in every respect. As to the entrance conditions, recent years have modernized the system by giving to the more naturalistic Realschule the same rights as to the classicistic Gymnasium. But in no case can a student be matriculated as a full student with the right to pass state examinations who has not passed the nine years' course of one of the higher schools which presuppose a three years' course in a primary school. This twelve years' work is usually completed with the 19th year and is tested by the Abiturienten examination, which closes the school life. It is difficult to compare this point of intellectual achievement with that of American schools. On the whole, it might correspond to the beginning of the junior year in the leading American universities or to the Bachelor's Degree in the smaller colleges of good reputation. Those German students who have not passed this examination can enter merely as special students, so-called Hörer, without the right to pass university examinations. Foreigners cannot pass State examinations at all; but they can be matriculated and attain the Doctor's Degree. The American Bachelor's Degree is, then, usually counted as substitute for the German school examination, and years of post-graduate work in such American institutions as belong to the American Association of universities are accredited to them to a certain extent.

The time of study toward the philosophical degree is nearly always four years; for the medical degree, five years. The unit of study is not the academic year but the half year, the semester, of which the one lasts from the middle of October to the beginning of March and the other from the middle of April to the beginning of August. The right of women to be matriculated dates from recent years only, and is not uniform throughout the different parts of Germany But every university now admits well-prepared women as special students.

The freedom of the student goes far beyond the American habit, and is not at all confined to complete freedom in the election of courses. He is not only not limited to a minimum or maximum number of courses, but the university also does not demand any kind of test for successful study in those courses. There are no course examinations, and, of course, no registration of attendance. The student is his own master and is expected to make just such use of his opportunity as befits his scholarly aims. No textbooks are prescribed in the courses; no questions are asked of the student and the final examinations have no reference to any particular courses. The majority of students change the university repeatedly, attracted by special great teachers, or by the special charms and facilities of a university town; this migration of students is one of the strongest ties which bind the States of the union together and make the German Empire an intellectual unity. But of course it works against that spirit of loyalty which binds American students toward a particular university. In the same direction works the fact that the graduates of a university have in Germany no further administrative connection with that particular place. That which binds many German students to their special Alma Mater for their whole life is rather their belonging to a special Corps or Burschenschaft or other social club.

The social life of the German student finds its characteristic expression in such club-like institutions, which have a strong intercollegiate affiliation. There is not and cannot be any class life comparable with the undergraduate departments of American universities, but these historical clubs furnish a large amount of particular academic feeling among the students. Those students who do not belong to them live, on the whole, like any private young gentleman. To live together in dormitories is unknown, and common academic occasions are somewhat rare; but the students of the fashionable Corps and of dozens of other clubs, with their colored ribbons and colored caps, dominate the social life so completely that they appear to the outsider as the only typical academic citizens. Their forms of social enjoyment can be understood merely historically. All the well-known excessive formalities in the regulation of beer-drinking and fencing and dueling are remainders of the 17th century and partly of earlier periods. Yet the overwhelming majority of the students spend their university years only for a limited time, or not at all, under the influence of these traditional forms of enjoyment. They are seriously working in pursuit of their earnest scholarly aims and in preparation for the difficult State examinations. Sport, beyond fencing, is on the whole little developed. It must not be forgotten that the year in the army, which is the real physical training for the German nation, falls into the university years of almost every student. Politics, too, plays a very small rôle in the academic body, while, to be sure, religious tendencies, especially Catholic and anti-Catholic movements with political character, have recently not seldom disturbed the peace of the student community.

The literature on German Universities is recorded in the recent work of Erman and Horn, 'Bibliographie der deutschen Universitäten' (Leipzig 1904). The first general part contains the references for 17,363 writings; the second part, referring to the special universities, contains 21,725 titles. The best books on German Universities are W. Lexis, 'Die Universitäten im Deutschen Reich' (Berlin 1904), and Friedrich Paulsen, 'Die deutschen Universitäten und das Universitätsstudium' (Berlin 1902).

Hugo Münsterberg,
Professor of Psychology, Harvard University.

15. **Germany — The German Army.** *Historical Outline.*—At the end of the 15th century the feudal system with its levies of tenants and vassals was in decay. The growing power of the princes, the rising spirit of the cities, the levies of foot soldiers able to contend against the knights, and especially the general introduction of firearms, accelerated the change. France organized companies of mounted orderlies which formed the first germ of a standing army.

The love of adventure and roving disposition of the Teutons was again manifested in extensive portions of the population. Armies arose composed largely of German and Swiss mercenaries. About this time Spain created a celebrated and powerful army; everywhere the feudal levy as a military force was being displaced by an army of hirelings.

The next century and a half formed a period of transition. At the time of the Thirty Years' War (1618–48) the armies generally consisted of mercenaries whose licentious character grew worse with the prolongation of the conflict. This condition continued to the time of the French Revolution. However, in nearly all European countries there existed a kind of militia, either as a survival of old institutions or as new creations.

In Brandenburg and Prussia the idea of recruiting the army from the people began to take form, and although it had many ups and downs, it was never entirely lost sight of. The Great Elector (1640–88) laid the foundation for the future greatness of Prussia by rigid economy in civil and military administration and by raising the national spirit of the Germans, which had fallen to a very low ebb. Recruitment at that time was largely from foreigners; he was the first to assign regiments to definite districts from which their recruits and reserves were to be drawn in time of war. The army was reorganized and the corps of officers placed on an efficient basis, foreigners being dismissed or naturalized. His son, as Frederick I., was crowned king of Prussia. He continued the policies of his father and established a militia for home defense. At the time of his death the Prussian army consisted of 18 regiments of infantry, 9 of cuirassiers, 5 of dragoons, and 9 organizations of guards.

Frederick William I., grandson of the Great Elector, entrusted Prince Leopold of Dessau, called the "Old Dessauer," with the organization of his military forces. The army was gradually augmented to 84,000 men. One of the king's caprices was a body guard of giants known as the Potsdam Guards. Rigid discipline, extreme accuracy of drill, and earnest performance of duty made the army not only fit for war but also gained the respect of the people. The corps of officers was selected from the nobility and carefully educated; it formed the mainstay of the forces of his successor who was to meet the armies of Europe and prevent the dismemberment of his country and the destruction of Protestantism on the continent. The system of sending the older and instructed soldiers on furlough was now introduced, and the king also formed four militia regiments for defense of the country.

When Frederick the Great came to the throne, in 1740, Prussia thus had an excellent army and a good system of recruitment which alone enabled him to keep up his forces under the strain of the Seven Years' War. The king was fortunate enough to inspire the army and the people with a strong national feeling and a degree of enthusiasm which accomplished wonders against the enormous odds organized by the coalition of Austria, France, and Russia.

At the end of the war the Prussian army stood without a peer in Europe. The king, while devoting himself principally to developing his country and building up material prosperity, increased his army, which retained its superiority in rapidity of mobilization and ability to maneuver. Abuses, however, crept in toward the end of the century and the spirit of the army departed with the death of the master mind which had astonished Europe by his victories. The hand of the giant of the French Revolution, of the great master of the art of war, with a national army, new methods of fighting, new and improved implements of war, and the strategy of the mass, destroyed the superannuated Prussian armies and humbled the state. By the treaty of Tilsit Prussia agreed to keep her army down to 42,000 men. Able men set to work to regenerate the army and to restore Prussia to her place among the great powers of Europe. The genius of Scharnhorst found a method of educating the youth of military age, at the same time keeping within the limits set by Napoleon. This was accomplished by discharging all recruits after one year's service and instruction. Many reforms were introduced and the Landwehr was established in 1813. In 1814 universal obligation to military service was adopted. Thus the armies under Blücher, Gneisanau, and York, in 1815, rose to 250,000 men.

In the long period of recuperation after the Napoleonic wars not many expensive changes could be made, owing to the condition of the finances. In 1859 the standing army consisted of 140,000 men. In the reorganization of 1860 the annual levy rose from 49,000 to 63,000. In the wars of 1864 and 1866 the Prussian army, with Landwehr organizations, brought 600,000 men under arms. For the second time in history the Prussian military system became the model for the armies of the world. Its organization utilized to the fullest extent the physical and intellectual powers of its people; its officers were highly educated, and progress in armament, instruction, and tactics had taken advantage of the most recent scientific discoveries. The people had come to look upon military service as a duty to the nation. After the formation of the North German Confederation and the enlargement of Prussia by the absorption of several German states, the organization, armament, and tactics of the Prussian army were extended to the entire North German army, and the South German States also adopted the Prussian system with some modifications. In the war of 1870–71, with France, the Germans were able to place much more than a million soldiers in the field.

On 18 Jan. 1871, the German Empire was proclaimed in the halls of Versailles. The standing army was by the law of 1874 fixed at 18 army corps, numbering in all over 400,000 men. The rapid growth of the German Empire in population and the desire to remain somewhat stronger than France led to continual increase of the annual contingent accepted for service. In 1899 the period of service for all men, except those of the cavalry and field artillery, was reduced to two years. As the result of constant development we have the German army of today — the most efficient fighting machine in the world. Only the essential details of its organization can be stated here.

Liability to Service and the System of Its Application.— Every male German is liable to military service. Only members of the ruling family and of mediatized princely houses are exempt. Evasion of service by means of substitutes is not permitted. The obligation to serve exists between the ages of 18 and 45 years, inclusive, and contemplates service either (1) in the Army or Navy, or (2) in the Landsturm.

Service in the Army begins at the end of the 20th year and terminates on the 31st of March of the calendar year in which the man completes his 39th year of age.

The first levy of the Landsturm consists of all men, from the end of the 17th year to the 31st of March of the calendar year in which they complete their 39th year, who have not served in the Army. The second levy of the Landsturm includes all men from the 39th to the end of the 45th year, whether they have served or not. The Landsturm is intended for home defense; in extraordinary cases it may be utilized to recruit the Army.

Service in the Army may be with the colors, followed by the Reserve and first and second levies of the Landwehr, or in the Ersatz Reserve. The periods of service are as follows:

	Cavalry and Horse Artillery.	All other arms of the service
With the colors	3	2
In the Reserve	4	5
In the Landwehr, 1st levy	3	5
In the Landwehr, 2nd levy (about)	9	7

Men in the reserve are simply on furlough and return to the colors when called for.

Volunteers of sufficient education who bear their own expenses are furloughed at the end of one year's service.

Volunteers serving four years in the Cavalry or Horse Artillery remain only three years in the second levy of the Landwehr.

Many soldiers of the Train are furloughed after serving one year or even less.

School teachers, apothecaries, and medical students have special reduction of service.

All the members of the annual contingents who are found fit for service and are not required with the colors are assigned to the Ersatz Reserve. Service therein is for 12 years, beginning 1 Oct. of the year in which the 20th year of age is completed. This reserve replaces the first vacancies in the standing army on mobilization and serves to form depot troops.

The annual contingents now taken for the Army are so large that the Ersatz Reserve, as formerly understood, has practically ceased to exist; no training with the colors is required in time of peace.

Officers and Noncommissioned Officers.— The officers are taken from the higher grades of society, that is, the nobility, sons of officers and officials, owners of estates, etc. Although the position of officers in the German Army is a distinguished one, they are not considered as forming a separate caste in society.

The corps of officers is recruited in two ways: (1) Through volunteers, now called *Fahnenjunker*, who join the ranks with a view to obtaining a commission; (2) through assignment of cadets.

All officers before being commissioned as second lieutenants of a regiment must be accepted by a vote of the officers of that regiment.

Officers of the Reserve are recruited from former one-year volunteers or from retired officers.

Officers of the Landwehr are taken from officers of the Reserve, from officers who have left the standing army, and from one-year volunteers and noncommissioned officers who on discharge are recommended for these positions.

Officers *at disposal* may be recalled to active service on mobilization.

The officers of the German Army are divided into grades as follows:

(1) Generals, including field marshals, colonel-generals, generals of infantry, cavalry, or artillery, lieutenant-generals and major-generals.

(2) Field officers: colonels, lieutenant-colonels, and majors.

(3) Captains; 1st and 2d class.

(4) Subalterns: 1st lieutenants and 2d lieutenants.

The noncommissioned officers are divided into two general classes. The first class are quasi-officers, wear officers' swords and correspond to our noncommissioned officers of the staff corps, first sergeants and quartermaster sergeants, and include candidates for a commission (*Fähnriche*). They are entitled to a salute from the other noncommissioned officers and men.

The second class correspond to our sergeants, corporals, and lance-corporals (*Gefreite*).

Numbers Available.— The peace strength (1900) is as follows:

Officers	23,844
Noncommissioned officers	80,556
Privates, lance-corporals, etc.	495,500
Volunteers	9,000
	608,900

The total number of trained men available (excluding Landsturm) is over 3,000,000. The number of men in the Ersatz Reserve and Landsturm is about 4,800,000, of whom 800,000 have been trained.

The number of young men annually reporting varies with the increase in population. The annual contingent of recruits changes with legislation, and had risen to 264,000 in 1897. When the law has had full time to operate, 24 years, about 4,500,000 trained soldiers will be available for war.

Men of the Reserve and Landwehr are called out for brief periods of training in accordance with the orders of the Emperor.

In time of war the Army is divided into (1) Field troops, (2) Field Reserve troops, (3) Landwehr troops, (4) Depot troops, and (5) Landsturm troops. The field troops consist of the standing army filled up by the reserves; the field reserve troops consist of the first levy of the Landwehr to which some officers and men are assigned from the active army. The Landwehr troops are formed from the second levy of the Landwehr; they usually serve on the line of communications. Depot troops are formed from the Ersatz Reserve and recruits. The Landsturm is for home defense and is called out by Imperial proclamation when required.

Organization.— The troops of the German Army in time of peace (1902) form —

625 battalions of infantry.
482 squadrons of cavalry.
574 batteries of field and horse artillery.
38 battalions of foot artillery.
26 battalions of pioneers.
8 battalions of railway troops.
3 battalions of telegraph troops.
23 battalions of train troops.

These are combined into Army Corps which are assigned to territorial districts with headquarters as follows:

Guard Corps	Berlin.
I.	East Prussia, Konigsberg.
II.	Pomerania, Stettin.
III.	Brandenburg, Berlin.
IV.	Prussian Saxony, Magdeburg.
V.	Lower Silesia, Posen.
VI.	Silesia, Breslau.
VII.	Westphalia, Munster.
VIII.	Rhineland, Coblenz.
IX.	Schleswig-Holstein and Mecklenburg, Altona.
X.	Hanover, Oldenburg, Brunswick, etc., Hanover.
XI.	Thuringia and Nassau, Cassel.
XII.	Saxony, Dresden.
XIII.	Wurttemberg, Stuttgart.
XIV.	Baden, Karlsruhe.
XV.	Alsace, Strassburg.
XVI.	Lorraine, Metz.
XVII.	West Prussia, Dantzig.
XVIII.	Hesse-Nassau, Frankfort-on-the-Main.
XIX.	Saxony, Leipzig.
I.	Bavarian, Munich.
II.	Bavarian, Wurzburg.
III.	Bavarian, Nurnberg.

The field army is divided into armies. The number and composition of the armies is kept secret, but it may be assumed that in a large war there will be four or five armies, each composed of from three to six army corps, several cavalry divisions and a variable number of reserve divisions.

Details of Organization.— The strength of units varies both in officers and men; those on the frontiers have a somewhat higher peace establishment than the normal given below.

Infantry units.	Peace.				War.					
	Officers.	Medical officers and officials.	Enlisted men.	Horses.	Officers.	Medical officers and officials.	Enlisted men.	Non-combatants.	Horses.	Wagons.
Company .	4	....	142	1	5	..	250	5	8	3
Battalion..	18	3	570	7	22	4	1,002	29	46	15
Regiment.	57	12	1,768	28	68	12	3,017	93	149	46
Brigade...	116	24	3,536	64	138	24	6,037	193	312	93

There are 11 Guard, 155 Prussian, 16 Saxon, 10 Württemberg, and 24 Bavarian Infantry Regiments.

There are also 18 battalions of Rifles (Jäger). In their strength and organization they closely resemble infantry.

Cavalry units.	Peace.				War.					
Squadron .	5	....	135	149	5	...	150	11	175	3
Regiment .	25	12	687	667	22	...	602	61	741	17
Brigade ...	...	...	...	...	48	18	1,206	135	1,496	35

Cavalry regiments have five squadrons in peace and only four in war, one being left as a depot. They are classified as follows:

Prussia (73 regiments.)— Ten cuirassiers (2 of the Guard); 26 dragoons (2 of the Guard); 18 hussars (1 of the Guard); 19 lancers (3 of the Guard); 5 squadrons Jäger zu Pferde.

Saxony (6 regiments).— Two heavy cavalry (1 of the Guard); 2 hussars; 2 lancers; 1 squadron Jäger zu Pferde.

Württemberg (4 regiments).— Two dragoons; 2 lancers.

Bavaria (10 regiments).— Two heavy cavalry; 2 lancers; 6 light horse.

Field Artillery.

War Strength.	Officers.	Men.	Horses.	Guns.	Caissons.	Store Wagons.	Provision Wagons.	Forage Wagons.
Horse batteries (42), each	5	157	218	6	6	2	1	1
Field Batteries (532), each	5	162	132	6	6	2	1	1

Two or three batteries form a battalion; two or three battalions a regiment, and two regiments a brigade.

Foot Artillery.— There are 149 batteries of foot artillery, organized into battalions and regiments. War strength of battery: 4 officers, 209 men. Armament: various calibers of siege, position, and coast-defense artillery.

Technical Troops — Pioneers.— Each Army Corps has a battalion of pioneers (4 companies); three of the corps have two battalions each. Each company has 4 officers and 154 men in peace, 6 officers and 200 men in war.

Cavalry divisions have pioneer detachments of 1 officer and 30 men.

Railway Troops.— There are 7 battalions of railway troops (4 companies each). A company consists of 5 officers and 151 men. In time of war the companies are expanded into construction companies, operating companies, and companies of laborers.

The Train.— In time of peace there are 23 skeleton battalions of the train, one for each army crops. In time of war these are expanded so that each provides transport for 6 provision columns, 7 wagon park columns, 1 field bakery column, 3 bearer companies, 1 horse depot, 1 reserve bakery column, and 1 reserve column for line of communications.

Medical Units.— There is one bearer company for each division and an additional one for each army corps. Each company has 3 officers, 8 medical officers, 2 officials, 39 men of the train and 210 bearers, nurses, etc., with 46 horses and 13 vehicles.

The Infantry Division.— This unit consists of: The staff of the Division; 2 brigades of infantry; 2 or 3 squadrons of cavalry; 1 brigade of field artillery; 1 or 2 companies of pioneers; 1 divisional brigade train; 1 bearer company.

Its fighting strength is 12,000 rifles, 300 to 450 lances, and 72 guns.

The Cavalry Division.— As a rule it consists of: The staff of the Division: 3 brigades of cavalry; 2 batteries of horse artillery with light ammunition column: 1 pioneer detachment.

Its fighting strength is 3,600 lances, 30 rifles, and 12 guns.

The Army Corps.— This unit forms a small army complete in all its parts. It is composed of: The staff of the Army Corps; 2 infantry divisions; 1 battalion of rifles; 1 telegraph section, and the corps trains.

Fighting strength — 25,000 rifles, 900 lances, and 144 guns.

Arms and Equipment — Infantry and Pioneers.— Magazine rifle, model 1898, caliber 7.9

mm. Ammunition: 120 cartridges on the person, 72 in the company wagon, a reserve in the ammunition column, total, about 300 rounds per man. Bayonet (*Seitengewehr*) new model.

Equipped for the field each soldier carries a pack (*tornister*) and in its compartments or attached thereto the following articles: 1 shelter tent and three-jointed pole; 1 pair of lace shoes; cleaning, polishing, washing, and sewing materials; 1 pair of stockings or foot cloths; 1 handkerchief; 1 shirt; 1 pair of drawers; 1 cap; 1 cooking utensil (of aluminum) with one ration; three iron rations; 1 handbook; and 1 song book.

The soldier also carries a felt-covered canteen of aluminum and a haversack containing 1 helmet cover, 1 knife, 1 fork, 1 spoon, and one ration of bread (26 2/5 oz.) for the journey by rail.

The overcoat and shelter tent in a roll surround the pack. The total load, including clothing on the person, arms and ammunition, is 58 3/4 lbs.

Cavalry.— The weapons of the German cavalry are (1) the lance, which is a hollow steel shaft 10 feet 6 inches long; (2) the cavalry sword or saber; and (3) the carbine, which is simply a short rifle and uses infantry ammunition. Officers and noncommissioned officers carry saber and revolver.

Artillery.—The field and horse batteries have the rapid-fire field gun of nickel steel, caliber 7.7 cm. The howitzer batteries have the field howitzer, model 1898, caliber 10.5 cm. Officers and mounted men carry swords and revolvers; men on foot carry sword bayonets and revolvers — in the ammunition columns, carbines and sword bayonets. The foot artillery have guns of various calibers, 3.7 cm to 21 cm, depending upon whether they belong to siege, fortress, or coast-defense artillery. The men were armed with carbine and sword bayonet.

Uniform.— The uniform of the German soldier is required to conform in cut and general appearance to that of the Prussian army.

Infantry.— Dark blue tunic, with scarlet trimmings; dark blue blouse (litewka); dark grey trousers with red piping; light grey overcoat; black leather helmet, with ornaments; short boots. The 108th (Saxon) regiment and the rifles wear dark green tunics; the Bavarians, light blue tunics.

Artillery.—General appearance of uniform, same as infantry; cuffs are black.

Cavalry.—Cuirassiers, white; dragoons, light blue; lancers, dark blue; hussars, various colors.

The combinations of colors in cuffs, collars, pipings, belts, plumes, etc., are so numerous on account of regimental traditions and the colors and coats of arms of the many minor states forming the empire, that recourse must be had to books of reference for detailed information.

Bibliography.— Deutschland, 'Die Heere und Flotten der Gegenwart' (1903); Edmonds, 'Handbook of the German Army' (1900); Lehnert's, 'Handbuch für den Truppenführer'; Drill Regulations of the different arms and other service manuals. J. T. Dickman,
Captain, General Staff U. S. A.

16. **Germany — The German Navy.** *Historical Outline.*— In the latter part of the 17th century, after the Thirty Years' War, the state of Brandenburg started a small fleet with three Dutch ships hired for operations against the Swedes in the Baltic. This was eventually increased to 12 ships; but later it fell into decay, and after the death of the Great Elector, disappeared entirely. Frederick the Great also maintained for a time some armed vessels for use against Sweden, but for over a century Germany was not represented on the high seas by a navy. In the early part of the 19th century numerous recommendations and projects were put forward, but nothing substantial resulted therefrom. In 1825 the first small gunboat was launched. In 1835 the Prussian government declared its determination to protect the Baltic shore, and a commission arranged for the establishment of a small coast fleet. The Amazone, acquired in 1841, may be regarded as the first coast defense vessel.

In 1848 a Danish fleet blockaded the ports and inflicted considerable damage on German commerce. In consequence, a small "Parliamentary" fleet was established, but afterward merged with the Prussian fleet organized at the same time. This fleet in 1864 fought the Danes at Jasmund, preventing a blockade of the German coasts. On the termination of the war it became the fleet of the North German Confederation. Construction under a program for a large increase had hardly begun when war broke out with France. The fleet then consisted of 37 ships, all told, of which only five were armored; it was limited to a purely defensive attitude during that war.

Under the empire, the fleet became the Imperial German Navy; its growth was slow but steady. A systematic scheme for obtaining a large fleet was not worked out until 1897, and adopted by the Reichstag in 1898. This plan was enlarged by the law of 1900, which provided for two double squadrons, each to consist of 17 battleships (one flagship and two squadrons of eight ships grouped in two divisions), four large and twelve small cruisers, and 40 destroyers (divided into eight flotillas). By 1920 the German fleet will consist of:

	Battleships.	Armored Cruisers.	Small cruisers (as scouts).	Destroyers.
Two double squadrons for home service	34	8	24	80
For foreign service	......	3	10	......
In reserve	4	3	......	16
Total	38	14	34	96

An important feature of the law stipulated that substitutes were to be laid down for old ships to be discarded on the age basis of 25 years for battleships and coast defense vessels, 20 years for large cruisers, and 15 years for small cruisers.

The development of the German Navy will continue to be a rapid one, the construction from 1901 to 1917 being on an average of nearly 2 battleships, 1 large cruiser, 2 small cruisers, and 6 destroyers for each year.

Present Strength.— The following is a list of the effective ships of the German Navy, 1 Jan. 1905:

BATTLESHIPS (35).

1st Class (22).

	Displacement.
"P"	12,992
"O"	12,992
Deutschland	12,992
Lothringen	12,992
Preussen	12,992
Hessen	12,992
Elsass	12,992
Braunschweig	12,992
Mecklenburg	11,613
Schwaben	11,613
Zähringen	11,613
Wettin	11,613
Wittelsbach	11,613
Kaiser Barbarossa	10,976
Kaiser Karl der Grosse	10,976
Kaiser Wilhelm der Grosse	10,976
Kaiser Wilhelm II	10,976
Kaiser Friedrich III	10,976
Wörth	9,874
Brandenburg	9,874
Kurfürst Friedrich Wilhelm	9,874
Weissenburg	9,874

2nd Class (5).

	Displacement.
Oldenburg	5,140
Baden	7,252
Württemberg	7,252
Sachsen	7,252
Bayern	7,252

3d Class (8).

Coast-Defense Ships.

	Displacement.
Hagen	4,049
Heimdal	4,049
Hildebrand	4,049
Odin	4,084
Aegir	4,084
Frithjof	4,049
Beowulf	4,049
Siegfried	4,049

Average age, counting from year in which laid down, 1st class, 7 years; 2d class, 28 years; 3d class, 12½ years.

ARMORED CRUISERS (7).

	Displacement.
"C"	11,319
Yorck	9,350
Roon	9,350
Friedrich Carl	8,858
Prinz Adalbert	8,858
Prinz Heinrich	8,759
Fürst Bismarck	10,570

Average age, 14 years.

PROTECTED CRUISERS (6).

	Displacement.
Hansa	5,791
Vineta	5,791
Freya	5,569
Hertha	5,569
Victoria Luise	5,569
Kaiserin Augusta	5,960

Average age, 10½ years.

SMALL CRUISERS (35).

Protected (24).

	Displacement.
Leipzig	3,200
Alexandrine	3,200
Meteor	3,200
München	3,200
Lübeck	3,200
Berlin	3,200
Hamburg	3,200
Bremen	3,200
Undine	2,657
Arcona	2,657
Frauenlob	2,657
Modusa	2,618
Amazone	2,618
Ariadne	2,618
Thetis	2,618
Nymphe	2,618
Niobe	2,603
Gazelle	2,603
Hela	2,004
Gefion	3,705
Comet	971
Prinzess Wilhelm	4,224
Irene	4,224
Jagd	1,230

Average age, 6 years.

With the exception of battleships of the second class, the Imperial German Navy may be considered as practically new.

Personnel.— The officers consist of:

1. Admiral of the Fleet (Gross-Admiral), namely, the Kaiser.

2. Twenty-seven flag officers,—5 Admirals (Admirale); 6 Vice-Admirals (Vize-Admirale); 16 Rear-Admirals (Kontre-Admirale).

3. Five hundred and fourteen staff officers,—67 Captains (Kapitäne zur See); 447 Commanders (Fregatten-Kapitäne) and Lieutenant-Commanders (Korvetten-Kapitäne).

4. Eight hundred and eighty-three Senior Lieutenants, Lieutenants, and Sub-Lieutenants (Kapitän-Leutnants, over eight years' service; Ober-Leutnants zur See, less than eight years' service; Leutnants zur See).

The entire naval personnel in 1905 consisted of 1832 officers, 208 doctors, 271 paymasters, 1762 warrant officers, 8461 petty officers, 27,302 seamen, 1109 ships' boys; aggregate 2311 officers and officials, and 38,632 men.

The officers are drawn from the naval cadets, the latter being selected from young men of approved origin and education. The recruits are taken from sailors, fishermen, sailmakers, ships' stewards, cooks, and waiters; also from men employed on rivers and canals, and from non-seafaring people, such as firemen, machinists, painters, etc.

The period of duty is divided into the active period and the furlough period. The active period is for three years; the furlough period is divided as follows:

Reserve	4 years.
Seewehr,— corresponding to Landwehr:	
1st Levy	5 years.
2d Levy	To end of 39th year.
Naval Ersatz (Supernumeraries) men of seafaring or quasi-seafaring population	12 years.

In extraordinary cases use is made of the Landsturm — same as in the Army — all seafaring and river people not in the Navy; first levy, 17th to 39th year; second levy, 39th to 45th year.

Bibliography.— Ferber, 'Organization und Dienstbetrieb der Kaiserlichen Marine'; Brassey, 'The Naval Annual'; Jane, 'Fighting Ships, 1905-6.'

Captain, General Staff, U. S. Army.

17. Germany — Agriculture and Forestry. At the last German Census of trades and callings (1895) the number of persons engaged chiefly in agriculture and forestry was 8,300,000, or about 37½ per cent of the total productive population. This is about the same percentage shown by the U. S. census of 1900, which was 35.9 per cent; but this latter figure would be increased by the large number of land labourers counted simply as laborers. At the same census of 1895 the number of individual agricultural undertakings was 5,500,000, with an area of 43,-200,000 hectares (1 hectare = 2½ acres). Of this total "agricultural" area 7,600,000 hectares are woods, to which must be added 6,100,000 hectares of timber-land devoted purely to forestry. The greater part of the forests, about 7,000,000 hectares, is in the possession of the German states, especially Prussia and Bavaria, and of the local parishes and municipalities; though many forests are owned by large landed proprietors and by private foundations and associations. In strong contrast to the primitive forestry conditions that prevail in the United States, German forests, usually even those owned privately, are nurtured with all the care that the highly developed technic of forestry has made possible, the period of cultivation not seldom being 100 years. In this way 11,000,000 hectares were devoted to the cultivation of high timber, *i. e.*, 2,600,000 hectares to leaf-bearing trees, 8,400,000 hectares to pines and firs. The yield of lumber in 1900 was 20,000,000, of firewood, 18,000,000, of stumps and brushwood, 10,-500,000 cubic meters, besides the byproducts, especially tan-bark. Yet this yield does not supply the demand for wood in Germany. In 1904 lumber and building timber were imported to the extent of $20,000,000.

Division of Land and Kinds of Production.— Of the total agricultural area in 1904, 26 per cent was woodland, 49 per cent arable land, including gardens and vineyards, 11 per cent meadows, and five per cent pasture-land. Of the arable land, 61 per cent was planted with grain and leguminous crops, 17½ per cent with chopped crops, especially with potatoes and sugar-beets, 10 per cent with forage, 2.6 per cent with fruit and garden vegetables, and 8.7 per cent remained fallow. As regards grain, the dependence of Germany on foreign imports has not increased essentially in recent years. At times it has even decreased. On an average the yearly imports of grain exceed the exports by 2,000,000,000 kilograms, worth $125,000,000; *i. e.*, as to value, about 1-6 or 1-7 of the German yield, or, as to quantity, about 1-5. In live stock, Germany imports horses, oxen, and cows for $45,000,000; also hogs, but to a limited extent, owing to the restrictive hygienic (in reality protective) measures; further, hides and guts. On account of the ever-increasing intensity in the cultivation of the soil, the number of sheep in Germany has decreased from 28,000,000 in 1860 to 9,700,000 at present (U. S. 62,000,000). On the other hand, from 1873 to 1900 the number of horses increased from 3,300,000 to 4,200,000 (U. S. 16,000,000), the number of cattle from 15,700,000 to 19,000,000 (U. S. 61,400,000), and the number of hogs from 7,000,000 to 17,000,000 (U. S. 48,600,000). In 1900 for every 100 inhabitants there were 7.5 horses (U. S. 22), 33.6 head of cattle (U. S. 81), and 30 hogs (U. S. 82). From the high and increasing prices of land alone one could infer that in Germany there has been a considerably greater increase in weight and quantity than in quality. In 1900 the sale-value of horses was $575,000,000, of cattle more than $1,000,000,000, and of hogs, $250,-000,000. As to the number of horses and cattle per hectare, Germany and England are about equal; but Germany is far ahead in hogs, and England in sheep. In all these categories, except sheep, Germany is ahead of France.

Of the great staple side-products of German agriculture, sugar and alcohol are by far the most important. Sugar-beets utilize the best German soils, while Irish potatoes for spirits make profitable the cultivation of the worst, especially the sandy soils in east Germany. In the form of alcohol the bulky crop, which could not be shipped profitably, is made easily transportable, and thus this soil is brought into cultivation. Both these industries have been nurtured up to their present importance by certain protective measures, and have been kept in immediate connection with the production of the raw material. Alcohol-distilleries owned by farmers, especially the smaller ones, have been favored in the way of taxation. Such a distillery is allowed to produce a certain fixed quantity of alcohol on the payment of the minimum of revenue. Accordingly, of the 13,200 grain and potato distilleries in Germany in 1900 there were less than a thousand that were not owned by farmers. Besides both industries are strongly organized into trade unions — ("Kartellē"). The total product of all alcohol distilleries in 1903–1904 amounted to 3,850,000 hectoliters of pure alcohol, of which 3,330,000 was distilled from grain and Irish potatoes. Of potatoes, 2,660,000,000 kilograms were used; of grain, 380,000,000 kilograms.

The total yield of Irish potatoes in Germany in 1904 was 36,330,000,000 kilograms. As a food-product, potatoes play a larger part in Germany than anywhere else; and in the production of potatoes Germany trebles the United States and is equaled only by Russia. Sweet potatoes are not raised in Germany. As to other products, the German climate prohibits the production of cotton and, practically, of Indian corn. The cultivation of tropical fruits is likewise excluded. As to other fruits, Germany and the United States are favored, each for special sorts. In the cultivation of grapes, for fine wines, Germany has a considerable advantage, owing to the age of this industry and the care that has been bestowed upon it. Of the world's total yield of grain, (wheat, rye, barley, oats) in 1903, which was estimated at 285,000,000,000 kilograms, Germany produced 24,500,000,000 kilograms, the United States 91,100,000,000 kilograms, or three and seven-tenths times as much as Germany. However, it is claimed that the estimate for Germany is too low. In 1903 Germany had 1,800,000 hectares in wheat, less than one-eleventh as much as the United States had; though the yield in the latter country was only four and eight-tenths times greater. In 1903 the yield of wheat per hectare in Germany was 1650 kilograms (U. S. 850 kilograms), in 1902 it was 1540; and in 1904 it was again 1650. On the better soils the average yield is often more than double this amount. The yield of rye was 10,-000,000,000 kilograms (U. S. 750,000,000 kilograms); of barley 3,300,000,000 kilograms (U. S. 3,000,000,000); and of oats 7,900,000,000 kilograms (U. S. 12,400,000,000). The money value of the American yield of 1903 is estimated at $1,740,000,000 (1902: $1,720,000,000), *i. e.*, only somewhat more than double the value of the German yield, if we apply here the same method of valuation. This is explained by the fact that for grain Germany is import-territory, and especially by the fact of the agrarian protective tariff.

Land Holdings and Indebtedness.— The superiority of Germany as regards the yield of grain per hectare is due to the more intensive cultivation of the soil, and particularly to the more general use of fertilizers. In this respect Germany would be even further ahead, if the size of the farms had been developed from a technical point of view, as has been the case in England and America. In contrast to the American farmer, who lives isolated in the midst of his broad acres, from time immemorial the small German husbandman has been a villager. This custom of settling in villages has perpetuated a system of piece-meal farming in Germany, which makes impossible the most economic utilization of the soil. On the other hand, large landed proprietors are not infrequently prevented from disposing of superfluous and outlying land by mortgages held on their estates; or their property may be entailed. In contrast to such estates as are too large to be farmed profitably, on account of the lack of capital on the part of their aristocratic owners, there is a very much larger class of holdings which are too small to permit the use of machinery. Both kinds, which are of impracticable size, diminish the average yield. This is especially true of the peasant-farms. But both classes show no inclination to adapt themselves to economic conditions,— the first, because their owners believe their social position of their family is determined by the limits of their real estate; the second, partly because of the usually equal division of land among the heirs, on the death of an incumbent, as opposed to the English common law, partly because the desire to be independent of the uncertainty of wages makes these small owners hold their land with great tenacity and even acquire more when this is possible, because in this way they have an opportunity to enjoy the fruits of their labor, of which no one can deprive them. From a business point of view, such piece-meal farming is unprofitable, but since practically no new land is to be had, except by reclaiming moors and swamps at great expense, this demand for small farms has run up the price very considerably. After deducting for wages and expenses even the larger farms net their owners only from one and one-half to two and one-half per cent. On account of the high price of land, the indebtedness is large. This has also been largely increased by the very favorable German laws regulating mortgages, which have, in fact, made mortgages one of the safest forms of investment. Consequently, credit is easy; and there are a number of public and private mortgage-banks, which lend money on real estate, up to a fixed part of its assessed valuation. These mortgages have a regular negotiable form and are handled on the stock exchange. On first mortgages the rate is low, being always under four per cent. Many of these mortgage-banks will liquidate the indebtedness in consideration of the payment of an additional interest; and recently the suggestion has been made to meet in this way also a life insurance premium, so that on the death of the debtor the obligation ceases. The total amount of such mortgage-indebtedness in Germany has not been determined statistically. The most recent assessments in Prussia, for purposes of taxation, show that here the indebtedness of those engaged chiefly in farming amounts to 26.4 per cent of their entire property, real and personal, and to 31.1 per cent of the value of their realty. Further, farms and parcels of agricultural land have been classified and graduated according to extent and yield; and on this basis it has been found that an indebtedness of 18.6 per cent in case of the small parcels averaging eight hectares each, increases to 33.1 per cent and more, in the case of the large rural estates. This is accounted for largely by the fact that such large holdings are regarded as a luxury and are subject to frequent transfer. In the northeast of Prussia, where there are few industries, in one district the indebtedness runs up to from 53 to 58 per cent, on an average, for all classes of freeholders; and in the Königsberg district the indebtedness of the second largest class of holdings (200 hectares average) is 67.3 per cent (entire property) and 73.5 per cent (real p.). In the district of Coblenz, Rhine, where small holdings are the custom, the indebtedness sinks as low as 2.4 per cent of the entire, 2.9 of the real estate. This is due to the fact that small lots, not offering a suitable opportunity for investment, are sold for cash. In Hanover and Westphalia, where holdings are of moderate size, the indebtedness fluctuates from 14 to 15 per cent (and from 23 to 28 per cent of real property). So far as there are any reliable statistics on these matters for America, it would seem that those farmers in the grain-states, for instance Nebraska, who have bought their land privately, instead of from the state, are more heavily in debt than the average German farmer, certainly than the small German farmer. But there is this difference: The failure of a German farmer means a much greater catastrophe than the failure of an American farmer. In the first place, there is proportionately more capital invested in buildings and equipment, and a failure involves a greater number of creditors. In the second place, class distinctions are rigid in Germany; there is a sharp differentiation between town and country, between farming and business. When the German farmer fails, there is nothing else for him to do. As compared with American conditions, the large amount of capital invested in buildings, as barns, sheds, etc., is especially noteworthy. This fact is explained by the climate and the more highly developed condition of the country. Despite the high price of land and the relatively backward condition of east Germany, the value of buildings in the extreme east is from 30 to 50 per cent of the value of the property; and even in the case of large estates the incumbrance of buildings amounts to from \$60 to \$75 per hectare of land, occasionally as much as \$175 per hectare (in England under \$50). In the east the value of tools and implements per hectare is only about \$12; in the west and southwest as much as \$65. In east Prussia the value of live stock per hectare varies from \$15 to \$100 for the different classes of farms; though of course in the case of regular stock-farms the figures are larger. In a large number of cases observed in east Germany the investment was, on an average, apportioned as follows: Land 49 per cent, buildings 24 per cent, live stock 13.6 per cent, tools, implements, etc., 4.4 per cent, supplies 9 per cent.

Considering the climate, the possible relations would be about thus: Land 30 per cent, buildings 23 per cent, live stock 20 per cent, tools, machinery, etc., 12 per cent, supplies 15 per cent. Deviations from this form are due to those social conditions which diminish the working capital by running up the cost of the land and of the dwelling-house.

Rotation in Crops.— On account of the exceedingly varied and manifold system of rotation in crops, it is impossible to lay down any universal principles regarding this feature of agriculture in Germany. On the best soils, i. e., in middle and western Germany, there is free succession in crops; but on many large estates in the east field-grass farming is the rule (Feldgraswirtschaft); but this is greatly modified and complicated by the cultivation of potatoes and sugar-beets. Stock-farms, pure and simple, are possible only here and there. The sowing of grain on the same land year after year, as it is done on the virgin soils of America, is regarded as a sort of agricultural robbery, and is practised only by farmers in reduced circumstances. For the rest, the living-conditions of the German husbandman are in many respects quite different from those of the American farmer:

Taxation.— In most of the German states, the old state tax on realty has been turned over to the local parishes and municipalities, and this has lightened greatly for the farmer the burden of taxation. For instance, a small husbandman in Prussia (which has assumed a very considerable part of the expenses of schools for the local communities pays to the state one-half per mille on his property and three per cent of his income. To this must be added the taxes for the parish, district, and province. As compared with an American farmer in a grain state, the total taxes of a German farmer are much lower, principally because the American method of taxation places a much heavier burden on realty.

Railways: In this connection the German system of state railways deserves mention. These not only surpass the American lines in cheapness and effectiveness of service, meeting especially the needs of the large middle class, but their management warrants a permanent and uniform tariff policy. A system of district railway councils makes possible the adaptation of the service to the needs of all interests.

Insurance (fire, hail, cattle): More than one-third of the fire insurance in Germany is in the hands of public societies ($12,000,000,000 against $23,500,000,000 in private companies), and is largely compulsory insurance. The advantage of this is that risks which are not first-class find a relatively cheap opportunity for insurance. Insurance against hail (about $625,000,000) is mostly mutual (about two-thirds), but has not yet become general by any means. There is also compulsory insurance against certain epidemics in cattle; but for the rest insurance on live stock is mostly local and mutual.

