Now, antistreptococcus serum as prepared by Marmorek has the property of killing the streptococcus in the blood and the tissues while it is absolutely harmless to the patient. It can be used in conjunction with any other treatment, and gives immediate results. It may be expected from the administration that by the following day the temperature will be greatly reduced; also there will be a considerable reduction in the amount of expectoration. By the end of two weeks the expectoration will be reduced from 50 to 75 per cent. less offensive and less purulent. The cough will also be less harassing and frequent and the patient improved in every way. These results must be the more permanent when the serum is used early in the case. The cases in which I used it were all necessarily fatal cases, one having intestinal tuberculosis, and the other two far advanced, with large cavities, and great emaciation.

*Case 1.*—Mrs. N. D., age 23, a case of rapid phthisis with extensive cavity formation in the right lung and consolidation of the left upper lobe. Temperature range of 7° F. and pulse 120 in the morning to 150 in the afternoon. Examination showed the sputum to be almost a pure culture of tubercle bacilli. June 25th, antistreptococcus serum was given and repeated every second day for three doses. After this the temperature remained below 100 for two weeks and the expectoration and cough was greatly reduced. The patient's general condition was greatly improved by the use of serum.

*Case 2.*—H. C., age 20, has had consumption for about six years, with a large cavity formation in the right lung, constant cough and expectoration, emaciation and loss of appetite. There occurred in this case a peculiar form of septic absorption which resulted in multiple inflammatory foci about the face, scalp and neck, which would certainly have resulted in abscesses but for the use of antistreptococcus serum. After a single dose of the serum the deposits disappeared, the temperature which was above 101 F. reduced to below 100 F. Expectoration was greatly diminished and considerable general improvement established.

*Case 3.*—Mr. E. E., age 22, had consumption for about one year, tuberculosis affecting the right upper lobe. For over one month has had tubercular diarrhea. The use of the serum in this case reduced the cough and expectoration about one-half and gave great relief, which continued up to the day of his death, two weeks later.

It will be observed from the nature of the disease under consideration and the remedy itself that it is not proposed as a cure for consumption in the sense of a specific, but as a valuable remedy for some of the most terrible complications which occur in the course of the disease. I am thoroughly convinced that by the intelligent use of this serum together with other appropriate treatment the ulcerative complications as well as the disease itself may be robbed

of at least some of their terrors and disastrous results. With this serum as with serum therapy in general the earlier it is used the better the results attained.

126 State Street.

RESECTION OF TWO INCHES OF THE HUMERUS AND WIRING, WITH A REPORT OF A CASE OF WIRING OF THE CLAVICLE FOR UNUNITED FRACTURE.

BY STEWART L. McCURDY, A.M., M.D.

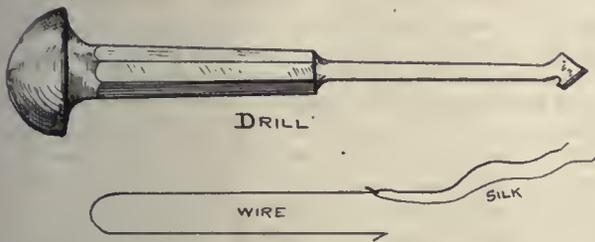

Orthopedic Surgeon to Presbyterlan Hospital, Member American Orthopedic, American Medical, and Allegheny County Medical Societies; Professor Anatomy and Oral Surgery, Pittsburg Dental College, etc. PITTSBURG, PA.

It is a matter of selection, after excision of joints or resection of bones, whether nails are selected to secure the bones, or whether wire is used.

Possibly I am stating the facts, when the statement is made that the majority of surgeons prefer spikes to wire. Especially is this true for excisions of the knee.

It is not the adaptation of bones after excisions for chronic tubercular disease, I desire to consider, but rather the use of wire for the treatment of compound and irreducible fractures.

FIG. 1.