Agricultural Associations.—Next to Denmark Germany has the most highly developed system of agricultural associations, or alliances. The most important form, and the first to appear in Germany, is that created by Raiffeisen. The Schulze-Delitzsch system also plays a considerable part. Of such societies there are more than 23,000, with a membership of about 3,500,000. There are 4,200 credit-societies, with 2,000,000 members, for the purpose of securing credit otherwise than on mortgages; 1,600 for the mutual buying of raw materials; more than 3,000 for mutual production, the most important being the creamery associations (2,700, with 200,000 members); and the associations for pressing grapes, with a membership of 10,000. The system of credit-associations created by Raiffeisen, though somewhat variable, depends in general on the payment by the member of a relatively small amount in cash (under $2.50 in almost half of the associations), and the assumption on his part of the obligation to pay further sums in case of necessity, such sums being either unlimited or else fixed by a maximum, or to furnish security to the creditors for the said amount. Of a total membership of 3,500,000 the obligation is unlimited for 1,750,000. Loans are made to the members on notes, and the safety of the transaction depends mostly on the personal knowledge the cashier has of the financial responsibility of the members. He is often a preacher or a teacher, and his position is usually an honorary one. Accordingly, all these associations are in small districts, being usually limited to a single village. Still, they are combined into larger unions to make their cash money more elastic, in that thereby the surplus of one association is used to fill the deficit of another. Such organization also makes possible the mutual inspection of books. Recently the Prussian government has formed a special department for credit-associations and has provided capital to be lent to such associations, at a low rate of interest, after an investigation of their financial responsibility has been made.

The Economic Structure.— The economic structure of agricultural Germany, with this mixture of self-reliance, co-operative societies, and state aid, forms an artificial and perhaps complicated system; but only such a system has made it possible for Germany to achieve such conspicuous success in the face of the manifest great disadvantage of the country, as compared with most other lands, in the matter of climate and soil, and in the irrational manner in which land has been cut up. What has been achieved has been the result of hard conscientious work, supported from the technical side by the agricultural academies and higher institutions of learning, by the agricultural schools (22), with courses of study extending over several years, by the winter schools for agriculture (128), and by the finishing schools (about 3,000). This splendid technical education, however, does not imply any particular business qualities. The German farmer of small, or even moderate, means cannot be chiefly a business man, like the American farmer; because for him there is no chance of speculative gains. On the other hand, the large landed proprietor does not want to be a business man, because he belongs to the privileged class: if his superior social position is no longer secured by law, as formerly, it is none the less a fact. This class has just begun to develop in America. In order to understand these facts and their bearing on the peculiar political conditions in Germany, it is necessary to take a glance at the social structure of the country population. While on the one hand England, with her large country estates, where landlord and renter are sharply distinguished from the farm-hand, is the typical land of aristocratic ownership, France on the other hand, with her great number of miniature farms, where landlord and farm-hand are one, is the typical land of democracy as regards the distribution of farm-lands.

Now, in this respect, Germany shows characteristic antitheses. Of the total number of individual farming industries in Germany 58 per cent have an area of less than two hectares, and only nine-twentieths per cent have more than 100 hectares. But these last cover almost one-fourth of the total area. While east of the River Elbe farms of 100 hectares each, or more, cover 44 per cent of the area, in the Rhine country they seldom cover five per cent. (On account of the lack of a uniform basis in the statistics, it is impossible to make any comparison with the corresponding conditions in America.) West and southwest Germany resemble France in the matter of agricultural holdings and social conditions. Farming-lands are cut up into fragments, which are usually further divided in succession by inheritance, and farms, as a rule, have a small extent; social inequalities within the country population are slight; and the distinction between the country and the town population is also slight. For the rest, the rural population is very dense, and agricultural products are of the most varied nature. On the other hand, east of the Elbe and the Saale large estates and large farming industries are the rule. Owners of manor estates, or "Rittergüter" (which are mostly separated from the village communities and administered by the lord of the manor) are engaged chiefly in raising grain and feeding cattle. Only about half of them belong to the nobility; but the important part they play in local political bodies in the east, and in the Prussian House of Lords, and, together with the Clericals, in the Prussian Diet (which is elected by the three-class system of voting), explains the domination of Prussia by this feudal class. They furnish the army its officers, as did once the planters in the southern states of the United States. Their views dominate officialdom and diplomacy. In the past they were indispensable to the Prussian state, because they provided military and civil administration at the least expense. Even till now it is this historical rôle that assures them their preponderating influence in the Prussian government. These large land-owners have dwelling-houses for their workmen, who, with their families, are under contract, usually for a year. In consideration for their work they receive: A house, with garden, and sometimes a strip of land; a part of the yield of grain, or a certain fixed allowance; also fire-wood, and the right to graze a cow on the pasture; and finally a small cash-wage. This class of laborers, which forms a mean between the small peasantry and the proletarians, begins recently to be pushed away by laborers from Russia and Galicia. These last are crowded into large sleeping-houses and are dismissed after the harvest. On account of the specialization in the cultivation of sugar-beets, farming has come to be more and more a matter of a short season. The work is compressed into a few months; and it no longer pays to keep a large force of farm-hands the year round. Thus the workmen become proletarians, just as in the manufacturing industries. The powerful attraction of the cities and of the high wages paid in the industries, and also, in many cases, the prospect of becoming independent in some foreign country, make the strongest appeal to farm-hands on the large estates in east Prussia, just where the population is thinnest. Naturally, this has increased the price of farm-labor; and the effect upon smaller farmers has been to cause them to limit their farming in such a way as to be able to do all their own work and thus make themselves independent of the labor-market. The competition of foreign grain has had a similar effect on production. In seeking to make themselves independent of the grain-market farmers have cut down their production of grain to an amount not much in excess of their own needs. These conditions, and the fact of division of land in succession by inheritance, caused an increase in the number of small peasant holdings at the expense of the larger and medium-sized farms. In this way, in the east, the number of small Polish farmers has multiplied. Their mode of life is so simple that they require only the smallest area. On the other hand, the large landed proprietors have been driven over to the side of protection. They brought about the great change from liberalism to protection and conservatism in 1878; and without them a majority for protection would be impossible in the German Reichstag. In connection with the rapid growth of capital of the country the agrarian crisis also manifests itself in the increasing number of enfeoffments in trust. Such entailed estates cannot incur debt and cannot be sold outside of the family; and there is the further proviso that they must pass to a single heir, usually the eldest son. In Prussia these estates cover about one-sixteenth of the area of the state and are half woodland. An increasing part of them represent complexes of land that have been bought up by men of wealth, who, for securing some title of nobility, have entailed the land in this manner. It is the same development that has crowded out the old resident squire in England, who corresponded to the German "Junker," and placed the landlord, a renter, in his stead — a development that America will not escape. Such large monoplies of land make possible, in the form of a lease, the separation of ownership from management and secure an elasticity against crises that is impossible for a capitalist farming his own land, especially in a country where the population is increasing and land becoming more expensive. Such an owner has to expend all his capital in buying land, or perhaps in paying off the claims of other heirs, or in paying interest on such claims. Thus, the agricultural development of Germany seems to tend, on the one hand, toward a multiplication of the smallest peasant holdings, and, on the other hand, toward an increase in the number of large monopolistic holdings.

The present government, which is strongly under the influence of the agrarian and related interests, has in view a change in the right of inheritance, intending to decrease the portions of the younger heirs, to fix a legal limit to indebtedness, and to provide for the liquidation of such indebtedness with the co-operation of the state. The change of the rules concerning the valuation of real estates in cases of inheritance might be a useful provision; but it would be of no basal significance. If the attempt to limit indebtedness by law did not prove an economic impossibility, it would only increase the buying up of land by monopolists, especially as the formation of enfeoffments is at the same time to be made easier. This last measure is in open contradiction to the plan of inner colonisation, which Prussia especially has taken up in a large way. On the one hand, the government would like to increase the number of the country population, and on the other secure stability of ownership without servitude to debt, and at the same time make Germany independent of foreign countries in the matter of food-stuffs. But it must be recognized that a reconciliation of these three conflicting ideals is impossible. From the technical view-point of the maximum of production, especially of grain — for the conditions are essentially different for stock-farming — the only possible way to attain to this is by decreasing the country population, *i. e.*, by doing away with small peasant husbandry entirely and extending large capitalistic farming. But the country population is greatest and most stable where ownership is least stable, namely, in west and southwest Germany; because here where the custom of small holdings prevails and ownership is fluent, there is the best opportunity to secure a bit of ground. The watchword, that Germany shall eat only her own bread, means a sharpening of the present social antithesis in the country, and therefore, under existing conditions of labor, the denationalization of east Germany. The domination of capitalistic farming favors the cheapest farm-hands, *i. e.*, the Poles, and means nomadism for the agricultural laboring class.

Problems.— The fact must not be lost sight of that, as a nation, Germany is surrounded by enemies and can maintain her position only by the military service of a maximum of strong and healthy men. The population is increasing rapidly; but so is the deteriorating influence of the large cities. What, then, should be the aim of the agrarian policy? Certainly not the greatest amount of agricultural products, but the greatest number of agricultural producers. The present high agrarian protective tariff, however, is exactly opposed to the interests of the small producer. The high tariff on grain accrues, in an increasing measure, to the advantage of the large capitalistic farmer. Certainly, so long as the period of land-robbing agriculture ("Raubbau") continues in foreign countries, it is impossible to put agricultural products on the free-list. Since, however, under the tariff-programme formerly in force, there had not been any appreciable falling off either in the extent of farming or in intensity of methods of cultivation, it is clear that the rate was high enough to protect the German husbandman against the temporary effects of the opening up of foreign virgin soils; and it was not necessary at all to increase the tariff on agricultural products. However, a new agrarian tariff-schedule, providing for higher rates, was put through,— in violation of the interests of the great majority of the population.

18. **Germany — Industries.** No general statistics regarding industrial products are published in Germany. True, such material is carefully collected, but it is placed exclusively at the disposal of the government, to be used in considering the commercial policy of the nation toward foreign countries. It is impossible to give exact statistics, except for the products of mines and foundries; further, for beer, alcohol, and sugar.

For the greater part, the coal and iron deposits of Germany are already in permanent ownership and are being worked. In 1903, a year of depression, the production of coal was 162,500,000 tons, worth $275,000,000; *i. e.*, 18 per cent of the world's output, or just half as much as the production in the United States, and about two thirds as much as the production in Great Britain. The production of iron ore was 21,200,000 tons (United States, 35,500,000); of pig-iron, 10,000,000 tons, or 21½ per cent of the world's output (United States, 18,300,000; Great Britain, 8,900,000 tons); of steel, 8,800,000 tons (United States, 14,700,000; Great Britain, 8,900,000). The exports of coal and other mineral combustibles exceeded the imports by only 5,000,000 tons (export principally to Belgium and Austria, import chiefly from Great Britain), so that the home-consumption was about 157,000,000 tons. In this respect Germany is in contrast to Great Britain, which exports a large part of her coal production. The exports of iron ore exceeded the imports by about 2,000,000 tons, so that about 23,200,000 tons were reduced in German furnaces. According to conservative estimates, the coal beds of Germany contain 120,000,000,000 tons of minable coal. It is further estimated that the coal beds of Upper Silesia, and especially those of Westphalia and the Rhine country, will outlast those of England by five centuries, taking into account the technical mining capacity of the coal and supposing the same rate of progress in both cases. No other country in Europe has similarly lasting coal deposits, except Belgium. In all other European countries the coal-fields are considerably less extensive, as, for instance, in France, Russia, and Austria; and they will be more rapidly exhausted than those of Germany. The consumption of coal per head is considerably less than in England, and also less than in Belgium or in the United States, but it is greater than in the other European states. The home-consumption of pig-iron was only 98.1 kilograms per head, as against 235 in the United States and 137 in England. These low figures for Germany are accounted for by the fact that in Germany the railway system is essentially already built; though the production of pig-iron per head in Germany has increased more rapidly in recent years than in the United States. In the depression-year of 1903 the production per head was 173.0 kilograms; so that four-ninths of this amount had to find a foreign market. In 1904 imports of iron ore increased; but exports of pig-iron decreased, showing an increase in home-consumption. The ratio of the production of steel to pig-iron in Germany was greatest in 1903, the proportion being 87.3 to 100 (United States, 80.7 to 100; Great Britain, 57.1 to 100). In recent years this proportion has increased more rapidly than in the United States, or in Great Britain.

Thus, as regards coal and the raw materials of the iron industry, Germany does not have to rely upon imports from foreign countries. For the most part, further, Germany consumes such raw materials, instead of exporting them. Only on the coasts and borders is there any exchange with foreign nations. As to the geographical relation of the coal mines and the iron mines to each other, it cannot be said that this is as favorable in every respect as in England or in certain parts of the United States. But since the discovery of the Thomas Martin method of reduction the large percentage of phosphorus contained in many German iron ores rather gives Germany the advantage in this respect, and is even one of the reasons for the rapid development of the iron industry in Germany. Besides, the phosphorus in the slag makes this an excellent fertilizer. Of the other non-precious metals, only copper is principally imported. The imports amount to three fourths of the amount consumed in manufactures, and of this, eleven twelfths come from the United States. Accordingly, the metal industry is an important export industry, especially as regards finished products. Not counting machines, wares, and ships, the exports of semi-manufactured materials in 1903 exceeded the imports by $46,750,000; but the exports of manufactured articles exceeded the imports by $104,000,000. The trade-balance against Germany on ores and metals, including precious metals, is almost wiped out by the excess in exports of combustibles alone.

In all modern civilized countries the second typical large industry, next to iron manufactures, is the textile industry. In Germany this industry rests upon a basis quite different from that of the iron industry. In the manufacture of cotton Germany takes the third place, with 8,500,000 spindles, being led by Great Britain, with 47,000,000, and by the United States, with 22,000,000 spindles. The exports of textiles amounted to $125,000,000, though this was not sufficient to cover the corresponding imports of raw material, which were $193,750,000. In 1903 Germany imported 344,000 tons of raw cotton, worth $88,750,000; and in 1904, 357,000 tons, worth $104,475000. Between two thirds and three fourths of this came from the United States. The cultivation of flax in Germany has continually decreased, owing to the superiority of the Russian article, which is due to the more favorable conditions of climate in Russia. In 1904 Germany imported 24,000 tons of flax, which is about the average for recent years. Four fifths of this came from Russia. Jute is imported annually to the extent of about 100,000 tons, almost all of it coming from British India; and the annual imports of hemp are from 26,000 to 30,000 tons. As to wool, the excess of imports over exports in 1904 were: raw wool, 138,000 tons; bleached wool, 9,000 tons, and combed wool, 13,000 tons. About half of this came from Argentine, and a third from Australia. Even in 1900 the home production had gone down to about 12,000 tons. The annual imports of raw silk are some 5,300 tons. Despite the limited use of silk in Germany, this is an amount that has been exceeded by the United States only in late years.

In spite of the very considerable stock-raising in Germany, the leather industry is on about the same basis as textile manufactures. In 1904 the imports of hides and skins were 108,000 tons, worth $50,000,000. To a great extent the wood-working industries have to rely upon foreign material, although Germany has considerable timber-lands. The imports of wood and lumber of all kinds in 1904 amounted to $30,000,000. In certain industries caonchac and gutta-percha are found indispensable and are imported to the extent of $20,000,000. Most of the entrails used in putting up sausage, and in other industries, are imported, such imports being 21,000 tons annually, of which 9,000 tons come from the United States. Though tobacco is raised in Germany to a large extent, the tobacco industry has to rely on foreign countries for certain kinds of tobacco. The annual imports of leaf tobacco are some $22,500,000. Petroleum is likewise imported for about $22,500,000, partly from Russia, partly from the United States. Leaving out of account tobacco and other luxuries, we can see that even if German agriculture could supply the demand for bread and meat, Germany would still be dependent upon imports of raw material to supply the demands for clothing, and, in part, the needs of the household in the way of lighting, utensils, etc.

Given the raw material, the next necessary condition for the existence of the German industries is the possibility of the exploitation of labor, such possibility depending upon social conditions, of course. For a long time the opinion was held, and is still held by some persons, that the important position occupied by German industries in the markets of the world was due to cheap labor, which was identified with low wages. The view that low wages is identical with cheap production has long since been refuted, as regards highly developed industrial countries. In Germany the time when articles made by cheap, poorly paid labor formed the chief part of German exports is already some decades in the past. The standard items of German export which in the last decade have in an increasing degree come to make up the volume of exports are, on the contrary, the products of the most highly paid working-classes to be found in Germany. To be sure, the scale of wages, all the way through, is lower in Germany than in the United States, and in the case of skilled laborers about 50 per cent lower on an average. This is true not only of the amount of money paid, but of the real wage, at least so far as the necessities of life are concerned. Accordingly, the position of the skilled laborer is much more favorable in the United States, certainly in the Northern States. The position of the unskilled laborer in America varies, of course; but in cities like Chicago, and other cities, his position is no better than in Germany. It is sometimes worse;

and it is very much more unstable. Emigration of German laborers to America has greatly decreased, and to-day it is very small, and, on the other hand, Germany employs several hundred thousand Italian, Polish, and other foreign laborers. The effect of low wages on the cost of production in Germany is offset by deficiencies in the individual laborer. Through inheritance and training, the German workman has acquired habits of eating and drinking less conducive to health and strength than those of the American workman; and his excessive use of alcohol particularly diminishes his efficiency for intensive and heavy work. Though, to be sure, the training of the German workman, which is not easily duplicated elsewhere, makes him far more careful and economical in his work than the American. On the whole, the relative cheapness of labor has not by any means always stimulated the technical development of German industries. On the contrary, the opposite is true, since cheap labor sets a smaller premium on labor-saving machinery. In 1895 the total horse-power of such machinery in Germany was only 3,427,000, or 33.4 horse-power for every 100 persons engaged in general industries, and 42 horse-power for every 100 persons engaged in industry in the narrow sense of the word. Since then these figures have been greatly increased: *f. i.* in Prussia, in 1904, the steam-engines had 4,700,000 horse-power (ship-machinery excluded). But they are still too low, and in comparison with England and America this showing is poor. American industries have an advantage over the German in that they do not have to carry the burden of social compulsory insurance, and in that there the possibility of exploiting labor is not so sharply restricted by labor laws as in Germany. When the maximum quota has been reached the annual cost of insurance against sickness, accident, infirmity, and old age will amount to about $175,000,000 for the manufacturing industries, agriculture, and domestic service. This expense is met largely by compulsory contributions from the employers and the laborers. The care of widows and orphans has been proposed. The existing laws for the protection of workmen are very much more effective than are such laws in America. The honesty and pedantry of German officialdom guarantee the execution of all laws in Germany, whether they be good or bad; and, further, there is a unity in labor legislation for the empire which is in sharp contrast to factory legislation in America, where uniformity is made impossible by the legislative powers vested in the individual States. And, too, the German laws are more rigid in their nature than the American laws. The employment of child-labor in Germany, in the manner followed in the Southern States, would be out of the question; no less so the absolute disregard for the life and health of the laborer, which is made possible by law in American factories. On the whole, the German employer has the support of the government organs against the laborer, and his position is further made more comfortable than that of the American manufacturer by the fact that order is strictly maintained; but this does not mean necessarily greater production on the part of the German laborer. On the whole, the work-day in Germany is 10 hours, in some trades nine hours, and in others even more than 10 hours; but it has been observed that long hours are by no means identical with increased production. The development of labor unions of late has been rapid, and it is expected that shortly as many as 2,000,000 workmen will be organized. All in all, the present physical capacity of the German laborer is not so great as that of the American; and labor laws prevent as high a degree of exploitation of labor in Germany as is possible in America. In opportunities for special technical education Germany has a decided advantage; and, thanks to the development of technical schools and colleges, the standard of education in the industries is higher than in America. The significance of these facts can be observed especially in the chemical industry.

Such are the conditions of labor and production in Germany; and German industries have been developed accordingly. Naturally, the most significant industries of Germany, those upon which the future of the country depends in the world-market, are not those which are devoted to the manufacture of heavy staple products, as is the case in America. In 1903 the excess of imports of raw materials for industrial purposes were $405,000,000; and that of exports of manufactured articles amounted to $515,000,000. The statistics for exports, however, show that more than one third of the entire exports, viz., $437,500,000, was divided among over a hundred different classes of articles, of which the most important class was represented by less than $4,500,000, *i. e.*, less than .3 per cent of the total exports, which were $1,226,000,000. In general, these are products of a large number of factories making finished articles, in which the cost of the raw material becomes insignificant in comparison with the value added to the articles by carefully trained and conscientious workmen. High-priced manufactured goods preponderate, too, in the large export items. To be mentioned especially: silk, wool, and cotton manufactures, clothing and millinery, machines and fine hardware, books and maps, gold and silver-ware, and coloring materials, these items together making up $275,000,000 in exports. Despite the mineral treasures of Germany, the economic importance of the country depends upon labor; and in the future this will be even more true than it is at present. Those numerous individual classes included in the one third mentioned above vary greatly in importance, owing to changing tariff legislation in foreign countries; but if markets are lost for these articles by protection, they are usually regained in a short time. The latest statistics show that the higher the specific value of the article and the more work there is in it, the quicker the lost market is regained. In such cases the protective tariff only becomes, in the long run, a burden for the consumer in the foreign country. Exports are either to countries with which Germany has commercial treaties, or to such as allow Germany the rights of a most favored nation, or to countries with which Germany has no kind of agreement whatever. Now, statistics show that, disregarding individual differences, exports in these three cases vary with great regularity, going up and down according to the ups and downs of the general business situation in the world. Of course, the influence of foreign duties on exports is considerable, especially when a new tariff schedule first goes into operation; and for wares of low specific value the effect of such tariff continues. On the other hand, the influence of foreign tariff legislation on those articles which are really the most important for Germany's commercial future has been much overestimated.

In view of the nature of German manufactures and the intensive work involved, the method of inner organization of German industry acquires a character which is not altogether favorable for further development along all lines. Corresponding to the trust movement in America, Germany has had the development of the kartell, a trade-union similar to, but different from, the trust. Economically speaking, the kartell is "conservative." By fixing prices, it attempts to maintain *not* only undertakings of the highest rate of output. The trust, on the other hand, is economically revolutionary, in that it aims to crowd out less profitable businesses and maintain only those that pay the best profit. The kartell seeks to protect the income of invested capital; the trust seeks to utilize floating capital by organizing production. However, the difference is only relative, and it is well known that within our largest kartell a trust movement on a large scale is now in progress. But the formation of large trusts on the American style is difficult in Germany. The railway lines are owned by the state; and lately the state has begun to retain a monopoly of shipping on proposed new canals. Therefore, in Germany it is impossible to establish a community of interest between industrial monopolies and transportation, as is done in the United States. The state is a large mine-owner and is increasing its possessions; it is the largest employer and a greater consumer than in any other country. At present the state is just about to join the largest of the German syndicates. If, on the one hand, German industry is more dependent on the state, on the other it is less dependent upon the power of the banks and the Stock Exchange than is American industry. Speculation in futures in industrial stocks is prohibited in Germany by law; but this fact is not decisive, as it only increases the power of the large bankers at the expense of the smaller ones. What is really decisive here is the rigorous law regulating the formation of joint-stock companies, which offers, in a way, a guarantee for the solidity of a company and makes impossible the issue of common shares, as is done in America. This has greatly retarded the development of stock companies. The total capitalization of stock companies of all kinds amounts to only $3,600,000,000, which is a small sum, considering the highly developed German industries. This makes it difficult to reorganize ownership in whole branches of industry merely by transactions on the Stock Exchange, though, of course, such a thing is not entirely impossible. The more conservative nature of the kartell gives greater stability to prices, thus making more certain the conditions of the further manufacture of a given material in other industries. But the higher prices of raw materials resulting from the effort to preserve less profitable plants in a given industry decreases the competing power of that industry in the markets of the world. The result has been that large mixed works have come into existence, which produce the raw material and then manufacture it into the finished article, whereby in some kartells a violent conflict has broken out between the "pure" and the "mixed" works. Another result has been the allowing of export-rebates to manufacturing exporters. This last remedy bears the defect of every premium-system: it endangers the elasticity of the industry in adapting itself to the market. The finishing manufacturers, of course, have now formed kartells of their own. In fact, in the several hundred kartells into which industrial Germany is organized almost every industry producing staple articles is included. But the power of these numerous individual kartells in the market is usually less than that of the large trade-unions which produce the raw materials. It is the numerous small specialized industries that are most important for Germany's commercial position, in which highly skilled labor and personal initiative and special training on the part of the manufacturer himself play the principal rôle. But just these have to bear the expense of kartellizing. It must be added that the large industries for raw materials and staples are in a better position to effect strong coalitions for influencing the press, public opinion, and the government, and this fact gives them predominant power in determining the commercial policy of the empire. In co-operation with the large landed proprietors the 'Centralverband Deutscher Industrieller,' into which large manufacturers of raw materials, iron, and textiles are organized, brought about the present system of protective tariff, which is against the interests of all manufacturers, except those producing massive and staple articles. This organization is further allied with the landed interests in the social-political reaction, and in its opposition to labor-unions and labor-protection.

The most recent available figures regarding the number of persons engaged in industrial pursuits are found in the census of special industries for the year 1895. At that time which was 11 years ago and before the recent tremendous advances in industrial progress, the number of persons engaged in the industries was 8,000,000. These figures include mining and building, but exclude transportation. From 1882 to 1895 the number of persons engaged in industry, trade, and transportation increased 40 per cent; those in the industries alone increased 31 per cent; at the same time the increase in population was 14 per cent. Most of this increase has been in the larger factories, the force of those employing over 50 persons being increased by 89 per cent, those employing over 1,000 persons being increased by 110½ per cent. Still, for every 100 industrial workers 46 (60 in 1882) are working in small shops of less than five persons, and of this number 16.7 work alone. Further, out of every 100 such persons 24 (19 in 1882) are working in shops of from six to 50 people, and only 30 (22 in 1882) are in factories employing more than 50 people. Owing to the force of tradition the old and long-established hand-industries persist and are only slowly transformed, in various ways, on modern capitalistic lines. One development has been the home industry, which is almost seven centuries old in Europe. It is mostly country people who are engaged in these home-industries; and by reason of training from early childhood they are able to produce valuable wares; but such production is decreasing rapidly and is being superseded by factory products. On the other hand, the modern development in Germany has created the house-work "Heimarbeit," especially in textiles and in clothing, since certain heavy articles can be manufactured cheapest in this way. Such work is done in large cities, in densely populated country districts, and in places where the small wages of the men compel the women to work. Often such work is organized into a complex system, with many middle-persons. Especially noteworthy for this sort of work are: Berlin (clothing and men's furnishings, women's wearing apparel, leather goods, jewelry and ornaments, embroideries), Danzig, Cologne, Bielefeld (linen and wash-articles), and other cities. The woodland and mountainous districts of middle and southwest Germany are the principal strongholds of household industry. Here are made wooden articles knit-goods, brushes, toys, embroideries; and in the Black Forest clocks are made. Besides the mining and foundry industries, the modern factory system dominates the chemical industry (in 1895 53 per cent of all works had more than 100 employes); machinery manufacturers (likewise 53 per cent); the paper industry (similarly 40 per cent); and also the textile industry, especially spinning (38 per cent with over 100 workmen), though here there has also been a strong development of home-work. There is scarcely a guild-trade of the old régime that has not already a considerable, and an increasing number of large modern factories. In 69 of the various kinds of industries employing at least 10,000 persons, in 1895, the majority of the laborers were in establishments of over 50 workmen; and in only 33 were a majority in establishments having from six to 50 workmen.

The geographical distribution of German industries is uneven, and this has been increased by the decay of home-manufactures among the country people, mentioned above. This has made the contrast sharper between the agrarian districts on the one side, and the great industrial centres on the other. To the first belong the greater part of Prussia east of the Elbe, considerable parts of Bavaria, and numerous smaller agricultural areas. To the second belong the kingdom of Saxony, the lower Rhine-Westphalia country, the Saar district, the upper Rhine-Main plain, northern Bavaria, parts of Württenberg, and all the large cities. It is in these industrial centres that there has been the greatest increase in population; but, since the old system of voting-districts remains unchanged, these populous centres gain no additional representation, and their increased democratic population does not mean any increase in political influence. Thus we have the opposition between the industrial and the strongly organized agrarian interests, between a progressive economy and a reactionary policy. The tariff-schedule of the conservative parties is the only thing that can endanger Germany's commercial power. Foreign duties, let them be ever so high, injure least of all those lines of merchandise which will in the future determine the position of Germany in the markets of the world. Any increase in the purchasing power of a foreign nation would even help exchange of wares with Germany, as is proved by the commercial-political significance of the most highly developed industrial countries. A successful attack against Germany on the sea could not hurt German industries any more than could high foreign duties. A small group of English interests have been dreaming of such a method of disposing of their inconvenient competitor, and they have kept up a tremendous campaign through the press in order to mould public sentiment; but in case of a war, even if they were victorious, they would be disappointed by the outcome. Since the offensive economic strength of Germany does not depend upon ships, but upon things which can neither be confiscated nor destroyed by gunnery, shortly after the war the same conditions would prevail as before — except that England, against the wishes of all German friends to English culture, and in the interest of a few selfish promoters, would have made for herself an irreconcilable enemy. The risk, too, would be much greater for England than for Germany, since the receipts of Germany depend much less upon exports and maritime trade than do those of England. The increase of the strength of Germany in the world-market is only a relatively slight concomitant of the rise of German industries. From the figures showing the increase in Germany's productive power a constant and strong decrease in the relative importance of exports has even been deduced; but this is not quite correct, since the growth of the large industries depends in part upon the suppression of smaller industrial forms. But it must be admitted that the bulk of the increase in trade certainly does rest upon the development of the domestic market. Now, it is just the strength of the domestic market that is endangered by the uselessly increased duties on agricultural products. Such duties only swell the revenue of the producer without increasing production, and compel the masses to spend a greater part of their income for provisions. Similarly, excessive duties on staple products of the heavy industries diverts production from those highly specialized individual articles, which form the economic strength of Germany, and hasten unnecessarily the exhaustion of mines. In creating artificial profits for the producer they hurt initiative and adaptability to the market; and, in strengthening the position of the ultra-conservative or feudal class, they accentuate social antitheses. The result has been a rapid growth of the social-democratic movement, which has led the government to endanger the productivity of German labor by trying in all sorts of artificial ways to prop up the "middle class," *i. e.* the handicraftsmen. Protection, if increased abnormally, will breed a feudalistic spirit such as that which dominates France, and thus weaken the intellectual impetus of industrial development. We reject such a political programme, therefore, because it would threaten the unique character of German culture and power, and because it contradicts the daring spirit of the Germanic peoples, but not because Germany must at all hazards export goods to foreign countries. Such is not the case. Germany would probably be able to meet increasing needs for raw materials with her even more rapidly increasing commercial revenues. It is to be hoped that, when the present existing commercial treaties have expired, the political situation, both within and without Germany, will be more favorable for a moderate form of protection. Those branches of German industry that decide the commercial importance of Germany in the world-market no longer need any protection, though of course absolute free trade with protective neighbors would not be welcomed in Germany. All that German industry needs is the «open door.»

MAX WEBER,
Professor of Political Economy, Heidelberg.

19. Germany—Commerce and Trade. The dissolution of the Holy Roman Empire in 1803 indicated only the end of a political but not an economic union. Its more than a hundred commonwealths had been completely independent of each other from the economic point of view and nearly so from the political. Germany emerged from the Napoleonic wars as a confederation of about 40 sovereign states, in which trade and commerce were the concern of each individual state. «Thirty-eight tariff lines paralyze domestic trade and produce almost the same effect as if every limb in the human body were bound-up,» wrote Frederick List in 1819. Although in the following period some progress was made, the decisive step was the founding of the German Zollverein (Customs-Union) in 1833, which was joined by most of the German states in the following decades, until the adhesion of Hanover and Oldenburg in the fifties, it possessed no port on the North Sea.

The wars of 1864, '66, and '70, gave Germany a territory unified and rounded off for trade. The formation of the North German League and of the German Empire created a central force for the weightiest legislative functions in the field of trade and foreign commerce, while domestic trade for the two largest waterways which flowed through many states, was already regulated in the days of the Confederation by the Rhine and Elbe Transportation Laws (*Akten*). For the natural and artificial waterways through individual states, for the roads and railways, legislation is still to-day enacted by the individual states. The Empire, however, according to the Constitution, has the right of supervision and of control for the general interests of trade and commerce.

Almost contemporaneously with the founding of the German Empire, there occurred an event of decisive significance for trade and commerce—the country's transition from an exporting to an importing nation. The population of the present Empire from 1815 to 1870 increased from 24,800,000 to 40,800,000. Railway construction, which began in the thirties, made particularly rapid progress since the fifties, and there gradually arose larger and modern industrial establishments well-equipped with machinery, in which the increasing population found employment. Agricultural production, it is true, developed steadily, but the then conditions did not suffice to maintain the largely increasing population on the soil, without exporting any grain surplus—especially as American competition now setting in was lowering grain prices in the world market and hence rendering here more unprofitable the cultivation of corn.

The industrial development was largely promoted by the wars and by France's prompt payment of 5,000 million francs indemnity. Interrupted by the crisis in the seventies, a remarkable industrial movement began which has steadily continued. In the magnificent opportunity for employment an army of industrial workmen rapidly sprang into life. While in the beginning of the century, more than three-fourths of the population took to agricultural pursuits, in 1895, out of a population of 51,800,000 only 18,500,000 were agriculturists, while 20,300,000 were engaged in the industries and building construction, and 6,900,000 in commerce and trade. Of the present population of 62,000,000, not less than 35,000,000 are active in the four pursuits just mentioned, while the agricultural population is not larger, but perhaps less than in 1860. Naturally the demand for food, as well as industrial raw materials, developed enormously and, indeed, not only in comparison to the growing population, but out of all proportion, considering the increasing prosperity and rate of consumption. Thus Germany become one of those Western European lands that needed in an increasing degree for the support and employment of its inhabitants the importation of food and industrial raw products which out-balances the export of manufactures and the income from capital invested in foreign lands, and which makes return on the profits of transportation and insurance enterprises. In these so-called industrial states the interest in the increasing imports for support and employment of the population is decisive, while it must be the task of a prudent economic policy so to provide for the production of the home demand for food material, and the acquisition at home of as many industrial raw materials as possible, so that an all-too-rapid growth of the need of imports be checked. The steady passive balance of trade was a healthy sign, for it shows that the foreign trade capital employed in foreign undertakings supply good results for the agricultural life of the German people. But an all-too-rapid increase of the import surplus would check the further flow of capital, and besides would endanger particularly the German Empire, which is exposed to attacks on all sides through its position in Central Europe. An all-too-rapid dependence on foreign supply of food products might easily weaken its political power of resistance.

From these considerations the tendency of recent German economics has gradually shaped itself. On its foundation the Zollverein assumed the principle of the liberal Prussian trade policy, which, in 1818, arranged the first liberal tariff of duties in Europe influenced by Adam Smith's doctrine. The history of the Zollverein is essentially then the history of further progress in the direction of free trade. In the fifties this tendency was strengthened by the commercial treaties concluded with France, England, etc., on the most favored nation basis. The free trade policy continued also the first years after the foundation of the Empire, and found its culmination in the removal of the duties on iron in the middle of the seventies. In the following period, however, the increasing financial needs of the Empire, which would base its income, like the United States, essentially on duties and indirect taxes, necessitated the introduction of a number of revenue duties. The protective policy of many lands, the increasing American competition in the world market for agrarian products, which made itself noticeable in Germany after the middle of the seventies, and the increasing competition of industrial countries of Western Europe in the world market for metals, textiles, etc., together with the latent ecomonic crisis since 1873, gave further impetus to the movement again in favor of a stronger protective tariff. Under the auspices of Bismarck, the agrarian and industrial interests were united, and in 1879 there took place a reform of the German tariff legislation which, by moderate agricultural and industrial tariff measures met the needs of the time. The principle of moderate duties since that date has been abundantly maintained, while the tendencies of agriculture with increasing force in the past 28 years have brought about a marked increase and extension of an agrarian protective tariff. In the course of the eighties certain duties, particularly for agricultural products were largely raised. In the beginning of the nineties arose the project of a Central European Zollverein, as protection against the prohibitive measures of the McKinley Tariff. This project did not succeed; but a number of custom regulations were adopted by Germany, Austria, Italy, Switzerland, Belgium, Rumania, and Servia, the so-called Caprivi Commercial Treaty. By according the most favored nation clause to the United States, and granting similar treaty privileges to Russia, the original idea was completely extended. A number of reciprocal tariff regulations of a moderating character led anew to a lowering of the protective tariff. The continued low price of grain in the world, unfavorable conditions in finance and trade, however, intensified the agricultural crises and an active optation began to raise the agrarian duties, which the commercial duties had lowered—formerly a metric ton of wheat brought in 50 mark, now it had been lowered to 35 mark. The still higher protective regulations of the Dingley Tariff in the United States made the conditions for competition in Germany as well as other parts of Europe steadily more difficult, even if Germany, on account of its good technical development and organization, due essentially to the former protective tariff showed good results, and at the end of the nineties assumed a degree of development which was never anticipated. To make allowance for the wishes of the agrarians, without endangering them, it was resolved on the work of tariff revision, then in progress, to apply in the care of industries in many lines a moderately increasing rate of protection while grain duties should again be raised — wheat from 35 to 65 mark per metric ton.

In 1904 a new tariff system was adopted as preparation for the commercial treaties which were soon after to expire. After this preparation new commercial arrangements were adopted, and to the states already mentioned, who had adopted tariff agreements on the basis of reciprocity, Bulgaria, Greece, and Sweden were added. Their number has been further increased with most of the remaining countries of the world, except Brazil, China, Cuba, Portugal, Venezuela, the Congo State, Portuguese, West Africa, and some smaller territories. Germany is bound by treaties with the most favored nation clause. Commercial relations with the United States, which in earlier years were regulated by similar treaties with Prussia, and the Hanseatic cities from 1828, and after the founding of the Empire, and continues on the basis of the most favored nation clause, were controlled since the nineties by the Saratoga convention, and then by the reciprocity convention of 1900. The last had to become void with the expiration of existing tariff treaties with Germany, and it was replaced in the spring of 1905 by a definite provisional reciprocity agreement until 1 July 1907, which ought to give ample time for the conclusion of a new treaty. The same conditions exist as to the Argentine Republic.

The character of grain duties appears from the following table:

IN MARKS PER DOZEN.

Grains—Varieties	Old General Tariff of 1885-7	Commercial Treaty of 1892-4	New General Tariff of 1902	Additional Treaties of 1905	
Rye	5	3.50	7		5
Wheat and spelt	5	3.50	7.50		5.50
Barley	2.25	2	7	Malt barley	4
				Other barley	1.30
Oats	4	2.80	7		5
Maize	2	1.60	5		3

Since the introduction of the Caprivi Commercial Treaties the average receipts from duties for the years 1892–94 amounted to 380,000,000 mark; for 1898–1900, 514,000,000 mark; for 1902–4, 549,000,000 mark, of which the preponderating receipts came from breadstuff and cattle, 398,000,000.

The distribution of imports free and dutiable for 1902–4 was as follows:

Year	Imports in General		Food		Raw Material for Industries		Manufactures	
	Free	Dutiable	Free	Dutiable	Free	Dutiable	Free	Dutiable
1902	5,806	2,833	1,969	1,845	2,560	359	1,208	689
1903	6,321	2,896	1,952	1,774	2,843	384	1,220	738
1904	6,854	2,949	1,956	1,790	3,181	410	1,390	749

In the new German Empire foreign trade has begun to play another role than in the past It is to-day an integral part of the entire economic life, while formerly it did little else than to import all kinds of luxuries and food together with a few raw materials, and to export certain surplus products of agriculture and some industries. Without its aid a full third of the population of the Empire would find no support. In reference to the development of custom-duties in the Empire since its founding, we have the statistics, but until 1888, the Hanseatic cities did not belong to the same territory, and the number for the former period are not comparable to those of the later. Yet the following table shows something. According to government statistics, the special foreign trade was as follows:

The entire value of German foreign commerce has risen since 1872 to seven and one-third milliards or 120 per cent., the weight to 70 1-2 million tons or 300 per cent., while the population increased at less than 50 per cent. In 1872 the proportion per capita of the population in the tariff-covered territory was 145.6 mark; in 1889, 150.5 mark per capita of the population of the Empire; in 1905, 219.8 mark. The proportion of tonnage in 1872 was 0.56 in 1905 it had increased to 157 tons.

Year	Imports		Exports		Total	
	Thous. tons	Thous. mark	Thous. tons	Thous. mark	Thous. tons	Thous. mark
1872	13.4	3,465	10.0	2,492	23.4	5,954
1887	14.8	2,990	16.7	3,040	31.5	6,030
1889	26.6	4,087	18.3	3,256	40.9	7,343
1891	29.0	4,403	26.1	3,339	19.1	7,742
1896	36.4	4,558	25.7	3,754	62.1	8,312
1897	40.2	4,865	28.0	3,786	68.2	8,651
1898	42.7	5,440	30.1	4,011	72.8	9,451
1899	41.7	5,784	30.4	4,368	75.1	10,152
1900	45.9	6,043	32.7	4,753	78.6	10,796
1901	44.3	5,710	32.4	4,513	76.7	10,223
1902	43.3	5,306	35.	4,813	78.3	10,619
1903	47.0	6,321	38.3	5,130	85.3	11,451
1904	48.9	6,864	38.9	5,315	87.7	12,170
1905	54.3	7,436	40.6	5,842	94.9	13,278

Until 1889, as Hamburg and Bremen are not included, the figures for imports appear too low, for exports too high. In any event, the centre of gravity of the upward movement is in recent years—foreign commerce since 1889 has increased six milliard marks or 50 million tonnage—a larger mass than it amounted to in 1889. Since then the proportion to the population per capita is as follows:

	Imports.	Exports.
1890	86.4	69.0
1891	81.3	65.5
1900	107.4	84.5
1905	123.1	96.7

In the meanwhile the negative character of the balance of trade has steadily increased. The excess of imports in millions of marks averaged for the years 1890–1895, 991; for 1896–1900, 1,003, and for 1901–5, 1,086. Only in the year of the panic, 1902, after German consumption had strongly diminished, while the exports had increased, did the export balance in the course of the last nine years sink below 1,000 million mark. Germany is hence compelled in payment to utilize in increasing extent its income from its marine transportation agencies, cable stock, foreign insurance enterprises and banks, industrial, mercantile, and financial concerns. It is estimated that perhaps one-third of the negative trade balance is covered by profits in trade and navigation, while of the German working capital in foreign lands, between 30 and 40 milliard mark, one milliard serves to cover the deficit, a further part is consumed by the Germans in foreign countries, and the remainder is employed for new investments.

The character of the foreign trade becomes clearer when we divide it into its chief divisions:

IN MILLION MARK.

Year.	Food		Cattle	Raw material for industries, exclusive of precious metal			Manufactures		
	Imports	Exports	Excess of imports	Imports	Exports	Excess of imports	Imports	Exports	Excess of imports
1890	1,397	471	926	1,767	708	1,059	981	2,148	1,167
1895	1,390	416	974	1,805	722	1,083	926	2,180	1,254
1900	1,763	518	1,245	2,803	1,111	1,692	1,200	2,932	1,782
1905	2,344	507	1,837	3,395	1,181	2,214	1,390	4,043	2,653

Food imports increased more than four-fifths; exports remain somewhat fixed; the importation of industrial raw material almost doubled, while the exports increased fully half. The imports of manufactures, however, rose less than 50 per cent.; on the other hand their exportation almost doubled. An excess on imports of food and industrial raw materials, in value three milliard mark, is met by an excess in exports of manufactures in value more than two and one-half milliard mark. The 12 most important wares in imports, apart from gold, are cotton, wool, wheat, coffee, barley, copper, hides, lumber, timber, eggs, caoutchouc, silk, coal, which together represented more than thirty per cent. of the income. The corresponding 12 most important wares for export are cotton goods, machines, woolens, coal, sugar, common iron-ware, silk goods, fine iron-ware, gold and silverware, clothing and finery, books, cards, and music, aniline, and other tar dye-stuff, which together form about 40 per cent. of the exports.

The complete transformation which German foreign trade has assumed is clearly shown as well in its lines of direction. In former years trade was restricted practically to neighboring lands. The past generation has witnessed a much rapider increase of maritime trade than inland trade. The former today includes 70 per cent. of the entire German foreign trade—that is more than 73 per cent. of imports and about 65 per cent. of exports. As Germany had no colonies of its own it was limited in its transmarine undertakings to carrying trade with the colonies of Western Europe. After the independence of the United States and the rest of America, there developed some transatlantic trade for Hamburg and Bremen; but the English carrying-trade had long the preponderance. Until the founding of the German Empire every seaboard state had its own flag; but it was only after that event that an effective merchant-fleet developed under German colors, and as quickly direct maritime trade assumed marked development. But maritime trade extends beyond the German coast. Germany's convenient position in Central Europe, permits a small portion of its southern trade to extend over Austrian, Italian, and French ports; and as harbors which lie on the important rivers Rhine and Maas don't belong to the German Empire, a considerable amount of imports and exports of the most prominent branches of industry passes through these foreign points. For 1903, for example, it appears that at least 24 per cent. of special German imports and 14 per cent. of exports go by way of Belgium and Holland, so that the German foreign trade can thus be exhibited:

DIRECT MARITIME.

Imports ....50 per cent.
Exports ....50 per cent.

INDIRECT MARITIME.

Imports (lowest)..........................24 per cent.
Exports (lowest)..........................14 per cent.

RAILROADS AND INLAND WATERWAYS.

Imports (highest)...................below 26 per cent.
Exports (highest)...................above 35 per cent.

The geographical distribution of foreign trade was as follows:

Localities	In thousand marks		In ratio to total	
	Imports	Exports	Imports	Exports
Europe	4,633	4,380	62.3	75.
America..........	1,897	957	25.5	16.4
Asia	508	317	6.8	5.4
Africa...........	228	124	3.1	2.1
Australia........	164	53	2.2	0.9
Not given........	6	12	0.1	9.2
Total.........	7,436	5,842	100	100

The eleven most important countries, according to rank, that participated in German foreign trade are as follows:

Countries	In thousand marks		In ratio to total	
	Imports	Exports	Imports	Exports
Great Britain.....	784	1,058	11	18
United States and Porto Rico	1,004	543	14	9
Russia	1,961	368	15	15
Austria-Hungary.	773	595	10	10
Netherlands	257	449	4	4
France	409	293	6	5
Belgium..........	278	312	4	5
Switzerland	190	370	3	6
Italy	216	175	3	3
Denmark	124	186	2	3
Sweden	119	159	2	3

The percentage of the total German foreign trade is thus computed:

American Tariff Treaty—States		Great Britain and Colonies		United States and Colonies	
Imports	Exports	Imports	Exports	Imports	Exports
32.7	35	18.7	22.5	13.5	9.4

However rapid has been the development of German foreign commerce, it gives by no means a satisfactory picture of the measure of German inner development. In connection with the census of trades and professions for 1882 and 1895, investigations have shown that the capacity of working people and machines employed in the industries has risen considerably higher than the foreign trade figures. This process of development may continue in similar fashion, so that foreign trade statistics give no perfect indication of the increase in the capacity of German consumption or production. The inner prosperity and buying capacity have increased out of proportion to the foreign trade. The coasting-trade also will, accordingly, show at any rate, a stronger growth than the foreign commerce. Trustworthy figures are not at our command, but statistics of the movement of traffic on the inland water ways and the railroads are confirmatory.

In olden days the German railroads had much to suffer from the land's dismemberment. No united system could be constructed. In the thirties private initiative took the first steps. In the forties some railroad companies received state subvention, and when not enough private capital was at hand some states began to construct roads. Since the fifties, however, the *laisser fairé* policy gave opportunity to favor private initiative, until after the middle of the seventies the advantages of management by the state appeared superior and the leading states of the Confederation, already to a small degree railroad owners, bought up the entire railroad system of the country; its development is thus seen:

1840	1860	1870	1890	1900	1905
469	11,088	18,450	42,869	49,878	55,000

The total length of the state railroads was:

	1871	1881	1891	1901	1903
Km.	9902	22325	37476	46550	48784
Per cent.	46.1	66.2	89.6	91.3	92.4

The capital invested reached in thousand million marks,

1871	1881	1891	1901	1903
4.3	8.9	10.5	13.1	13.8

Of railroads that are private property, about 200 km. are under government control. In 1880, to every 100 square miles of territory 6.23, and to every 10,000 inhabitants, 7.44 km. railroads. In 1900 the figures had risen to 9.22 and 8.91 respectively; in 1903 to 9.77 and 9.02.

The following table gives the number of

	1880	1890	1900	1903
Locomotives	10,86[illegible]	14,188	19,069	20,845
		In millions		
Passengers carried	215	426	848	949
		In million km.		
Passengers, mileage km.	6,479	11,224	19,999	22,431
		In million tons		
Freight carried	165	218	359	391
		In million km.		
Mileage tonnage km	13,487	22,411	36,911	39,073

In 1890 the combined receipts of all German railroads amounted to 2,031,000,000 mark; expenses, 1,290,000,000 mark. In 1903, the receipts reached 2,161,000,000; the expenses, 1,357,000,000. The surplus of the combined capital stock bears interest at almost 6 per cent. It is, of course, not to be forgotten that the lion's share of the surplus falls entirely to the largest railroad organization—the Prussian-Hessian railroad system, which in 1903, out of a total of 52,814 km. locomotives possessed 31,813 km., while the smaller railroad systems are less favorably funded. The railroad employees numbered in 1900, 536,000 persons, of whom 315,000 were workmen, 221,000 officials. The relation of inland to foreign trade can be shown by these statistics: In 1890, out of 151,700,000 tonnage, 128.4 or 84.6 per cent. belonged to inland traffic, 11,000,000 went abroad; 10,200,000 entered entered from abroad, 3,300,000 crossed in transit. In 1903, out of a tonnage of 290,100,000, 248,800,000 or 85.8 per cent. belonged to inland traffic, 23,000,000 tons went abroad, 15,900,000 tons entered from abroad, 3,300000 crossed in transit. Of this there was maritime trade from seaports of 5,800,000 tonnage, and to seaports went 3,300,000 tonnage.

Ernst von Halle.

Professor of Economics, University of Berlin.

20. Germany — Home and Foreign Commercial Intercourse. The river traffic was the most voluminous at the great Channel Station Emmerich an the Rhein, where in 1904 17½ million tons merchandise were registered, in juxtaposition to which Hamburg-Enterwärder only registered 5–6 million tons, and Rûhrort and Berlin each 6–7 million tons.

Of great significance are the recent establishments of special Inland ports on all rivers west of the Oder, in many instances in connection with industrial ports, that were erected to fill the requirements of the environs. A comparison of the achievements of the railroad and inland water streets, shows the following:

Sea Intercourse.— The upward trend in the German sea intercourse also first dates back since the founding of the empire. Scarce a shadow of the oldtime commercial greatness was reflected by the maritime traffic of the individual German States, with their manifold flags, up to the seventies of the 19th century. Hereto came the fact that the few steamships, in their possession, were mostly built in England. Since then a lively increase in maritime traffic took place, and shipbuilding also showed an upward tendency in the eighties.

On an average, the traffic in the years 1873–75 amounted to 91,100 ships, with 13,000,000 registered tons, of which 67,400 ships were laden with 10,000,000 registered tons. In 1904 the traffic amounted to 191,000, with 45,000,000 registered tons, and of that number 15,400 ships were laden with 36,000,000 tons. The number of steamships among the above has increased from 17,500 ships, with 7,000,000 tons, to 114,000 ships with 39,000,000 tons. Therefore, while the traffic has doubled, and the capacity been trebled, the number of steamships have increased nearly seven-fold, and space capacity 5½ times as much. The intercourse in 1873 and 1904 is given in table on next page.

It will, therefore, be observed that the volume of the intercourse of ships, along the German coast, has increased five-fold, the non-German European trips trebled, and the trans-continental voyages increased five-fold.

The tonnage of the laden vessels, amongst the above, was as follows: 1904.— In the German commerce, 8,000,000 tons. It has increased 6½ times, as compared to 1873. 1904.— In the non-German European commerce, 17.2 million tons. It has increased 2⅔ times, as compared to 1873. 1904.— In the non-European trips, 10.5 million tons. It has increased 5¼ times, as compared to 1873.

Transcontinental traffic has increased the most in volume and the European the least. This makes manifest the fact that the German sea interests are taking on a more transcontinental character and tendency, while the strong increase of the coast commerce is but a reflex of the intensive impetus of the German railroad and river traffic, and conclusively proves how the commercial centres of the transcontinental intercourse equally distribute along the coast the importations and also attract the exportations. This picture though, as well as that of the German sea commerce, is inadequate and incomplete on account of the fact that the Belgian and Hollandish ports, which in truth

Year.	Length of		Average length of transport.		Average compactness per km.		Total traffic achievements.		Increase total traffic achievements compared to 1875.	
	Railroads.	Water streets.	Railroads.	Water streets.	Railroads.	Water streets.	Railroads.	Water streets.	Railroads.	Water streets.
	Km.		Km.		Thousand tons.		Million tons kilometer.		Percent.	
1875	26,500	10,000	125	280	410	290	10,900	2,900		
1900	49,600	10,000	152	315	740	1,150	36,900	11,500	239	297

It will, therefore, be seen that the inland water-streets, in competition with the railroads, have more rapidly increased their powers of achievement than the latter.

serve the German intercourse, are not included in same.

As heretofore, Germany holds by far the strongest commercial intercourse with the

United Kingdom. In 1904 it amounted to 11,000,000 tons. Next on the list comes the United States, with 4,600,000 tons. The English traffic, however, was 4.2 million tons, or two-fifths unladen while the intercourse with the United States there were but 0.2 million tons, or two-thirds unladen, so that in reality to-day the volume of the traffic with the United States is nearly two-thirds that of England.

At the present time the whole tendency of the development has been to change the commercial centre of shipbuilding and maritime intercourse which, at the beginning of the 18th century was mainly located on the Ostsee, which in 1871 claimed nearly half of the ocean vessel space as her own, to that of the North Sea in an overwhelming manner, the latter now practically calling four-fifths of the vessels and nearly nine-tenths of the net vessel space her own. (In 1874 there arrived in the ports of the Ostsee tributaries 3.6 million ship tons, against 3,000,000 tons in the North Sea region, whereas in 1904 there arrived in the Ostsee 7.0 million tons, against 15.4 million tons in the North Sea, an increase which would be still larger if the German intercourse via Rotterdam and Antwerp were taken into consideration.)

YEAR.	GERMAN PORTS. IN MILLIONS.		NON-GERMAN EUROPEAN PORTS. IN MILLIONS.		NON-EUROPEAN PORTS. IN MILLIONS.	
	REGISTERED TONS.	NUMBER OF STEAMSHIPS.	REGISTERED TONS.	NUMBER OF STEAMSHIPS.	REGISTERED TONS.	NUMBER OF STEAMSHIPS.
1873	1.9	0.6	8.2	4.8	2.2	1.0
1904	9.7	6.8	24.2	22.1	10.8	10.2

Of the ships of commerce in German ports, in 1873, there were 3,000,000 tons under the German flag, and 3.2 million tons under foreign flags. In 1904 there were 13.0 million tons under German and 9.2 million tons under foreign flags. From being a participant of less than 48 per cent the German flag has increased to 58 per cent.

Herein lies a reflex, in part, of the development of the German commerce. In 1871 the commercial fleet was composed of the following: 4,519 ships, with 1,000,000 tons, and with a crew comprising 39,000 men. Amongst this number were 147 steamships, with less than 0.1 million tons, with a crew of 4,700 men. Although up to 1905 the number of ships had decreased to 4,224, the tonnage had increased to 2.4 million and the crew to 61,000. Amongst this number were 1,657 steamships, with 1.8 million tons and a crew composed of 47,000 men.

If we figure the working capacity of a steamship in 1873 to be three, and in 1905 to be four sailing-vessel tons, it shows an increase in the working capacity of the German commercial fleet, in this period of time, to be from 1.2 million tons to 7.7 million tons, nearly 6½ times as much.

This development not only benefits the intercourse of the German ports, but the connecting of foreign places amongst themselves as well, who, hitherto, were served by England, to a great extent, even through the medium of a third country.

To-day Germany commands over more than 10 per cent. of the entire international commercial fleet, and has thereby become the second greatest seafaring nation of the world, although England, which is the first in rank, is 4½ times as large.

As per the figures shown, the intercourse has also developed its organization to a great extent. Large and gigantic organized enterprises have replaced the smaller ones. To-day even the coast traffic is served by large stock companies. In the European commercial intercourse the small enterprises have also been replaced by the larger companies, and a few gigantic enterprises now practically control the transcontinental intercourse, notably the Hamburg-American line and the North German Lloyd. The stupendous number of transports of which Germany is in need are carried out in perfect harmony by tremendous enterprises.

Comparison of the Intercourse Resources.— A comparison of the disposible intercourse space shows that in 1902 the German inland vessels possessed over 4.7 million tons packing space, the German ocean ships 3.31 million tons, and the German freight cars of the railroad over 5.23 million tons packing space.

The achievements of the freight German commercial fleet, in the intercourse between German and non-German ports in 1903, was estimated at 53 milliard sea-miles tons, a much larger figure than the total intercourse achievements of the combined German inland water-streets and railroads.

To this, of course, must be added the transportation of passengers, which is not a material factor in the inland water-streets, but which plays an important part with the railroads, and thus the latter, to a great extent, excels the achievements of the sea traffic, in spite of the strong increase of the former in the last year.

The most characteristic feature in regard to the German intercourse development is the rapidly growing intensity of all internal traffic, offset by the constantly rapid growing intensity and extensiveness of the outside intercourse; in the growing rigidity of concentration of the railroad intercourse, governed harmoniously by the State, with the river traffic's former free operating private initiative of all natural, and with the moderate taxation of royalties of granted franchises, also private initiatives on all artificial water-streets, the last named will experience an active development on account of the building of the Middleland canal.

In connection with this canal a new era will dawn, inasmuch as a governmental transport service must be inaugurated, and a freight tariff system for the entire water-street net must be sought for.

In the sea traffic complete operating freedom, so far as the governmental control is concerned, but increasing concentration of the management through capitalistic organization.

and beginning of negotiations between the interested enterprises for the purpose of regulating intercourse, and the development of a net, which would meet with the demands of the ever-increasing intercourse and commerce, and fill the requirements of the populace in the most efficient manner.

ERNST VON HALLE,
Professor of Economics, University of Berlin.

21. **Germany.— Money, Bank, and Exchange System.**— *Metal Currency.*— Under the same political disadvantages of breaking into shives, which the German livelihood life was subject to, the people suffered in regard to the money systems until the founding of the German Empire. The various issues which existed created undue complications and hardships. After the founding of the Tax Society this existence of the various issues continued, and only slowly was a unity of currency prepared, through the medium of several treaties, the most important of which were concluded in the years of 1838 and 1857. After many simplifications practically but two money systems remained, namely, that of the Thaler issue of North Germany and the Golden issue of South Germany. For both of these the Society Thaler of 1857 was supposed to serve the purpose of a connecting link. There yet remained in a few commercial sea cities some special currency issues, the principal one being the old Hamburg Bank issue, which was of great importance to the international commercial intercourse.

With few exceptions, the basis of the currency issue in Germany was silver. In the sixties a tendency manifested itself in Germany, as well as in other countries, to introduce a gold currency issue, but the establishment of the German Empire first brought with it the possibility of a unity in the currency issue, and the payment of the French war indemnity sum of five milliard francs was the basis of the rapid and pronounced growth of the gold basis in the German Empire.

The laws of 4 Dec. 1871; 9 July 1873; 1 April, 1886, and 1 June, 1900, enacted for the purpose of regulating the currency issue, developed in the following manner:

The lawful currency consisted of the gold coin of the Empire and the one-thaler pieces that were in circulation. The latter, however, will be gradually withdrawn, and will have entirely disappeared in about 1910, thus making it possible for Germany to possess a true gold basis. From the latter part of 1871 until the end of March, 1906, the following became lawful currency:

Furthermore, certain designated classes of bank notes, to be used as a circulating medium, but not as a legal tender, and until 1905 a limited number of German Empire bank notes.

From 1880 to 1900 the estimated Thaler fund diminished from 475,000,000 to 300,000,000 mark, and during the same period of time the number of circulating bank notes decreased from 159,000,000 to 120,000,000 mark.

They have fallen away somewhat of late since the right to issue small notes to the sum of 20 and 50 marks has been transferred to the state bank. The confusion, already great in the monetary system in the German Confederation, was considerably increased after the fifties by the establishment in the smaller German confederate states of numerous banks having the right to issue notes. In 1873, 140 different kinds of bank notes and paper money were in circulation in the country. One of the first measures to alleviate this condition was undertaken through the restricting law of 27 March 1870, for the prevention of the establishment of new note issuing banks. By the law regarding the establishment of the state bank of 1876, the right to issue notes was restricted to the new state bank and to the 32 note-issuing banks already in existence. A regulation was made to the effect that an unlimited amount of notes, covered by a full gold deposit, might be issued by these institutions and in addition notes to the amount of 385 million marks, distributed among the 33 institutions. Of this sum 250 million marks were allotted to the state bank. Beyond this sum notes could be issued to any desired amount, but subject to a tax of 5 per cent. Up to the banking law of 1899, 25 institutions had already relinquished their right to issue notes. In that year the untaxed amount of notes not covered by a gold deposit was raised to 541.6 millions, of which 450 millions could be issued by the state bank. Since that time, two more banks have relinquished their right, which has raised the contingent of the state bank to 470 millions, and, according to the amount in deposit, to 590 million marks. It is probable that within a short time only two note-issuing banks will remain besides the state bank.

Banking.— The banking system in its present organization is a child of modern times. It is true that Germany has long had some celebrated banks. The Hamburg and Nuremburg banks were two of the four celebrated European circulation banks which date from the 17th century. Individual state banks were founded in the 18th century, such as the Prussian bank by Frederick the Great. Their number increased, particularly

Treasury Notes.— Besides these German Empire coins there are still in circulation over 250,000,000 Thaler (metal currency) which will remain legal tenders until their final withdrawal.

in the fifties of the 19th century. Besides there were reputable banking houses in the chief commercial towns; thus, after the downfall of the Augsbuerm and Nuremburg bankers, in the fair town places like Leipsig and Frankfort-on-Main, in the Hansa towns, chiefly Hamburg and in the other sea ports, chief commercial centres and governmental seats. At the beginning of the 19th century Frankfort and Hamburg were the centers for the large money and loan transactions, and for credit transactions connected with the trading of goods respectively. In the former place especially were concentrated the state local transactions, supported by the rising house of Rothschild, and Frankfort became with Paris, Vienna, Amsterdam, and London, the centre of the growing stock exchange business. When, in the face of the large money advances needed by railroads and industries after the forties and fifties, greater demands were made on the financial capabilities of the bank systems, the private banks, despite the fact that they had been gradually growing stronger, proved not to have enough capital, while the mercantile loans for the foreign trade were taken up abroad, chiefly in London, and there began the establishment of stock banks, partly with the restriction of their note issue to their business territory, partly without. In the individual German states, however, the right to establish anonymous companies with limited security was dependent on special concessions, down to the introduction of freedom of industry and of general German commerce and stock rights. As the oldest of the modern non-issuing banking enterprises was the Bank of Commerce and Industry; then followed the Diskontogesellschaft, the Berliner Handelsgesekschaft, the Norddeusche Bank, and finally as the last of the "concession" banks, the Deutsche Bank. The free establishment of a considerable number of additional stock banks in the period of speculation following 1873 and the crowning of the structure by the fusion of the Prussian bank into the German state bank furnished the kernel to that organization of loan transactions, as it obtains in the German banking system of today. This state bank itself was from the very beginning established as a central institution with a network of numerous branches covering the whole country. The operations allotted to it by the banking law were: trade in precious metals and coin; trade in short exchanges; furnishing short term loans in return for secure deposits with strict limitation of the loan system; buying and selling of government, confederate states, and railroad bonds and those of real estate loan institutions; taking in and paying out cash and issuing certificates on branch institutions; buying and selling of stocks and precious metals on commission; acceptance of deposits and the carrying on of an endorsement business. The bank was furthermore to serve as a receiving and paying station free of charge for the state, and might do so for the confderate states.

Its development then proceeded as follows: In the year 1876 it opened with 182 establishments, whose number increased to 330 in 1001, and to a round 400 in 1906. The total exchanges amounted in millions of marks during the period 1876–1880 to 45.626.6; from 1886–1890 to 89.802.2; from 1896–1900 to 161.145.8; and to 1905, 251.267. The growth of the business transacted in the deposit account was as follows: from 1876–1880, 27.333.9; from 1886–1890, 67,064.7; from 1896–1900, 117,928.1; to 1905, 178,572.6. The estimated total sums were: 1896–1890, 15.823.7; 1896–1900, 26,957.8.

The tendency toward bank centralization, emanating from this primary bank organization influenced in special fashion the remaining banking institutions of the country. With the growth in importance of Berlin as a financial, commercial, and industrial center, the central seat of the state bank quickly won first place in the German loan business and the majority of the large banks subsequently established took up their chief domicle in that city. The tendency to spread out, emanating from the state bank, led them, however, before long to establish branches in other German cities and as a result to set foot over the sea and in London.

In this process a bank sometimes founded its own branches, sometimes bought out the existing business of private or stock banks, or took a majority interest in them so that the central bank controlled them, sometimes bought out the local institutions within the sphere of power of the central institution either through the creation of a community of interest or finally through the giving of credit. There are then to-day about 18 large banking institutions besides the central bank, eight of which control the business of the institution and the policy of their groups from their chief seat in Berlin; further 8 or 10, in individual parts of the country, which have a local influence extending over an extensive territory. The most important are the so-called D-banks Deutsche Bank, Diskontogesellschaft, Dresdener Bank (with a community of interest with the Schaafhausenscher Bank verein) and Darmstadter Bank which exercise by far the greater influence. In 1905 the total circulation of the largest banks in million marks was as follows: Deutsche Bank, 77.206; Diskonto Gesellschaft, 34.154; Dresdener Bank, 53.211; Schaaffhausenscher, ?; Bank-verein, ?; Darmstädter Bank, ? Besides these the remaining large stock banks and a small number of large private banks play an important role. The Handelgeschaft reports over 10¼, and the National bank over 10¾ million marks exchange for the year 1905. Since the exchange of the independent provincial banks are not contained in the above figures it appears that their united exchange is not less than that of the state bank. In the year 1896 the 10 central banks controlled 69, in 1902 over 185, and to-day nearly 250 establishments and institutions connected with it by continuous intercourse.

The number of independent bankers is constantly diminishing, but there must nevertheless be a dozen private banks in the country which do not stand second to the large banks in the extent of business while the total number of persons calling themselves bankers in Germany amounts to about 1,500.

At the end of 1902, 122 German banks controlled 7.085 million marks of their own and foreign capital. to-day the amount is not less than 10.000 millions.

The capital stock and reserves of the chief banks in 1905 were:

	Capital.	Reserve
	In Million Marks..	
Deutsche Bank	180.9	176.7

Bank of Commerce and Industry..	154	29.5

	Capital. In Million Marks.	Reserve.
Berliner Handelsgesellschaft	100	*29
National Bank	80	11.2

*Capital stock.

Another important manifestation in the German banking system besides this concentration is that in Germany the so-called purely banking business is not separate from the trade in stocks and state bonds, as in England and America; on the contrary in the large German banks the interests are often united which in America are divided among the banks and bankers, the trust companies, the promoters, the stock dealers and brokers. The large German banks accept deposits on the one hand, carry on a circulation and check business, and give credit for exchange, mercantile and other securities as in the ordinary bank routine, while on the other hand they buy and sell stocks for others and on their own account, engage in all sorts of financial, industrial and mercantile undertakings, promote the establishment or development of industrial enterprises, and undertake the flotation of public and industrial loans of every kind. They are thus central institutions for loan transactions in the broadest sense which are regulated in their administration by the general stock exchange law but not by a special banking law, deposit law and check law. They are purely private undertakings which are under no state control.

Real Estate Loan Institutions.— Besides the above named institutions and private bankers which look out for the business of loans on movables there are a large number of institutions which serve the real estate business. In 1903 there were 40 mortgages banks with a capital of 663.5 and reserve funds of 239.5 million marks. They had placed in circulation mortgage bonds to the amount of 7,491 million marks. These institutions give loans on city property. For rural property there are further from 3 to 3½ million marks of agricultural real estate loan institutions, which occupy either a state official or a publicly regulated position.

Stocks.— In the 15 years from 1887–1902 Germany issued stocks to the sum of 20–25 billion marks. About a third of the annual property increase, amounting to from 6–7 billions of the German people is invested in stocks and more than a fourth of German capital is employed in the stock markets. From 1884–1893, there were 8.7 billions, from 1895–1905 19.3 billions, in 1905 a total of 3.1 billion marks paid out according to the issue list, of which 5 or 3.9 billions were in foreign stocks. The amount of foreign stocks in the possession of the Germans was estimated in 1892 at 10, and is to-day calculated at 16 billion marks.

The stock transactions take place mostly in the stock exchanges of which there are 30 in all, in Germany; two-thirds of them carry on a stock business, the others deal exclusively in wares and produce. A farther part of the exchange of stocks takes place without the intervention of the stock exchanges through the banks, another part has gone out of the country on account of the stamp tax on stocks in Germany, and the limitations of the stock exchange law. The Berlin stock list notes about 700–800 valuations.

The transformation of private undertakings into stock companies is being accomplished in quick time, whereby one form of undertakings plays an important part, viz., the stock companies, with limited rights. There are anonymous stock companies with limited rights of the capitalists concerned, which in many respects exercise the same functions as the other stock companies, although from the fact that they are not subject to certain restrictions of the stock law as regards publicity and the stamp tax on stocks, they offer special advantages, whereas on the other hand their stocks are not so easily sold because they are not publicly listed. Originally intended only for smaller undertakings and family establishments, some of them now have a capital running as high as 90 million marks, and an active unofficial trade in their loans. From 1901–1904 there were 5,520 companies with this restricted scope founded; in October 1904 there were in all a total of 8,000 with a business capital of 1,960 million marks. In the year 1905 there were 1,800 companies created with a capital of 300 million marks. It is evident that an increasingly large part of German capital is to-day being invested in stocks and an increasingly large number of companies in the form of anonymous undertakings are being established. The tendancy which appeared earlier in other countries is now being manifested in Germany in an increasing degree and has already won an important position in spite of the comparatively short period of unhindered opportunity for modern enterprises and in spite of the difficulties offered by the legislation of the nineties, which was hostile to movable capital. The strong concentration and the comprehensive organization of the banking system have rendered valuable service in this connection. The comparatively small capital with which Germany began the race was used in the most effective way imaginable and in a short period of time has been turned into productive enterprises.

Imperial and State Finances.—The Imperial Government meets its obligations in three ways: (1) Indirectly by raising duties and taxes on the sale and consumption of certain commodities (salt, sugar and tobacco are taxed uniformly throughout the empire, whereas the taxation of beer and brandy is carried out by the states of Bavaria and Wurtemberg on their own account); (2) directly by raising duties and fees and from the proceeds of the various fiscal enterprises; and (3) by holding the states responsible for any deficits arising unless they be the result of loans. The states, however, divide among themselves any surplus accruing from certain sources of revenue. In 1902 the gross Imperial receipts were 2,441 million marks, and the expenditures the same. The state receipts aggregated 4,356 million marks, and the expenditures 4,375 million; Prussia's receipts were balanced by expenditures, 2,622 million marks. In 1902 the Imperial debt amounted to 2,734 million marks, of which 146 million was expended for railways. The state debts aggregated 11,216 million marks, of which 7,404 million was for railways. Of the state debts Prussia held 6,720 million marks, and Bavaria 1,460 million marks.

ERNST VON HALLE,
Professor of Economics, University of Berlin.

22. **Germany — The Colonies.** The German colonies were acquired in 1884–1899. Their combined area reaches 2,604,775 sq. km. In the tropics are situated Togo, Kamerun, East Africa, and the South Sea possessions, Samoa, Emperor William's Land, Bismarck Archipelago, Marshall Islands, Mariana, Pelew, Caroline, halfway in the tropics, and halfway in the southern tropics of Southwest Africa; in the northern temperate zone Kiautschou. The territory under protection is German as far as the international status is concerned, as the German Empire alone represents it against foreign states. On the other hand the Empire's commercial treaties do not extend over the colonies and the extradition treaties are valid for them only where this is expressly stated. According to the state law, they are regarded mostly as a foreign country; for instance, in reference to the custom laws (also among each other). The rights of the people and the administration is subordinate to the commands of the Emperor (that is, his representative) in finances, with the co-operation of the Confederate Council and Parliament. The Imperial Chancellor is the responsible head of the Imperial officials. The highest civil authority for the colonies of Africa and the South Sea is exercised by the Colonial branch of the Foreign Office, which is directly subordinate to the Imperial Chancellor; the administration of the Kiautschou territory, on the other hand, is in the hands of the Imperial naval office. At the head of the local jurisdiction in every independent colony is a Governor, subordinate to whom are the district officials (and of the military stations). The colonies have no autonomy as yet; government and district associates have only an advisory voice.

A line of troops to protect the African territories has been formed, whose supreme head is the Emperor. Next to him is the Imperial Chancellor, under whom the commanding general of such constabulary control the military, and the colonial division the civil affairs. In the separate protectorates the Governor represents the highest military power, while the direction proper is transferred to the commander of the constabulary concerned. Such troops are independent next to the army and the navy.

In Togo and the South Sea the police are wholly blacks. The force of Kiautschou form a portion of the active navy and are under control, after the Emperor, of the Secretary of State for the Imperial Navy. The Governor (a superior naval officer) is the chief commander in the colony, both for military and civil affairs. The financial administration is also under control of the Emperor; but this is regulated by the imperial laws, in reference to receipts and expenses of dependent colonies. The receipts consist of the imperial surplus and the receipts proper — customs, taxes, and duties. Every colony forms its own customs territory — Kiautschou is a free port. Each colony has a special establishment of its own — to which, the expenses for the military constabulary (Schutztruppe) are charged — which is opposed to the general customs of other nations toward their colonies. The administration of justice for the white population of the colonies rests on the decisions of the consular jurisdiction. There are two courts of resort. In civil and commercial disputes a single judge decides; in difficult cases two laymen act as his associates. In criminal actions, almost all matters are brought before an associate bench, a judge with two laymen in the lighter, and with four in more difficult cases. As a second court of resort is a special upper tribunal for every colony. In civil cases, where the value of the object concerned is not above 300 marks, and in criminal processes where the damage is less, no suits will be admitted. Lawyers and notaries are taken care of, but are not yet provided in every colony. Law for the native is differently treated in the different colonies. A certain consideration for old tribal law is encountered very widely — the administration is carried on partly by whites and partly by native officials. The death penalty can be given only by the governor. Civil law follows in the colonies the decisions of the German, that is, the Prussian statutes. For commercial law colonial commercial customs are given the preference. Only such marriages are valid as are executed under registrar's seal. Slave-stealing and slave-traffic are forbidden in the German colonies. Household slavery, where it existed, has not been abolished; but there appear certain regulations whose aim is its gradual extinction. Labor contracts with natives are partly regulated by due provisions. Lawyers and notaries are admitted to all German forums of law. Especially created for the colonies are the "German Colonial Societies." A regular system of bookkeeping is introduced, but for Kiautschou there are special rules. The mining rights of the various colonies are different — in some societies have still the mining rights.

The German colonies belong to the World Postal Union. There is the same rate of postage for letters, papers, etc., sent to Germany and to each colony as within the German Empire. Postal parcels are received to weight of 5 kg.; postal orders and money-letters to value of 800 marks. All the colonies on the mainland, are connected with the submarine cable. Further communication follows on land as far as the telegraph lines extend, otherwise by post. The African colonies and Kiautschou have direct steamship connection for passengers and freight with Hamburg and Bremen. There is only indirect communication with the South Sea colonies, for the South Sea by German branch lines from Sydney, by way of Hongkong; for Samoa by American lines. A number of railroads, whose construction in recent years receives at least proper attention, provide for trade within the African colonies and Kiautschou. Let us now describe the colonies in detail:

Southwest Africa, acquired 24 April 1884, 835,100 sq. km. in size, is a terrace-formed territory with extensive plateaus and mountain ranges and separate hills to the height of 2,680 m., composed of primitive rock, partly of sandstone, and with a cross-formation of volcanic rock. The rivers are cut in deeply, flowing only in rainy season, excepting the border rivers Kunene in north, Orange in south, which are not navigable by ships. The largest are: In the west, Omaruru, Swakop, Kuiseb; in the east, Omurambo, ua Matuko, Eupkiro, Fish river. The climate shows great differences in the day but none in the seasons, less collective rainfall from the northeast quarter in the months February to April. The western and southern sections are least rainy. The natural precipitation of rain is scanty. The plant-life is of the nature of prairies; forests wind along the rivers; in the north the woods are tropical in their foliage; the coast is more like a desert. The animal world is rich in antelopes and prairie birds. The population numbers about 110,000 persons, of whom 80,000 are Ovambo, 14,000 Hercoro, 4,000 Hottentots, and Damara hillmen, bushmen, and bastards, 2,000 each. There are now about 4,500 white settlers, besides soldiers, with their white and black attendants, about 20,000. The cattle industry is the leading trade. Agriculture is almost exclusively on irrigated land and for certain south tropical products very advantageous. Industries are beginning. Mining for the present restricts itself to copper, which exists in large quantities. In addition, iron-ore, and marble (coal?) are found extensively. Means of communication are: Railroad, Swakopmund-Windhuk, Swakopmund-Otavi (almost completed), Lüderitzbecht-Kubub (in construction); otherwise the Cape colony ox-carts, horses, and mules. Connection is maintained with Germany and Cape Town by means of the Woermann Line twice monthly. The harbors are Swakopmund and Lüderitz Bay. The capital, with the seat of government, is Windhuk; the chief district towns are Keetmannshoop, Gibeon, Windhuk, Gobabis, Outjo. Swakopmund is connected with the Cape Town cable. There are some land telegraph lines. Postal facilities, in the absence of railroads, are maintained with the postal steamers by means of ox-carts and messengers. Imperial currency is used. The circulation of money is facilitated by postal orders, the large mercantile houses, and the bank of Swakopmund. Exports consist of oxen and small cattle, wool, skins, horns, ostrich feathers, rosins, dyestuffs, guano, copper. Imports consist of beverages, necessaries of life, tobacco, clothing, furniture, etc. Complete statistics could not be furnished on account of the war of 1903. Exports 3,540,000; imports, 8,300,000 m. Everything points to a healthy development.

Togo, acquired 5 July 1884, 87,200 sq. km. in size, on the northern bank of the Guinea basin, a flat rising tropical territory well wooded until it rises in the interior mountain 900 m. in altitude. The flat sandy coast is about 50 km. long, without harbors, and with strong breakers. The rivers Mono and Volta which are navigable in their course flow freely the entire year, but discharge into English and French territory. The Haho which runs into the Togo is only for canoes. The climate is tropical, with two rainy seasons, from the end of April to the middle of August, and from the middle of October to the middle of November. The rain-winds come from the southwest. From December to the middle of January the stormy, dry Harmattan rages from the northeastern quarter. There are 1,500,000 natives, on the coast the heathen Bantus, in the deeper interior Mohammedan Soudan tribes. There are only 224 whites. The natives are industrious agriculturists and skillful artisans. The plant-life is only rich on the mountains. Plants for food and use are constructed in extended masses naturally as in plantations (palm-oil, cotton, maize, cassada, etc.) Caoutchouc is gathered from the woods. Cocoa and cola cultivation is possible only in some places. Cattle flourish in the interior, but their breeding is often hindered by the pest (tsets). At Lome (seat of the Governor), a bridge is built far out over the breakers, which is well kept, and joined therewith is a road to Nuecho and Palime. Sea-traffic is provided for every two weeks by the Woermann Line. Lome is connected with West African cable. Trade in the interior is conducted by carriers. The currency is that of the Empire. Exports, palm oil, palm seed, cotton, maize, caoutchouc, ivory, living animals, 1903, 3,616,061; 1904, 3,551,358 m. Imports: Beverages, preserves, cotton goods, colonial ware, tobacco, wood, and woodenware. 1903, 6,104,863; 1904, 6,898,323 m. Government districts are: Lome, Anecho, Misahöhe, Atakpame, Kete-Kraschi, Sokode, Mangu-Jendi.

Kamerun, acquired 14 July 1884, area 495,-600 sq. km. has its highest elevations on the coast, the Kamerun mountain range, volcanic (4,070 m. in altitude), and connecting mountains (Bakoss, etc.). For the rest it rises terrace-shaped and forms in the interior great plateaus, with mountains in the east and northeast. The rivers flow the entire year and have far-extended, marshy estuaries, lined with mango forests. The most important from the north to the south are: Rio del Rey, Kamerun river, Sanaga (not navigable), Njongo (in upper stream navigable); in the interior, (Adamaua), the navigable Benue, the Niger's largest neighboring river; in the southeast the Gsanga (the Congo's supply), with the Dscha; in the northeast the navigable Schari which discharges into the Tsad lake. The climate is very tropical, particularly on the coast. February is the warmest, July the coolest month. The two strong downpours especially on the coast (Kamerun to 7,000 mm.) fall in the south in two rainy seasons; in the northern section, only in one from May to October. The interior and south (perhaps from 4° N.) have much scantier rainfall than particularly the north coast, which accordingly is very unhealthy. A primeval forest (from 130 to 300 km. in breadth) skirts the coast and lines the mountain. In the grass prairies of the highlands it disappears in a wilderness of wooded thickets. The animal world is very varied, with elephants, buffaloes, etc., in large numbers. The cattle industry has much to contend with in many neighborhoods by reason of pest (Tsetse), and Texas fever, etc. The natives number about 3,500,000, and consist on the coast, in the west, south, and northwest of Bantus, in the northeast and north of Fellah and Soudan tribes. While the negroes on the coast are now only agents, the other tribes carry on agriculture in large degree, with the oil-palm and the cola tree as special articles of trade. In 1904, 826 whites lived in Kamerun, chiefly on the coast, as officials, traders, and plantation builders. Of minerals, petroleum and tin are found profusely on the coast. Exports: Palm seed, palm oil, cocoa, cola nuts, caoutchouc, timber, copal, cattle, ivory; value, 1903, 7,564,512; 1904, 8,020,731 marks. Imports: Manufactured goods, beverages, colonial wares, salt, wood, woodenware, ironware, tobacco, rice, etc.; value, 1903, 9,637,939; 1904, 9,378,283 marks. The currency is that of the Empire. English gold is taken in payment. Inland expended in turn. The north and Kamerun main line of the Woermann Line provide steamship communication, twice together monthly. There are many harbors. In Duala is a swimming dock of 1,200 tons carrying capacity. Trade in the interior is undertaken through carriers and boats. A railroad from Duala to the Manenguba mountains is in course of construction; besides, there are country roads in the large plantation along the stretch of coast. District officials are in Victoria, Duala, Edea and Kribi. Other administrative districts are Bamenda, Banjo, Buëa, Campo, Ebolowa, Fontem, Jabassi, Johann-Albrechtshohe, Joko, Lolodorf, Ossidinge, Rio de Rey, Molunda, Lomie, Jaúnde. Seat of the Governor is Buëa.