That it is possible for me to secure a more perfect adaptation of bones by the use of wire goes without further discussion. That other operators can not get as perfect results with wire and use spikes instead, also goes with saying. Whether these men have tried wiring and discarded it for the nails, I am unable to say. To attempt to do a bone wiring without the proper instruments would be as difficult as to do a vaginal hysterectomy without an equipment.

To Dr. Wm. F. Fluhrer of New York, must be given the credit for perfecting instruments for bone wiring. In order that bone wiring might be speedily done it is necessary to use a notched drill. It is an easy matter to pass a drill through a bone, but it is not such an easy matter to keep the drill hole pervious or reënter again after the drill has once been withdrawn.

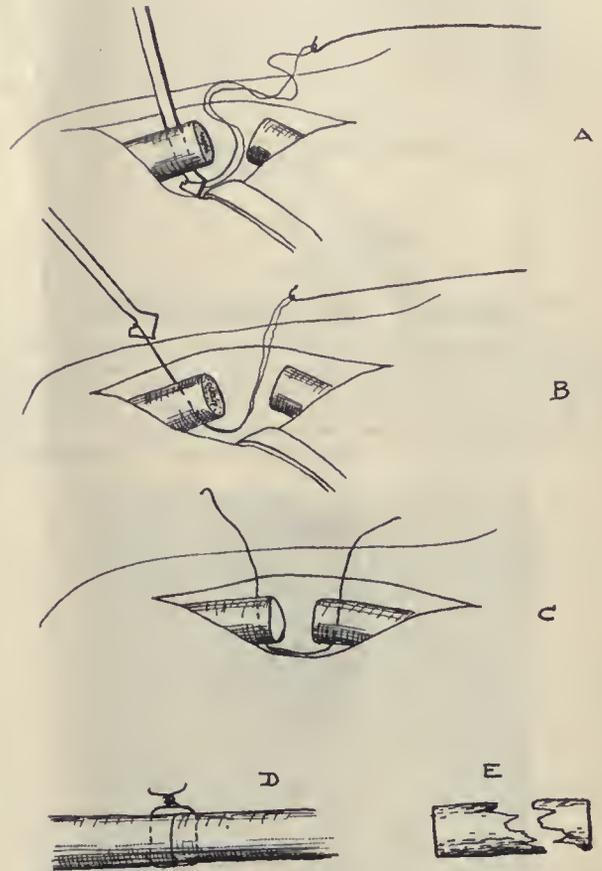

As will be observed the drill is notched near the point. After it passes through the bone a silk thread is thrown around the point and allowed to engage in the notch, after which it is withdrawn. The drill hole once loaded with silk, the wire is attached and drawn through either way as desired.

Case 1.—Mr. P. F., aged 35, was thrown from a carriage and received a dislocation of the left shoulder and fracture of the left clavicle. After reduction of the dislocation the shoulder recovered promptly. The displacements of the fragments in the fractured clavicle were so great that no effort was made by nature to repair the injury. About six months after the original injury he was again injured and the shoulder was dis-

located. The ununited fracture of the clavicle was more or less disturbed.

The fracture was painful at all times when the arm or shoulder was moved. The internal end of the external fragment appeared to be sharp and the patient, if he had had the

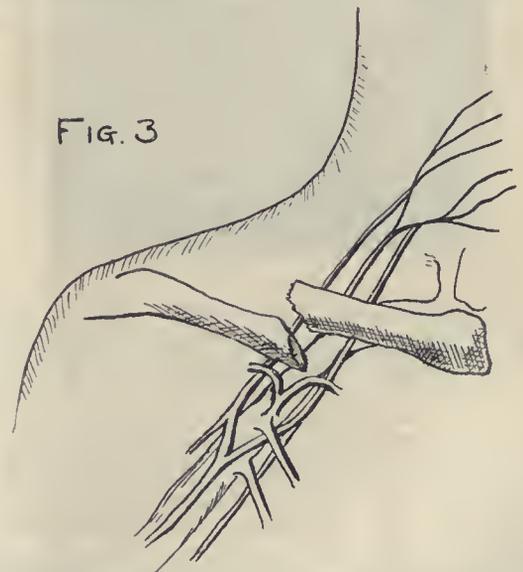

FIG. 2.

power in the arm, could not work on account of the pain caused by the motion.