German East Africa, acquired 25 Feb. 1885, with area of 995,000 sq. km., has a very mixed geological formation and just as peculiar land surface, as the large North African ditch crosses it. Broad, undulating plains vary with the mighty mountain ranges, single heights, jagged precipices. Old and still active volcanoes are found in greater number; for instance Kilimandscharo on the northern border 6,010 m. in altitude. Richly watered fields alternate with barren plains, which indicate in part salt deposits. Accordingly the downpours, the climate, the plant and animal world vary in the different parts of the country. In general the plateaus have a scanty rainfall, the sea and inland coasts as well as the mountains (on the side of the wind bringing rain) have copious rains. The rains come with the southeast tradewind, which, however, in some places can be very much averted and thus distributed into two rainy seasons; the longer March and April, and the other in November. The height of downpour even in the localities where the rain is copious does not exceed 3,000 mm., but varies very strongly according to the years. On the western border lie the large inland lakes, Victoria-Nyanza (66,000 sq. km.), Tanganyika (35,000), Nyassa (27,000),—only in part on German territory. Of the rivers there empty into the Indian Ocean (from north to south) the following: The Umba (not navigable in its lower course), the Pangani, Wami, Kingari, Rufiji, Mbemkuru, and the southern boundary river Rowuma; in the Tanganyika the Mlagarassi; in the Cictoria-Nyanza the Kagera. In the low-lying localities the climate is genuinely tropical: in the mountains and plateaus it is very much cooler. In Uhehe, for instance, throughout the cold season night-frosts are not infrequent. The plant-life varies between impassable primitive forest, bush, and grassy prairie, to the barrenness of the wilderness; similarly the fauna. The population shows similar variety; in the more favored regions it is comparatively dense; but the poorest stretches one can consider almost uninhabited. It is estimated at 7,000,000 and consists chiefly of Bantu tribes. In the north live the (Presemitic?) Massai; in the south genuine Zulus. Principally on the coast but also in the interior are found Arabs, much blended with the negro, who have emigrated thither, and Indians. Besides there are to be met in smaller number representatives of all the tribes possible of Asia, South and North Africa. In 1905 the census of whites gave 1,324, mostly officers, officials, and traders, but with an increasing number of men engaged in industries, plantations, and even agriculture. Exports: Ivory, hippopotamus teeth, caoutchouc, copal, petrified and resinous wood, timber, mangrove bark, sesame, negro peas (chiroko), negro millet, maize, cocoanuts, copra, coffee, negro butter, some cotton, manilla hemp, horns, live cattle, mats, grass-woven articles, etc. Exports, forwarded also over the inland boundaries in the north (Uganda road), and the south, not only by sea, were valued, 1903, 7,054,207; in 1904, 8,950,565 marks. Of which goods to the value of 1,284,280 marks were conveyed across the inland boundaries. Imports were: Cotton goods, shelled rice, iron and ironware, wine, beer, butter, grease, cheese, ham, bacon, preserves, petroleum, fruit, meal, tobacco, etc.; value, 1903, 11,188,052; 1904, 14,338,880 marks, of which the value of goods transported over the inland boundary reached 1,448,307 marks. Of the minerals, gold is found in good quantity in Abbau; also graphite, mica, garnet, together with workable layers of coal.

East Africa has safe harbors, the best of which are Tanga, Daressalam (swimming dock), Kilwa, Mikindani. The German East African line maintains a 14 days' connection from Hamburg via Naples, through the Suez canal, besides a monthly trip around the Cape of Good Hope; and it has, also, a branch line from Bombay via the German East African ports to Cape Town, which makes the journey in both directions every month. In addition is a monthly connection through the Messagieres Maritimes (Marseilles), the Austrian Lloyd (Brindisi), and monthly from Aden by the British India line (in connection with the P. & O. steamships. The German steamboat *Ukerewe* plies on the Victoria-Nyanza; on the Tanganyika the *Hedwig von Wissmann;* on the Nyassa the *Hermann von Wissmann.* Of existing railroads, there can be mentioned the line from Tanga to Mombo, 126 km. in length (further construction is in progress), the line from Daressalam to Mrgoro, whose entire construction is planned, and part already completed; and a third railroad is being financed in the south from Kilwa to Wiedhafen. Otherwise trade is arranged by carriers. The stations in part are connected by very good roads. The customs-territory is joined to the Zanzibar cable; in the interior there are numerous telegraph lines. Apart from the railroads, postal communication is carefully provided for by messengers and carriers. The official currency is the German imperial rupee of 100 heller, equalling 1⅓ marks. The German East African Bank at Daressalam and the large commercial houses provide for the exchange of money. In the interior barter continues almost exclusively. Daressalam is the seat of government. The protectorate is divided into 22 administrative districts, of which hitherto 16 are under civil authority; the introduction of a purely civil administration is being undertaken. The most important places are: Daressalam, Tanga-Wilhelmstal, Pangani, Kilwa, Morogoro, Upapua, Tabora, Moschi, Muansa, Langenburg, Bismarckburg.

Kaiser Wilhelmsland, the German portion of

New Guinea, was placed under German protection 15 May 1885. Of an area of 179,000 sq. km., it is a distinctly tropical country, with a narrow coast 800 km. in length rich in inlets, and with mountain ridges rising to height of 4,300 m. in the still unknown interior. Coral reefs are deposited before the coast. The climate is hot — on the coast a yearly average of 26° C.— and damp; the downpours occur during the entire year. The localities exposed to the southeast tradewinds which blow during the entire year enjoy more frequent rains. The sections reached by the northwest monsoon from October to March have less rains. Of the numerous, rapidly-flowing rivers, the Kaiserin Augusta, the Ramee, the Gogol, and the Markham are navigable for large vessels. The plant-life is exceedingly luxuriant, originally primeval forests everywhere, with lofty trees. The population consists of Melanesians and Papuans, who together number about 100,000. In 1905 there were 128 Europeans in the colony. Exports are: Copra, timber, cotton, tortoise-shell, mother-of-pearl, etc., whose value in 1903 reached 243,645, and in 1904 54,272 marks. Imports were chiefly food, tobacco, ironware, textiles, whose value in 1903 was 798,857, and in 1904 566,503 marks. The steamship connections are the Imperial Steamship line via Hongkong, and the Australian-Japanese line from Sydney, both monthly. There is also connection with the Netherland-Indian cable. Friedrich Wilhelmshafen is seat of the district administration.

Bismarck Archipelago, acquired 15 May 1885, consists of New Pommerania, New Mecklenburg, the Admiralty Isles, New Langeburg, New Hanover, the Solomon Isles, Birka, and Bougainville, with a number or smaller islands, with total area of about 61,000 sq. km. All the islands are mountainous — the Kaiserberg in Bougainville is 3,067 m. in altitude. A tropical ocean climate prevails, with the least rainfall in July–October. The population consists of Melanesians and Papuans. In 1905 there were 335 whites. Exports were chiefly copra, mother-of-pearl, tortoise-shell, coffee; value, 1903, 963,-066 marks; 1904, 1,210,071 marks. The imports consisted mainly of meat, fish, textiles, tobacco, and metalware; value, 1903, 2,114,957 marks; 1904, 1,759,156 m. The currency is German imperial — in the interior shell-money (Dewarra). Steamer and cable connection exists with Kaiser Wilhelmsland. A place of settlement is at Simpson harbor in New Pommerania. There is now the office of the district. Seat of the Governor (for German New Guinea, Bismarck Archipelago, and Kaiser Wilhelmsland) is Herbertshöhe in New Pommerania.

The Carolines, Pelew Isles, and Mariana, were acquired by purchase from Spain in 1899, and have a combined size of 2,676 sq. km. The most of these islands are mountainous, of volcanic origin; the others, especially the eastern, are coral islands. Extended reefs surround also the mountainous islands, upon which the plant-life is very luxuriant, while in the low-lying islands it is very scanty. Fountains and brooks are found only in the mountainous islands. The climate is in general tropically damp, rich or poor in downpours according to the direction of the monsoon or tradewind. The territory is divided into three districts of government — West Caroline (Jap.), East Caroline (Ponape), and Mariana (Saipan). The first has 13,264 natives, and 47 Europeans; the second, 25,000 natives, and 92 Europeans; the third, 2,508 natives, 31 Japanese, and 22 Europeans. Exports consisted of copra, tortoise-shell, mother-of-pearl; value, 1903, 870,375 m.; 1904, 479,990 m. Imports were: Woven-goods, tobacco, food, etc.; value, 1903, 852,848; 1904, 710,140 m.

Marshall Islands, acquired 15 Oct. 1885, about 400 sq. km. in area, consist of 33 separate coral isles and atolls in two rows — the eastern chain with 15, and the western with 18 atolls. The climate is very warm and damp — uniformerly tropical (27°C.) with 300 rainy days and a precipitation of 465,000 mm. The pure Mikranesian population is about 15,000 in number — 84 whites lived there in 1904. The chief exports are copra, mother-of-pearl; its value, 1903, 522,210 m.; 1904, 583,353 m. Imports are chiefly woven-goods, tobacco, and ironware; value, 1903, 497,792 m.; 1904, 444,198 m. The imperial steamer *Oceana* of the Jaluit line makes the passage at six weeks' interval. There is a postal agency at Jaluit, on which island Jabor is the seat of the chief of the country and Nauru of the district head.

Samoa (Navigator's Islands). The islands Sawaii (1,691, sq. km.), Upolu (868), Manono (8.5), Apolima (4.7), together 2,572 sq. km., were conceded to Germany on 2 Dec. 1899, by treaty with England and the United States. They are all of possible volcanic origin. Sawaii and Upolu have still active volcanoes (1,646 and 975 m. in altitude). The climate is tropical. The rains are brought in the summer months by the northwest wind and reach a precipitation of 3,400 mm. From May to September the southeast tradewind blows, which produces little rain. The wealth of water in the brooks is hence very changeable. The coast is surrounded by coral reefs; there are no good harbors. The construction of plantations (cocoa and caoutchouc) increases of late years, so that Chinese laborers must be introduced. Exports chiefly copra, fruits, and lately, also, cocoa; value, 1903, 1,384,507 m.; 1904, 1,674,881 m. Imports are: Articles of clothing, biscuits, meat, etc.; value, 1903, 2,681,405 m.; 1904, 2,306,878 m. Steamers of the Oceanic Steamship Company arrive every three weeks from San Francisco via Pago-Pago (Tutuila) to Sydney. Direct connection is made from Pago-Pago to Apia by the *Maori*. The Governor's seat is at Apia on Upolu.

Kiautschou. Occupied 14 Nov. 1897 (treaty compact of 6 March 1898 for 99 years), embraces only the Bay of Kiautschou with islands, tongues of land, and bordering hills, together about 551.7 sq. km. in area. In a zone or circuit of 50 km. further landwards is the consent of the German government necessary for all measures. The bay, deeply indented and commodious as a harbor, is surrounded by a jagged bare chain of hills, the forerunners of the Schantung mountains. The climate is considered the healthiest in China. The winter is dry and moderately cold; the summer warm and very damp. There are no navigable rivers. The hills are bare, but only through Chinese mismanagement. The rear country is rich in coal, which will be exploited. It is also said to contain gold, mica, and iron. The population of treaty land in 1905 was in the city limits of Tsingtan 28,477 Chinese, 207 Japanese, 1,225 Europeans (besides the military, 1,879 whites and 67 Chinese). The population of the suburban territory is computed at 100,000 — that of the 50 km. zone is not known. There are large harbor buildings and on the site of the Chinese town was built the city of Tsingtau, seat of the government. The Schantung railroad leads therefrom to Tsinanfu, 45 km. Exports: Chiefly straw mats and silk pongees from 1 Oct. 1903 to 30 Sept. 1904, in value 14,700,000 m. In the same period 1904–05 they reached 20,000,000 m. Imports consist mainly of goods in transit. Those not of Chinese origin were valued, without the railroad and mining materials, in 1903–04 at 24,000,000 marks, and a year later at 37,000,000. The value of imported goods of Chinese origin for 1904–05 reached over 12,000,000 marks. Schantung taels and Mexican dollars are currency. The German East Asian Bank has the right to issue its own paper money. Direct connection with Germany is made by the Hamburg-American line, and the Imperial Steamship line. L. SANDER,

Secretary of the German Colonial Association, Berlin.

23. Germany — The Germans in the United States. *Some Statistics* — The Federal Census of 1900 places the number of persons living in the United States and born in Germany (more correctly the German Empire) at 2,663,418 among a total white population of 66,809,196. But the term German being not a political, but rather a racial one, the Germans from other sources (Austria-Hungary, Switzerland, Russia) are to be included. A conservative estimate fixes their number so as to swell the immigrated German population in the United States to 3,060,186. As to the number of persons of German blood in the United States Emil Mannhardt (in Deutsch-Amerikanische Geschichtsblätter, October 1903) makes the following estimate: German immigration and their offspring before 1830, 12,046,919; immigration during the 19th century and first generation of their offspring, 8,714,233; the following generations, 4,716,431; making a total of 25,477,583. The 'Handbuch des Deutschtums im Auslande' (Berlin 1904) arrives at a figure of about 11,000,000 persons in the United States speaking the German language, which is probably too high, considering the rapidity with which the generations born in this country adopt the English language as a principal if not exclusive means of expression.

History — The history of the Germans in the United States is first of all the history of their immigration. The characters of and the motives actuating the German immigrants to leave their native land may be largely inferred from the political, religious, and economic history of the countries they came from notably of the states now forming the federation of the German Empire. It has been said (by Friedrich Kapp) that in the cultural and political conquest of the new continent the Latin races (notably the French) fought with officers having no army to back them, that the English had both officers and army, but that the Germans had the army but lacked the officers. While the history of the United States is largely the history of the expansion and constructive adaptation of Anglo-Saxon institutions to new environments, one looks in vain for a similar process with regard to German ones. Indeed there were none to expand, since the German body politic after the Reformation had proved to be sick and decayed, crumbling into ruins, and totally unable to hold the civilization and culture of a great modern nation. From a people without a great concerted national life, without vigorous national policy nor even a national consciousness, no constructive political ideas were to be expected, and when, during the 19th century the German immigrants had political ideas and ideals, these were entirely untried, unpractical, and unable to generate a strong political and social life, especially in competition with Anglo-Saxon law and statecraft.

In the beginning of the 17th century we find traces of larger bodies of German Protestants being settled in Virginia. Conspicuous as individuals we note Peter Minuit from Wesel, Governor-General of New Netherlands and founder of New Amsterdam (later New York) in 1626, and Jakob Leisler from Frankfurt a/M, the martyred forerunner of a republic free from English rule. Yet the German-Americans rightfully date the beginning of their history on American ground from the 6th day of October, 1683, when, from the good ship *Concord*, 13 Quaker and Mennonite families from Crefeld headed by the learned lawyer, Franz Daniel Pastorius from Frankfurt, landed in Philadelphia. The 6th day of October has, since 1883, become the festival *German day*, so regarded by an ever-increasing number of German-Americans. These settlers had bought land from William Penn, on whose solicitation they came, and settled in Germantown, near Philadelphia, as the nucleus of the vast German population of the State of Pennsylvania, which for some time was in danger to become German in language, officially and otherwise. These Pietists (the German species of Puritans) emigrated, like the so-called pilgrim fathers of New England, for religious reasons, but with no political-theoretical aspirations nor with despotic intolerance toward others. Besides their various forms of religion they brought their skill as farmers and craftsmen ("vinum, linum et textrinum," says the seal of Germantown). Christopher Saur, the printer, published his first German Bible at Germantown in 1743, the first Bible in a European language printed on the western hemisphere. And, also, from the midst of these German sectarians, came the first documentary protest against negro slavery.

From this beginning the German immigration may be divided into four distinct periods: the first from 1683–1820, the second from 1830–1871, the third from 1871–1894, the fourth up to date. The economic cause, of course, has been present and even prevalent in all of the four periods, as with the other races, prompting Germans to come from overcrowded conditions into a land with vast resources, with abundant land to colonize and prosper upon, into a country with greatly superior chances for a living not only, but for rising in the social scale. It is in the concomitant causes that the four periods differ Up to the Napoleonic wars the German people as such had hardly any political life or concepts or ideals at all; what drove them across the Atlantic, beside famine, calamities of war and peace, was the oppression of their religious and social individuality, the despotism over soul and body. But even during the 19th century German Protestants, Lutherans or others, have sought refuge in the United States from State interference with their religious views. Yet this religious motive ceased to be a decisive one after the war of liberation had engendered political aspirations and national ideals, and the second period is clearly characterized by a desire to escape the reactionary Metternich system at home and the persecutions resulting from the failure of the German revolution, as well as to participate and even to improve upon political conditions and social ideals of the native American people. Conditions in the newly-founded German Empire sent forth, in the third period, the vast overflow population, actuated, secondarily, not by doctrines of a republican democracy but by the international, Marxistic dogmas of socialism. The German anti-socialist legislation during the eighties, no doubt, influenced countless numbers of socialistic workingmen to seek the other shore. Socialism in the United States may be traced principally to this German influx. The marvelous growth of prosperity, of industrial and commercial efficiency, under the regime of William II, has resulted, in the fourth period (1895 to the present time), in an emigration from the Empire comparatively very insignificant, the 30,000 mark of annual German immigrants into the United States, never having been attained again since 1897. It may be inferred that these latter-day crossers of the Atlantic, aside from the numbers shunning military and other civil duties in the realm of the Emperor, as contemporaries of their vigorous-minded ruler and belonging to the post-bellum generation of proudly self-conscious and patriotic Neo-Germans, are far less prone to hail the United States as the Mecca of political and social freedom, such as did the generations before them. It is very likely that a great number of these late comers have not come to stay, but only to gather information and experience, and finally to repatriate themselves. The German vital statistics for the period of 1895–1900 seem to point in this direction, since they record, for those five years, a surplus of nearly 100,000 of immigration over emigration for the Empire. In all probability the great immigration of Germans into the United States has ceased never to be revived.

The ups and downs in industrial prosperity of the two countries involved are clearly mirrored in the statistical tables. So German immigration is at a low-water mark during the war of secession, as well as during the great business depression from 1873–1879, which partly coincided with an unprecedented business boom in the Empire. The succeeding turn in the scales then, in the years 1880–1894, brought over two millions of Germans into the United States.

Politics and War.— The Germans in America, from causes connected with their history in Europe, never took such an important part in the shaping of American institutions as the Anglo-Saxons, or even the Irish. Compared with the latter they are too highly individualistic ever to submit to such clannish party allegiance constituting the strength of the Irish people and making for their success in politics. The failure of the German Revolution of 1848 led an unusually large number of educated Germans into the American republic, but with the one exception of the late Carl Schurz (q.v.), politician, reformer, statesman, diplomatist, writer, general, and journalist combined, none of them rose to a position of first rank in American history. Their doctrinarianism, which they liked to call idealism, condemned so many of their good intentions to remain fruitless, at least to take no direct practical shape. It remains to be shown by historical investigation how much, indirectly, they contributed to form modern American policy. It stands though to their credit that no race stood more loyally, and more solidly to the cause of the Union, in peace as in war. Lincoln's coming to the foreground was greatly due to their assistance. The army lists of the war of secession include over 180,000 Germans, among whom Franz Sigel, Peter Osterhaus, and Willich are conspicuous as generals, and the resolute military action of German 'Turner'-soldiers saved Missouri for the Union cause at the beginning of the conflict. Nor will the names of Mühlenberg, Herkheimer, de Kalb, and Steuben ever be forgotten in the history of the War of the Revolution. The school- and text-book invective, though, against the Hessian mercenaries, who, by the way, fought very bravely, might well be toned down to tally with the appreciation of Scotch, Irish, or other mercenaries pressed into the service by the well-known British recruiting methods of that time. As to the 'Winning of the West,' President Roosevelt's essay on the subject needs less a revision than an important addition relating the paramount importance of the German pioneer farmer. There is a task for a historian to decipher correctly the frequently obliterated documents of German beginnings and achievements. The loss of the language has proved, no doubt, also a loss, sometimes irretrievable, to correct historical statement.

Social Life.— As a race the Germans (from the standpoint of Völkerpsychologie as Wundt conceives it) brought with them their language, their religion, and their customs (Sitte). The struggle to retain their language as a dear inheritance was and is fought by them with varied success. On the whole, fought against so great odds, it is far from being lost. May there be, with the declining immigration, no doubt, a loss numerically, as each succeeding generation is less prone to cherish this greatest national shibboleth, the rest, and they are likely to be the best, will loyally stick to the vernacular. In the family, partly in the schools (Catholic and Lutheran Germans are equally tenacious in this respect), in the churches, and in their countless clubs (athletic, singing, benevolent, military, etc.) the German language has her sway. In the farming districts of the West as well as in the large cities with a considerable German population the language is handed from generation to generation, a language, moreover, which many of the immigrants, by intermingling with representatives of all the German tribes, learn only in this country to assimilate to the literary language, the "Schriftdeutsch.." As both a linguistic and an ethnographic curiosity the so-called Pennsylvania-Dutch dialect of several counties in Pennsylvania deserves mention, with its interesting admixture of English to an essentially Rhenish-Franconian structure.

But even here we have no record of higher or highest achievements. The non-sectarian German schools, founded by the "forty-eighters," have gone out of existence. Lutherans and other German sects still maintain a number of secondary schools and theological colleges. but have been unwilling or unable to develop them into real colleges with a distinctly German culture. The dream of a German university on American ground was never realized. The German-American Teachers' College in Milwaukee, founded by German freethinkers (non-religious persons, organized or not) is something of a German 'Lehrerseminar' without its theological accessories.

Countless is the number of clubs in this country in which Germans organize on the lines of provincial, tribal, dialectal requirements. In this they now outdo, from the immanent stagnation of German life in this country, their countrymen in Europe. But more amiable, directly or indirectly influencing American life around them, they become in their singing, rifle, military, and athletic societies. Addicted, almost as a body, to the moderate use of stimulants, nicotine or alcoholic, the latter in the form of wine or beer, they have materially contributed towards making popular life and enjoyment in America less stern, less rigidly puritanic, less dull, and have added color and music to it. Their Sängerbünde, Männerchöre and Sängerfeste are a decided gain for American life, combining, for the average man, most felicitously, thoughtful practice of art, which is always a refining element, with social enjoyment. The peculiarly German form of athletics represented by the 'Nordamerikanischer Turnerbund' is perhaps too military in its discipline to suit the Anglo-Saxon taste. This association, spread all over the United States, has well deserved, however, of the country by its agitation for introducing physical culture into the public schools. Otherwise this organization, taking up the ideas of the German Liberals of '48 and, of late, combining them with radical and socialistic tendencies, stands in glaring contrast to its sister organization in the German Empire and Austria, which demonstrates and practices more strictly the patriotic and godfearing spirit of its founder, the venerable Ludwig Jahn.

Cultural Activity.— The Germans as a race, collateral with their lack of constructive political ability, have evidenced no genius for civic organization, none of the great American centres of industrial and commercial life owing its origin to Germans, excepting Peter Minuit who acted in the interests of Holland and Sweden. Yet, individually, they take their full share not only in the development of agriculture and industries, but also as inventors, business organizers, engineers, etc. Mergenthaler, the inventor of the linotype, may stand for a host of names, demonstrating that the inventive genius of the race that gave the world the art of typesetting and gunpowder, has not disappeared. Jakob Astor, the founder of the business dynasty bearing his name, set the pace for many more captains of industry. Bridge-building, the refining of sugar, and the brewing industry may be called pre-eminently, if not exclusively, the work of Germans, and the names of Röbling, Havemeyer, Spreckels, Pabst, Annhäuser-Busch will be forever connected with their history. Science and scholarship, of course, have had and still have many able German representatives in the American colleges and universities and elsewhere, but none to compare with the splendid array of geniuses in the old countries. It seems that the higher productive power of the scientific intellect did not come over with the immigrants. But here, referring to President Schurman's (of Cornell University) statement, the Anglo-Saxon elements, with the possible exception of one or two minds, have by no means shown up more efficient or more productive. To enumerate a list of names, therefore, appears to be unnecessary.

More nationally the genius of a people expresses itself in literature, art, and music. There is, however, no Emerson, no Whitman, no Poe, no Hawthorne in German-American literature. Much has been written, in prose and in verse, but very little, if anything, rises above mediocrity or will stand as a lasting acquisition in German literature. The novels of Sealsfield-Postl of course hold their distinctive rank in the history of the German novel, but the poems of Solger, Nies, Castelhun, Krez, Edna Fern, the essays and feuilletons of Carl Schurz, Holls, Robert Reitzel, and many others will soon have none but historical interest. German, as the medium of all these literary products, seems to have no intrinsic formative powers in America, for reasons not far to seek. Moreover, it is perfectly obvious to the close observer that the real genius and spirit of German classical literature and philosophy was alive and bearing fruit in Emerson and the other New England Transcendentalists, while the literature of German America was steeped in the shallow insipidities of the 'Force and Matter'— philosophy of Büchner, Vogt, and Moleschott, winning for the Germans from Americans the reputation of being gross materialists. The bulk of literature, periodicals not books, coming from the German presses in the United States is quite considerable, but the quality does not at all tally. Of the German-American newspapers the 'New Yorker Staatszeitung,' with its excellent literary Sunday paper of partly original contributions, can best claim any eminence, politically, as a literary sheet, or as a newspaper.

Playwrighting there has been none to speak of for the German-American stage. While the history of the German drama during the 19th century was more brilliant, as a whole, than that of any other literature, the German stages in this country felt satisfied in reproducing the plays written in the mother country. But the efforts of the New York Irving Place Theatre, under Heinrich Conried's management, have been a model for the whole country to show what can be done, even with modest means, not only in the art of skillful and artistic ensemble play, but also in serving the people with a repertory of serious dramatic art. The stage as an institution of æsthetic and ethical culture, such as Schiller wanted it, will perhaps take permanent form, under the stimulus of German influence, in the proposed National Theatre at New York.

Music, although universal in its means of expression, this truly divine art, enters into the life of every German, unless he be completely anglosaxonized. It is undisputed that the Germans have performed a mission, and are still doing so, in bringing with them what is perhaps the most adequate expression of the German soul, German love of music. This expresses itself at every step where Germans are gathered. But, and this is the greatest, above the layer of popular music practice rises the cultivation of the classical in this art, symphonic or operatic, the rise and history of which is forever connected with the lives of Theodore Thomas, Anton Seidl, Walter Damrosch, to name only the most eminent of bygone times. But even here the productive power lags far behind the reproductive; the Germans have produced no composer on this soil, even none to compare with MacDowell.

To enter into the causes of the failure, not only of Germans, but also to some degree of Anglo-Saxons coming here, to furnish the world with genius of the high creative order, is not the task. The leveling influence of democratic doctrine, which best befits mediocrity, certainly has something to do with it. Nor must it be overlooked, that much of the higher service done by Germans in this country came from such as would strenuously object to being classed as German-Americans, they are and remain Germans. The German-American, on the other hand, of the more or less anglosaxonized type, has yielded, as facts demonstrate, nearly always just those elements of his racial soul from which spring forth the most excellent cultural achievements of the race. The question, if Germans in the United States will obtain a stronger beneficial influence on American civilization, rests on the determination and on the possibility of drawing new, refreshing, and strengthening currents from the great mainspring of German culture; currents of quality, not of quantity, *i. e.*, ideas and ideals. Only then will they have reason to be proud of what Richard Wagner conceived to be the essential German characteristic. "To be German," he said, "means to do things on account of their intrinsic values."

Bibliography.— An excellent guide (catalogue raisonné) to the literature on the subject is contained in Dr. Julius Goebel, 'Das Deutschtum in den Vereinigten Staaten von Nord-Amerika' (München 1904). This pamphlet is a spirited introduction into the whole subject written from a moderately Pan-German point of view. Merely bibliographical in character is 'A List of Works Relating to the Germans in the United States,' compiled under the direction of A. P. C. Griffin, chief bibliographer of the Library of Congress. This list represents the contents of the Library of Congress on the subject, but is far from being complete or even from containing the more important literature with reasonable completeness. For a negative statement, *i. e.*, what the Germans have failed to accomplish in America, see the chapter 'Die Amerikaner und die Deutschen' (pp. 1–51) in 'Hugo Münsterberg, Die Amerikaner' (Berlin 1904). Of the periodicals devoted to the study of the history and influence of Germans in the United States th 'German American Annals' (succeeding the 'Americana Germanica') flourishes beside the excellent 'Deutsch-Amerikanische Geschichtsblätter,' a quarterly edited by the 'Deutsch-Amerikanische Historische Gesellschaft von Illinois.' Of the older writers on German-Americans, Friedrich Kapp, Oswald Seidensticker, and H. A. Rattermann rank highest.

KARL DETLEV JESSEN,
Professor of German Literature, Bryn Mawr College.

Germany, Weights and Measures. Since 1 Jan. 1872 the French metrical system of weights and measures has been in force throughout the German empire. It had previously been adopted by a law of the diet of the North German Confederation, and under the constitution of the new German empire the new system of weights and measures was introduced into the south German states according to the terms of separate treaties previously concluded by them with the North German Confederation. The following are the German names of the various denominations of the metric system:

Measures of Length —

Das Millimeter or Der Strich	=	the Fr.	Millimètre.
" Centimeter or " Neuzoll	=	"	Centimètre.
" Decimeter	=	"	Décimètre.
" Meter or Der Stab......	=	"	Mètre.
" Dekameter or Die Kette	=	"	Decamètre.
" Kilometer	=	"	Kilomètre.

The new German mile is equal to 7,500 metres.

Measures of Surface —

Das Quadratmeter or Der Quadratstab	=	the Fr. sq.	Mètre.
" Ar	=	"	Are.
" Hektar	=	"	Hectare.

The unit of the measures of capacity is *das Kubikmeter* or *der Kubikstab* — the French *stère*.

In liquid measure the following terms are used:

Das Liter or Die Kanne......	=	the Fr.	Litre.
" Hektoliter or Das Fass..	=	"	Hectolitre.

A measure equal to half a liter is called a *Schoppen*, and one equal to 50 liters a *Scheffel*.

Measures of Weight —

Das Milligramm	=	the Fr.	Milligramme.
" Decigramm	=	"	Centigramme.
" Centigramm	=	"	Décigramme.
" Gramm	=	"	Gramme.
" Dekagramm	=	"	Décagramme
" Kilogramm	=	"	Kilogramme.

Half a kilogramm is one *Pfund*; 50 kilogramms, or 100 *Pfund*, make one *Centner*; and 1,000 kilogramms one *Tonne*. See WEIGHTS AND MEASURES; METRIC SYSTEM.

Ger'micides, agents used to destroy or to hinder the growth of microscopical forms of plant and animal life.

Germicides may be grouped under three general heads, those that act mechanically, those that destroy life by physical means, and those whose action is chemical. Inasmuch as each particular germ is an individual with its own particular characters, definite methods for its killing must be devised. Thus it is well known that quinine, for instance, is very active in destroying animal parasites, such as the malarial organism, but it is practically of no service in combating a large number of vegetable forms; and *vice versa*, many substances which are capable of destroying plant germs are inefficient when applied to animals.

Of the physical agents, heat, light, cold, and electricity, heat is the most satisfactory. High degrees of temperature will destroy all forms of parasitic life. The animal forms succumb very readily to the influence of heat, and most of the plant parasites are destroyed by it; but whereas heat may be applied with great success as a germicide in general disinfection, it naturally cannot be used as a general agent on the body. The red-hot iron in the form of a galvanocautery, or a heated wire, makes a most efficient form of cautery to destroy the poison of dog-bite, or to destroy localized forms of tuberculosis, etc., but heat is thus limited in its application.

Cold is not an efficient germicide. Ordinary freezing temperature (32° F.) kills but very few forms of either plant or animal organisms. Even the extreme cold of liquid air does not kill bacterial spores.

Light, especially sunlight, is a very efficient germicide, but the exposure must be continued for an appreciable length of time. Sunlight is nature's great germicide. Within recent years the light given by the Röntgen ray (X-ray), by radium, polonium, thorium, and similar agents, has been used with great success in the treatment of certain parasitic skin-diseases, but whether the effects are due to any germicidal action of the light, or to a normal tissue stimulation, is not decided. It seems from experiments thus far recorded that these forms of light are not definite germicides. Various colored lights, particularly red and amber, are known to restrict the growth of certain forms of bacteria. They do not, however, destroy them. This principle is made use of in smallpox hospitals and similar institutions, but it does not seem that the results are sufficiently striking to base any general deductions thereon. Electricity is not an efficient germicide. The passage of electrical currents through water does not necessarily kill the bacteria contained therein, notwithstanding the many claims made by enterprising manufacturers of electrified water, said to be made germ-free by the electrical current. What the future may reveal along this line of experimentation it is impossible to prophesy, but thus far satisfactory evidence of the germicidal effects of electricity are lacking.

Chemical germicides are numerous, both for external and internal use, although intracellular germicides, or those that can be used within the tissues of the body, are much to be desired. The list of chemical germicides is enormous. Thousands of different agents have been used and these exhibit varying degrees of germicidal activity. As has already been said, each form of germ possesses its own powers of resistance, and each germicide its ability to kill in varying degrees of strength. The germicides in popular use are chlorinated lime, carbolic acid, creosote, alcohol, boracic acid, ammonia, formaldehyde, hydrogen peroxide, iodine and its preparations, mercury and its preparations, volatile oils of cinnamon, mustard, peppermint, turpentine, pennyroyal, oxygen, quinine, salicylic acid and its derivatives. Of these for external use, for use in closets, in bedding, for linen, etc., carbolic acid in the percentage of 1 to 50 of water, formaldehyde in percentage of a teaspoonful of the 40 per cent solution of the gas to a quart, bichloride of mercury in the proportion of 1 part to 1,000, are the most practical and convenient germicides. So far as is now known, quinine is about the only efficient chemical substance that can be used as an intracellular germicide. It has the singular property of poisoning the malarial parasites within the red blood-cell without poisoning the blood-cell itself, a selective property which most poisonous agents lack.

JEAN LÉON GÉROME.

The great germicide of the human body, and the one that protects it in its various struggles with different forms of parasites is the blood-serum. This is a very efficient germicide, a full consideration of the action of which will be taken up under the heading of IMMUNITY. Consult: Buck, ‹Reference Hand-Book of Medical Sciences› (1902), article on *Germicides;* Harrington, ‹Practical Hygiene› (1901). See BACTERICIDE; BACTERIA; DISINFECTION; GERMS; IMMUNITY.

Germinal, zhăr-mē-näl, the 7th month of the first French republican calendar, 21 March–19 April.

Germina'tion, in botany, the first act of growth which takes place in an embryo plant. See SEED.

Gernsheim, Friedrich, frēd'rĭн gĕrns'hīm, German composer: b. Worms 17 July 1839. He studied at the Leipsic Conservatory, became an instructor in the Conservatory of Cologne in 1865, and in 1873 also Kapellmeister of the theatre there. In 1874 he was appointed director of the Rotterdam school of music, and in 1890 of the Stern Choral Union of Berlin. His works include chamber-music, three symphonies, and other instrumental compositions: the song-cycle ‹Hafis,› for solo, chorus, and pianoforte; and various vocal compositions.

Gérôme, Jean Léon, zhôṅ lā-ôṅ zhā-rōm, French painter: b. Vesoul, Haute-Saône, 11 May 1824; d. Paris 10 Jan. 1904. He was a pupil of Delaroche, who early credited him with originality and style. When he exhibited his ‹Fighting Cocks› in 1847, Théophile Gautier wrote in *La Presse,* «Let us mark with white this lucky year, for unto us a painter is born.» He followed Delaroche to Rome in 1848, and visited Russia and Egypt. He first showed his power in some Egyptian studies, but only reached the level of intensity and vividness which characterized all his succeeding work in his ‹Duel after a Masked Ball.› This was followed by his ‹Death of Cæsar.› In 1855 he exhibited ‹The Age of Augustus,› a picture in which were harmoniously blended marvelous historic faithfulness with a powerful allegory by which the culmination of pagan civilization, and its gradual paling in the dawn of Christianity was finely suggested. His grasp of classic motifs was united to an extraordinary mastery of archæological detail, and his Roman ‹Gladiators in the Amphitheatre› (1859), and ‹Phryne before her Judges› (1861), are startling in the impression which they convey of antique life in its movement, sentiment, and passion. In this special department of historical genre Gérôme easily led the European painters of his century. See Claretie, ‹Peintres et sculpteurs contemporains› (1884); Cook, ‹Art and Artists of Our Time› (1888); Van Dyke, ‹Modern French Masters› (1896).

Gerona, hā-rō'nä, Spain, a city and capital of the province of Gerona; 65 miles from Barcelona. It contains a beautiful Gothic cathedral of the 14th and 15th centuries. The town has undergone several notable sieges, particularly in 1653, 1684, 1694, 1706, and 1809, on each occasion by the French. Pop. 15,407. The province of Gerona has an area of 2,264 square miles. Pop. (1900) 299,287.

Geronimo, jĕ-rŏn'ĭ-mō, Apache chief of the Chiricahua band. In 1884–6 he became noted as the ring-leader in the harrying of Arizona and New Mexico (see APACHES). Gen. Crook forced him to a stand on 25 March 1886, but Geronimo refused to surrender except for two years, the band to be sent East with their families and then replaced on the old reservation. Crook accepted the terms and started for Fort Bowie, but on the march the entire band slipped away to the mountains and began the old forays again. The subsequent criticism of Crook, as the Indians' dupe against the protests of the settlers, caused his replacement by Gen. Nelson A. Miles, who gave the Indians no rest, till Geronimo once more surrendered, this time on condition of being sent out of Arizona. Gen. Miles ordered them sent to St. Augustine, but Geronimo and 14 others were sent to Fort Pickens, Fla., instead. He has since been held as a military prisoner at Fort Sill, Oklahoma.

Gerontes, gĕ-rŏn'tēs, in ancient Greece, a number of magistrates of Sparta who, with the ephors and kings, had the supreme power in the state. They were not eligible for election before they had attained the age of 60 years. Their number is variously stated at 20 and 32.

Gerrish, Theodore, American Methodist clergyman: b. Houlton, Maine, 19 June 1846. He served during the Civil War in the 20th Maine regiment, and was wounded four times; later entering the Methodist itinerant ministry. His publications include: ‹Reminiscences of the War,› ‹The Blue and the Gray,› ‹Life in the World's Wonderland,› etc.

Gerry, gĕr'ĭ, **Elbridge**, American statesman: b. Marblehead, Mass., 17 July 1744; d. Washington, D. C., 23 Nov. 1814. He was a member of the Continental Congress 1776–80 and 1783–5; delegate to the constitutional convention in 1789; member of Congress from Massachusetts 1789–93; commissioner to France 1797–8; governor of Massachusetts 1810–12; and Vice-President of the United States 1813–14. It was during his term as governor that an unsatisfactory redistricting of the State took place, in which he was supposed to have taken part, whence arose the term «gerrymander» (q.v.). See Austin, ‹Life of Elbridge Gerry, with Contemporary Letters› (1828–29).

Gerry, Elbridge Thomas, American lawyer and philanthropist: b. New York 25 Dec. 1837. He was graduated from Columbia in 1857, was admitted to the bar in 1860, and was a member of the State constitutional convention of New York 1867. Subsequently he became an associate of Henry Bergh in the American Society for the Prevention of Cruelty to Animals, of which he was for many years vice-president. In 1874 he was the leading organizer of the Society for the Prevention of Cruelty to Children, of which he was the president in 1876–91, and which became so closely identified with his name as often popularly to be termed the Gerry Society. He was chairman of the commission on capital punishment which substituted execution by electricity for that by hanging, in New York State (1886–8). He also held many important offices of trust, and became known for his interest in yachting affairs, having been commodore of the New York Yacht Club in 1886–93. He is a grandson of Elbridge Gerry (q.v.).

Gerrymander, gĕr'ĭ-măn-dėr (hard g: now chiefly used as a verb), the arranging of election districts by one party in a State so as to concentrate its opponent's majorities and scatter its own, thus giving itself as many with light majorities and its rival as few with heavy ones as possible. Many States are to some extent gerrymandered by nature, the heaviest vote of one party being compacted into a minor section: Indiana and New York are notable cases — the one on account of the southern agricultural population having been kept from expansion by more energetic streams of a different character, the other from the development of a vast city at political odds with the rural parts. Law usually and fairness necessarily provide that the State shall be districted in solid blocks of contiguous territory, so that (subject to the above limitation) the district elections shall correspond roughly to the popular majorities in the State. But since early in the century, all parties in turn have often violated political equity by establishing artificial gerrymanders when in power; sometimes creating a popular revolt which has cost them the object of the scheme, but the rival party has rarely learned wisdom from that result, usually reversing the gerrymander for its own profit. As counties are fair models of what election districts should be, the gerrymander is generally worked by disregarding them; but the following illustration of its working with them is the simplest form. Suppose nine counties casting 10,000 votes each, the whole lying in a block thus arranged, and the votes divided between party A and party B as indicated within:

1 A 8750 B 1250	4 A 5250 B 4750	7 A 4850 B 5150
2 A 4500 B 5500	5 A 7500 B 2500	8 A 4750 B 5250
3 A 5100 B 4900	6 A 4300 B 5700	9 A 7000 B 3000

Now let one district be formed from the diagonal counties 1, 5, and 9, and three others, respectively, from 2 and 4, 3 and 6, and 7 and 8. Party A has 52,000 against B's 48,000 altogether or a popular majority of 4,000; but it only carries one district out of four because the gerrymander has made it waste most of its votes and its rival wastes almost none. Yet the law has been observed, as all the counties in each district are contiguous. Of course, in practice such perfect cases do not occur, and towns or counties are grouped raggedly in forms often grotesque. The origin of the name was from one of these, among the earliest. Massachusetts, in 1812, had its senatorial districts identical with the counties; the State Constitution gave the legislature the power of redistricting, however, and the Republicans, carrying the legislature in that year over the Federalists, at once gerrymandered it in a very outrageous fashion. The Boston *Sentinel* published a colored map of one district in Essex County, whose sprawling towns with a huge prong to the northwest seemed like some monstrous animal of fable; and on an indignant Federalist saying that it «looked like a salamander,» another retorted, «Better call it Gerrymander,» from the Republican governor, Elbridge Gerry (q.v.), whose signature had made it law. Gilbert Stuart (q.v.), the artist, drew a completion of it into an ungainly bird, which figured largely as a campaign document. The Federalists recaptured the legislature the next year and repealed the bill. The most famous of many great gerrymanders in the United States is the «Shoe-tring District» (Sixth Congressional) of Mississippi, formed to minimize the negro vote, and consisting of all the counties in the State touching the Mississippi River; it is about 300 miles long by an average of 20 broad.

Gerster, găr'stĕr, **Etelka** (MADAME GARDINI), Hungarian singer: b. Kaschau, Hungary, 16 June 1857. She was a pupil of Madame Marchesi in Vienna, and made her first appearance in Venice in 1876, as Gilda, in 'Rigoletto.' In 1878, and also in 1883 and 1887, she made successful tours in the United States. In 1887 she married her director, Pietro Gardini, and since 1896 has been at the head of a singing school in Berlin.

Gerstle, Lewis, Californian pioneer: b. Bavaria 17 Dec. 1824; d. San Francisco, Cal., 17 Nov. 1902. Coming to the United States as a lad, he settled in Louisville, Ky., and joined the fortune-seekers in California in 1850. With Lewis Sloss he subsequently formed the Alaska Commercial Company. Their enterprises by sea and land aided largely in building up California, and Gerstle always displayed a public spirit and faith in the future of the State. He was treasurer of the University of California, and identified with many Jewish and general charities, to all of which he was a generous giver.

Gertrude of Wyoming, a narrative poem by Thomas Campbell, written at Sydenham, in 1809. He chose the Spenserian stanza for his form of verse, and for his theme the devastation by the Indians, in 1778, of the quiet valley of Wyoming, in Pennsylvania, on the Susquehanna. The poem opens with a description of «Delightful Wyoming,» which Campbell, who had never seen it, paints as a terrestrial paradise. The whole style and manner is pseudo-classic and old-fashioned; the treatment vague, unreal, and indefinite; but a certain sweetness and pathos, combined with the subject, has kept the poem alive.

Gervinus, Georg Gottfried, gā-ŏrg' gŏt-frēd gĕr-fē'noos, German historian: b. Darmstadt 20 May 1805; d. Heidelberg 18 March 1871. In 1825 he went to the University of Heidelberg, where the lectures of Schlosser inspired him with a peculiar love of historical studies. In 1831 he visited Italy, where he remained for a year collecting materials for the works he was meditating. His 'Historische Schriften,' published after his return (1833), excited the attention of scholars, and secured him in 1835 an extraordinary professorship in the University of Heidelberg, where he was in 1844 appointed to an honorary professorship. From 1845 he took an active part on the liberal side in the movements then going on in Germany. It was at this period that he wrote his 'Mission der Deutschkatholiken' and 'Die Protestantische Geistlichkeit und die Deutschkatholiken.' In 1847 he founded in Heidelberg, in conjunction with Mathy, Mittermaier, and Häussy, the 'Deutsche Zeitung,' which at once became one of the leading organs of the party which advocated a representative system for Germany and a clearly defined federal constitution. His chief works are 'Geschichte der poetischen Nationallitteratur der Deutschen' (1835–42), in which he endeavors to show how the development of German poetry is connected in all its phases with the history of the nation and other European countries; 'Shakespeare' (1849–50); 'Geschichte des neunzehnten Jahrhunderts' (1855–66). All his works, even his more purely æsthetical ones, such as that on Shakespeare, are more or less colored by his political views and aims. In the last years of his life he zealously endeavored to secure the popularity in Germany of the works of Handel, whom he regarded as the greatest genius in the musical sphere that the world had even seen. His 'Autobiography' appeared in 1893.

Geryon, jē'rĭ-ŏn, in the mythology of Greece a king of Hesperia, son of Chrysaor and Callirrhoe, a three-headed giant. He possessed numerous and fine herds, which were guarded by the two-headed dog Orthrus and the giant Eurytion. The herds were carried away, and Geryon slain by Hercules, in obedience to the command of Eurystheus.

Gesenius, Friedrich Heinrich Wilhelm, frēd'rĭн hīn'rĭн vĭl'hĕlm gā-zā'ne-oos, German Orientalist: b. Nordhausen, Saxony, 3 Feb. 1786; d. Halle, 23 Oct. 1842. He studied at Helmstedt and Göttingen, and at Halle in 1810 became extraordinary, in 1841 ordinary, professor of theology. Here he lectured for more than 30 years, broken only by the closing of the university during the War of Liberation (1813–14), and by lengthened visits to France and England in 1820, to England and Holland in 1835. His first great work was his 'Hebrew and Chaldæan Hand Dictionary.' His 'Elementary Hebrew,' consisting of the 'Hebrew Grammar,' and the 'Hebrew Reader,' has contributed enormously to the knowledge of the Hebrew language, not only in Germany, but through translations also in England and the United States. Later works are his 'Critical History of the Hebrew Language and Literature' (1815); 'On the Origin, Genius and Authority of the Samaritan Pentateuch' (1815); 'A Critical Grammatical System of the Hebrew Language' (1817), and a new translation of and commentary on Isaiah (1820–21). His greatest work is the monumental 'Critical Grammatical System of the Hebrew and Chaldæan Languages in the Old Testament,' of which the first part was published in 1829, but which was completed only in 1858 by Rödiger. See Hayne, 'Gesenius, eine Erinnerung für seine Freunde' (1842).

Gesner, Abraham, Canadian geologist: b. Cornwallis, N. S., 2 May 1797; d. Halifax, N. S., 19 April 1864. He studied medicine in London, and returned to Nova Scotia. Later he became interested in scientific researches. In 1838 he was appointed to examine and report on the geological resources of the lower provinces of British North America. Afterward he discovered how to produce oil suitable for lamps from bituminous shale and cannel coal. He thus originated the discovery of "kerosene" (which name he gave his oil) in the United States. His publications include: 'Remarks on the Geology and Mineralogy of Nova Scotia' (1837); 'Reports on the Geological Survey of the Province of New Brunswick' (1844); 'New Brunswick, with Notes for Emigrants' (1847); 'Industrial Resources of Nova Scotia' (1848); 'A Practical Treatise on Coal Petroleum and Other Distilled Oils' (1861); etc.

Gesner, Konrad von, kŏn'räd fŏn gĕs'nĕr, Swiss naturalist: b. Zürich, Switzerland, 26 March 1516; d. there 13 Dec. 1565. His early studies, in medicine, natural history, and Greek and Latin literature, were prosecuted at Zurich, Strasburg, Bourges, and Paris, and in 1537 he was appointed professor of Greek at Lausanne. This chair he exchanged four years later for that of physics and natural history at Zürich. He was an indefatigable writer of books and in the course of his life published no less than 72 works, besides leaving at his death 18 others in progress. His 'Universal Library' (1545), contained the titles of all the books then known in Hebrew, Greek, and Latin, unpublished as well as published, with criticisms and summaries of each. His next undertaking was the 'Animal History' (1551–8). The first book treats of viviparous quadrupeds, the second of oviparous animals, the third of birds, and the fourth of fishes and aquatic animals. He collected more than 500 plants undescribed by the ancients, and appears to have been the first who made the great step toward a scientific classification of distinguishing genera by the fructification. He also wrote on other branches of science, as medicine and mineralogy, and composed a great number of works dealing with the ancient classics, the 'Mithridates sive de Differentia Linguarum' (1555) being the most notable.

Gessler, gĕs'lĕr, **Albrecht**, or **Herman**, called also Gessler von Bruneck, legendary Austrian official, in 1300 appointed joint-governor with Berenger von Landenberg, of the Waldstädten or forest cantons (Schwytz, Unterwalden, and Uri), by Albrecht I. of Austria. According to the traditions connected with William Tell (q.v.), his oppressive edicts and wanton cruelty so enraged the inhabitants that a conspiracy was formed against him, and he was shot by Tell in a narrow pass near Küssnacht in 1307.

Gessner, gĕs'nĕr, **Salomon**, German poet, painter, and etcher: b. Zürich 1 April 1730; d. there 2 March 1788. In 1762 he published, in four volumes, the poems which he had previously given to the world on different occasions. In 1772 he published another volume containing a collection of poems, to which he gave the name of 'Idyllen' (idyls), a name which he had already given to a previously published volume of poems. Their quiet, amiable character pleased many in Germany; and in France, where they were translated by Huber, they were received with enthusiasm, and the author was regarded as a poet of the first rank. From France his fame spread over all Europe. The most popular of his idyls is the 'Death of Abel,' since translated into many foreign languages. In landscape painting he has merits which no age will diminish. His etching is light and powerful; his views are select, wild, and romantic; and his trees are particularly fine. Twelve engraved landscapes, published in 1770, are considered among his best works.

Gesta Romanorum, jĕs'ta rō-mä-nō'rŭm, 'Deeds of the Romans,' the title of a collection of short tales, legends, etc., in Latin, very popular in the Middle Ages. The book was probably compiled about the close of the 13th century. The separate tales making up the Gesta are of diverse contents, and belong to different times and countries, the sources from which they are derived being partly classical, partly Oriental and partly western. Whatever may have been the intention of the original compiler, they very soon were adapted to the moralizing tendencies of the time, and moral reflections and allegorical interpretations were added to them, it is said, by a Petrus Bercorius or Pierre Bercaire of Poitou, a Benedictine prior.

Gesta'tion, the period of development of the fœtus from the time of conception to birth. Even in animals, where only a single insemination is allowed, the length of the gestation cannot always be foretold with exactness. The human fœtus is carried in the uterus about 280 days. For periods of gestation in animals, see BREEDING. See also OBSTETRICS; PREGNANCY.

Geta, jē'ta, **Septimus**, Roman emperor: b. 189 A.D.; d. 211 A.D. He was the second son of the Emperor Severus, and brother of Caracalla, with whom he was associated in the empire on the death of his father. Caracalla, who envied his virtues and was jealous of his popularity, after having endeavored to effect his death by poison, murdered him, and wounded their mother, who was attempting to save him.

Gethsemane, gĕth-sĕm'a-nē, or **Gethsemani** (*Boustanez-Zeitoun*), an olive garden or orchard in the neighborhood of Jerusalem, on the road leading from the brook Kedron to the Mount of Olives. The place is noted for being the scene of "Our Lord's Agony in the Garden" (Luke xxii. 39–53). It is said that when St. Helena (q.v.), the mother of Constantine, visited the Holy Land in 425, she found abundant evidences to aid her in locating the exact site of the "Garden of Olives" or Gethsemane. The place is now in possession of the Franciscan Fathers of the Holy Land who, in 1848, built a wall around it the better to protect it. They have planted many flowers which they give gratuitously to travelers who desire some memento from this historic spot. Maudrell described the place in his day (1697) as "well planted by olive trees"; but there are now only eight trees which are supposed to have been in the grove at the time of our Lord. Some historians seek to throw doubts upon the age of these trees because of the order issued by Titus to destroy all the trees within a certain limit. These trees were so near the walls that they could not well be destroyed even if the tops were cut off. From the earliest days of the possession of Palestine by the Mohammedans every olive-tree has been taxed except these trees. In the 17th century there were nine trees, but one was destroyed by tourists. The present appearance of the garden is in accordance with the description as found in the Gospels. Another site, a little to the north, is claimed by some to be the real Gethsemane. Consult: De Hamme, 'Ancient and Modern Palestine'; Vogue, 'Les Eglises de la Terre Sainte,' p. 314; Thomson, 'The Land and the Book'; Costello, 'The Gospel Story.'

Getty, George Washington, American soldier: b. Georgetown, D. C., 2 Oct. 1819; d. Forest Glen, Md., 3 Oct. 1901. He was graduated from the United States Military Academy in 1840, fought in the Mexican and Seminole wars, in the Civil War attained the brevet rank of major-general, United States army. He subsequently was commander of numerous military districts; was transferred to the artillery in 1871 and retired from the service in 1883.

Get'tysburg, Pa., a borough and county-seat of Adams County; 35 miles southwest of Harrisburg; on the Philadelphia & R. and Western M. R.R.'s. It is the seat of a Lutheran theological seminary founded in 1826, and Pennsylvania College (Lutheran) founded 1832. One of the most famous battles of the Civil War was fought here. Pop. (1900) 3,495. See GETTYSBURG, BATTLE OF.

Gettysburg, Campaign and Battle of. After the battle of Chancellorsville (q.v.), 1–3 May 1863, the opposing armies resumed their positions on the Rappahannock, Lee's army on the south side of the river, at Fredericksburg, Hooker's on the north side, opposite. Encouraged by victory, and desiring to relieve Virginia of the presence of the Union army, Lee determined to transfer the seat of war north of the Potomac. His army, 1 June, was composed of the three corps of Longstreet, Ewell and A. P. Hill, and Stuart's cavalry force of 12,000 men, in all about 76,000 men, with 190 guns. Hooker's Union army was composed of seven corps, the First, commanded by Reynolds; Second, by Hancock; Third, by Sickles; Fifth, by Meade; Sixth, by Sedgwick; Eleventh, by Howard; and Twelfth, by Slocum; aggregating, 10 June, 82,000 infantry and artillery "present for duty and equipped," with 410 guns, to which were added Pleasonton's cavalry force of about 12,000.

Lee began his campaign 3 June by sending Longstreet and Ewell to Culpeper Court House, where the cavalry, under Stuart, was also concentrated. A. P. Hill remained at Fredericksburg to watch and detain Hooker. Hooker suspected Lee's movement and, under his direction, Sedgwick laid bridges, crossed the river, and reported that Lee's main body seemed to be still there. Pleasonton was ordered to feel the position at Culpeper. Reinforced by two infantry brigades, he crossed the Rappahannock on the morning of the 9th, encountered Stuart at Fleetwood and Brandy Station (see FLEETWOOD AND BRANDY STATION, BATTLE OF), and reported the greater part of Lee's army at Culpeper, preparing to move on Washington. Hooker sent three corps up the Rappahannock to prevent Lee's crossing. On the 10th Lee sent Ewell, preceded by two brigades of cavalry, to the Shenandoah Valley to clear it of Union troops. Ewell defeated and dispersed Milroy's command at Winchester (see WINCHESTER, BATTLE OF), took Martinsburg and cleared the valley; and on the 15th Rodes' division crossed the Potomac at Williamsport, sending Jenkins' cavalry brigade in advance to Chambersburg, and on the 19th moved to Hagerstown. Johnson's division crossed the Potomac and marched to Sharpsburg, and Early's moved to Shepherdstown to threaten Harper's Ferry. In these positions Ewell waited until the 21st for the other two corps to close up, when he advanced to Chambersburg. Longstreet moved from Culpeper on the 15th and, advancing along the east side of the Blue Ridge, occupied Ashby's and Snicker's Gaps. Stuart's cavalry was thrown out in front of Longstreet to watch Hooker, and

ENTRANCE TO NATIONAL CEMETERY, GETTYSBURG, PA.

NEW YORK STATE MONUMENT IN NATIONAL CEMETERY, GETTYSBURG, PA.

on the 17th had a severe fight with the Union cavalry at Aldie and was driven back to Middleburg. A series of cavalry combats ensued, at the end of which Stuart was driven behind the Blue Ridge. On the 24th Longstreet moved by way of Berryville, crossed the Potomac at Williamsport on the 25th and 26th, and marched to Hagerstown, thence on the 27th to Chambersburg. A. P. Hill remained at Fredericksburg until the 14th, when, Hooker having fallen back, he moved down the Shenandoah Valley, crossed the Potomac at Shepherdstown, and joined Longstreet at Chambersburg. Stuart was left to guard the passes of the Blue Ridge and watch Hooker, whom he was to harass as much as possible, should he attempt to cross the Potomac. Meanwhile Hooker, starting from the Rappahannock on the 13th, was moving cautiously back toward the Potomac and covering Washington. On the 25th, 26th and 27th he crossed the Potomac at Edward's Ferry, near Leesburg, and on the 28th his army was grouped about Frederick, with Slocum's corps on the left near Harper's Ferry. He desired to send Slocum's corps and the 10,000 men, composing the garrison at Harper's Ferry, against Lee's rear, but Gen. Halleck, commander-in-chief, refused the request for the garrison, and Hooker asked relief from command. His request was promptly granted, and 28 June Gen. George G. Meade was assigned to the command. Halleck granted Meade's request to utilize the garrison at Harper's Ferry and Meade ordered the abandonment of the place and the transfer of the garrison to Frederick and Washington.

Lee, deprived of the use of his cavalry, had been unable to get information of Hooker's movements; and to retain him on the east side of the mountains, after he had entered Maryland, Ewell had been instructed, on the 24th, to send a division across the South Mountain to threaten Baltimore. Early's division, detailed for the purpose, went as far east as York, the other two divisions of the corps marching from Chambersburg to Carlisle. Jenkins' and White's cavalry were in advance at Wrightsville and above on the Susquehanna, threatening to cross and take Harrisburg. Lee now made preparations to advance upon Harrisburg, but, on the night of the 28th received information that the Union army had crossed the Potomac and was moving northward, its head of column already at South Mountain. His communications thus menaced, Lee resolved to prevent the further progress of the Union army by concentrating his own on the east side of the mountains; accordingly Ewell was ordered to turn back from the Susquehanna, Carlisle, and York, and march for Gettysburg, and Longstreet and Hill were directed to march from Chambersburg to the same place. On the night of the 30th Rodes' division of Ewell's corps was at Heidlersburg, eight miles northeast of Gettysburg, with Early's and Johnson's divisions near. Hill was at Fayetteville and Cashtown, eight miles from Gettysburg, and Longstreet was still at Chambersburg.

On the morning of the 29th under the impression that all of Lee's army was along the Susquehanna, Meade marched by three divergent roads in that direction and on the night of the 30th his forces were thus distributed. Buford, with two brigades of cavalry, was in advance at Gettysburg; Reynolds' First corps on Marsh Creek, five miles southwest of Gettysburg; Sickles' Third corps at Taneytown, and Howard's Eleventh corps at Emmitsburg. These three corps, constituting the left wing of the army, were under command of Gen. Reynolds. Hancock's Second corps was at Uniontown; Sykes' Fifth corps at Union Mills; Sedgwick's Sixth corps at Manchester; and Slocum's Twelfth corps at Littlestown. Gregg's cavalry division was at Westminster. Kilpatrick's division, after a spirited fight with Stuart's cavalry at Hanover, bivouacked near that place. When Buford reached Gettysburg he went into camp just beyond the western limits of the town and threw out skirmishers three miles west and north.

The First Day's Battle.— Heth's division, the advance of Hill's corps, moved from Cashtown at 5 o'clock on the morning of 1 July, coming in sight of Buford's skirmishers about 9 o'clock, at which hour Buford fired his first gun as a signal for his skirmishers to open fire, and the battle of Gettysburg began. Heth advanced and Buford was slowly driven back, contesting every foot of ground, until Reynolds came up with Wadsworth's division, which became immediately and desperately engaged. During this encounter Reynolds was killed. Doubleday succeeding to the command of the First corps, continued the contest. The other two divisions of the corps came up at 11 o'clock, followed at 12.45 by Howard's corps, one division of which was placed in reserve on Cemetery Hill, the other two forming on Doubleday's right along Seminary Ridge. Meanwhile Hill had arrived with the remainder of his corps, and Ewell, arriving at 2.30 P.M. with Rodes' and Early's divisions, formed on Hill's left. Hill made successive assaults on Doubleday from the west, and Ewell upon Howard from the north, which were repulsed; but finally, after desperate fighting and great losses on both sides, Early struck Howard in flank, causing him to give way, and the entire Union line was driven back through the town to Cemetery Hill, about half a mile south, which had been chosen by Howard as a rallying point for the two corps, and upon which he had placed one of his own divisions. When Meade heard that Lee's advance had reached Gettysburg, and that Reynolds had been killed, he was at Taneytown, 14 miles away, preparing to take up a defensive line along Pipe Creek. He ordered Hancock to ride forward and take command at Gettysburg. Hancock arrived as the Union troops were retreating through the town, was struck with the advantages presented by Cemetery Ridge for a defensive battle, determined to hold it and so notified Meade, sent one of Doubleday's small brigades to hold Culp's Hill, on the right, and made an ostentatious display of Buford's cavalry on the extreme left; which show of force, and the great loss — over 7,000 — sustained by the Confederates during the day, caused Lee to defer operations. Two divisions of Sickles' corps came up at dark; Slocum's corps came about the same time, and Slocum, as ranking officer, assumed command of the field, Hancock riding back to report to Meade that Gettysburg — to which point Meade had already ordered the concentration of his army — was the proper place to fight a battle. Hill's and Ewell's

Confederate corps were all up by night, and Longstreet bivouacked four miles in rear of Hill.

The Second Day.— Gen. Meade arrived on the field at 1 o'clock on the morning of the 2d. All his troops except the Sixth corps were up by noon. The Sixth corps, having 34 miles to march from Manchester, did not come up until between 2 and 4 o'clock in the afternoon. The position on which Meade disposed his army was in the shape of a fishhook. As finally posted, the Twelfth corps was on the right at Culp's Hill, facing east; Wadsworth's division on its left, facing north; the Eleventh corps on Cemetery Hill, on the left of Wadsworth, its right facing northeast, its centre and left facing northwest, with Robinson's division of the First corps on its left. Doubleday's division in reserve. The Second corps, facing west, was on the left of Robinson; the Third corps on the left of the Second, with the Fifth, later in the day, on the extreme left. The Sixth corps was in rear of Round Top, on the left, as a reserve. Sickles, not satisfied with the position assigned the Third corps, moved to the front about three fourths of a mile, from where Meade would have recalled him, but it was too late to do so in presence of a vigilant enemy.

The main part of Lee's army was on Seminary Ridge, a short mile west of Meade's left and centre; Longstreet on the right, with Hill on his left. Ewell's corps on the left held the town, and was at right angles to Hill and Longstreet. Pickett's division of Longstreet's corps had not come up. Skirmishing began in the morning. At 4 o'clock in the afternoon the battle opened by Longstreet's advance. He attacked Sickes with great fury and, although reinforced by Caldwell's division of the Second corps, and Barnes' and Ayres' divisions of the Fifth, after heavy fighting and great losses the Third corps and its supports were driven back beyond the main line. Longstreet followed, but was checked by a charge of Crawford's division of the Fifth corps and the firm and solid appearance of the Sixth corps. On Longstreet's right Hood's division advanced to seize Round Top, but was repulsed by Vincent's and Weed's brigades of the Fifth corps. Vincent and Weed were killed, and Hood wounded. During the latter part of Longstreet's engagement with Sickles two of Hill's brigades assailed Hancock's line and broke it, but were soon driven back. At about the same time Hays' and Hoke's brigades of Early's division assaulted Howard's line on Cemetery Hill, but were driven back with the assistance of two regiments and Carroll's brigade of Hancock's corps. Still further on the Confederate left Johnson's division of Ewell's corps assaulted Culp's Hill, then held by Wadsworth's division of the First corps and Greene's small brigade of the Twelfth corps, the rest of the corps having been withdrawn and sent to the assistance of the left. Johnson's right, continuing the fight until late in the night, was repulsed, but his left entered, unopposed, the strong works thrown up by the Twelfth corps, and was perilously near the practically unguarded reserve artillery and ammunition train of the Army of the Potomac. Upon the return of the Twelfth corps during the night to its former position, finding it occupied, it waited until daylight before attempting to retake it. Meanwhile Johnson was being reinforced by three brigades, that he might hold his ground and renew his fight.

The Third Day.— The battle of the third day began by a struggle of the Twelfth corps to regain their works. At 4 A.M. the corps artillery, five batteries, opened a furious fire upon Johnson, at a range of 600 to 800 yards, other batteries followed, in the midst of which Johnson attacked the left of the Twelfth corps and the right of Wadsworth's division; the combat extended to the right, was taken up by Williams' division, and for six hours the struggle continued, at the end of which Johnson was repulsed. At 10.25 Johnson massed his forces in column of regiments and made a determined assault upon the right of Geary's division, by which, with the assistance of Shaler's brigade, he was repulsed, and driven beyond Rock Creek with a loss of nearly 2,000 killed and wounded, and three colors. At 11 o'clock the battle ceased on the Union right, with the Twelfth corps line fully re-established. There was more spectacular fighting on other parts of the field, but none more desperate and bloody than on the wooded Culp's Hill. Meanwhile Lee was preparing an attack upon the left centre of Meade's army. Pickett's division had now come up, and Longstreet was directed to form a column of assault composed of Pickett's division, Pettigrew's division, and two brigades of Pender's division, under Trimble, of Hill's corps. To prevent Meade from reinforcing the threatened point, Stuart's cavalry was ordered to go around Meade's right and attack his rear; 135 guns were disposed on Seminary Ridge; and at 1 P.M. the signal-gun was fired, and the 135 guns opened fire to crush out all opposition at the point to be attacked; the fire was replied to by 85 Union guns, and for two hours the hills shook and the earth trembled. As soon as the Union fire slackened, the great column of attack moved forward, Pickett's division on the right and Pettigrew's on the left. Pettigrew was supported by the two brigades of Trimble, and Pickett by the brigades of Wilcox and Perry. Pickett and Pettigrew, at the start from Seminary Ridge, covered a front of 1,600 yards; they had 1,400 yards of open ground to traverse before reaching the Union line; and the assaulting column numbered 14,000 men. As soon as it started, the Union artillery opened on it with shot and shell, tearing great gaps in the line; as it came nearer, canister did its deadly work; it was attacked on both flanks; and as it approached the Union line, held by Gibbons' and Hays' divisions of Hancock's corps, a flame of musketry burst forth before which nothing could live, and the men began to retreat; but, on the right, Armistead, commanding one of Pickett's brigades, broke the Union line and, with less than 100 men, crossed the Union works and seized a gun; a short hand-to-hand encounter ensued; Armistead was killed, and his small party killed or captured. Pickett saw the failure of his assault, and ordered a general retreat, after losing over 5,000 men. Wilcox's and Perry's brigades, which should have supported Pickett's right, were not prompt in starting, became separated from it and, attacking the right of the First corps, were driven back, losing many prisoners, and the battle of Gettysburg was ended. On the Union right Gregg's cavalry division, aided by Custer's brigade, defeated Stuart, after a severe fight, and thwarted his attempt on Meade's right and rear. On the left Kilpatrick, with two cavalry brigades, recklessly charged Confederate infantry in dense woods, and behind stone fences, west of Round Top, in which assault Gen. Farnsworth, commanding one of his brigades, was killed. On the morning of 4 July Lee withdrew from his advanced positions, put his trains in motion for the rear, retreated at night and, followed and harassed by the Union cavalry, reached Williamsport on the 7th; but as the pontoon bridges had been destroyed and the Potomac had risen, he was unable to cross, and so entrenched. Meade followed by a circuitous route through Frederick and, after some delay, again confronted Lee on the 13th. He was about to attack when Lee recrossed the Potomac on the night of the 14th, his rear-guard, under Gen. Pettigrew, being attacked by Kilpatrick, during which fight Pettigrew was mortally wounded and many prisoners were taken.

From first to last the Union forces on the field numbered about 88,000 effective men; the Confederate forces on the field numbered about 73,000 men. As officially reported, the Union loss was 3,072 killed, 14,497 wounded, and 5,434 missing; an aggregate of 23,003; the Confederate loss 2,592 killed, 12,709 wounded, and 5,150 missing; an aggregate of 20,451. E. A. Carman.

Geulincx, hė'lĭnks or zhė-lănks, **Arnold,** Dutch philosopher: b. Antwerp, 1625; d. Leyden 1669. He was one of the disciples of Descartes (q.v.), and a leading exponent of the speculative doctrine known as Occasionalism. For 12 years, from 1646, he lectured successfully at Louvain, was then deposed for some reason not ascertained, and, after living at Leyden in great distress, was in 1665 appointed professor of philosophy there, but died four years later. His ideas are expounded in books entitled: 'Saturnalia'; 'Logica'; 'Ethica,' published in his lifetime, and in 'Annotata præcurrentia ad Cartesii Principia' (1690), and 'Metaphysica Vera' (1691), which appeared after his death. The salient point of his teaching is an endeavor to explain the relations which obtain between soul and body, the mutual interaction of which under stimulus he ascribed to divine intervention and preordained arrangement. See Grimm, 'Arnold Geulincx'; 'Erkenntnisstheorie und Occasionalismus' (1875); Pfleiderer, 'Arnold Geulincx als Hauptvertreter der Occasionalistischen Metaphysik und Ethik' (1882).

Geum, jē'ŭm, a genus of *Rosaceæ,* sub-order *Potentilleæ,* distinguished from *Potentilla* by the hardened hooked styles which crown the carpels, so that the fruit becomes a burr. They are perennial herbs with pinnate or pinnatifid leaves, and white, yellow or purple flowers. There are about 40 species, 14 being found in North America. They are commonly known as avens. The roots of *G. rivale,* purple or white avens, and of *G. urbanum* have astringent and tonic properties. The latter is used for flavoring ale. *Geum strictum* is known as chocolate-root. Many of the species are cultivated, *G. chiloense* being especially ornamental.

Geyserite, gē'sėr-īt, or **Siliceous Sinter,** is amorphous silica containing a varying amount of water. It is white or grayish in color, and is deposited about the geysers and hot springs of Wyoming, Montana, Iceland, and New Zealand as hard masses or in filamentous or cauliflower-like forms sometimes of great beauty. In the Upper Geyser Basin in the Yellowstone Park the formations of geyserite are abundant and most beautiful. The great terraces of the Mammoth Hot Springs are not geyserite, but are chiefly calcareous deposits.

Geysers, a name derived from an Icelandic word signifying "to burst forth with violence," and applied to natural springs of hot water of the kind that were first observed in Iceland, and since in Wyoming and California in the United States, and in New Zealand. They may be described as volcanoes of hot water, for they resemble volcanoes in every particular — in the vibrations of the earth and dull rumbling sounds or loud reports by which the eruptions are preceded, in the intermittence of the phenomenon, and in the form of the opening at which the eruptions take place, like an inverted cone with a deep central throat. Natural philosophers are not agreed as to the mode in which this phenomenon is to be explained, but the most generally prevailing and most probable hypothesis is that it is caused by the disengagement of large quantities of vapor, which force the water up into the air when the successive disengagements have produced a sufficient pressure.

The geysers of Iceland lie about 30 miles west of Mount Hecla, and 16 miles north of the town of Skalholt, in a plain covered by hot-springs and steaming apertures. They are nearly 100 in number, and are scattered over a surface scarcely more than two square miles in extent. The two most remarkable are the Grand Geyser and the New Geyser or *Strokkur* (churn). The Great Geyser rises from a tunnel-shaped basin, lined and edged with silicious deposits. The pipe or throat at the bottom, from which the jet issues, is about 10 feet in diameter, and the basin at its outer edge is above 70. The emissions generally take place at intervals of six hours, and last for about five minutes at a time. The column, as measured by a quadrant, has been seen to rise as high as 212 feet. It is impossible to fix the age of the Great Geyser, but that its eruptions have taken place from the most remote antiquity is proved by the fact that, although there has been no sensible increase in the depth of the silicious deposit since the earliest recorded observations, it is now more than 16 feet deep.

The geysers of Iceland, long the only ones known to exist, are surpassed by those which have been discovered in comparatively recent times in the Yellowstone National Park. The largest of them is called the Grand Geyser. It begins an eruption by filling its basin with boiling water, forming a well 20 by 25 feet in diametric measurements, and having a visible depth, when quiet, of 100 feet. The explosion is preceded by clouds of steam rushing up to a height of 500 feet; the great unbroken body of water succeeds, ascending in one gigantic column to a height of 90 feet; while from the apex of the column there radiate five great jets, which shoot up to the unparalleled height of 250 feet from the ground. Among the other remarkable geysers of this district are those named Old Faithful, the Beehive, the Giant, the Giantess, etc. The number of hot-springs in the Yellowstone is not less than 1,500, all varying in times of action, force, deposits, and color of water.

Ghaleb, gä-lēb', the last of the great poets of the old Turkish school. His 'Husn-u-Ashk' (Beauty and Love), written about 1800, has been called one of the finest productions of Ottoman genius.

Ghavial, găv'ĭ-al. See GAVIAL.

Ghee, gē, or **Ghi**, a peculiar kind of butter in use among the Hindus. It is made in the following manner: The milk when brought from the cow is poured into earthen vessels, in which it is boiled for one hour, often for two or three hours. It is then put in a cool place, and a little curdled milk is added. By the next morning the whole is converted into sour curdled milk. A layer 5 or 6 inches deep is then taken off the top of the contents of each vessel, and is put into another larger vessel, in which the whole mass is gently stirred for half an hour with a split bamboo-cane. A little warm water is then added, and the stirring is continued for another half-hour, when the butter begins to form. After being kept for three days — a period long enough for the butter to become rancid in so hot a climate — it is melted in another earthen vessel, and boiled until all the water it contains is evaporated. A little more curdled milk is then added, along with some salt or betel-leaves, and the butter, which is now ready, is then put in pots, in which it is kept till required. In this state it will keep for a long time, being sometimes used a year after it is made. This butter has naturally a very strong taste, insupportable to a European stomach, but it is in general use among the Hindus who are rich enough to buy it and is an important article of commerce.

Ghent, gĕnt, Belgium (French, Gand; Flemish, Gend or Gent, capital of the province of East Flanders, at the confluence of the Lys with the Scheldt. It is upward of six miles in circumference, and is divided by canals into a number of islands connected with each other by bridges. Except in some of the older parts, it is well built, and has a number of fine promenades and many notable buildings. Among the latter are the cathedral of St. Bavon, dating from the 13th century; the church of St. Nicholas, the oldest in Ghent; the church of St. Michael, with a celebrated Crucifixion by Van Dyck; the university, a handsome modern structure, with a library of about 100,000 volumes and 700 manuscripts; the belfry, a lofty square tower surmounted by a gilded dragon, and containing chimes of 44 bells; the Marché du Vendredi, an extensive square, interesting as the scene of many important historical events; and Les Béguinages, extensive nunneries founded in the 13th century, the principal occupation of whose members is lace-making. Ghent has long been celebrated as a manufacturing town, especially for its cotton and linen goods and lace. Other industries of importance are sugar-refining, hosiery, thread, ribbons, instruments in steel, carriages, paper, hats, delftware, and tobacco. There are also machine works, engine factories, roperies, tanneries, breweries, and distilleries. The trade is very important. A canal connects it with the Scheldt at Terneuzen. Another canal connects the Lys with the canal from Bruges to Ostend. Ghent was mentioned as a town in the 7th century. In the 9th century Baldwin, the first Count of Flanders, built a fortress here against the Normans. Under the counts of Flanders Ghent continued to increase. Two great revolts took place under the leadership of the Van Arteveldes (1338 and 1369) against Burgundy, and again in the 16th century against Charles V., and the citizens of Ghent, besides losing their privileges, had to pay for the erection of a citadel intended to keep them in bondage. In 1792 the Netherlands fell under the power of France, and Ghent became the capital of the department of Escaut (Scheldt). In 1814 it became, along with Flanders, part of the Netherlands, till the separation of Belgium and Holland. Pop. (1900) 160,949.

Ghent, Treaty of (24 Dec. 1814), the treaty which closed the War of 1812. The British advantage was enormous: the war had been discreditable and rather disastrous to America on land, and was half paralyzed by incompetent administration and dissensions among the States; while even the fleet had not maintained its early triumphs; the overthrow of Napoleon had let loose an irresistible army, and had they persevered they might almost have exacted their own terms. But the British were tired of the burdens of a 20-years war, and the ministers were anxious like them to have done with fighting and settle down to peace; and the American privateers and navy were injuring their commerce unbearably. To our good fortune, also, they had the old-fashioned British contempt for American diplomatic ability, and sent third-rate negotiators to Ghent — Lord Gambier, an ex-naval captain, a junior lord of the admiralty, entirely inexperienced in foreign affairs; Henry Goulburn, a young under-secretary of state, narrow and lacking self-control; and William Adams, an unknown lawyer. America, on the other hand, sent some of the strongest men in the country: John Quincy Adams, James A. Bayard, Henry Clay, Jonathan Russell, and Albert Gallatin, men with no superiors in the world in ability, experience, knowledge, and clearness of purpose, and three at least unsurpassed in tenacity of will. In 1813, when Russia offered mediation, Bayard and Gallatin went to St. Petersburg to negotiate, but England refused the offer. Their instructions had included an article against impressment; but as it was notorious that the Napoleonic wars alone made this a practical question, and those were now ended, the government allowed them to waive that point. The British claims at first set up were impossible: the establishment of the boundary fixed by the Indian Treaty of Greenville in 1795 (see GREENVILLE, TREATY OF), as a permanent line beyond which neither party should acquire territory, thus cutting off the entire Northwest from the United States; the cession of the mouth of the Niagara and Sackett's Harbor, in New York, prohibiting the United States from keeping land or naval forces on the Lakes; and allowing free navigation of the Mis-

OLD FAITHFUL GEYSER, IN YELLOWSTONE PARK.

sissippi to England. Finally the struggle of the entire autumn and early winter ended in this treaty, which was scarcely more than an agreement to cease hostilities and settle the disputed questions at some other time. The questions of impressment, on which the war had been opened; of the extent of the right of blockade; of the American right to fish in British waters; of the British navigation of the Mississippi, and trade with the Indians; of the armaments on the Lakes; of the American claim for British spoliations; all were silently passed over. The treaty, as ratified 17 Feb. 1815, and proclaimed on the 18th, restored the *status quo* of territorial possessions except some islands in Passamaquoddy Bay — public or private property in the surrendered places not to be destroyed or removed, provided a commission to decide on the ownership of the islands above, the matter to be referred to arbitration if they failed to agree; and other commissions to settle the boundaries provided in the Treaty of Paris (1783) — from the St. Croix to the St. Lawrence at lat. 45° N., thence to Lake Superior, and from St. Mary's River to the Lake of the Woods. The last article binds both parties to use their best endeavors to suppress the slave trade.

Ghent, University of, Belgium, founded 1816 by William I., of Holland. In 1820 an old Jesuit college was remodeled for its use. Various other schools have been merged into the university. There are 750 students, over 100 being foreigners. The institution is maintained by the state, which supports a combined library of city and university, containing over 350,000 volumes.

Gherardi, gā-rär'dē, **Bancroft,** American naval officer: b. Jackson, La., 10 Nov. 1832; d. Stratford, Conn., 10 Dec. 1903. He entered the navy in 1846, and was at the Naval Academy in 1852. He was lieutenant on the Lancaster of the Pacific squadron at the commencement of the Civil War, and in 1862 was made lieutenant-commander. During the War he commanded the Chocorua and the Port Royal, being on the latter vessel in the battle of Mobile Bay, in which he was distinguished for bravery and gallantry. He became rear-admiral in 1887; was commandant of the Brooklyn navy yard in 1887; commanded the North Atlantic squadron; and directed the Columbian naval review in New York harbor in 1893. He retired in 1894.

Ghetto, gĕt'ō, **The,** a Jewish quarter in large cities. The ghetto of Rome, instituted in 1556 by Pope Paul IV., was removed in 1885, its demolition having been rendered necessary by the new Tiber embankment. The Ghetto in New York is one of the largest and most densely populated in the world. In a single tenement building are housed as many as 600 persons and a single city block or square contains 3,000 to 5,000 population. The majority of these people are employees of the sweat-shops (q.v.). The population of the New York Ghetto is estimated at 350,000.

Ghibellines, gĭb'ĕ-lĭnz, Italian political party of the 12th to the 15th centuries. On the death of Lothaire II., emperor of Germany, 4 Dec. 1137, Conrad, Duke of Franconia and Lord of Weiblingen (which by corruption became Ghibelline), was elected his successor. His right to the imperial throne was, however, disputed by Henry the Proud, Duke of Saxony and Bavaria, who was in consequence declared an outlaw and shortly afterward died. His adherents transferred their allegiance to his son, Henry the Lion, at that time a boy of 10, and the whole empire was divided into the partisans of Conrad, who assumed the name of Ghibellines, and those of Henry, or the Guelphs. These titles were first used at the battle of Weinsberg in 1140. The strife between the two parties subsided in Germany, but continued in Italy, resulting in war in 1159. The supporters of the popes were termed Guelphs and those of the emperors Ghibellines. Charles of Anjou expelled the Ghibellines from Italy in 1268; but the contest between the two factions continued till the French invasion in 1495 united them against a common enemy.

Ghiberti, Lorenzo, lō-rĕnd'zō gē-bĕr'tē, Italian sculptor: b. Florence about 1378; d. there 1 Dec. 1455. He early learned from his stepfather Bartoluccio, an expert goldsmith, the arts of drawing and modeling, and that of casting metals. He was engaged in painting in fresco at Rimini, in the palace of Prince Pandolfo Malatesta, when the priori of the society of merchants at Florence invited artists to propose models for one of the bronze doors of the baptistry of San Giovanni. The offering up of Isaac was to be executed in gilt bronze, as a specimen of the work. The judges selected the works of Donatello and Ghiberti as the best, but the former voluntarily withdrew his claims, giving the preference to Ghiberti. After 21 years' labor Ghiberti completed the door, and, at the request of the priori, executed a second, after almost as long a period. Michelangelo said of these, that they were worthy of adorning the entrance to paradise. During these 40 years Ghiberti also completed many other important designs, such as the bronze reliquary of St. Zenobius. The dryness of the school of Giotto appears in his early works; the later are in imitation of the Greeks, and are marked by continually increasing vigor and firmness. The reliquary and the baptistery doors of San Giovanni are, to this day, among the finest specimens of art in modern Italy. Ghiberti also executed some excellent paintings on glass for the churches Or-San-Michele and Santa Maria del Fiore. His 'Commentarii,' a work on Florentine art, is still preserved in MS. See Scott, 'Ghiberti and Donatello' (1882).

Ghirlandajo, gēr-län-dä'yō, **Il** (originally **Domenico Bigordi**), Italian painter: b. Florence 1449; d. there 11 Jan. 1494. There were three brothers of this name (Davide, Benedetto, and Domenico) among Italian artists of the 15th century, and Domenico was the greatest of the three. He was thoroughly original and independent in his style and while he lived just after Masaccio and just before Michelangelo, he was distinct from either. He was skilful in portraiture and his large frescoes of religious subjects are historically interesting from the fact that he introduced as spectators of the incidents portrayed the figures of distinguished Florentines of his day. His great fresco of 'The Calling of Peter and Andrew' in the Sistine Chapel at Rome is much admired, and in his 'Last Supper' at Papignano he has introduced the portrait of Amerigo Vespucci. His finest work is the 'History of St. Francis' in the Church of The Trinity at Florence. He was also a skilful worker in mosaics, which he called "painting for eternity."

He died of the plague in his 45th year and was buried in Sta. Maria Novella, in Florence.