A study of the anatomy of the parts (Fig. 3) shows that the free end of the under fragment was pushed down on the tissues overlying the subclavical artery and brachial plexus, when

FIG. 3.

even the arm was elevated. Operative interference was advised for two reasons: 1, that union of the bones might be

secured; 2, that the pain caused by the projecting end of the bone might be relieved.

Operation: Free longitudinal incision was made along the clavicle and the ends were dissected out. The ends were sawed off by the use of a chain saw. The bones were drilled and brought together with silver wire.

Result: Union was perfect, and the wound healed without suppuration. The arm is practically as good as before the injury. The wire was subsequently removed.

Case 2.—H. B., aged 30, brakeman, received an injury of his left thumb while making a coupling. The muscles of the palmar surface of the thumb were squeezed through the skin, and the bone was broken; the thumb was practically torn off. Preparation was made to amputate. While my assistant was

FIG 4.

anesthetizing the patient, it occurred to me that wiring might save the thumb, and the latter operation was done. In six weeks the wound had entirely healed and in three months the thumb was as well as before the accident, save some limitation in extension as a result of the extensive laceration of the muscles. This was my first wiring and was done in June, 1885.

FIGURE 5.

Case 3.—D. W. C., aged 37 years. The contents of a shotgun had passed through the arm internally to the thickest portion of the biceps and making its exit near the insertion of the deltoid. The humerus was entirely torn off; the patient favored amputation at my first visit, but we concluded to adjust fracture and wait for results.

The bones showed no signs of union, and the case was complicated by a severe hemorrhage three weeks after the injury, and at this time the patient insisted upon amputation. I assured him that amputation was not demanded, but instead I would advise excision and wiring, which operation was done, three weeks after the injury.

Two inches of bone were removed (Fig. 4), and the bone adjusted the wire. The ends of the bone were ragged and showed no evidence of repair.

The case from the date of wiring did not have an unfavorable symptom, and in six weeks was entirely healed.

The man is a farmer and has made a full hand at every kind of work ever since. The two inches of shortening did not interfere with this in the least. (See Fig. 5.)

Description of cuts: Fig. 1 shows notched drill, the wire and silk and the method of attaching them. Fig. 2 shows, diagrammatically, the method of loading the drill hole with the wire as the drill is withdrawn, as well as other steps in wiring. Fig. 2 E shows the bone removed in the clavicle case.

## SELECTIONS.

**The French National Population Alliance.**—The *London Times* states that an organization, with medical men at its head, has been formed in Paris to stay the French population's decline. The organizers are Dr. Jacques Bertillon, chief of the bureau of statistics of Paris, Dr. Charles Richet, professor of the faculty of medicine in the same city, and Dr. Javal, member of the Academy of Medicine. For years these men have noticed with regret that the population of France was not increasing proportionately with the population of other countries, and now they come forward with what they believe to be an infallible remedy for this evil. That some drastic remedy is needed they insist, as otherwise France must soon sink to the rank of a second rate, or even a third rate nation. A hundred years ago the great countries, in other words, the great powers of Europe contained 98,000,000 inhabitants, of whom 26,000,000, or 27 per cent., were residents of France. To-day these same countries contain 300,000,000 inhabitants, of whom 38,000,000, or only 12 per cent., live in France. These figures speak for themselves, and the obvious conclusion, according to Dr. Bertillon and his colleagues, is that if the births continue to decrease at the same ominous rate, France, which was once one of the most powerful countries in Europe, will soon be one of the weakest. These gentlemen have begun their novel campaign by founding a society which is styled "The National Alliance for the Relief of the French Population." The defensive measures which they propose to adopt are numerous, but for the immediate present they will confine their attention to three points: 1, they will try to get the laws relating to inheritances greatly modified; 2, they will try to get all direct taxes removed from those families which have more than three children, and 3, they will try to have the laws relating to succession duties thoroughly reformed. As it is manifest that the nation's treasury would be seriously affected by the removal of taxes in the case of all families which have more than three children, it is proposed to place a tax of 1.5 per cent. on all families which are childless, or have only one or two children. There is said to be excellent reasons for these proposed reforms. The larger a man's family is in France, we are told, the more he is taxed, both directly and indirectly, with the result that thrifty parents do not care to have many children. Moreover, the parents' property must be divided among the children, and if the children are numerous and the property small, the disastrous results can easily be foreseen. In other countries the law of entail is maintained pretty rigidly and though its operation seems hardly equitable or natural, as regards younger children, it certainly seems to act in some degree as a preventive of depopulation. "Remove all burdensome taxes from fruitful families," say the members of the National Alliance, "and let Frenchwomen and Frenchmen know that even from a monetary point of view, it will be fortunate for them to have many children. Then as the national treasury must be supported, let us tax those adults who have few or