Ghost Dance, a religious ceremony which originated among the Piute Indians in Nevada about 1889, so named from the fact that the dancers wear a white robe over their ordinary dress. It was the outcome of a religious belief which maintained that a messiah was soon to appear, who would rid the land of the white man and restore to the Indians all their rights. A Piute Indian named Wikova and known among the whites as "Jack Wilson," claimed to be this savior and obtained a marvelous influence over not only his own tribes but those of the surrounding country, who sent their chiefs to listen to his teachings. These were very much in the same line as those of modern Spiritualists, he promising to procure them communication with the spirits of deceased friends. He advocated peace and refused to allow any references in their ceremonies to warlike subjects. The ghost dance is held at night, men and women joining hands and circling around, singing the ghost songs, which are principally chants in the form of messages from their spirit friends. Sometimes the participants appear to fall into a trance, during which they are supposed to commune with residents of the other world. The Sioux outbreak of 1890–1 was due indirectly to the ceremonies of this dance and the United States government sought to suppress it. Since that time no trouble has arisen, though it is still practised by the Indians. See INDIANS.

Ghost-moth, a British nocturnal swift-moth (*Hepialus humuli*), so called from the male being white and hovering in the twilight over one spot (often in churchyards), where the female, which has gray posterior wings and red-spotted anterior wings, is concealed. The caterpillar feeds on the hop and allied plants, and often does considerable damage to the first-named. See SWIFT-MOTHS.

Ghosts. The belief that the spirits of the departed are occasionally presented to the sight of the living, has existed in all ages and countries, and usually declines only when a people has advanced considerably in the knowledge of physical conditions and laws. We can understand the inability of the primitive man and the savage to realize death. The memory of the deceased lends power to call up his appearance. The primitive man does not observe accurately the distinction between fact and fancy — between what is seen in dream and what is seen in reality. (See DREAMS.) The belief that man has a soul capable of existing apart from the body it belongs to, and continuing to live, for a time at least, after that body is dead and buried, fits perfectly in such a mind with the fact that the shadowy forms of men and women do appear to others, when the men and women themselves are at a distance, and after they are dead. We call these apparitions dreams or phantasms, according as the person to whom they appear is asleep or awake; and when we hear of their occurrence in ordinary life, set them down as subjective processes of the mind. Among the less civilized races, the separation of subjective and objective impressions, which in this, as in several other matters, makes the most important difference between the educated man and the savage, is much less fully carried out. The Dyaks regard dreams as actual occurrences; and many savage races believe that dreams are incidents which happen to the spirit when it is wandering from the body. In sleep, the soul is supposed to leave the body and travel about. The man who fancies he sees at night the figure of a friend, or of an enemy, supposes he sees this dreamer's wandering soul. Among primitive races there is a superstitious objection to rousing a sleeper, lest he should awake before his soul has had time to return to the body. Death is regarded as another form of sleep; and during that sleep the spirit is wandering, and when wandering, may be met. See SLEEP.

Witchcraft, necromancy, has always been intimately connected with the spirits of the dead, and this is regarded as the parent of all religious worship. The savage man fears the dead and seeks to propitiate them, and gradually forgets that the ghosts are those of ancestors, and considers them as demons, a separate order of spirits; and later, as he advances in intelligence, these demons cease to be altogether demoniacal, and become gods. Be that as it may, it is certain that the propitiation and even worship of the dead has formed an integral part of all primitive religions, and has maintained its hold among the more ignorant after it has ceased to affect the more educated.

The fear of seeing something often so dazzles and bewilders the visual organ, that it sees the things that were feared. This accounts for many stories of the sight of apparitions in haunted houses. A crime is supposed to have been committed in some old house, and superstition believes that the spirit of the murderer or of the murdered person cannot rest. Whoever is nervous and timid, and visits this house at night, is predisposed to see the wandering spirit, and the fear that is present deprives the judgment of its power of taking accurate observations of what really is seen, and so superinduces a lax condition which is ready to be deceived. There may be conditions of body which allow of a sight beyond what is given to most, as it is certain that beasts see and scent and hear what our own faculties fail to perceive. But what we insist on is, that the greatest caution should be exercised in receiving stories of apparitions, and the utmost care taken to investigate every case of apparent spiritual manifestation. Before we can admit that there are genuine cases of ghosts having been seen, we must be satisfied that the observer was in full possession of his faculties, that his attention was on the alert, that he was capable of judging between subjective and objective presentments, and that he was healthy in mind and body.

In 1882 a Society for Psychical Research was founded in London for the scientific and systematic investigation of reported apparitions, clairvoyance, haunted houses, hypnotism, thought-reading, and spiritualistic phenomena; it publishes regular reports of its investigations.

The subject of ghosts is treated from other and various view points under APPARITIONS, and the reader is also referred to SPIRITUALISM and WITCHCRAFT, and the following works: Brewster, 'Natural Magic' (1832); Ingram, 'Haunted Houses' (1884); Myers, 'Phantasms of the Living' (1886); Owen, 'The Debatable Land' (1874); Stead, 'Real Ghost Stories' (1891).

Ghosts, a powerful play by Henrik Ibsen (1881), giving dramatic embodiment to the modern realization of heredity. Ibsen, treating this subject on its tragic side, considers the case of the darker passions as they are handed down from father to son. It is a Greek tragedy translated into the littleness and barrenness of modern life. ‘Ghosts’ is perhaps the most remarkable of Ibsen's dramas in its searching judgment, its recognition of terrible fact, its logical following of the merciless logic of nature.

Ghuri, goo'rē, an Asiatic dynasty who had the seat of their empire in the country of Ghur, and ruled over Persia, Afghanistan, northern Hindustan, and Transoxiana. Ghur first appears in history in connection with Mahmud of Ghazni and his son Masaud, the latter of whom subjugated the region in 1020. About a century later Malik Izzuddin made himself ruler of all the Ghur country. His son, Alauddin Jahansoz (the Burner), fell upon Ghazni, and burned it to the ground. This prince's nephews, Ghiyassuddin and Muizuddin, established their power in Khorasan and Ghazni. The latter, crossing the Indus, then conquered successively the provinces of Multan (1176), Lahore (1186), and Ajmere (1190), and, in the course of the next six years all Hindustan as far south as Nagpur and east to the Irawaddy. On the death of Muizzuddin the Indian states asserted their independence, the power of the Ghuri being confined to Ghur, Seistan, and Herât. This last feeble remnant was taken from them by the Shah of Kharezm about 1215. Some 30 years later the Ghur princes managed to revive something of their former power at Herât, which they retained by sufferance from the Mongols down to 1383, when the city was captured by Timur, and the Ghur sovereignty came to an end.

Ghurkas, goor'kaz, **Gurkahs**, or **Goorkhas**, a tribe of northern India, named from the village of Ghurkas in Nepal, formerly the capital of the Ghurkas, before the formation of the present kingdom of Nepal. The Ghurkas are the mountaineers of Nepal, and speak a Sanskritic language. The Mohammedans drove them out of Rajputana, and they migrated to Nepal, of which they took possession in 1768. When the English first invaded India, the Ghurkas were formidable opponents, but are now most friendly. A large number of them are in the Anglo-Indian army, chiefly in the infantry, as they have no regard for the cavalry service. Besides their rifle they carry a formidable short-bent sword called a koorkree, with the edge on the inside of the bend, with which at close quarters they do dreadful execution. See NEPAL.

Giacomotti, Félix Henri, fā-lēks ŏṅ-rē zhä-kō-mō-tē, French artist: b. Quingey, Doubs, 19 Nov. 1828. He was a pupil of Picot at the Beaux-Arts, Paris; obtained the Grand Prix de Rome in 1854; established his studio at Paris in 1861, and painted numerous subjects from mythology, religious works, and portraits. Among his canvases are: ‘Centaur and Nymph’; ‘Christ Teaching in the Temple’; ‘The Mount of Calvary.’ He also executed a fresco for the ceiling of one of the salons of the Luxembourg representing the apotheosis of Rubens and painting.

Giant Cells, in pathology, a form of large cells many times the size of the cells of the body with which they are associated. They very frequently have a large number of nuclei, sometimes as many as 100 or more. It is supposed that giant cells originate from a lack of cell-division, rather than by a coalescence of a number of small cells. Many giant cells are found in the neighborhood of active growing tissue, associated with infectious disease processes, such as tuberculosis and carcinoma. It is thought that the function of giant cells is protective.

Giants, people of extraordinary stature. History, both sacred and profane, makes mention of giants. The first mention of giants in the Bible is in Gen. vi. 4, where the Hebrew word used is *nephilim*, a word which occurs in only one other passage, where it is applied to the sons of Anak, who dwelt about Hebron, and who were described by the terrified spies as of such size that compared with them they appeared in their own sight as grasshoppers. A race of giants called the Rephaim is frequently mentioned in the Bible. In Gen. xiv. 5, and xv. 20, they appear as a distinct tribe, holding possessions in Canaan. At the period of the conquest of Canaan, Og, king of Bashan, who had a bedstead 9 cubits long, is said to have remained alone of this tribe, but this must be taken to mean alone on the east side of Jordan; for giants, who were probably of the same stock, are subsequently mentioned as living about Mount Ephraim (Jos. xvii. 15) and among the Philistines (2 Sam. xxi. 18). Goliath, who measured 6 cubits and a span, and who was slain by David, is the most celebrated of the giants mentioned as living among the Philistines. The other races of giants who are mentioned in the Bible (besides the sons of Anak already referred to) are the Emim, who occupied the country afterward held by the Moabites, and the Zuzim (a branch of the Rephaim), who lived on the east side of the Jordan, between the Arnon and the Jabbok. In Deut. ii. 20 they are said to have been called by the Ammonites, who conquered them, Zamzummim.

The giants of Greek mythology are believed by some to represent the struggle of the elements of nature against the gods, that is, against the order of creation. They were said to have sprung from the blood of Uranus, which fell into the lap of Ge (the earth). Their mother, indignant at the banishment of the Titans into Tartarus, excited them to revolt against the gods. They hurled mountains and forests against Olympus, disdaining the lightnings of Zeus. An oracle having declared that the gods could not conquer except by the assistance of a mortal, Athene called Heracles to their aid. He slew Alcyoneus and Porphyrion, the most formidable of the giants. Apollo and Heracles shot out the eyes of Ephialtes; Dionysus slew Eurytus with his thyrsus; Hecate and Hephæstus killed Clytius with clubs of hot iron; Poseidon hurled a part of the island of Cos on Polybotes; Athene buried Enceladus under the island of Sicily, and flayed Pallas, and made a shield of his skin. The remainder perished under the hands of other deities by the thunderbolts of Jupiter or the arrows of Heracles. This fable perhaps indicates volcanic eruptions, for which the Phlegræan fields, where the chief scene of this struggle is placed, and where the two principal giants were born, were remarkable. Cos and Sicily, which figure in this fable, are also volcanic. Ovid has described the war of the giants in the beginning of his 'Metamorphoses.'

Giants figure rather largely in Celtic and Scandinavian mythology and legends. In the legends of the Irish there are the two giants, Fingall or Finn MacCumhal and his son Ossian. The giants of the Welsh are familiar to every one through the achievements of Jack the Giant Killer, the representative of the Scandinavian Thor, the destroyer of Skrimmer, and the Swiss giants.

The following are regarded as authentic instances of giant stature: In the time of Augustus there were to be seen in the Horti Sallustiani at Rome, the bodies of a giant, Posio, and a giantess, Secundilla, each 10 feet 3 inches high. In the reign of Claudius, an Arabian giant named Gabbaras, 9 feet 4 inches high, was exhibited at Rome. The Emperor Maximin, a Thracian, was nearly 9 feet high. A Jewish giant, about 10 feet high, is mentioned by Josephus. Long Mores, an Irish giant, of the time of Edward III., was 6 feet 10½ inches high. Queen Elizabeth's Flemish porter was 7 feet 6 inches; and J. Middleton, or the Child of Hale, born in 1578, attained the height of 9 feet 3 inches. C. Munster, a yeoman of the guard in Hanover, who died in 1676, was 8 feet 6 inches high; and Cajanus, a Swedish giant, about 9 feet high, exhibited in London in 1742. C. Byrne, who died in 1783, attained the height of 8 feet 4 inches; and Patrick Cotter O'Brien, a native of Kinsale, who lived about the same time, was 8 feet 7¾ inches. In 1884 died Pauline Wedde (called Marian), a German giantess, over 8 feet 2 inches at the age of 18; and in 1887 Josef Winkelmaier, an Austrian, 8 feet 9 inches, aged 22. Anna Swan, a native of Nova Scotia, above 8 feet high; her husband, Capt. Bates, a native of Kentucky, of the same height; Chang-wu-gon, the Chinese giant, 7 feet 9 inches high; and Feeder Machow, a Russian, 7 feet 9 inches, who as late as 1900 were living in retirement, after many years of public exhibition.

Giant's Causeway, Ireland (deriving its name from a legend that it was the commencement of a road to be constructed by giants across the channel to Scotland), a natural pier or mole of columnar basalt, projecting from the north coast of Antrim, Ireland, into the North Channel, 7 miles northeast of Portrush. It is part of an overlying mass of basalt from 300 to 500 feet in thickness, which covers almost the whole county of Antrim, and the eastern part of Londonderry. It is exposed for 300 yards, and exhibits an unequal pavement, formed of the tops of 40,000 vertical closely fitting polygonal columns, which in shape are chiefly hexagonal. The diameter of the pillars varies from 15 to 20 inches. Each pillar is divided into joints of unequal length, the concave hollow at the end of one division fitting exactly into the convex projection of the other. The rock is compact and homogeneous, and is somewhat sonorous when struck with a hammer. The Giant's Causeway is itself formed of three causeways, the Little, Middle or Honeycomb, and the Grand Causeway. On the Little Causeway may be seen an octagon, pentagon, hexagon, and heptagon all together; on the Middle Causeway is the famous Wishing Chair, with two arms and a back, on a platform where the columns rise to a height of about 10 feet. On the Grand Causeway are pointed out the Lady's Fan, an exact arrangement of five perfect pentagons surrounding a heptagon; the Keystone of the Causeway — a sunk octagon; and the single triangle. At the starting point is the Giant's Loom, an imposing row of columns 30 feet high, each intersected by about 30 joints; to the left is the Giant's Well, to the right the Giant's Chair.

Gibara, gē-bä'rä, Cuba, a seaport on the northern coast of Santiago province. It has a fine harbor protected by a fort at the entrance. There is a military hospital here. Pop. 6,841.

Gibbes, Robert Wilson, American scientist and historian: b. Charleston, S. C., 8 July 1809; d. Columbia, S. C., 15 Oct. 1866. He was graduated from South Carolina College in 1827, from the Medical College of South Carolina in 1830. In 1827–35 was assistant professor of chemistry, geology, and mineralogy in the South Carolina College, and in the Civil War was surgeon-general of South Carolina. His contributions to science appeared in the 'Journal' of the Academy of Natural Science, and other learned publications. His paper on 'Typhoid Pneumonia' ('American Journal of Medical Sciences,' 1842) was the first to urge the substitution of stimulants for the knife in the treatment of that disease. He published: 'Documentary History of the American Revolution' (1853 et. seq.).

Gibbet, jĭb'ĕt, a gallows, formerly in use in Europe, on which the bodies of criminals who had been guilty of particularly atrocious crimes were suspended after execution, encased in an iron frame, near the spot where the crime was committed.

Gibbon Gĭ'bŏn, **Edward**, English historian: b. Putney, Surrey, 27 April (May 8) 1737; d. London 16 Jan. 1794. He was the eldest son of Edward Gibbon and Judith Porten. The family was originally Kentish and Gibbon gives some extended account of its origin in his justly celebrated 'Memoirs.' He there erred, however, as he suspected before the close of his life, in tracing the connection to Robert Gibbon of Rolvenden. He was really descended from Thomas Gibbon of West Cliffe, a younger branch of the family. It is significant that the arms of this younger branch, rather than that of the Rolvenden Gibbons, appears on the Gibbon bookplate, perhaps one that his father had used before him.

Gibbon's father was a care-free, pleasure-loving gentleman. He married against his father's wishes and lost thereby a large share of an ample fortune. He lost still more in the expensive pleasures of the mid-eighteenth century, in which he took a too active part. His public life was limited to sittings in two parliaments as a Tory, and to an aldermanship of the city of London for a few months. After some ten years of married life Gibbon's mother died and his father, deeply mourning his loss but also deeply in debt, retired to Buriton and the quiet life of a secluded country gentleman.

Gibbon's grandfather was a man of more force of character. The son of Matthew Gibbon, linen-draper of London, he, became an unusually successful business man. He contracted to clothe King William's troops in Flanders. He was made one of the commissioners of customs, and was commended by

Lord Bolingbroke for his exceptional knowledge of the trade of England. He became a director of the ill-starred South Sea Company, only to lose the labors of 30 years in the crash of 1720. Yet before his death, 16 years later, he amassed another fortune, almost, if not quite, as large as the first.

The future historian was a sickly child whose life was often despaired of. The famous practitioners of the time were frequently called to attend him. Fortunately, in addition to a mother's care, he had the loving devotion of her maiden sister Catherine, to whom he acknowledges that he owed his life. He was taught at home, partly by a domestic tutor, until almost nine, when he was sent to the school of Dr. Wooddeson at Kingston-upon-Thames. Here he remained some two years "reviled and buffeted" as a Tory, yet gaining an elementary knowledge of Latin "at the expense of many tears and some blood." But the precocious boy was gaining more from his "early and invincible love of reading," which was encouraged by his cultivated and judicious aunt. Of her he says, she was "the true mother of my mind as well as of my health." He thus read Pope's 'Homer,' the 'Arabian Nights,' Dryden's 'Virgil,' Ovid's 'Metamorphoses,' besides "many English pages of poetry and romance, of history and travels." Gibbon was next sent to Westminster School, which his father had attended before him. This was the easier because his aunt, who had been left dependent by the bankruptcy of her father, now took charge of one of the homes for the boys and could still care for him. Yet his bodily afflictions sadly interfered with his studies. He was finally transferred to Bath, and then to the house of a physician at Winchester. In his 15th year Gibbon's health wonderfully improved, and after a few ineffective weeks in the home of Rev. Philip Francis at Esher, Surrey, he was quickly transferred to Oxford, where he became a gentleman commoner of Magdalen College in April 1752.

Even before this time the genius of the future historian had asserted itself in the character of his reading. Some 20 volumes octavo of a 'Universal History' were devoured by the mere boy as they appeared. He then took up individual works on ancient or modern times, ranging through a vast number with great rapidity. It was Echard's 'Roman History' that first led him to the period he was later to make his own. From this he extended his reading to the mediæval age of Europe and, before he was 16, had exhausted all English sources in his favorite field. While he was yet to make himself the authoritative scholar, he already showed that marvelous ability in acquiring historical knowledge that marked his later manhood.

This remarkable self-education may be emphasized the more because Gibbon was soon to experience the inadequacy of university training in his time. He entered Oxford before he was 15 years old. Yet he soon found that regular tasks were not enforced, that absence from the university was not noticed, that folly and even vice were not restrained. Though unusually fond of reading, as we know, he fell into idleness and the mild, if expensive, pleasure of travel. Only in the long vacation did he again read assiduously, and begin his first independent work, an essay on the 'Age of Sesostris.' Under such circumstances it is not strange that Gibbon so severely arraigned the university in his 'Memoirs': "To the University of Oxford I acknowledge no obligation. . . . I spent 14 months at Magdalen College; they proved the 14 months the most idle and unprofitable of my whole life."

Yet Gibbon's mind was not wholly inactive at this time. The key of Magdalen library had been delivered to him and he was soon tempted by what he had heard of Middleton's 'Free Inquiry' (1749) as a dangerous book. Strangely enough he was repelled by the scepticism and led to consider seriously the claims of the Catholic Church. Falling in with a student who was already a Catholic, he was furnished with Catholic books and by boyish dependence on his own reason was led to embrace the faith. Not realizing the full consequences of his act he asked admission to the Catholic Church in June 1753. His father, to whom he wrote at once, unwisely disclosed the young man's conversion to the authorities at Oxford, and he was forever excluded from the university.

The course taken by Gibbon's father in these unusual circumstances was to have more than one important effect on the historian's life. He was sent to Lausanne, Switzerland, to the home of a Protestant pastor, who became his tutor and guardian. Here he remained almost five years, pursuing a regular and valuable course of instruction with pastor Pavilliard. Through the same instrumentality and his own reflections he again became a Protestant. He also learned French as a native, thus commanding another important literature. He acquired a thorough acquaintance with Latin and a beginning in Greek. He carried on with growing maturity his historical reading. His keenness for intellectual pursuits led him to correspondence with several European scholars, and he once visited and was received by Voltaire. So valuable were these years that Gibbon put the highest estimate upon them: "Such as I am, in genius or learning or manners, I owe my creation to Lausanne."

Nor must one other episode of those years be forgotten. At Lausanne the young Gibbon met and loved the brilliant and beautiful Susanne Curchod, daughter of a Swiss clergyman. The affection was sincere on both sides. But the engagement was conditioned on the approval of Gibbon's father, on whom he was dependent, and that approval was promptly refused on his return to England. Under these circumstances Gibbon did what many another young man of his country has since done. He "sighed as a lover," he "obeyed as a son." And if the failure of marriage was harder for the daughter of the poor Swiss clergyman, she was consoled not many years after with what proved a more remarkable match. She became the wife of Necker, afterwards French minister of finance, and the mother of Madame de Staël.

Before leaving Switzerland Gibbon had begun his first published work, his 'Essay on the Study of Literature.' It was written in his adopted language and was the result of his classical studies, with which it especially dealt. It was completed in the year of his return to England, though not published until 1761. Then it gained some recognition on the continent, where it was republished the following year. In England it was little noticed, though a translation was finally made.

Gibbon returned to England in 1758. As he had taken up no profession he was still dependent for the next 12 years upon his father's bounty. Two years and a half of this time (1760–62) he spent as captain in the South Hampshire militia, the result of a wave of military enthusiasm which had swept England on a threatened invasion by the French. This largely withdrew him from historical studies, but he acknowledges that these years again made him an Englishman and that the military experience had "not been useless to the historian of the Roman Empire." Every vacation, too, was spent with his beloved books, and he meditated for treatment several historical subjects, among them the life of Raleigh, the liberty of the Swiss, and a history of the republic of Florence.

As soon as he was freed from the militia, Gibbon hastened to the continent to complete his education by travel and study. In this he spent another two years and a half, at Paris, Lausanne, and in an extended Italian tour. Everywhere he was reading as well as seeing, so that it is not strange that on this tour he should finally have chosen the subject of his life work. The resolution was taken in Rome as he sat musing in the evening, while the Franciscan friars "were singing vespers in the temple of Jupiter on the ruins of the capitol." It was 15 Oct. 1764, and Gibbon had about half completed his 28th year.

Yet the great work could not be immediately begun. Gibbon was still dependent. At home he could not be master of his time. In London he could not use his books. Other plans also intervened in the five years following his second return to England (1765). His friend Deyverdum visited him and with his assistance Gibbon undertook the history of the Swiss, writing it also in French. But the historian was unacquainted with German and far from the Swiss archives, so that the first book of his projected work was finally committed to the flames. Then Gibbon assisted his friend in the 'Mémoires Littéraires de la Grand Bretagne,' which were published in 1767 and 1768. In 1770 he also printed anonymously his 'Critical Observations on the Sixth Book of the Æneid,' a brilliant and conclusive answer to a theory of Warburton in his 'Divine Legation of Moses.'

Meanwhile the historian had begun the more serious study of his Roman subject in 1768, after the failure of the Swiss project. Two years later he was left independent at his father's death, and establishing himself in London in 1772 he began the composition of his 'History of the Decline and Fall of the Roman Empire.' On the death of Goldsmith (1774) he was made professor of history at the Royal Academy. The same year he was elected to Parliament, "at the beginning of the memorable contest between Great Britain and America." Yet he was to attain fame not by tongue but by pen. Silent in the House of Commons he sprang at once into public esteem when the first volume of his 'History' issued from the press in 1776. The first impression was soon exhausted. A second edition was sold and a third printing within a year. "My book," he says, "was on every table, and almost on every toilette; the historian was crowned by the taste or fashion of the day, nor was the general voice disturbed by the barking of any profane critic." The lasting fame of the author was once for all established.

From the publication of the first volume of the 'Decline and Fall' to the issue of the last three (1788) is a period of 12 years, the whole period of collecting materials and composition covering two decades. Of these 12 years the first seven were the most active. After the first enthusiasm for his 'History' had subsided, a storm of clerical criticism burst upon his treatment of the growth of Christianity in the early centuries. This he did not at first answer, but when his good faith was attacked he at last replied in a 'Vindication' (1779). In the same year he prepared a state paper, the 'Mémoire Justicatif,' against the French course in relation to the American war. He was also made one of the Lords Commissioners of Trade. In 1781 he published the second and third volumes of the 'Decline and Fall.' The following year he lost his seat in Parliament and his place as Lord Commissioner, and though some offers were made of other public positions he never again took part in public life.

Gibbon now resolved on an unusual move for an Englishman. While by no means a poor man, he thought his income insufficient for English life. He therefore decided to remove to Lausanne and unite his establishment with that of his friend Deyverdun. To his friend and the place he was bound by ties of early affection. He could live well in Switzerland and yet save money. He could complete his 'History' and return to England at the age of 50 a comparatively rich man. So he explained his purposes, and he finally settled in his new home in 1783. Four years later he returned to England with the last three volumes of the 'Decline and Fall,' which were published on his birthday, 1788. After a year in England, however, he went back to Switzerland, fully satisfied with his foreign residence. Deyverdun died in 1789 but he still clung to his adopted country.

He was now to undertake the one other important literary work of his lifetime. In the year of the publication of his 'History' he began the celebrated 'Memoirs' which have delighted the world for more than a century. On these he was engaged at intervals for the next six years, and he left six different sketches covering more or less fully different portions of his life. The 'Memoirs' were finally printed in 1796 with the 'Miscellaneous Works' of the historian, edited by Lord Sheffield. The manuscripts remained in the possession of the Sheffield family for a century, when they were deposited in the British museum and the whole of the six partial sketches were published. Then it was seen that Lord Sheffield had taken unusual liberties with Gibbon's autobiography, though preserving much the larger part of the sketches not overlapping.

In 1793 Gibbon hastened to England on the death of the wife of Lord Sheffield, his intimate friend. During the year he was still full of plans. He had once hinted a supplement to his 'History.' He now meditated a series of biographies of eminent Englishmen. He even set his hand to a prospectus which should announce the editing of English historical writers by John Pinkerton. But all such plans were to be stayed. A disorder with which he had long been afflicted led to dropsy, for which he was treated at different times in the fall of 1793. At last he became rapidly worse at the beginning of the new year and died very suddenly.

Gibbon's fame rests upon his one great undertaking, the 'History of the Decline and Fall.' It was the most monumental work of its age, as he was the most erudite historical student of his time. In his 'Memoirs' Gibbon hesitates to class himself with Hume and Robertson, but he is the only one of the three to outlive a century of wonderful progress in historical research. It is true some defects have been found in his famous 'History,' and newer views of historical development find some omissions. But the century old work has been the basis for all later research, while it is still edited by learned historians instead of being replaced by labors of their own.

Bibliography.—For the 'Decline and Fall': Oxford ed., 8 vols., 1828; ed. by H. H. Milman, 12 vols., 1838–9; by W. Smith, 8 vols., 1854–5; latest and best by J. B. Bury, 7 vols., 1896–1900. French, German and Italian translations appeared in Gibbon's lifetime, Polish, Greek and Magyar since.

For 'Memoirs': 'Miscellaneous Works,' 2 vols., ed. by Lord Sheffield, 1796; sec. ed., enlarged to 5 vols., 1814; 'Memoirs,' ed. by Milman, 1739; 'Letters of Gibbon,' ed. by Prothero, 2 vols., 1896; 'Autobiographies,' ed. by Murray, 1897; 'Memoirs,' ed. by O. F. Emerson, 1898; by G. B. Hill, 1900. Notes on life in *Gentleman's Magazine*, lviii, lix, lxiv, lxvi; Egerton Brydges's 'Autobiography'; Boswell's 'Johnson'; Walpole's 'Letters'; Mme. de Deffand's 'Letters to Walpole'; D'Haussonville's 'Salon of Mme. Necker' (1882); 'Girlhood of Maria Josepha Holroyd,' ed. by J. H. Adeane (1896); 'Historic Studies in the Vaud, etc.', by Meredith Read (1897).

Oliver Farrar Emerson,
Professor of English, Western Reserve University.

Gibbon, John, American soldier: b. Holmesburg, Pa., 1827; d. 1896. He was graduated from the United States Military Academy in 1847, and after service in the Mexican War was assistant instructor in artillery in the Academy 1854–7 and quartermaster 1856–9. He served in the Civil War and became major-general of volunteers and brevet major-general United States army. In 1891 was retired from the service. He published 'The Artillerists' Manual' (1859).

Gibbon, a tailless anthropoid ape of the East Indies, the several species of which constitute the genus *Hylobates* of the family *Simiidæ*. They are nearly allied to the orangs and chimpanzees, but are smaller, of more slender form, and their arms are so long as almost to reach the ground when the animal assumes an erect posture; there are also naked callosities on the buttocks. In general the gibbons are the lowest among the anthropoid apes, and connect them with the Old World monkeys by way of the semnopithecine group. (See Langur.) The gibbons are inhabitants of forests, their long arms enabling them to swing themselves from bough to bough, which they do to wonderful distances and with extreme agility. They cannot, however, move with ease or rapidity on the ground. The conformation of the hinder extremities adds to their difficulty in this, while it increases their adaptation to a life among the branches of trees, the soles of the feet being much turned inward. None of the gibbons are of large size, averaging about three feet tall. Eight or ten species are named in the books, but probably increased knowledge will reduce this number. One, the siamang (*H. syndactylus*) has the second and third digits of the hind limb partly united, and the hair of the upper arm pointing downward, while that on the forearm grows upward. It is a native of Sumatra, and has been set apart as the type of a separate genus (*Siamanga*) by some naturalists. The other species have the digits mostly free; they are natives of Cambodia, the Malay Peninsula, Sumatra, and Java, and are known as lars, hoolocks, agile gibbons, white-handed gibbons, etc., but are much alike. One species is called "wow-wow" in imitation of the howling cry that is characteristic of all. Consult Cassell's and the Royal 'Natural Histories,' and Hartmann's 'Anthropoid Apes' (1886).

Gibbons, Abigail (Hopper), American philanthropist: b. Philadelphia 7 Dec. 1801; d. New York 10 Jan. 1893. She was daughter of Isaac T. Hopper (q.v.) and wife of James Sloan Gibbons (q.v.). She taught in Philadelphia and New York, in 1845 assisted in founding the Women's Prison Association, and was also a founder of the Isaac T. Hopper Home for discharged prisoners. In the Civil War she was active in Federal hospitals and camps. It was chiefly through her instrumentality that the New York State reformatory for women and girls was established by the legislature.

Gibbons, Grinling, English sculptor and wood-carver: b. Rotterdam 4 April 1648; d. London 3 Aug. 1721. In 1671 Evelyn found him at Deptford carving on wood Tintoretto's 'Crucifixion'; and on Evelyn's recommendation he was appointed by Charles II. to a place in the Board of Works, and employed in the ornamental carving of the choir of the chapel at Windsor. His works display great taste and delicacy of finish, and his flowers and foliage have almost the lightness of nature. For the choir of St. Paul's, London, he executed the foliage and festoons, and those in lime-tree which decorate the side aisles. At Chatsworth, at Burleigh, at Southwick, Hampshire, and other mansions of the English nobility, he executed an immense quantity of carved embellishment; the ceiling of a room at Petworth is regarded as his *chef d'œuvre*. He also produced several fine pieces in marble and bronze. Among these are the statue of James II., Whitehall; the base of the statue of Charles I., at Charing Cross; and that of Charles II., at the Royal Exchange.

Gibbons, James, American cardinal: b. Baltimore, Md., 23 July 1834. When very young he was taken by his father to Ireland to be educated. He returned to America in 1853 and resided in New Orleans until 1855, when he matriculated at St. Charles College, near Ellicott City, Md., where he was graduated with distinction in 1857. He then pursued his theological course at the Seminary of St. Sulpice and at St. Mary's University, Baltimore. On 30 June 1861 he was ordained a priest, his first mission being at St. Patrick's Church, Baltimore, where he was assistant. Transferred to St. Bridget's Church, Canton, he ministered to a small congregation till 1865, when Archbishop Spalding made him chancellor of the archdiocese and his private secretary. The second plenary council at Baltimore, 1866, made him its assistant chancellor, and in August 1868 he was consecrated titular bishop of Adramyttum *in partibus infidelium* and first vicar-apostolic of North Carolina, erected by bull of His Holiness, Pius IX., dated 3 March 1868. He found three churches, two priests, and about 1,000 Roman Catholics scattered over the entire State. He opened a school, which he personally conducted; built six churches; introduced into the vicariate the Benedictine order at Belmont, Gaston County, where Mary Help abbey was later erected; established the Sisters of Mercy and built for them a school for whites and one for negroes in Wilmington. He made the personal acquaintance of every adult Roman Catholic in the State, and met them at their homes, traveling from the seaside to the mountains, up and down the State, that none should be neglected. After four years he was translated to the see of Richmond in 1872. Here he erected five churches, St. Peter's Academy in charge of the Xaverian Brothers, and St. Sophia's home for old people in charge of the Little Sisters of the Poor, in Richmond, Va., and parochial schools in Petersburg and Portsmouth, Va.; and enlarged St. Joseph's female orphan asylum, Richmond, Va. In 1877 Archbishop Bayley asked to have Bishop Gibbons appointed his coadjutor, and on the death of Archbishop Bayley in October of that year Bishop Gibbons became archbishop of Baltimore, the highest ecclesiastical dignitary of the Roman Catholic Church in the United States. He headed the delegation of American prelates who visited Rome in 1883 to represent the affairs of the Church in the United States at the Vatican, and to outline the work of the third plenary council, to meet in 1884. Pope Leo XIII. appointed Archbishop Gibbons to preside over the council. In directing the proceedings of the council he co-operated in the enactment of many important new decrees, made necessary by the progress and development of Catholicism in America; and these acts and decrees were, after mature deliberation, approved by the ecclesiastical authorities. Leo XIII. expressed his approval of the action and course of Archbishop Gibbons and created him cardinal 7 June 1886, and on 30 June 1886 Archbishop Kenrick of St. Louis, representing the Pope, bestowed the insignia of his office upon the newly made cardinal. Cardinal Gibbons sailed for Europe the next year to receive the apostolic benediction and to be admitted to membership in the college of cardinals, the 25th in succession. While in Rome he interpreted to the Pope the democratic spirit of American Catholicism in respect to the labor organizations in the United States and the exact relation existing between the employers and the employed. He was installed as pastor of his titular church 25 March 1887, and was assigned to the Church of Santa Maria in Trastevere, a church of great antiquity, on the Tiber. He returned to America in November 1887; on 24 May 1888 laid the cornerstone of the Catholic University, Washington, D. C., and dedicated the divinity building 13 Nov. 1889. Cardinal Gibbons has been chancellor of the University since its foundation. In November 1888 he celebrated at Baltimore the centenary of the founding of the Catholic hierarchy in the United States, subsequently convening a congress of Catholic laymen, the first ever held in the United States. Cardinal Gibbons is president of the Bureau of Catholic Indian Missions, and is the first American cardinal to take part in the election of a pope. A model Churchman, he is also a typical American citizen, loyal, progressive, and public-spirited. He has published: 'The Faith of Our Fathers' (1876; 58th ed. 1903); 'Our Christian Heritage' (1889); 'The Ambassador of Christ' (1896); etc. The archdiocese of Baltimore now (1905) has a Catholic population of 250,000; 396 priests; 261 churches; 95 parochial schools; 3 universities; 2 diocesan seminaries; 6 hospitals, and other charitable and educational institutions.

Gibbons, James Sloane, American banker: b. Wilmington, Del., 1 July 1810; d. New York 17 Oct. 1892. He early became a strong abolitionist, and in 1863 his house in New York was sacked by a mob, during the draft riots, because he had illuminated it in honor of Abraham Lincoln. His fame rests chiefly on his patriotic song, which was very popular during the Civil War, 'We are Coming, Father Abraham, Three Hundred Thousand More.'

Gibbs, Alfred, American soldier: b. Sunswick, L. I., 22 April 1823; d. Fort Leavenworth, Kan., 26 Dec. 1868. He was graduated from the United States Military Academy in 1846, served in the mounted rifles during the Mexican War, was brevetted captain, and until 1861 was employed in frontier and recruiting service. He served in the Federal army during the Civil War and attained the rank of major-general of volunteers and brevet brigadier-general United States Army. He was mustered out of the volunteer service in 1866, became major of the Seventh cavalry in that year, and until his death was stationed at various Kansas forts.

Gibbs, George, American mineralogist: b. Newport, R. I., 8 Jan. 1782; d. Newtown, N. Y., 5 Aug 1833 Early becoming interested in the study of mineralogy, he collected during his travels in Europe, chiefly by purchase, a very extensive and valuable cabinet of minerals, the most extensive at the time that had been brought together in the United States. This collection he set up in the public rooms of Yale College, where it remained without charge from 1811–25, and in the latter year it was purchased for the college for $20,000.

Gibbs, James Edward Allen, American inventor: b. 1 Aug. 1829; d. Raphine, Rockbridge County, Va., 25 Nov. 1902. While a young man the subject of the sewing-machine was called to his attention, and presently he thought out the idea of the revolving hook which is the main feature of the Willcox & Gibbs machine. In all he took out 12 patents covering the sewing-

HIS EMINENCE JAMES, CARDINAL GIBBONS.

Archbishop of Baltimore

machine. The village in which he resided was named by him when he returned to it in middle life. The name is from the Greek word which means "to sew."

Gibbs, Josiah Willard, American philologist: b. Salem, Mass., 30 April 1790; d. New Haven, Conn., 25 March 1861. He was graduated at Yale College in 1809, and in 1824 was appointed professor of sacred literature in the theological department of Yale College, which he held till his death. He published a translation of Gesenius' 'Hebrew Lexicon of the Old Testament' (1824); 'Manual Hebrew and English Lexicon,' abridged from Gesenius (1828); 'Philological Studies' (1857); 'Latin Analyst' (1858), etc., and contributed to the periodical works of his time numerous important papers on topics of philology and criticism.

Gibbs, Josiah Willard, American mathematician: b. New Haven, Conn., 11 Feb. 1839; d. there 28 April 1903. He was a son of the preceding and was graduated from Yale in 1858. He was professor of mathematics at Yale in 1871 and held the position at the time of his death. Thermodynamics was the field in which he achieved his greatest renown. He was original in his manner of teaching and extremely successful in the class-room. The work that brought him first into prominent notice was his treatise on the 'Equilibrium of Heterogeneous Substances,' published in 1875 by the Connecticut Academy of Arts and Science. His last contribution on this subject was his book in the Bi-Centennial series at Yale, entitled 'An Elementary Treatise on Statistical Mechanics,' wherein he set forth what are likely to be the foundations of this branch of science in the future. In 1881 he began the development of the Vector analysis and applied it to problems in crystallography and to the computation of the orbits of the planets and comets and also to problems in the theory of light. His work gave strong support to the electro-magnetic theory and powerful influence in securing a general adoption of this theory by physicists.

Gibbsite, gĭb'zīt, a mineral usually occurring in mammillary or stalactitic masses or incrustations, or in monoclinic crystals (hydragillite). Its color is usually white, often tinted with green, yellow or red. Its hardness is 2.5 to 3.5 and its specific gravity about 2.4. It is an aluminum hydrate, $Al(OH)_3$, containing 28 per cent of aluminum. It occurs in the Urals, Norway, Brazil and at Richmond, Mass. It was named after George Gibbs (q.v.).

Gibeah, gĭb'ē-ā, the name of several towns in ancient Palestine, the birthplace of Saul, and the scene of Jonathan's romantic exploit against the Philistines.

Gib'el, or **Prussian Carp,** a European carp (*Cyprinus gibelio*) of small size, without barbels and with a forked tail. It occurs in England and is good food.

Gib'eon, one of the ancient cities of the Canaanites, in Palestine, a "great city" of the Hivites, who at an early stage of Joshua's conquests entered into a stratagem to get terms of peace for themselves. Taking old clothes on their persons, and dry and moldy bread in their bags, they professed to have come from a far country, and proposed an alliance with the Israelites, which was accepted by Joshua before the stratagem was discovered. When the discovery was made, the covenant was strictly observed, but the Gibeonites were condemned to be "hewers of wood and drawers of water unto all the congregation" (Jos. ix. 21). The town of Gibeon fell afterward to the lot of Benjamin. It was made a Levitical city, and the Tabernacle was transferred there from Nob after the slaughter of the priests. The engagement between the men of Abner and David took place here. Gibeon has been identified with the modern El-Jib. A large number of the Gibeonites, who had made a covenant with Joshua, were massacred by Saul, for which crime seven of Saul's sons were delivered up by David to the Gibeonites to be hanged (2 Sam. xxi. 1–9).

Gibraltar, jĭ-bràl'tar (Sp. hē-bräl-tär'), a town and strongly fortified rocky peninsula at the southern extremity of Spain, at the western entrance of the Mediterranean, belonging to Great Britain. This remarkable fortress, which lies opposite Ceuta in Africa (distance between Europa Point and Ceuta 14½ miles), and forms the key to the Mediterranean, is connected with the mainland of Spain by a low sandy isthmus, the peninsula having the Bay of Gibraltar on the west, and the open sea of the Mediterranean on the east. The British territory has a length of 2¾ miles and a greatest breadth of ¾ of a mile, the greater part of it consisting of "the rock," at the foot of which, on the north, is a race course, cemetery, etc. The highest point of the rock is about 1,400 feet above sea-level. Its north face is almost perpendicular, while its east side also presents tremendous precipices. On the south it is almost inaccessible, making approach from seaward impossible; the west side, again, although nearly as rugged and precipitous as the others, slopes toward the sea; and here the rock is secured by extensive and powerful batteries, and other works rendering it apparently impregnable. The body of the rock consists of a kind of dense limestone arranged in beds of 30, 40, and 50 feet in thickness. There are a number of remarkable caves in various parts of the rock, but all difficult of access.