no children. Persons who have no children, or only one or two children, may reasonably be required to contribute a goodly quota toward the support of the state, whereas it is improper and unjust to expect any support from those parents who have to provide for numerous children. Do this, and France will soon become, as she was in the past, one of the greatest powers in Europe; fail to do this, and France will soon sink to the level of Denmark, Belgium or Holland." The members of the alliance intend to hold several public meetings and to publish several pamphlets setting forth their views. They offer membership to all who care to assist them, irrespective of creed or political opinions. Many persons throughout France have already announced their adhesion to the program of the Alliance, and it is confidently expected that in the near future the necessary bills in regard to succession duties and the abolition of taxes will be presented to the French legislature.

**Cumol as a Sterilizing Agent.**—The *American Therapist*, July, contains an interesting abstract of the work done at the Johns Hopkins Hospital, by Drs. Clark and Miller, with the agent above named. In January, 1893, a very serious reign of infection occurred in the gynecologic wards of the Johns Hopkins Hospital, which was believed to be due to catgut prepared by boiling in alcohol under pressure. The most perfect means of sterilization of catgut for surgical purposes is, unquestionably, by heat. Until the method of Benckisser and Reverdin, 1888, it was considered impossible to raise any form of animal ligature material to a temperature sufficient to render it sterile without making it brittle. Reverdin demonstrated that it was not the oil, as previously supposed, but the hygroscopic water in catgut, which caused it to become brittle when heated. If this is driven off by dry heat at a temperature of 70 degrees C., it can be carried safely up to a temperature of 250 C., without impairing its integrity. The complicated apparatus, consisting of a hot-air oven and a thermo-regulator, however, prevented the general adoption of the methods of these writers. Brunner found that the boiling point of xylol was 136 to 140 degrees C., and at once adopted it as a sterilizing medium, but Kronig found spores occasionally present in catgut, which were more resistant than the anthrax spores, with which Brunner had experimented. "After a further research Kronig found that the boiling point of cumol, a hydrocarbon compound, ranged between 168 and 178 C., and substituted it for xylol. After a careful review of Kronig's article, his method was adopted in the gynecologic department of the Johns Hopkins Hospital. Kronig's method is as follows: 1. Roll the catgut in rings. 2. Dry it in a hot air oven or over a sand bath for two hours at 70 C. 3. Heat it in cumol to a temperature (165 C.) a little short of the boiling point, for one hour. 4. Transfer it to petroleum benzine for permanent preservation, or if desirable, leave it in benzine for three hours, and transfer the sterile Petri dishes. A bacteriologic study of this method by the writers shows that the sterilization by this method is perfect, but that the transference from boiling cumol to benzine is open to serious objection. Clark and Miller have found from this investigation that benzine is not a germicide, also that it can not be rendered sterile by heat without danger and, therefore, have found it necessary to modify the method of Kronig as follows: 1. The catgut, twelve strands, is rolled in a figure-of-eight form, so that it can be slipped into a large test-tube. 2. Bring the catgut up to a temperature of 80 C., and hold it at this point for one hour. 3. Place in cumol, which must not be above 100 C., raise it to 165 C., and hold it at this point for one hour. 4. Pour off the cumol, and either allow the heat of the sand bath to dry the catgut, or transfer it to a hot-air oven, at a temperature of 100 C., for two hours. 5. Transfer the rings with sterile forceps to the test tubes previously sterilized, as in a laboratory. In drying or boiling, the catgut should not come in contact with the bottom or sides

of the vessel, but should be suspended on slender wire supports or placed upon cotton loosely packed in the bottom of the beaker glass. Cumol, which is of a clear limpid or slightly yellowish appearance when procured from the chemist, is changed to a brownish color by boiling. The catgut is allowed to remain in the sand bath until the excess of cumol is driven off and it appears entirely free from any oily matter. A period of one to two hours is usually sufficient to dry it thoroughly. From the sand bath or hot-air oven it is transferred with sterile forceps to sterile test tubes, such as are used for culture media, in which it is preserved from contamination until ready for use. Small quantities should be placed in each tube, to obviate the necessity of opening them too frequently. In conclusion, it is well to bear in mind that while cumol is not explosive it is very inflammable, and great care should be observed in lifting the wire screen from the beaker glass to prevent drops of the cumol from falling in the flame or on the heated piece of metal on which the sand bath rests, as it will take fire, flare up and ignite the fluid in the beaker glass. Such an accident has occurred three times in our experience." There has been about one year of practical experience in the wards of Dr. Kelly and others, and this has left the distinct record of this agent as being the most satisfactory substance that has come under their observation for the purposes above described.

**The Relation of the Urine to Disease.**—Dr. M. D. Hoge, Jr., brings together in the August number of the *Virginia Medical Semi-Monthly* a collection of diagnostic points showing the effects of different diseases on the urine, with hints on treatment.

**Acute renal hyperemia.**—Blood; albumin (10 per cent. by bulk); small hyalin casts; quantity increased; sp. gr. reduced; reaction acid. Treatment: Produce a skin reaction—warm baths, pilocarpin, nitroglycerin, large quantity of pure water.

**Passive renal hyperemia.**—Quantity diminished; sp. gr. 1.025–1.030; color dark; reaction acid; urates increased; uric acid crystals; mucus increased; albumin present, but small in amount; small hyalin casts; a few blood corpuscles. Treatment. Increase the arterial tension, digitalis.

**Acute Bright's disease.**—Quantity diminished (at first); if quantity increases, either recovery or chronic nephritis follows; sp. gr. increased (1.025–1.030); color dark red (blood); reaction acid; urea diminished; albumin considerable; hematuria; renal epithelium; dark granular casts; hyalin casts; epithelial casts. Treatment: Non-nitrogenous food, milk, digitalis, lithia waters, small doses of calomel, diaphoretics, hot bottles.

**Chronic parenchymatous nephritis.**—Quantity diminished; sp. gr. normal or diminished; color lemon or dark brown; cloudy by transmitted light; albumin in large quantity; urea diminished; chlorids diminished; fatty degenerated kidney epithelium; dark granular casts; hyalin casts; fatty casts. Treatment: digitalis, large quantities of water, small repeated doses of calomel, warm baths, jaborandi, nitroglycerin, non-nitrogenous food, milk, iron, strychnin.

**Chronic interstitial nephritis.**—quantity increased or normal; color pale and transparent; reaction acid; sp. gr. below normal; albumin, very small quantity; very few hyalin casts; granular casts; crystals of uric acid and calcium oxalate; urea diminished; phosphates diminished. Treatment: Symptomatic, bichlorid of mercury in minute doses.