Vast sums of money and an immense amount of labor have been spent in fortifying this celebrated stronghold. Numerous caverns and galleries, extending two to three miles in length, and of sufficient width for carriages, have been cut in the solid rock, forming safe and sheltered communications from one part of the garrison to another in cases of attack. Along these galleries are port-holes opening toward the bay or toward the Spanish territory (between which and the British territory there is a strip known as "the neutral ground"); while trees, shrubs, and flowers of various kinds have been planted at different points, both for ornament and utility. On the summit of the rock there are barracks, signal-stations, etc. Of late years the fortifications have been carefully strengthened at every vulnerable point, and guns of the newest construction have been mounted in them. Gibraltar has a naval dockyard, and is a victualing and coaling station of the British navy. Great harbor works have for some time been in course of construction (at a cost of some $20,000,000), including a large area of sea enclosed by massy walls, and graving-docks large enough to accommodate the largest battle-ships. The materials have been mostly brought from the east side of the rock by means of a tunnel specially constructed for this purpose.

The town of Gibraltar is situated on the west side of the peninsula, fronting the bay. It consists of two portions, the North Town and the South Town, the former being much the larger and separated from the South Town by the Alameda Gardens, parade ground, etc. The principal buildings are the governor's house, the naval hospital, the civil hospital, the garrison library (45,000 vols.), the court-house, revenue offices, remains of an old Moorish castle, and the barracks. The water for the supply of the town and garrison is collected in tanks during the rainy season. Splendid reservoirs for water have recently been constructed by the government. Gibraltar is a free port, and serves as a valuable entrepôt for the distribution of British manufactures to the neighboring countries. The administration is vested in the governor, who is also commander-in-chief of the troops; and the settlement is treated as a garrison town, the power of enacting laws being vested in the governor alone. All criminal cases are determined according to the laws of England. Newcomers to Gibraltar are stringently looked after. Foreigners are permitted to remain during specified periods only, and on giving the required security. The population in 1901 amounted to 27,460, including a garrison of 5,349 men. The permanent residents are of very various origin — Spanish, Portuguese, Maltese, etc.

The name is formed from the Arabic words *gebel al Tarik* (the height or rock of Tarik), since Tarik Ibn Zeiad, the general of the caliph Valid, at the time of the irruption of the Moors into Spain (711 A. D., and following years), landed at the foot of this rock (known as the *Calpe* of antiquity and one of the *Pillars of Hercules* — Abyla in Africa being the other), where he founded a strong fortress. About the beginning of the 14th century it was taken from the Moors by Ferdinand, king of Castile, but in 1333 it was recovered by them, and was not finally acquired by the Spaniards till 1462, when it was taken in the reign of Henry IV. The Duke of Medina-Sidonia, who had assisted in gaining it for the Christians, took forcible possession of it for himself, and it remained in the keeping of his family till 1501, when the Spanish sovereign got it into his own hands. The third duke unsuccessfully tried to recover it in 1506, by which time the fortress had undergone altogether some half score of sieges. The pirates of Algiers subsequently made an attack upon it, but were forced to retire. The German engineer, Speckel of Strasburg, in the reign of the Emperor Charles V., substituted for the old Moorish fortifications works in the European style. In the war of the Spanish Succession the Spaniards were obliged to surrender this fortress, 4 Aug. 1704, to the British admiral Rooke, assisted by a body of troops under Prince George of Darmstadt. From October 1704 to April 1705 it was besieged by the Spaniards. It was secured to Britain by the Peace of Utrecht in 1713. Since this time nothing has been omitted by Britain to render this fortress, which forms a bulwark of her Mediterranean trade, absolutely impregnable. As the increasing value of the place rendered the possession of Gibraltar more desirable to Spain, the siege of it was commenced 7 March 1727, but raised upon the approach of Admiral Wager, with 11 ships of the line. Spain then offered £2,000,000 sterling for the delivery of the place, but in vain; and by a compact at Seville in 1729 Spain agreed to renounce all its claims upon it. Still the Spaniards omitted nothing to prevent all entrance into the fortress, and to cut it off from the mainland, by constantly strengthening the lines of St. Roch and Algeciras. But it was easy to supply the inhabitants and garrison by sea. In the war which broke out between Britain and Spain in 1779 the last attempt was made for the recovery of Gibraltar. It now underwent the famous four years' siege from 1779 till 1783, but was ably and successfully defended by Gen. Elliot, afterward Lord Heathfield. It was secured to Britain by the Peace of 1783. Since that time, in the various British and Spanish, and also French wars, Gibraltar has only been blockaded on the land side.

Gibraltar of America, Quebec, Canada; so called on account of its commanding situation and its well-nigh impregnable defenses, both natural and artificial. It is the most securely fortified city in America.

Gibraltar of the East, a name given to Aden, a town and seaport of Arabia. Since 1839 it has belonged to the British, and its fortifications have been greatly strengthened and improved. The citadel is built on a rocky eminence, and is of great strategic importance, having a position between Asia and Africa like that of Gibraltar between Europe and Africa.

Gibraltar, Bay of, an inlet of the Atlantic formed by the headland of Cabrita and Europa Point, four miles distant from each other, and is spacious and well adapted for shipping, being protected from all the more dangerous winds; the extreme depth within the bay is 110 fathoms. To increase the security of the harbor, two moles have been constructed, which respectively extend 1,100 and 700 feet into the bay. The Spanish town and port of Algeciras lie on its western side.

Gibraltar, Straits of (anciently called PILLARS OF HERCULES); the straits connecting the Mediterranean Sea with the Atlantic Ocean, extending from Cape Spartel to Cape Ceuta on the northwest coast of Africa, and from Cape Trafalgar to Europa Point on the southwest seaboard of Spain. They narrow toward the east, their width between Europa Point and Cape Ceuta being only 15 miles, while at the west extremity it is 24 miles. Length, about 36 miles. Through these straits a constant current runs so strongly from the Atlantic that sailing vessels bound west can pass them only by the aid of a Levanter, or strong breeze from the east. It is believed that the waters of the Mediterranean find an outlet here by means of an undercurrent.

Gibraltar Ape or Monkey. See BARBARY APE.

Gibson, Charles Dana, American illustrator: b. Roxburg, Mass., 14 Sept. 1867. He studied at the Art Students' League (New York), became known as an illustrator for periodicals, particularly for the comic weekly, 'Life,' and through his satirical presentations of wealthy society attained a wide reputation. He has published various collections of his drawings.

Gibson, John, English sculptor: b. near Conway, Wales, 19 July 1790; d. Rome 26 Jan. 1866. He was the son of a landscape gardener, and was apprenticed to a wood-carver at Liverpool, where he attracted attention by a figure of 'Time,' modeled in wax, which he exhibited at the age of 18. The patronage of W. Roscoe (q.v.) assisted him to go to Rome, where he was cordially received by Canova. On the death of Canova in 1822 Gibson entered the studio of Thorwaldsen. In 1836 he was made a royal academician; but to the end of his life continued to make Rome his chief place of residence. Among his best works are: 'The Wounded Amazon'; 'The Hunter and His Dog'; 'Hylas and the Nymphs'; 'Helen'; 'Proserpine'; and 'Sappho.' The subjects of most of Gibson's works are taken from classical mythology, but he was no servile imitator of the antique; on the contrary, he exhibited thorough originality in his treatment, and gave marked individuality and expression to the goddesses, nymphs, and heroines of antiquity that proceeded from his studio. He was the author of one remarkable innovation, at least in modern sculpture, that of coloring his figures, and though he believed to the last that the experiments of this nature which he made were successful, he never succeeded in securing the approbation of other artists for the practice.

Gibson, Randall Lee, American politician: b. Spring Hill, Woodford County, Ky., 10 Sept. 1832; d. Hot Springs, Ark., 15 Dec. 1892. He was graduated from Yale in 1853, studied law in Tulane (then the University of Louisiana) and Berlin, was a sugar planter in Louisiana until the Civil War, entered the Confederate army in the ranks, and finally attained the rank of major-general. Subsequent to the War he practised law, and having entered public life was elected to Congress as a Democrat in 1872, though not seated, was in the House from 1874–82, and in the Senate from 1882 until his death.

Gibson, Robert Atkinson, Protestant Episcopal bishop: b. Petersburg, Va., 9 July 1846. He entered the ministry in 1870, was rector of Moore Memorial Chapel, Richmond, Va., 1872–8; of Trinity Church, Parkersburg, W. Va., 1878–87; and Christ Church, Cincinnati, 1887–97. In November of the year last named he was consecrated coadjutor-bishop of Virginia, succeeding to the bishopric on the death of Bishop Whittle in 1902.

Gibson, Robert Williams, American architect: b. Essex, England, 17 Nov. 1854. He studied at the Royal Academy of Arts, came to the United States in 1881 and has since practised his profession in New York. He has designed many important American buildings, among which are the Episcopal Cathedral at Albany, N. Y., and many churches, the Botanical Museum, New York, and banks at Buffalo, Albany, Utica, and elsewhere.

Gibson, William Hamilton, American artist and author: b. Sandy Hook, Conn., 5 Oct. 1850; d. Washington, Conn., 16 July 1896. Many of his illustrations appeared in the 'Art Journal' and in 'Picturesque America'; and his illustrations of books were numerous and popular. He published: 'Camp Life in the Woods' (1876); 'Pastoral Days' (1881); 'Highways and Byways' (1883); 'Strolls by Starlight and Sunshine' (1891); 'Sharp Eyes' (1896).

Gid, gĭd, **or Staggers,** a disease of sheep caused by a larval tape-worm (*Coenurus*) in the brain. See SHEEP, DISEASES OF.

Giddings, Franklin Henry, American sociologist: b. Sherman, Conn., 23 March 1855. He was graduated from Union College in 1877, and engaged in journalism until 1888, when he became lecturer in political science at Bryn Mawr. In 1894 he became professor of sociology at Columbia University. He has written: 'The Principles of Sociology'; 'The Theory of Socialization'; 'The Elements of Sociology'; 'Democracy and Empire'; and 'Introduction to Sociology.' He has greatly aided in systematizing the facts and theories of his department, and is distinguished from other modern sociologists by the emphasis he lays on the "consciousness of kind" as the distinguishing motive of the social individual, and one of the chief factors in the organization of society.

Giddings, Joshua Reed, American statesman: b. Athens, Pa., 6 Oct. 1795; d. Montreal, P. Q., 27 May 1864. He was admitted to the Ohio bar in 1820; elected a member of its legislature in 1826, and of Congress in 1838, where he was prominent as an opponent of slavery. Not only did he predict the tightening of the slavery chain about the neck of the two parties, but he foresaw the armed struggle. On different occasions in different speeches, he prophesied the Civil War and as a political abolitionist sought to hasten it by using the power of political organization. In 1861 he was appointed consul-general to British North America. Among his works are: 'The Exiles of Florida' (1858); 'The Rebellion: Its Authors and Causes' (1864).

Gid'eon (Heb. Feller, Hewer), deliverer of Israel from the Midianites. These nomad Arabs of the Syrian and Arabian deserts had invaded the central district of Palestine. In one of their expeditions they had murdered Gideon's brothers at Tabor. He is called by an angel of the Lord to save Israel. He is also bidden to destroy the altar of Baal, and to erect a sacrificial altar to Jehovah in its place. He gains from the performance of this command the name of Jerubbaal. Collecting the men of his clan Abieger he surprises the Midianites under cover of night, drives them toward the Jordan and captures and slays the two princes Oreb and Zeb. Continuing his pursuit to the Jordan he overtakes and kills the kings Zeba and Salmunna. The Israelites wished to make Gideon king as a reward for his valor, but he asks merely for the golden earrings taken in the spoil, out of which he makes and sets up an ephod to Jehovah. The victory of Gideon is one of the remarkable events in Jewish history. "The day of Midian" is spoken of in the prophets, and allusions are found to it also in the Psalms, and even in the Book of Revelations.

Giessbach (gēs'bäh) **Falls,** Switzerland, a cataract of the Giessbach, falling into Lake Brienz; consisting of 7 cascades, the largest of which has a fall of 190 feet.

Giffen, SIR **Robert,** English economist: b. Strathaven, Scotland, 22 July 1837. He went to London in 1862, where he was acting editor of the ‘Economist’ under Walter Bagehot 1868–76; then founded the ‘Statist’ and became chief of the Statistical Department in the board of trade and assistant secretary in 1882. He was John Morley's assistant on the ‘Fortnightly Review’ in 1873–6; and is the author of reports, papers, and essays which have given him a high rank. His works include: ‘American Railways as Investments’ (1873); ‘Stock Exchange Securities’ (1877); ‘Essays in Finance’ (1879); ‘The Progress of the Working Classes in the Last Half Century’ (1884); ‘The Growth of Capital’ (1890); ‘The Case Against Bimetallism’ (1892).

Gifford, Robert Swain, American artist: b. Naushon Island, Mass., 23 Dec. 1840; d. New York 15 Jan. 1905. He studied with Albert Van Beest in Rotterdam, Holland; traveled through California and Oregon in 1869, and in Europe and North America 1870–1. He was best known as a painter of landscapes and seashore scenes, and among noted paintings by him were: ‘The Rock of Gibraltar’; ‘A Lazy Day in Egypt.’

Gifford, Sandford Robinson, American artist: b. Greenfield, N. Y., 10 July 1823; d. New York 29 Aug. 1880. He was educated at Brown University; studied painting in Europe 1855–7. His works include: ‘A Lake Scene on the Catskills’; ‘Ruins of the Parthenon’; ‘Sunrise on the Matterhorn’; ‘Home in the Wilderness’; ‘Lake Geneva’; ‘Fishing-Boats in the Adriatic’; ‘San Giorgio, Venice’; etc.

Gifford, William, English critic: b. Ashburton, Devonshire, April 1757; d. London 31 Dec. 1826. He studied at Oxford, afterward traveled on the continent with Lord Belgrave for some years, and on his return to England devoted his time to literary pursuits. In 1794 he published ‘The Baviad,’ a poetical satire, in which the poetasters of the Della Crusca school are the chief objects of his ridicule; and in 1795 appeared ‘The Mæviad,’ a severe animadversion on the degraded state of the drama. These works, though virulent and coarse, display much critical ability. In 1797 he became editor of the Anti-Jacobin newspaper — an office which involved him in a quarrel with Dr. Wolcot, against whom he published a pamphlet in verse, entitled ‘An Epistle to Peter Pindar.’ His translation of the ‘Satires of Juvenal’ was published in 1802, and is executed in a manner highly creditable to his abilities. He edited the plays of Massinger, with notes, and a life of that dramatist (1805); and afterward in a similar manner the works of Ben Jonson, Ford, and Shirley. He also translated the ‘Satires of Persius.’ In 1809 he entered on the editorship of the ‘Quarterly Review,’ of which he continued to be conductor till 1824, when he resigned. He was interred in Westminster Abbey.

Gift, Theo. See Boulger, Dorothy Henrietta.

Gigan'tism, a rare form of disease supposed to be associated with changes in the pituitary body; characterized by abnormal processes of growth, chiefly in the bones of the face and extremities. Most giants, as seen in circuses, etc., have this disease or develop it in time. Technically the disease is known as acromegaly (q.v.).

Gigantostraca, jī-găn-tŏs'tra̤-ka̤. See Eurypterus.

Gignoux, François Regis, frāṅ-swā rā-zhē zhēn-yoo, French painter: b. Lyons 1816; d. Paris 6 Aug. 1882. He studied at the Beaux-Arts and with Delaroche, and in 1840–70 was in the United States, where he became a national academician. Many of his works are in the possession of private collectors of New York. He painted chiefly studies of natural scenery, such as ‘The Indian Summer’; ‘Niagara by Moonlight’; ‘The Bernese Alps at Sunrise.’

Gigoux, Jean, zhŏṅ zhē-goo, French painter: b. Besançon 8 Jan. 1809; d. 10 Dec. 1894. He studied at the Beaux-Arts, and as a pupil of Géricault and Sigalon, and achieved a high reputation by his historical works, religious and secular, in which he displayed forceful coloring and a faithful attention to detail. By his drawings on the stone, he did much to further the development of lithography. He executed 600 illustrations for an edition of ‘Gil Blas.’ Among the best of his paintings are: ‘The Eve of Austerlitz’; ‘The Good Samaritan,’ and ‘The Death of Leonardo da Vinci,’ his chief work now hung in the Besançon Museum. He published: ‘Causeries sur les artistes de mon temps’ (1885).

Gihon, gī'hŏn, **Albert Leary,** American sanitarian: b. Philadelphia, Pa., 28 Sept. 1833; d. New York 17 Nov. 1901. He was appointed assistant surgeon in the United States navy in 1855; took part in the attack and capture of the barrier forts, near Canton, China, in 1856; and served throughout the Civil War. He was promoted medical director in 1895, and was retired with the rank of commodore the same year. He published: ‘Practical Suggestions in Naval Hygiene’; ‘Need of Sanitary Reform in Ship Life’; ‘Sanitary Commonplaces Applied to the Navy’; ‘Prevention of Venereal Diseases by Legislation’; and was editor of ‘Annual of the Medical Sciences’ for six years.

Gil Blas (zhēl blās) **of Santillane,** sāṅ-tīl-āṅ, **The Adventures of,** a famous romance by Alain René Le Sage. It is a series of pictures of life among all classes and conditions of people in Spain two centuries ago. The narrative runs on, with excursions and interpolated histories, and the thread of the story is as inconsequential as that of a tale of the ‘Arabian Nights.’ The charm of the work is its absolute truth to human nature, and its boundless humor and satire. These qualities have made it a classic. Le Sage was a Frenchman, who never saw Spain; but through his familiarity with its literature he produced a work so essentially Spanish in its tone and spirit as to provoke long controversy as to its originality. Its writing occupied 20 years; the first two volumes appearing in 1715, and the last in 1735. It has been translated into many languages, the earliest in English; the one which has remained the standard being by Tobias Smollett.

Gila, hē'lā, a river of the United States, an affluent of the Colorado, origin in New Mexico; length 450 miles. Its upper course is through mountains, with many deep and precipitous cañons; farther south it flows through an open and comparatively level country, the valley being productive when irrigated. About 200 miles from the Colorado is the reservation of the Maricopa and Pima Indians. Ancient ruins are numerous on the banks of the Gila.

Gila Monster, the poisonous lizard (*Heloderma suspectum*) of the sandy deserts of the southwestern United States, so called because first brought to notice in the valley of the Gila River, Arizona, and on account of the great size (two feet in length) which it sometimes attains. Another "species" (probably a variety — *H. horridum*) exists in the arid parts of Mexico, where it is called "caltotepon" or crust-lizard. These constitute a family *Helodermatidæ,* characterized by the presence of pleurodont, fang-like teeth, each with a groove on its front and rear surface, and each having near its base a labial gland which secretes venom of the same nature as that of serpents. The food of these lizards consists of worms, centipedes, the eggs of birds and lizards, frogs and other small animals which its bite paralyzes or kills. It is slow to anger, but instances are on record of its biting men, producing illness and in some cases death.

Gilbert, Anne Hartley, American actress: b. Rochdale, England, 21 Oct. 1821; d. Chicago, Ill., 2 Dec. 1904. She was a graceful dancer in early life, and later became very successful in high comedy. She was married to George Henry Gilbert, a dancer, in 1846. She visited the United States in 1846, and in 1849 made her home here. For many years before her retirement she was a member of the Daly Company, her especial roles being those of old women, in which she achieved very marked success. On 21 Oct. 1899, her birthday was observed by her admirers by a special performance, a reception, and the presentation of a silver service at the Lyceum Theatre, New York. Her 'Stage Reminiscences' was published in 1901.

Gilbert, Charles Henry, American educator: b. Rockford, Ill., 5 Dec. 1859. He was graduated at Butler University, Ind., in 1879, and became professor of zoology in the Leland Stanford University in 1891. He is the author of 'Synopsis of the Fishes of North America,' with D. S. Jordan (q.v.).

Gilbert, Grove Karl, American geologist: b. Rochester, N. Y., 6 May 1843. He was graduated from the University of Rochester in 1862 and has been geologist of the United States Geological Survey from 1879. He has published: 'Geology of the Henry Mountains' (1879–82); 'Lake Bonneville' (1890); and numerous reports issued under the direction of the United States government.

Gilbert, Sir **Humphrey,** English navigator: b. Devonshire 1539; d. September 1583. He studied at Eton and Oxford, and adopting the military profession, he served with reputation in France and Ireland. He was knighted in 1570, and sat in the House of Commons as member for Plymouth in the following year. Possessing a strong propensity for speculation and enterprise, he turned his attention to maritime exploration, and published 'A Discourse of a Discovery for a New Passage to Cataia' (1576; reprinted in Hakluyt's collection of voyages, Vol. III.). In 1578 Sir Humphrey Gilbert obtained from the Queen a patent empowering him to discover and colonize in North America any land then unsettled. His first voyage ended in failure, but in 1583 he sailed again with a small fleet, and, having landed on Newfoundland, he took possession of the harbor of St. John's. On his return voyage to England in a small sloop he was lost in a storm. See 'Lives by Tytlor (1833); St. John (1868); Edwards (1868); Payne, 'Voyages of the Elizabethan Seamen' (1880).

Gilbert, Sir **John,** English painter: b. Blackheath, near London, 21 July 1817; d. Villers-sur-Mer, France, 5 Oct. 1897. In 1836 he began to exhibit both in oil and water colors; and in 1852 he was elected an associate, in 1853 a member, in 1871 the president of the Society of Painters in Water Colors, receiving soon after the honor of knighthood. He also became an A.R.A. in 1872, an R.A. in 1876, and a chevalier of the Legion of Honor. His oil paintings include: 'Don Quixote and Sancho Panza'; 'Education of Gil Blas'; 'Murder of Becket'; 'Joan of Arc Entering Orleans'; 'Crusaders'; 'Wolsey at Leicester,' and 'Morning of Agincourt.' He was a well-known and popular illustrator of books.

Gilbert, Linda, American philanthropist: b. Rochester, N. Y., 1847; d. 1895. She became known for her work in the interest of prison reform, and by her success in placing libraries in prisons. She was also foremost in obtaining the incorporation under the laws of New York of the Gilbert Library and Prisoners' Aid Society.

Gilbert, Rufus Henry, American inventor: b. Guilford, N. Y., 26 Jan. 1832; d. New York 10 July 1885. He was graduated at the New York College of Physicians and Surgeons: served as surgeon in the Union army in the Civil War; and was appointed superintendent and medical director of the United States army hospitals. Owing to the failure of his health after the war he abandoned his profession and engaged in the railroad business, making a special study of the needs of rapid transit in New York. The result was the erection of the first elevated railroad in that city.

Gilbert, William, English physician and physicist: b. in 1540 at Colchester, a town in Essex 50 miles from London; d. in 1603, and was buried in Trinity church, Colchester. At the age of 18 he entered Saint John's College, Cambridge, from which he graduated in 1560. In 1564, after taking his M.A. degree, he was appointed mathematical examiner of his college. Later, he devoted himself to the study of medicine, obtaining the Doctorate in 1569 and at the same time a senior fellowship in the University. Leaving Cambridge the same year, he went abroad for four years. In 1601, he was elected President of the Royal College of Physicians, an honor which was followed by his appointment as chief physician to Queen Elizabeth.

Gilbert's fame rests on the discoveries which he made in electricity and magnetism and which he tersely recorded in his work on the magnet, 'De Magnete magneticisque Corporibus,' published in London in 1600. He devoted all the time he could spare from his professional duties during a period of 18 years to the researches described in this remarkable treatise, which researches he informs the "candid reader" cost him over £5,000. By way of distinction, he marks his discoveries with marginal asterisks, large ones denoting important discoveries and small ones, those of minor note. Of the former, there are 21; of the latter 178. Besides a remarkable title-page, the work contains 84 illustrations.

In magnetism, Gilbert recognizes the magnetic field, the effects of heat, magnetic induction and magnetic screening; but his cardinal discovery is that the earth itself is a great magnet with its magnetic poles, equator and axis. He was led to this generalization by prolonged experiments with globular magnets, or terrellas, on which he poised small magnetic needles, finding that, however placed, they always pointed to the poles. He confirmed his theory by reference to the prevalence of magnetic materials in the crust of the earth, the behavior of the compass-needle and the dip circle, and also by the magnetic condition of vertical masses of iron such as the crosses of church-steeples.

Gilbert was an ardent advocate of the Copernican theory and there is reason to believe that his magnetic work was undertaken in its defence, convinced as he was that the revolution of the earth round the sun and its suspension in space would follow at once from the magnetic attraction of the other planets provided the earth itself could be proved to be a colossal magnet. Gilbert was belittled in *De Augmentis Scientiarum* by Chancellor Bacon, who was a staunch anti-Copernican, but was praised and admired by Galileo and Kepler. Two translations of 'De Magnete' have been made, the first by P. Fleury Mottelay of New York (1893), and the second by the Gilbert Society of London (1900). Gilbert's work stands out as the second landmark on magnetic philosophy, the first being a treatise on the lodestone by Peregrinus (q.v.) A.D. 1269.

Brother Potamian,
Professor of Physics in Manhattan College.

Gilbert, William Schwenck, English dramatist: b. London 18 Nov. 1836. He was the son of William Gilbert (1804–89), who published 30 novels, tales, etc. He was a clerk in the Privy Council Office 1857–62, and in 1864 was called to the bar. He contributed to the magazines, and was on the staff of 'Fun,' in whose columns his 'Bab Ballads' first appeared. His burlesque 'Dulcamara' (1866) was followed by other burlesques, dramas, comedies, fairy comedies and operas, chief of which was the celebrated series of Savoy operas written in collaboration with Sir Arthur Sullivan (q.v.) as composer. In nearly all his better-known works Gilbert displays fantastic humor that is often subtle, nearly always healthy in tone, and none the worse for a slight flavor of cynicism. His operas and 'The Bab Ballads' have been exceedingly popular in America. See P. Fitzgerald, 'The Savoy Opera and the Savoyards' (1894).

Gilbert Islands, or Kingsmill Group, a group of 15 islands in the South Pacific Ocean, between lat. 1° 0′ S. and 2° 30′ N.; and lon. 172° 0′ and 174° 30′ E. They are the most easterly of the groups collectively constituting Micronesia and are of coral formation, all low, the highest land in the group not exceeding 20 feet. The natives resemble the Malays. The whole group is under the protection of Great Britain, but the islands are self-governed, a sort of republicanism prevailing. Pop. (est.) 40,000.

Gil'bertines, The, a religious order founded about 1141 by Saint Gilbert (1083–1189), a parish priest of Sempringham, Lincolnshire, England. It was the only purely English order ever established prior to the Reformation. At the dissolution of the order, in the reign of Henry VIII., it numbered 22 convents. See Graham, 'Saint Gilbert of Sempringham and the Gilbertines' (1901).

Gilboa, gil-bō'a, a chain of hills in Palestine, between 500 and 600 feet high, overhanging the site of the ancient city of Jezreel, and rising between the fertile plain of Esdraelon and the valley of the Jordan. It is memorable as the scene of the defeat and death of King Saul and his three sons at the hands of the Philistines.

Gilchrist, gĭl'krĭst, **William Wallace,** American musician: b. Jersey City, N. J., 1846. He was a pupil of Clarke at the University of Pennsylvania, was an organist in Cincinnati 1872–83, and from that time was in Philadelphia, where he became a member of the faculty of the Musical Academy and a leader of choral societies in eastern States. His setting of Psalm XLVI. for solo voices, chorus, organ, and orchestra obtained the prize for composition at the Cincinnati festival of 1882, and his choral works are well known.

Gilder, gĭl'dėr, **Jeannette Leonard,** American editor: b. Flushing, N. Y., 3 Oct. 1849. Having entered journalism in 1869, she became editorially connected with 'Scribner's Monthly' (the present 'Century Magazine'), was a member of the New York *Herald* staff as literary editor and later musical and dramatic editor (1875–80), and in 1881 with her brother, J. B. Gilder (q.v.), founded and became editor of the 'Critic,' a monthly review of literature, drama, and art. Her publications are: 'Taken by Siege' (1886–96): and 'The Autobiography of a Tomboy' (1900). She also dramatized Sienkiewicz's 'Quo Vadis.'

Gilder, Joseph B., American journalist: b. Flushing, N. Y., 29 June 1858. After varied experience in journalism he, with his sister, J. L. Gilder (q.v.), established the 'Critic,' of which he became an editor. In 1895 he was appointed literary adviser to the Century Company and subsequently London representative of Dodd, Mead & Company. He edited 'Orations and After-Dinner Speeches of C. M. Depew' (1890), and other publications.

Gilder, Richard Watson, American editor and poet: b. Bordentown, N. J., 8 Feb. 1844. After secondary schooling he was a private of artillery during the emergency campaign in Pennsylvania (1863), and later managing editor of the Newark (N. J.) *Advertiser.* He subsequently established, with Newton Crane, the Newark *Register,* was editor of 'Hours at Home,' a monthly of New York, and when this was merged in 'Scribner's Monthly' became managing editor of the latter (1870). In 1881 he succeeded J. G. Holland (q.v.) as editor-in-chief of the 'Monthly,' in which capacity he remained after it became the present 'Century Magazine.' He was prominently identified with public affairs as chairman of the New York Tenement-house Commission (1894), member of the council of the National Civil Service Reform League, and other posts, and was a founder of the Authors' Club, the International Copyright League, and the Society of American Artists. The best of his verse, most of which originally appeared in magazines, was collected in 'Five Books of Song' (1894). Later volumes are: ‘In Palestine, and Other Poems’ (1898), and ‘Poems and Inscriptions’ (1901).

Gilder, William Henry, American journalist and arctic explorer: b. Philadelphia 16 Aug. 1838; d. 1900. He served in the Civil War, and was brevetted a major at its close. He accompanied Lieut. Schwatka in 1878 on a polar expedition, and in 1881 was a member of the Rodgers expedition as a correspondent of the New York *Herald*. His chief works are: ‘Schwatka's Search’ (1881); ‘Ice Pack and Tundra’ (1883). He was a brother of R. W. Gilder (q.v.).

Gil'dersleeve, Basil Lanneau, American classical scholar: b. Charleston, S. C., 23 Oct. 1831. He was graduated at Princeton in 1849, and studied in Germany for several years. He was professor of Greek and Latin at the University of Virginia from 1856 to 1876, when he was appointed professor of Greek at Johns Hopkins University. He is the founder and editor of the ‘American Journal of Philology.’ Among his works are: ‘Satires of Persius Flaccus’ (1875); ‘Justin Martyr’ (1875); ‘Odes of Pindar’; ‘Latin Grammar’ (1867); ‘Essays and Studies’ (1890); ‘Greek Syntax’ (1900).

Gilding, the art of applying and permanently attaching gold leaf or gold dust to surfaces of wood, stone, metals, etc. The Egyptian monuments present numerous traces of the existence of the art in ancient Egypt. The process seems to have been the same with that now used. The Persians also were acquainted with this art, as appears from the ruins of Persepolis. The Greeks and Romans employed gilding for many purposes. The Greeks used to gild the hoofs and horns of victims. The practice of gilding statues prevailed in the infancy of the art of sculpture, and was never entirely dropped by the ancients. The Romans used to gild sweetmeats; and many articles of furniture and utensils which have come down to us are gilt. There are also specimens of gilt glass and metals. The gilding which still remains on some ancient bronze monuments is remarkable for its brilliancy. The ancients carried the practice of gilding to a greater extent than the moderns: they gilded almost all their statues of bronze, wood, or plaster, and frequently those of marble, the ceilings of rooms, and even marble columns. The most remarkable examples of gilding employed with taste and effect in architecture, are the ceiling of St. Peter's, and that of Santa Maria Maggiore.

The art of gilding at the present day is performed on metals, or on wood, plaster, leather, parchment, paper, glass, etc. Chemical processes are those which are usually employed for metals. Gilding on copper is performed by the process called wash or water gilding, with an amalgam of gold and mercury. The surface of the copper, being freed from oxide, is covered with the amalgam, and afterward exposed to heat till the mercury is driven off, leaving a thin coat of gold. Copper, however, is rather too soft and dark-colored a metal to be treated in this way with advantage. Brass is a very suitable metal for this mode of gilding, but the best of all is a mixture of copper with one seventh of brass. The following method of gilding articles of copper, brass, etc., was patented by Elkington in 1836: Five ounces troy of fine gold are dissolved by heat in a mixture of 21 ounces of pure nitric acid of specific gravity 1.45, 17 ounces of pure hydrochloric acid of specific gravity 1.15, and 14 ounces of distilled water. The liquid is then poured off into a stone vessel, the sediment being left at the bottom of the vessel in which it was first contained. Four gallons of distilled water and 20 pounds of the best bicarbonate of potash are now added and the whole is boiled moderately for two hours. At the end of this time the mixture is ready for use. The articles are gilded by being attached to wires and plunged into the mixture, where they are allowed to remain as long as the workman thinks necessary, from a few seconds to a minute, when the mixture is newly prepared, but longer if it has been used for some time. Gilding is also performed by dipping a linen rag in a saturated solution of gold, and burning it to tinder. The black powder thus obtained is rubbed on the metal to be gilded with a cork dipped in salt water till the gilding appears. Iron or steel is gilded by applying gold leaf to the metal, after the surface has been well cleaned and heated till it has acquired the blue color, which at a certain temperature it assumes. Several leaves of gold are thus applied in succession, and the last is burnished down cold. The same process may be applied to copper. The operation of gilding may also be performed on iron and steel by diluting the solution of gold in nitro-hydrochloric acid with alcohol and applying it to the clean surface. A saturated solution of gold in nitro-hydrochloric acid, being mixed with three times its weight of sulphuric ether, dissolves the chloride of gold and the solution is separated from the acid beneath. To gild the steel it is merely necessary to dip it, the surface being previously well polished and cleaned, in the ethereal solution for an instant, and on withdrawing it to wash it instantly by agitation in water.

Gilding on wood, plaster, leather, parchment, or paper, is performed by different processes of mechanical gilding. The first of these is oil gilding, in which gold leaf is cemented to the work by means of oil size. In the case of paper or vellum the parts to be gilded receive a coat of gum water or fine size, and the gold leaf is applied before the parts are dry. They are afterward burnished with agate. Lettering and other gilding on bound books are applied without size. The gold leaf is laid on the leather and imprinted with hot brass types. Brass rollers with thin edges are employed in the same way for lines, and similar tools for other ornaments. When the edges of the leaves of books are to be gilded they are first cut smooth in the press, after which a solution of isinglass in spirits is laid on, and the gold leaf is applied when the edges are in a proper state of dryness. Japanner's gilding is another kind of mechanical gilding which is performed in the same way as oil gilding, except that instead of gold leaf a gold dust or powder is employed.

Porcelain and other kinds of earthen-ware as well as glass may be gilded by fixing a layer of gold in a powdered state by the action of fire. The gold dust or powder required in this operation may be obtained by precipitating it from a solution in aqua regia, either by means of sulphate of iron or protonitrate of mercury. In order that the gold powder may be applied to the surface of the article to be gilded it must be well mixed with some viscous vehicle such as spirits of turpentine mixed with some fatty matter, or strongly gummed water. It is then laid on with a fine camel's hair brush. When the article to be gilded is made of soft porcelain, delft-ware, or any kind of earthen-ware with a plumbiferous glazing, nothing else is required than to apply the gold in this manner, and then subject the piece of earthen-ware to a heat sufficient to soften the glazing, and thus fix the gilding. But in the case of hard porcelain, some kinds of stoneware and other varieties of pottery, in which the glazing does not soften at a suitable temperature, the gold powder, before being mixed with the viscous vehicle by which it is applied, must have a flux added to it, which serves as a means of attachment between the metal and the earthen-ware. The best flux is oxide of bismuth precipitated by water from a solution of nitric acid, with the addition of one twelfth part of melted borax. One tenth or one fifteenth part of this flux is added for every part of gold contained in the mixture, which is applied to the surface of the earthen-ware. Heat is applied in the same way as in the previous case to melt the flux, and thus fix the layer of gold to the article. The gilding must finally be burnished in order to bring up the gold color. Another method of gilding these substances is to mix neutral chloride of platinum with rectified spirits of turpentine in such a manner that the chloride is held in suspension in a finely divided state in the turpentine, to apply this liquid to the article to be gilded by means of a brush, and then to subject the article to heat so as to volatilize the spirits of turpentine and leave a uniform layer of platinum affixed to the glass or earthen-ware. The article, after being cooled, cleaned with aqua fortis, and washed with water, is next dipped in a gilding liquid prepared like that already described as patented by Elkington. The gilding is completed by rubbing the gilt parts with chamois leather. This method of gilding has the advantage of enabling the gilder to dispense with the burnishing, which is a very hazardous operation for fragile articles, and in the case of those which are of a very intricate form or very deeply cut out often impracticable. See Metallurgy.

Gilead, gĭl'e-ad (rough, rugged, hard), a country on the east side of the Jordan, at one time a portion of the kingdom of Israel. Its exact area is doubtful; but the southern boundary, the River Arnon, and the western boundary, the Jordan River, are well defined. The Yarmuk is given by some as a northern boundary; and some historians mention the country of Gilead as extending to the shores of the Sea of Galilee and the Plains of Bashan. The eastern boundary was "the desert." It is a mountainous country traversed by many small streams which flow into the Jordan. All the mountains are mentioned frequently as "mountains of Gilead," and one peak is called in ancient history, "Mount of Gilead." This peak is thought to be the one now known as Jebel or Djabal (mount) Osha. The soil is fertile and the vegetation generally luxuriant. The low round mountains or hills are no hindrance to cultivation as practised by the native inhabitants. A considerable portion is devoted to pasturage and large herds of cattle and flocks of sheep graze on the hillsides and table-lands as in the times mentioned in the Old Testament. The balm of Gilead, a small evergreen tree of the *Terebinthine* family, has long been noted because of the efficacy of its balm (balm of Mecca) in healing wounds. The terebinth tree and the oak still flourish in Gilead, especially in the valley of the Jabbok. Gilead is mentioned frequently in the Bible. Much of its history before the birth of Christ is given in the Old Testament. In Deuteronomy and Numbers may be found an account of the conquest of the country and the transfer of a part to Reuben and Gad. In Judges and Kings is a record of the wars waged upon Gilead by the Syrians, the Midianites, and the Ammonites, and finally the victory of the Assyrians. The flight of Absalom is given in 2 Sam. xiii. In 1 Sam. xxi. is an account of the battle in which the sons of Saul were slain, and of Saul's own death. It is there told that "the valiant men of Jabesh-Gilead arose and went all night, and took the body of Saul and the bodies of his sons from the wall of Beth-Shan," and burned them according to the custom of the times. And afterward these "valiant men" fasted several days. The chief cities of Gilead were Jazer, Mizpeh, Mahanaim, Penuel, and Succoth.

Giles, jīlz, **Saint (Saint Aegidius)**, a native of Greece, who, according to legend, lived in the 7th century. He gave all his property to the poor, and went to France, where he lived in solitude for many years. Finally he permitted companions in his retreat, and founded a house of the Benedictine order. A town grew up around it, and was called Saint Giles. The saint is the patron of many churches in France, Germany, Scotland, and Poland.

Giles, Saint (Saint Giles in the Fields), a parish in London, a mile to the northwest of St. Paul's. The church is in classical style, and contains the remains of Chapman, Shirley, Marvell, Lord Herbert of Cherbury, and Sir Roger L'Estrange. One district of it, by its poverty and wretchedness, long formed a very striking contrast to the west end of the metropolis, so that Saint Giles and Saint James were spoken of as typical of wretchedness and luxury respectively. There is another London church of Saint Giles, called Saint Giles Cripplegate, which contains the tomb of Milton.

Giles, William Branch, American politician: b. Amelia County, Va., 12 Aug. 1762; d. Albemarle County, Va., 4 Dec. 1830. He was educated at Hampden-Sidney College and at Princeton, studied law and practised at Petersburg, was a member of the Federal House of Representatives in 1790–8 and 1801–2, and of the Senate in 1804–15. In 1827–30 he was governor of Virginia. Originally a Federalist, he later became a Republican, and was the leader of his party in the Senate 1804–11. He took a prominent part in the Virginia Constitutional convention of 1829–30. He was an effective speaker, assertive in methods and frequently broke with his party, in which he finally lost influence. His 'Political Letters to the People of Virginia' appeared in 1813.

Gilgal, gĭl'găl, the name of several ancient towns near the Jordan, where the Israelites passed the river into Caanan, where they were circumcised and held the first Passover after leaving the desert (Joshua iv. 19). Here rested the tabernacle, till removed to Shiloh; here

Samuel held court as judge of Israel, and here Saul was crowned. It is frequently mentioned in the Bible; a school of the prophets was established here (2 Kings iv. 38), yet it afterward became a seat of heathen worship (Amos iv. 4). Josephus places one of the towns within two miles of Jericho, but no traces of it are at this day extant.

Gill, gĭl, Sir **David**, Scottish astronomer: b. Aberdeen 12 June 1843. He was chief of staff of Lord Lindsay's observatory, founded in 1870; in charge of Lindsay's expedition to Mauritius in 1874 to observe the transit of Venus and the opposition of Juno, by means of the heliometer, for the determination of the solar parallax. He determined the longitudes of Malta, Alexandria, Suez, Aden, Bombay, Seychelles, Reunion, Mauritius, and Rodriguez by cable and chronometers, and measured the first base-line for the Egyptian triangulation at the request of the khedive. In 1877 he was in charge of the expedition to Ascension to observe the opposition of Mars for parallax; and in 1879 appointed director of the Cape Observatory. He has published many valuable professional papers and reports.

Gill, Henry Z., American physician: b. Richboro, Pa., 6 Oct. 1831. He was a surgeon in the Union army during the Civil War; and was professor of chemical and operative surgery in Wooster University 1883–6; removing to Kansas in the year last named. His publications include: ‹Report on the Prisons of the United States›; ‹Gill's Sanné on Diphtheria, Croup, and Tracheotomy›; etc.

Gill, Theodore Nicholas, American educator: b. New York 21 March 1837. He became professor of zoology in Columbian University in 1884. His publications include: ‹Arrangement of the Families of Mollusks›; ‹Arrangement of the Families of Mammals›; ‹Catalogue of the Fishes of the East Coast of North America›; and ‹Scientific and Popular Views of Nature Contrasted› (1882); ‹Principles of Geography› (1884); etc.

Gill Net, a net suspended vertically, by means of floats, and leaden weights, in standing or running water, fresh or salt. It has meshes which allow the head of the fish to pass, but are too small for the body beyond the gills to get through, and when the captive tries to draw back, catch in the gills, from which no effort can disentangle them.