**Amyloid kidney.**—Quantity increased; color pale; sp. gr. low (1.012); reaction acid; albumin considerable; hyalin casts; waxy casts. Treatment: That of causative disease.

**Tuberculosis of the kidney.**—Quantity increased; pale milky color; sp. gr. lowered; reaction alkaline; pus suspended; hematuria; bacillus tuberculosis. Treatment: Symptomatic; improving the general condition.

**Cancer of the kidney.**—Hematuria; albumin in small quan-

tity; quantity increased; pus; acetone; kidney débris. Treatment: Palliative; extirpation.

Renal gravel.—hematuria; quantity normal; color dark red; reaction acid; pus; urates and oxalates; small concretions; epithelium. Treatment: Restrict meat diet, no alcoholic or acid drinks, bodily exercise, vegetable diet, milk, large quantities of water, phosphate of soda, carbonate of lithium, anodynes.

Uremia.—Urea diminished (200 to 50 grains); uric acid diminished; quantity diminished; sp. gr. diminished; albumin; casts. Treatment: Diuretics, hydragogue cathartics, diaphoretics.

Diabetes insipidus.—Quantity enormously increased (ten to fifty pints); sp. gr. diminished; no sugar, no albumin; color pale and clear; reaction faintly acid; urea increased; phosphates increased; indican. Treatment: Tonics; valerian.

Diabetes mellitus.—Color light yellowish; sp. gr. much increased (1.030 to 1.045); reaction acid; quantity much increased; sugar 1 per cent. to 8 per cent. (half a pound per day); urea increased; acetone and diacetone; albumin (occasionally). Treatment: Strict diet, opium, Fowler's solution, cod liver oil, Silurian spring of Waukesha water.

Pyelo-nephritis ("surgical kidney").—Color, dirty yellow, pale and cloudy; foul odor; sp. gr. diminished (1.008—1.016); quantity diminished; reaction acid; rapidly undergoes ammoniacal fermentation; urea diminished; albumin present; pus, blood, epithelium; casts of bacteria. Treatment: Astringents, tannin, alum, lead, antiseptics, salol, chlorate of potash, milk in large quantities.

Pyelitis-calculosa.—Quantity increased; color pale straw; sp. gr. diminished; reaction acid; pus; albumin; spindle-shaped epithelium; odor very offensive. Treatment: As above for surgical kidney.

Cystitis.—Pus; blood; albumin; color light; reaction alkaline (chronic); sp. gr. diminished; triple-phosphate; bacteria; bladder epithelium. Treatment: Bodily rest; light diet, large quantities of fluids, chlorate of potash, salol, gelsemium, turpentine, warm applications, washing out of the bladder, opium, suppositories.

Febrile diseases.—Quantity diminished; color dark; sp. gr. increased; urate deposits; hyalin casts; albumin; acetone and diacetic acid; urea increased; hemoglobin; grape sugar; phosphates diminished.

Anemia.—Quantity diminished; color pale; sp. gr. diminished; reaction neutral or alkaline; albumin (occasionally); hyalin casts; urea increased, kreatinin.

Leukemia.—Reaction acid; uric acid increased; albumin; phosphates increased.

Chlorosis.—Reaction alkaline; kreatinin.

Scurvy.—Reaction acid; pepton (constant).

Gout.—Uric acid diminished; phosphates diminished; albumin; hyalin casts; oxalate of lime crystals.

Cirrhosis of the liver.—Quantity diminished; urates (large quantity); urobilin.

## PRACTICAL NOTES.

**Use of Argon in Gonorrhœa.**—Dr. George K. Swinburne recommends the use of a 10 per cent. solution in the acute stages. The inflammation is quickly allayed and the discharge rapidly diminished.—*Jour. Cul. and Genito-urinary Dis.*, August.

**Indications for Use of Papain.**—Papain has been found beneficial in gastric troubles caused by a lack of sufficient HCl (dose from  $\frac{1}{2}$  to 1 gram three times a day), but it is absolutely injurious where there is excess of HCl or an ulcerous lesion.—*Semaine Méd.*, August 5.