Gil'lem, Alvan Cullem, American soldier: b. Jackson County, Tenn., 1830; d. near Nashville, Tenn., 2 Dec. 1875. He was graduated from the United States Military Academy in 1851, served in the Seminole war (1851–2), in the Civil War became brevet colonel, United States Army, and brigadier-general of volunteers, and upon the reorganization of the State government of Tennessee was vice-president of the convention for revision of the Constitution and a member of the first legislature of the new régime. In 1867–8 he commanded the district of Mississippi. He attained the rank of colonel and brevet major-general in the regular service.

Gillenia, jĭ-lē'nĭ-a̤, or **Proteranthus**, a North American perennial genus of *Rosaceæ*, closely allied to *Spiræa*, embracing only two known species; also called Indian physic, bowman's root, and American ipecac. See Bowman's Root.

Gillespie, gĭ-lĕs'pĭ, **Eliza Maria**, American philanthropist: b. near West Brownsville, Washington County, Pa., 21 Feb. 1824; d. Notre Dame, Ind., 4 March 1887. In 1853 she became a member of the congregation of the Holy Cross, and after a novitiate in France was appointed in 1855 superior of the St. Mary's Academy, Bertrand, Mich. She later transferred the academy to its present location, St. Mary's, Ind., and established nearly 30 similar institutions in the United States. During the Civil War she directed from Cairo, Ill., an important hospital work for Federal soldiers. Upon the separation of the congregation of the Holy Cross in the United States from the order in Europe she was for two terms superior.

Gillespie, George de Normandie, American Protestant Episcopal bishop: b. Goshen, N. Y., 15 June 1819. He was graduated from the General Theological Seminary in New York in 1840, entered the ministry and held rectorates at Leroy, N. Y.; Cincinnati, Ohio; Palmyra, N. Y., and Ann Arbor, Mich. In 1875 he was consecrated bishop of Western Michigan. He published ‹The Communion of Saints› and other religious works.

Gillette, William, American actor and playwright: b. Hartford, Conn., 24 July 1853. He studied at the University of Boston, and at New York University; and in 1877 commenced his work on the stage, playing with different stock companies in New Orleans, Boston, New York, and other cities. He has since then acted important parts in many of his own plays. Among his best-known productions are: ‹The Professor› (1881); ‹Esmeralda› (1881), with Mrs. F. H. Burnett; ‹The Private Secretary›; ‹Held by the Enemy› (1886); ‹A Legal Wreck› (1888); ‹Too Much Johnson› (1895); Secret Service› (1896); and ‹Sherlock Holmes.›

Gillis, gĭl'ĭs, **James Melvin**, American astronomer: b. Georgetown, D. C., 6 Sept. 1811; d. Washington, D. C., 9 Feb. 1865. He entered the navy in 1827, soon obtained leave of absence and was graduated at the University of Virginia, and then spent six months in study in Paris. He was in charge of the observation of occultations and transit observations made in connection with the Wilkes exploring expedition, Gillis making the observations at the Washington end at a little observatory on Capitol Hill. He had charge of the United States astronomical expedition to the southern hemisphere, and in 1861 was appointed superintendent of the national observatory at Washington, D. C. He published: ‹Astronomical Observations› (1846); ‹Report of the United States Astronomical Expedition of 1849–52› (1855).

Gillis Land, an arctic region north of Spitzbergen, first sighted in 1707 by Gillis, a Dutchman, in lat. 81° 30′ N. and lon. 36° E., but not visited by him. Some geographers identify it with King Charles or Wiche Land, one of the Spitzbergen group.

Gill'man, gĭl'man, **Henry**, American botanist: b. Kinsale, Ireland, 16 Nov. 1833. He settled in Detroit, Mich., in 1850; and was United States consul at Jerusalem in 1886–91. During his consulate he so strongly opposed the Turkish government in its expulsion of Jews from Palestine that several European countries supported him, and the exclusion laws were modified. He is the author of 'The Wild Flowers and Gardens of Jerusalem and Palestine' (1894); 'Hassan' (1896); etc.

Gillmore, gĭl'môr, **Quincy Adams,** American military officer: b. Black River, Lorain County, Ohio, 28 Feb. 1825; d. Brooklyn, N. Y., 7 April 1888. He was graduated at West Point in 1849; promoted captain in 1861, and brigadier-general of volunteers in 1862. He displayed skill as an engineer by the capture of Fort Pulaski in April 1862, and was appointed commander of the Department of the South in June 1863. He made a successful attack on Morris Island in July 1863, began to bombard Fort Sumter and Charleston in August, and took Fort Wagner in September; Fort Sumter was reduced to a ruinous condition, but its garrison continued to hold it till 17 Feb. 1865. Gen. Gillmore commanded the Tenth corps near Richmond in 1864, and was brevetted major-general, United States Army, in 1865.

Gillott, jĭl'ŏt, **Joseph,** English manufacturer: b. Sheffield 11 Oct. 1799; d. Birmingham 6 Jan. 1872. He shares with Sir Josiah Mason the credit of having brought the manufacture of steel pens to its present state of high perfection.

Gills, gĭlz, the breathing organs of fishes, larval amphibians, crustaceans, and certain other aquatic animals. See *Respiratory System*, in article ANATOMY; also FISH.

Gillyflower, jĭl'ĭ-flow-ėr, a popular English name for some of the cruciferous plants most prized for the beauty and fragrance of their flowers, as the wallflowers and stocks; also for *Hesperis matronalis,* dame's rocket or dame's violet (q.v.). The name gillyflower has been regarded as a corruption of July-flower; but in Chaucer it appears in the form *gilofre;* and the French *giroflée* indicates the true derivation from *girofle*, a clove, the smell of the clove-gillyflower, or clove-pink, having suggested the name of that flower.

Gilman, gĭl'man, **Arthur,** American educator and author: b. Alton, Ill., 22 June 1837. He was engaged in banking in New York 1857–62, when he removed to Lenox, Mass., and devoted himself to literary and educational work until he went to Cambridge in 1870. He was the originator (1876) of the Harvard Annex, of which he became executive officer, and, upon its organization as Radcliffe College, regent. In 1886 he founded and became director of the Cambridge school for girls, known as the Gilman School. He edited Chaucer's works (1879) and other collections, collaborated in several volumes of the 'Stories of the Nations' series, and wrote a number of educational works, chiefly historical in character, such as 'The Story of Rome' (1886); 'The Colonization of America' (1887).

Gilman, Caroline Howard, American author: b. Boston 8 Oct. 1794; d. Washington, D. C., 15 Sept. 1888. In 1819 she was married to the Rev. Samuel Gilman (q.v.) and removed with him to Charleston, S. C., where she began to edit in 1832 the 'Rosebud,' a juvenile weekly newspaper, which subsequently took the name of the 'Southern Rose,' and contained articles of much literary merit. From this periodical she reprinted at different times the 'Recollections of a New England Housekeeper' (1835); 'Recollections of a Southern Matron' (1836); 'Ruth Raymond, or Love's Progress'; 'Poetry of Traveling in the United States'; 'Verses of a Lifetime'; 'Mrs. Gilman's Gift Book'; and other volumes. The first two of these works attracted particular attention by their practical lessons as well as their genial simplicity and humor, and passed through many editions. She was especially successful, also, in her books for children.

Gilman, Charlotte Perkins Stetson, American writer: b. Hartford, Conn., 1860. She is a daughter of Frederic Beecher (q.v.) and was married to G. H. Gilman in 1900. She is a prominent advocate of equality for women and has published 'Woman and Economics' (1898); 'In This Our World,' a book of verse (1898); 'The Yellow Wall Paper' (1899); 'Concerning Children' (1900).

Gilman, Daniel Coit, American educator: b. Norwich, Conn., 6 July 1831. He was graduated at Yale College in 1852; was professor of physical and political geography in Yale in 1856-72; and president of the University of California 1872–5. When Johns Hopkins University was founded in Baltimore, Md., in 1875, he was elected its first president and served in that capacity till 1901, when he resigned. In 1896–7 he was a member of the commission to settle the boundary line between Venezuela and British Guiana, and in the latter year also served on the commission to draft a new charter for Baltimore. He was president of the American Oriental Society 1893–1901, and has been vice-president of the Archæological Institute of America, executive officer of the Maryland Geological Survey, and president of the National Civil Service Reform League in 1901. His publications include: 'Life of James Monroe' (1883); 'University Problems' (1898); Introduction to DeTocqueville's 'Democracy in America'; 'Life of James D. Dana'; etc. On the organization of Carnegie Institution, Washington, D. C., 29 Jan. 1902, he was elected president, and in 1893 president of the American Bible Society.

Gilman, John Taylor, American statesman: b. Exeter, N. H., 19 Dec. 1759; d. there 31 Aug. 1828. In 1775, on the morning after the news of the battle at Lexington and Concord reached Exeter, he marched with 100 other volunteers to Cambridge, Mass., where he served in the provincial army. In 1782 and 1783 he was a member of the Continental Congress, and in 1797 he was chosen governor of New Hampshire, and was annually re-elected for 10 successive years. In 1813–14–15 he was again elected governor, after which he declined to be a candidate. He was a zealous Federalist, and his popularity in New Hampshire was so great that he was frequently chosen governor when his party was in the minority.

Gilman, Nicholas, American statesman: b. Exeter, N. H., 3 Aug. 1755; d. Philadelphia 2 May 1814. He was a brother of J. T. Gilman (q.v.) and like him served in the Continental army during the War of the Revolution. He represented New Hampshire in Congress in 1786, and again 1789–97, and was a United States Senator 1805–14. He was one of the

DANIEL COIT GILMAN,

LATE PRESIDENT CARNEGIE INSTITUTE.

framers of the Constitution of the United States.

Gilmer, Jeremy Francis, American soldier: b. Guilford County, N. C., 23 Feb. 1818; d. 1 Dec. 1883. He was graduated at West Point and entered the engineer corps of the United States in 1839. At the opening of the Civil War he resigned his captain's commission and entered the Confederate service, becoming major-general in 1863.

Gilmor, gĭl'môr, **Harry,** American soldier: b. Baltimore County, Md., 24 Jan. 1838; d. Baltimore 4 March 1883. He entered the Confederate army at the beginning of the Civil War, became known for his exploits as scout, in 1863 raised a battalion of horse of which he was made major, and later in that year, in command of the 1st Maryland Confederate regiment, captured Frederick, Md., and Chambersburg, Carlisle, and Gettysburg, Pa. In 1864 he led Early's advance into Maryland. He was elected Baltimore's police commissioner in 1874, and wrote 'Four Years in the Saddle' (1866).

Gilmore, gĭl'mōr, **James Roberts** («Edmund Kirke»), American miscellaneous prose writer: b. Boston, Mass., 10 Sept. 1823. He was at first in mercantile life, subsequently entering journalism and literature, and his earlier works were written under the pseudonym, «Edmund Kirke.» He wrote: 'Among the Pines' (1862); 'My Southern Friends' (1862); 'Down in Tennessee' (1863); 'Life of Garfield'; 'Among the Guerrillas'; 'Adrift in Dixie' (1863); 'On the Border'; 'Patriot Boys'; 'The Rear-Guard of the Revolution'; 'John Sevier as a Commonwealth Builder'; 'The Advance-Guard of Western Civilization' (1888); etc.

Gilmore, Joseph Albree, American politician: b. Weston, Vt., 10 June 1811; d. Concord, N. H., 17 April 1867. He became superintendent of various New Hampshire railway lines, was elected to the State Senate in 1858, and re-elected in 1859. In 1863 he was elected governor by the legislature, and in 1864 re-elected by popular vote. His energy increased the troops furnished by New Hampshire to the Federal armies from 15,500 to 33,258.

Gilmore, Patrick Sarsfield, American musical conductor: b. near Dublin, Ireland, 25 Dec. 1829; d. St. Louis, Mo., 24 Sept. 1892. He went to Boston at 18 and the next year organized Gilmore's band. In 1869 he arranged the Peace Jubilee in Boston, and in 1872 the World's Jubilee, in Boston also. Later he formed the noted 22d Regiment band in New York, which gave concerts in the United States and made a European concert tour in 1882. He composed but little; an anthem entitled 'Columbia,' intended to serve as the country's national hymn, was his only work of note.

Gilmour, gĭl'moor, **Richard,** American Roman Catholic prelate: b. Glasgow, Scotland, 28 Sept. 1824; d. St. Augustine, Fla., 13 April 1891. He was ordained priest in 1852, and after various pastorates, including those at Portsmouth, Ironton, Cincinnati, and Dayton, was consecrated bishop of Cleveland in 1872. His administration of the diocese was markedly efficient, and particularly so along the lines of Roman Catholic education. He published a Bible history, a series of 'Catholic National Readers,' and other books, and in 1874 founded the 'Catholic Universe,' an influential journal.

Gilolo, jē-lō'lō, **Jilolo,** or **Halmahera,** an island of the Molucca group in the Indian Archipelago, belonging to the Netherlands; area 6,500 square miles; length 225 miles. It is of singular form, consisting of four peninsulas, radiating from a common centre, and having large bays between. It is rugged and mountainous, the mountains being volcanic. The original inhabitants have been gradually pressed into the interior by the Malays. Pop. 120,000.

Gilpin, gĭl'pĭn, **Henry Dilwood,** American lawyer: b. Lancaster, England, 14 April 1801; d. Philadelphia 29 Jan. 1860. He was graduated from the University of Pennsylvania, studied law and became State attorney in 1822. He was United States attorney for Pennsylvania in 1832, and attorney-general of the United States 1840–1. Besides 'Reports of Cases' he published 'Opinions of the Attorney-Generals of the United States from the Beginning of the Government to 1841' (1841) and edited 'The Papers of James Madison' (1846).

Gilpin, John, the hero of a well known ballad by William Cowper, entitled 'The Diverting History of John Gilpin, Showing how he Went Further than he Intended and Came Safe Home Again.' It was first printed anonymously in 1782, and published with the author's name in 1785.

Gilsonite, gil'sŏn-īt, also called **Uintahite,** a natural hydrocarbon compound; a pure hard variety of asphaltum. It is very brittle, a lustrous black in color and fuses. It is used for a great variety of purposes in the arts, for instance in the manufacture of varnishes. Mixed with heavy California maltha or with petroleum residuum it has been used as a paving cement. The principal deposits in the United States are near Soldiers' Summit in Uintah County, Utah. The total output in 1902 was 4,052 short tons, valued at $61,182.

Gilthead, or **Gilteye,** English names for a small and beautiful sea-bream (*Chrysophrys aurata*), with conspicuous gold-colored spots over the eyes. It abounds in the Mediterranean, and ranges northward to England and southward to the Cape of Good Hope. This was one of the fishes kept and fattened by the Romans in their vivaria. Several other species are known in the Far East, one species (*C. berda*), being one of the favorite fishes of Madras under the name of black rock-cod.

Gin (more properly Geneva, from Fr. *genièvre*, «juniper»), a compounded spirit, prepared by redistilling plain spirit with juniper berries, coriander seeds, angelica root, etc., or by adding various essential oils to rectified spirit. The gin produced by distilling possesses a much more delicate flavor than that produced by mixing or compounding. The strength of gin varies from proof to 50 under proof. It was first made in Holland, notably at Schiedam.

As used in machinery the word gin is an abbreviation of engine and is used of Whitney's device for separating cotton-seed from the fibre and more generally of a portable hoisting machine whose frame is a tripod, one leg being movable so as to vary its angle of elevation, and thus determine the height of the apex. The other two legs preserve their relative distance.

and form standards for the drum, round which the rope is wound by power applied to the handspikes. For heavy weights a fall and tackle is used; and for hoisting a bucket from a well or mine, simply a couple of pulleys to change the direction of motion of the rope. One pulley is suspended from the apex, and the other attached between the two permanent legs, so as to change the rope to a horizontal position, for the attachment of a draught horse.

Gin, Cotton. See COTTON; COTTON GIN.

Ginatilan, hē-nä-tē'län, Philippines, a town on the western coast of Cebu, at the mouth of the Rio Ginatilan. There is valuable timber in the vicinity. Pop. (1900) 12,144.

Ginevra, gĭ-nev'ra, or jē-nĕv'ra, the title of a noted narrative poem by Samuel Rogers. It is named for its heroine whose affecting story is also recounted in 'The Mistletoe Bough,' a ballad by Thomas Haynes Bayly.

Gingal. See JINGAL.

Ginger, in botany, *Zingiber officinale*, common or narrow-leaved ginger, and in ordinary language the rhizomes of the same plant, which has subsessile linear lanceolate smooth leaves, oblong spikes, acute bracts, and a three-lobed lip. It is a native of India, but is cultivated in most tropical countries. A broad-leaved ginger, *Z. zerumbet*, also a native of India, is used externally for cataplasms and fomentations, but is not eaten. The pieces or races of the rootstocks are usually from 2 to 4 inches long, branched, flat, and of a pale buff color. Ginger is known in commerce under two forms, coated and uncoated or scraped; the latter is deprived of its epidermis when in the green state, and sold as white ginger. The chief varieties imported into the United States are Jamaica, Cochin, Bengal, Japan, and African. The first three are scraped gingers, and of these Jamaica is the most esteemed owing to its color and flavor. Ginger is an agreeable aromatic, and a valuable stomachic; but is more largely used as a condiment than as a medicine. Preserved ginger, imported from China in jars, consists of the young rhizomes boiled in syrup. Ground ginger is frequently adulterated with sago flour, wheat flour, ground rice, and arrowroot.

Ginger Ale or **Beer**, an effervescent drink, made of ginger, water, sugar, cream of tartar (or lemon juice), etc. A well-known method is by pouring a gallon of boiling water over ¾ pound of loaf-sugar, 1¼ ounces of sliced ginger, and the peel of one lemon, and after allowing the mixture to cool till it is milk-warm adding the juice of a lemon and a spoonful of yeast.

Gingerbread Tree. See DOOM PALM.

Ging'ham (*ali, gingamo*, from Guingamp, a town in Brittany, where the fabric was woven), a kind of cotton, the manufacture of which was introduced into Great Britain through France from India. It is distinguished from calico by having the colors woven in with the fabric, not printed on it. The patterns are various; sometimes fancy designs, sometimes checkered, and sometimes striped.

Gingili (jĭn'jĭ-lĭ) **Oil**, a name often given to the bland fixed oil obtained by expression from the seeds of *Sesamum Indicum*. It is used medicinally as laxative or mild purgative. See SESAME.

Ging'ko, the Japanese name of a genus of trees (*Salisburia*), of the yew group of conifers. The *S. adiantifolia* (*Gingko biloba* of Linnæus), the only species, is a tree which sometimes attains a height of nearly 100 feet. Its head is conical, and the branches are usually horizontal. The leaves are compound, with from two to four thick coriaceous leaflets marked with small longitudinal nervures, their resemblance to the maidenhair fern giving it its English name of maidenhair tree. It is a native of China and Japan, and was first introduced into Europe in 1754. Its fruit, which is of the size of a small plum, has a pulp with a disagreeable odor of butyric acid and enclosing a kernel which, when roasted, may be used as food, having a taste like that of maize. It is largely eaten throughout China and Japan. The Japanese consider the tree sacred and plant it near their temples. The gingko is considerably used as an ornamental tree in England and in the United States. It flourishes best in the shade, in a deep and somewhat moist soil.

Ginigaran, hē-nē-gä'rän, Philippines, a pueblo of the province of Negros Occidental, at the mouth of the Ginigaran River on the east shore of Guimarás Strait, 29 miles south of Bacólod; it is also on the West Coast road. Pop. 13,620.

Ginseng, jĭn'sĕng, several species of herbs of the genus *Panax*, natural order *Araliaceæ*. The most noted species are *Panax ginseng*, a native of China, and *P. quinquefolium*, of America. These two species so closely resemble each other that the discovery of the latter near Montreal, Quebec, in 1716, was based upon a description of the former. The plants grow about 18 inches tall, bear five long-petioled nearly smooth leaves arising from one point, whence also arises the flower-stem bearing an umbel of small flowers from which develop conspicuous scarlet, generally two-seeded berries. The light yellow root, especially of the former species, is used by the Chinese for every conceivable domestic and medicinal use and specimens resembling the human body often command their weight in gold because of supposed occult virtues. Neither species, however, is considered by American or British physicians to have any pronounced medical qualities. The Asiatic species has long been cultivated in China and Korea.

Shortly after the discovery of the American species a shipment of the wild root was made to China and soon a trade was established. Since the plant has a natural range from the valley of the St. Lawrence to the mountains of Georgia and westward to the eastern bank of the Mississippi, the wild supply of roots long met the demand. In 1858 the price was 52 cents a pound; in 1902, $5.55, the advance being largely due to the decrease of the native supply. In the latter year many lots of northern root (considered always better than southern) sold for $8.00 or even more. The advancing price led to many attempts to cultivate the plant, but until about 1885 none were reported successful. Then George Stanton, of Apulia, N. Y., succeeded by growing the plant in beds prepared in the forest and later under lath sheds. These methods have led to the establishment of American ginseng growing. Cultivated ginseng has commanded about 20 per cent more than wild root from the same locality.

The plants thrive best in a well-drained, rather loose soil, well supplied with humus, potash and phosphoric acid, but not with nitrogenous material. Little has been done to improve the plant, but the time required to mature a crop of roots can probably be shortened considerably and the size of the root increased. In 1902 most growers calculated upon five years as necessary to mature a crop, but at the price of $2.50 a pound they figured upon making a profit under reasonably favorable conditions. The atrocious prices paid for plants and seed during 1898–1903 were largely due to speculation, an exaggerated estimate of the demand in China, which is almost the sole market, and to the novelty of the industry, and hence the scarcity of plants and seed. Consult: Revised edition of Bulletin No. 16, Division of Botany, United States Department of Agriculture (Washington, D. C.); Kains, 'Ginseng' (New York 1902).

Ginx's (gĭnks'ĕz) **Baby,** the title of a famous book by John Edward Jenkins. It is a satire on the English poor-laws and the administration of sectarian charitable associations, and was published anonymously in London in 1871. It speedily ran through many editions, was republished in the United States, and excited warm controversy in the press and even in parliament. It was followed by satires on other phases of social economy, but none of the other works of this author attained such a vogue or exerted such an undoubted influence upon the direction of social reforms.

Giobertine (jō-bĕrt'ĭn) **Tincture,** a preparation for restoring writings which have become illegible through age, or faded pictures. The inventor of it was Giovanni Antonio Gioberti, a native of Piedmont (1761–1834). This invention has been invaluable in restoring the original writing of palimpsests. See PALIMPSEST.

Gioja, jō'yä, **Flavio,** Italian mariner: b. Pasitano, near Amalfi, in the latter part of the 13th century. He is said to be the inventor of the mariner's compass, of which he made use in 1302–3. The tendency of the loadstone to turn toward the north was known before his day, but the compass then in use consisted only of a magnetized reed floating upon cork in a vessel of water. Gioja invented the plan of suspending it on a pivot, thus leaving it free to move in any direction, whereby observations were rendered both easier and more exact.

Giorgione, jŏr-jō'nĕ (easel name of GIORGIO BARBARELLI or BARBARELLA), Italian painter: b. Castelfranco 1477; d. Venice 1511. He was a pupil of Giovanni Bellino, and painted history and portraits. He was one of the most celebrated of the Venetian school, was a fellow student of Titian, whom he might have rivaled, had he not died of the plague in early life, while Titian lived for nearly a century. To him Venetian painting owes much of its marvelous technique, and by his example in the use of pigments and glazings he set an example many followed; he has had more pictures by other hands attributed to him (nearly a hundred) than any other Italian master. Even connoisseurs have been deceived by the depth and richness of coloring, the luminosity of aërial perspective, which his imitators had learned from him too well. Yet there are not more than 12 authentic pictures by Giorgione, and these are dispersed among the public galleries of Florence, London, Madrid, Dresden and Vienna.

Giotto, jŏt'tō (called GIOTTO DI BONDONE), Italian painter and architect: b. Vespignano, near Florence, about 1266; d. Florence 8 Jan. 1337. He was the son of a peasant, and was employed, it is said, in tending cattle. But having been once seen by Cimabue, as he was drawing figures of his sheep upon a piece of slate with a stone, that artist obtained leave from his father to take him with him, carried him to Florence, and taught him painting. This may be a mere story, but at any rate his first teacher was Cimabue. His natural talent, and especially the gracefulness so peculiar to him, developed so rapidly that he soon surpassed all contemporary artists. He represented the human figure in his pieces with truth and nature, and excelled in the dignity of his figures, a pleasing arrangement of them, and a regard to correct proportions and natural disposition of the drapery. His earliest extant works are mural paintings in the Church of St. Francis at Assisi, executed before the end of the 13th century. He was now called to Rome, and after painting various works there he went to Padua, in 1303, and adorned the chapel of the Annunciata dell' Arena with a series of famous frescoes, including 38 subjects, disposed in three rows, on the sides of the chapel and the front of the chancel wall, with a vast representation of the 'Last Judgment' filling the west end. Dante was his guest at Padua in 1306, and he is celebrated in the great poet's 'Divina Commedia.' He was also a friend of Petrarch. He worked also at Milan, Verona, Ravenna, Rimini, and Arezzo. In 1330–33 he was at Naples, and in 1334 was appointed master of the cathedral works and other undertakings at Florence, where he designed the celebrated Campanile, a structure finished by his scholar and godson, Taddeo Gaddi. Besides the frescoes at Assisi and Padua, comparatively few works of Giotto are extant. Among his most celebrated pieces is the 'Navicella' (ship) at Rome (a picture of 'Peter Walking upon the Waves,' in mosaic). The National Gallery possesses a 'Coronation of the Virgin' painted in tempera, on wood. "The influence of Giotto was profoundly felt over the greater part of Italy. His example caused a revolution in art, the effects of which are traceable into the 15th century." Many anecdotes of more or less authenticity are told regarding this painter. On one occasion, when asked for a sample of his art to show the Pope, Giotto is said to have drawn a perfect circle with a single stroke; whence "round as the O of Giotto" became proverbial. See Crowe and Cavalcaselle, 'History of Painting in Italy' (1864–6); Janitscheck, 'Die Kunstlehre Dantes und Giottos Kunst' (1892); Ruskin, 'Giotto, and his Works in Padua' (1854–60); Zimmermann, 'Giotto' (1899); Thiorle, 'Giotto' (1902).

Gippsland, gĭps'lănd, Australia, one of the four important districts into which Victoria is divided, so named after an early governor. It forms the southeast portion of Victoria, and has an area of 13,898 square miles. Its length from west to east is 250 miles, and mean breadth about 80. It was originally called Caledonia Australis by Macmillan, its first explorer (1839).

Gipsies, jĭp'sĭz (from Egyptians, the name by which they were called in the English statutes), a wandering nation. They are called by the French Bohémiens, from the belief that they were Hussites driven from their country; in Switzerland, the Netherlands, and the Black Forest they go under the names of Heiden (Pagans); in North Germany, Denmark, and Sweden they are called Tater (Tartars). The name they most frequently pass under in Germany is Zigeuner, which is not unlike the Italian Zingaro or Zingano, the Spanish Zingaro or Gitano, the Hungarian Cigany, the Turkish Tschinganeh. They call themselves Rom, whence Romani, or Romany, the name of their language. The number of gipsies in Europe is roughly set at perhaps 750,000. Of this number about 200,000 are in Rumania; 95,000 in Austria-Hungary; 120,000 in European Turkey; 40,000 in Spain; 40,000 spread over Germany, France, and Italy; 18,000 in Great Britain; and the remainder scattered over other countries. The main body of their language is the same throughout Europe, and even now has a close affinity with the dialects of Hindustan, though it is mixed with a great number of words and expressions borrowed from the races among whom they have sojourned. The gipsies are distinct from the people among whom they dwell, especially in their bodily appearance as a race and in their language. They are slight and agile in frame, though sometimes tall of stature. Their skin is tawny, or olive-colored, their eyes large, dark and brilliant. They have long hair, raven-black, and sometimes ringletted. The mouth of the gipsy is small and finely shaped, and the teeth of pearly whiteness. Scientific men have come to the conclusion that these wanderers are neither of European nor of African origin, but are a remnant of some obscure Indian tribe. This ethnological conclusion is borne out by the fact that their language is undoubtedly derived from the Sanskrit, although intermingled with Oriental terms and inflections appear words of Greek, Slavic, Rumanian, Magyar, German, French, and English origin.

Their history is curious and interesting. Organized gipsy bands first appeared in Europe at the beginning of the 15th century, and in Italy their number in 1422 was computed at 14,000. Five years later they made their first appearance in Paris, saying that they were Christians of Lower Egypt, driven to take refuge in Europe from the Saracens, and had recently left Bohemia. They professed to be performing a penance imposed upon them by Pope Martin V., who, after hearing their confessions of sins committed during their travels, had ordered them to wander over the earth for seven years without taking rest on beds. They were permitted to settle outside the city of Paris, but when they began to practise palmistry and fortune-telling the archbishop had them driven away, and excommunicated the vast number of citizens who had consulted them. Other bands succeeded the 120 gipsies who first made their appearance in Paris: these latter had crossed the channel for England. They were great thieves and in every European country they visited were regarded with disfavor. In vain laws were passed against them. Francis I. of France ordered them to leave the country on pain of being sent to the galleys without trial. The States-General of Orleans condemned them to perpetual banishment. In the middle of the 15th century Pope Pius II. cites them as thieves from the Caucasus. In 1492 Spain exiled them and renewed the decree 100 years later. Elizabeth of England followed Henry VIII. in uttering a proclamation against them. In Scotland they were sheltered and protected, and John Faw, Lord and Earl of Little Egypt, was empowered by royal writ to exercise authority over his gipsy subjects. Germany tried to eliminate them, and Maria Theresa in 1768 undertook to settle them as peasants on the land. This attempt was not successful, but Joseph II., by severe measures induced many of them to settle, practise trades, and have their children educated. Though their number in Europe must be estimated at three quarters of a million they are less a vagrant class than formerly, a fact which is due largely to the stricter policing of the rural districts, and the increase of intelligence among the peasantry, and among the gipsies themselves. Gipsies have never settled in the United States as vagrant communities.

Gipsy-moth, a large moth (*Porthetria*, or *Ocneria*, *dispar*), of the family *Liparidæ*, imported into Massachusetts, in 1868, where it soon became a pest by defoliating shade-trees: and up to 1900 it had cost the commonwealth $1,550,000. The sexes of the moth differ greatly, the male expanding only about one and a half to two inches, while the female measures across its expanded wings two and a half inches; the female is spotted brownish, and the male is white, marked with black lines. The former lays her eggs in masses to the number of 500 wherever convenient, covering them with hairs and scales from her own body. The females have such heavy abdomens that the wings are inadequate for flight, hence the insect, owing to the measures which have been employed to prevent its artificial carriage has not spread far beyond the place where originally introduced, near Malden. The caterpillar measures when mature about 1.5 inches, is white, with black markings, and furnished with long hairs. It is arboreal and capable of being most troublesome on shade, forest, and fruit-trees, but when abundant it feeds and develops on any form of vegetation. A single generation is produced annually. The best means of combating it are spraying with arsenical mixtures, the collection of the cocoons and egg-masses and destroying them; the scraping of loose bark from trees, thus destroying the young and depriving them of hiding places; also the destruction of the eggs by means of oily substances, and the trapping of the larvæ with strips of burlap placed about the infested trees. Consult: 'The Gipsy Moth,' by Forbush & Fernald (Boston 1896); Howard, 'The Gipsy Moth in America,' Department of Agriculture, (Washington, 1897).

Giraffe, jĭ-răf', or **Camelopard**, the tallest of mammals (*Giraffa camelopardalis*), the type of a family of ruminants (*Giraffidæ*), intermediate between deer and antelopes, and also containing the okapi (q.v.). It is a native of Africa south of the Sahara, but is now to be found only in the interior, remote from civilization and where there are brushy plains or open forest, and is fast decreasing. It occurs generally in small herds of from 5 to 40. It feeds on the leaves and small branches of trees, especially mimosas, which, in districts where the animals abound are kept cropped to a convenient height for browsing. Its general aspect is remarkable from the height of the foreparts and great elongation of the neck, the head being sometimes 18 feet from the ground. The number of vertebræ in the neck, however (seven), is not greater than in other quadrupeds, and it has no extraordinary flexibility, although its form and movements are very graceful. The length, therefore, is due to the elongation of each cervical vertebra. The body is short, and the back slopes from the shoulder to the tail; yet the greater height of the foreparts is not entirely owing to the greater length of the fore-legs, but to the neural processes of the vertebræ, which form a basis for the support of the neck and head. The head is long, capable of a wide range of movements, and the upper lip is projecting and somewhat prehensile, while the tongue is remarkably capable of elongation, and can be thrust far out of the mouth, and employed to grasp and take up even very small objects; it is said that its tip can be so tapered as to enter the ring of a very small key. The usefulness of such an organ for drawing in leaves and branchlets to the mouth is obvious. The giraffe adroitly picks off the leaves of acacias and other thorny plants, without taking the thorns into its mouth. The dentition of the giraffe agrees with that of antelopes, sheep, and oxen; the upper jaw of the male is destitute of the canine teeth which are present in the male of many deer.

Anatomically the most remarkable feature of the giraffe is the presence in both sexes of two protuberances between the ears, generally described as horns, but very different from the horns of other animals, and each consisting of a permanent bone united to the skull by an obvious suture, covered with skin and hair, and terminated by long hard bristles. These long outgrowths correspond to the bony core of the antelope's horn or to the pedicel of the antler in the deer. There is also a projection on the forehead, which, in the giraffes of South Africa, is so elongated as to indicate a separate species (*G. australis*) in the opinion of recent naturalists. If this view be accepted then the name *camelopardalis* applies properly only to the giraffes now to be found only in Somaliland. Moreover, Sir H. Johnston has reported that there exists in Uganda a very brilliantly colored form which has five horny protuberances, instead of three, upon the head; and when better known may prove to be in a new genus as well as of a novel species. The hair of the giraffe is short and smooth, with a short mane on the neck, and a tuft on the end of the tail. The color is reddish-brown in irregular areas sharply marked off by white borders, like the mortar between brick-work; but there is much variation in tint as well as pattern. A few extinct forms are found fossil in the Pliocene beds of China, India, and Greece, of which *Samotherium* and *Hallidotherium* are prominent examples; they had a shorter neck and legs and more bovine appearance than their successors, and the males alone have horns.

The giraffe is an inoffensive animal, and generally seeks safety, if possible, in flight, although it is capable of making a stout resistance, and is said to beat off the lion by kicking with its hind-legs, discharging a storm of kicks with extraordinary rapidity. It is not easily overtaken even by a fleet horse, and has greatly the advantage of a horse on uneven and broken ground. Its pace is described as an amble, the legs of the same side moving at the same time. The giraffe was known to the ancients, and was exhibited in Roman spectacles. Representations of it appear among Egyptian antiquities. It has been supposed to be the zemer of the Jews, translated chamois in the English Bible (Deut. xiv. 5).

It is one of the costliest and most uncommon animals in menageries, although in former years they were kept and bred in Europe. The flesh is excellent meat, and the hide is thick and makes good leather. Consult: Beddard, 'Mammalia' (1902), and the writings of naturalists and sportsmen in Africa, especially Johnston, Baker, Bryden, Holub, and Selous.

Giralda, hē-räl'dä (Spanish *girar*, "to turn round"), a weathercock in the form of a figure or statue. It is pre-eminently applied to the weathercock, and from that to the Moorish tower or minaret (part of the cathedral) which it surmounts at Seville, Spain. The figure in this weathercock is that of Faith, which turns round to face every wind and storm. In the copy of the tower of Seville cathedral which appears in Madison Square Garden, N. Y., the figure of Faith is replaced by that of Diana.

Girard, jĭ-rärd', **Charles**, American naturalist: b. Mülhausen, France, 1822. In 1839 he was a pupil of Agassiz, at Neufchâtel, Switzerland, and soon became one of his assistants, accompanying him to America, and remaining his assistant until 1850. He was attached to the Smithsonian Institution 1850–9, and has published: 'Herpetology of the United States Exploring Expedition under Capt. Wilkes' (1858); and many professional articles and monographs.

Girard, zhē-rär, **Marc Amable**, Canadian politician: b. Varennes, P. Q., 25 April 1822; d. Winnipeg 10 Sept. 1892. In 1871 he was admitted to the bar of Manitoba, in whose politics he was long active as treasurer (1870–2), premier (1874), and later secretary, minister of agriculture, and president of the council. In 1871 he became a senator of the Dominion of Canada and in 1872 a member of the executive council for the Northwest Territories.

Girard, Philippe Henri de, fē-lēp ŏṅ-rē dĕ, French inventor: b. Lourmarin, France, 1 Feb. 1775; d. Paris 26 Aug. 1845. He was a man of versatile, scientific tastes, but concentrated his powers on mechanics. When Napoleon offered 1,000,000 francs as a prize for a machine that would spin flax, Girard invented the machine, but the fall of Napoleon deprived him of the reward. In 1815 he settled in Austria, built a flax-mill at Hirtenberg, and inaugurated steamboat service on the Danube. At the invitation of the Russian czar he went to Poland in 1825 and established a flax-mill which became the centre of the village of Girardou.

Girard, jĭ-rärd', **Stephen**, American philanthropist: b. Bordeaux, France, 24 May 1750; d. Philadelphia 26 Dec. 1831. In 1769 he settled in Philadelphia and engaged in various trades. Later, in 1780–90, he formed a partnership with his brother John and for some years continued a most successful West Indian and coastwise trade. He became interested in the first United States Bank in Philadelphia, and in 1812 had purchased the controlling interest and building. The bank continued to do business under the name of the Girard Bank, and soon became one of the foremost financial institutions of the country. He was a man of peculiar habits, ill-tempered and repellent in manner, but with all, a man uncommonly generous in his charities, chief among which was the $5,000,000 left for the erection and maintenance of a college for male white orphans. During the rage of yellow fever in Philadelphia he was ever present in relieving the afflicted, both by his free giving and by his personal care.

Girard, Kan., a city and county-seat of Crawford County, on the Atchison, T. & S. F., and St. Louis & S. F. R.R.'s. Its situation is well adapted to agricultural pursuits. It has 6 churches, 2 banks, and 3 public schools. The industries include zinc smelting, stove manufacturing, and flour-mills. The city owns its own water-works. Pop. (1900) 2,473.

Girard College, Philadelphia, Pa., an institution for the education of poor white orphan boys; founded under the will of Stephen Girard, and opened 1 Jan. 1848. By a provision in the will no ecclesiastic, missionary, or minister of any sect whatever is to have any connection with the college. At the close of the school year 1900 it reported: Professors and instructors, 67; students, 1,731; volumes in the library, 16,800; productive funds, $15,938,293; income, $1,000,000; number of graduates, 4,754; president, A. H. Fetterolf, Ph.D., LL.D. The total value of the college property exceeds $16,000,000.

Girardin, MADAME **Delphine Gayde**, dĕl-fēn gādė zhē-rär-dăn, French poet and novelist: b. Aix-la-Chapelle, Rhine Province, Prussia, 26 Jan. 1804; d. Paris 29 June 1855. Carefully educated by her mother, Sophie Gay (q.v.), she won fame with her poetry at the age of 15, an academic prize at 18, and a royal pension at 20. In 1831 she married the eminent journalist M. Emile de Girardin, and began now to turn her attention to prose fiction, producing successively: 'Le Lorgnon'; 'Le Marquis de Pontanges'; 'La Canne de M. de Balzac'; 'Il ne faut pas jouer avec Douleur'; and 'Marguerite.' She also contributed to the 'Presse,' conducted by her husband, her 'Lettres parisiennes,' which, under the pseudonym of the "VICOMTE DE LAUNAY," attracted great and deserved admiration by their wit and liveliness. As a writer for the stage Madame de Girardin obtained some distinction, two of her most successful pieces being: 'Lady Tartuffe' and 'La joie fait peur.' She also composed two tragedies, 'Judith' and 'Cleopatra,' for the celebrated Rachel; and a little piece by her, 'Le Chapeau de l'Horloger,' became a popular farce in England under its English title of 'The Clockmaker's Hat.'

Girardin, Emile de, ā mēl dė, French journalist and politician: b. Paris 22 June 1806; d. there 27 April 1881. He bore the name of Delamothe till 1827, when he assumed that of his father, who acknowledged him in 1847; and his first attempt in literature was a novel, 'Emile,' in which he pleaded the cause of adulterine children. After the July revolution of 1830 he established the 'Journal des Connaissances Utiles,' and in 1836 founded the 'Presse,' an Orleanist journal with Conservative leanings. Its rivals accused it of being subsidized by the government, and one of the unfortunate results of the quarrels thus fastened on Girardin was his duel with Armand Carrel, editor of the 'National,' in which the latter fell. He promoted Louis Napoleon's election to the presidency, and afterward became a Socialist. In 1856 he sold his share of the 'Presse,' but became its editor again in 1862, eventually abandoning it for the direction of the 'Liberté,' which he maintained till 1870. During the Commune he proposed a scheme for splitting up the republic into 15 federal states. In 1874, however, he founded the 'France,' and both in its pages and in the 'Petit Journal' supported the republic. He wrote a few pieces for the stage; his political ideas he gave to the world in a host of brochures.

Girder, a beam, of wood or metal, spanning the distance from wall to wall or pier to pier, and used to support a superstructure or superincumbent weight, as a floor, the pathway of a bridge, etc. Girders are often compound, the timbers being scarfed together and stayed by truss-work, or fished at the joint. The ends of the girder rest on the wall or pier to an extent varying according to the span; thus for a girder of 10 foot span, the bearing at each end should be 7 inches; for a 20-foot span, 14 inches. The ends rest on templates. Girders are of various sorts, according to the purpose for which they are required. A sandwich girder is one which is composed of two wooden beams with an iron flitch plate between, all bolted together. See BRIDGE BUILDING; BUILDING.

Gir'dler, a small American longicorn beetle (*Oncideres cingulatus*), which in August lays an egg in a hole bored into a twig of a hickory, pear, or other tree, and then gnaws a deep groove below the egg, thus girdling the twig. This kills the extremity and provides a supply of dead wood as food for the grub which is soon hatched. The grub eats all the woody tissue, and within the concealing shell of bark remaining, pupates and passes the winter, becoming a full beetle and emerging the following spring. When this insect is numerous it may do serious damage to forests and orchards.