**Lactophœnia.**—Dr. H. D. Peterson says clinical tests have shown it to be of special value in relieving pain and reducing

temperature gradually and maintaining it at a lowered degree, without frequent repetition. It is readily taken by patients who can not take antipyrin. It is not disagreeable to the taste and is easily administered.—*Med. Recorder*, August.

**Results of Treatment of Whooping Cough with Ichthyol.**—In eight cases treated it materially diminished the frequency and the severity of the attacks and shortened the course of the disease. No inconveniences follow its use and the general health improves. Dose, according to age, from 0.05 to 0.20 centigram a day, increasing to 0.60 and 1 gram.—*Semaine Méd.*, August 5.

**Section of the Sympathetic in Exophthalmic Goitre.**—Jaboulay of Lyons recently cured the exophthalmus, palpitations and trembling in a case of exophthalmic goitre in a young girl by cutting the cervical portion of the sympathetic on each side, above the middle ganglion on the right and below it on the left. A slight, transient local congestion was the only inconvenience.—*Semaine Méd.*, August 5.

**Experimental Extirpation of the Stomach and Intestines.**—Monari has been experimenting on dogs since 1892 to determine the effects produced by removing the stomach and intestines. He announces that the metabolism of the organism is not essentially affected, permanently, by total extirpation of the stomach. He also states that as much as seven-eighths of the small intestine can be extirpated without injury. The colon partially assumes the functions of the absent intestine. If more than nine-tenths are removed the animal succumbs to inanition. Monari concludes that man can have at least half of the small intestine safely removed.—*Cbl. f. Chir.*, August 1, from *Beitrag zur klin. Chir.*, No. 2.

**Formalin Gelatin as an Antiseptic.**—This is a hard, transparent substance, affected neither by heat, acids nor alkalies, but decomposed, when pulverized, by the action of the living cells of the organism in such a way that the antiseptic properties are being constantly liberated. Schleich of Berlin asserts that it will arrest in twenty-four hours any acute suppurating process and insure absolute asepsis to the course of every wound. It is passive on necrosed tissues unless moistened with the following solution: Pepsini, 5.0; acid. hydrochlor., 0.3, and aqu. dest., 100.0, when the disinfecting process goes on as usual. It is made by adding 25 drops of Schering's pure formalin solution to 500 g. of dissolved and cleansed gelatin. When dry the hard sheets are pulverized ready for use.—*Wien. klin. Rundsch.*, August 2, from *Therap. Monats.*, No. 2.

**Treatment of Cholelithiasis with Potassium Iodid.**—Dunin announces that we have in potassium iodid a most powerful remedy for this obstinate disease. He has employed it in over 100 cases with results which he calls "not merely satisfactory, but amazing." It is especially efficacious in those cases where the attacks are not so severe, but are almost continuous, which is usually the most difficult form to conquer. In one week the patient is relieved from pain and the region is less sensitive to pressure, while appetite, sleep and peace return. Dunin administers 0.3 to 0.6 potassium iodid twice a day for four to five weeks, and then a systematic course of mineral waters (Carlsbad) completes the cure.—*Therap. Woch.*, July 19.

**Treatment of Enteroptosis with "Yeast" of Beer.**—This morbid condition is extremely difficult to cure and often resists every treatment, even external appliances. Dr. Günzburg has obtained excellent results by the administration of a piece of dried beer yeast, the size of a pea or bean, three times a day. It produces an intestinal tympanism not disagreeable to the patient, which lifts and holds up the viscera, counteracting the tendency to displacement. The gases are due to the formation of carbonic acid, and do not resemble the gases of putrefaction in their effect on the intestinal absorption. The usual constipation is relieved and the appetite improves, while the patient soon begins to gain in weight. As this trouble is more

apt to occur in thin persons, this latter point is of much importance in securing a permanent cure. The only contraindication is actual gastrectasia.—*Semaine Méd.*, July 15.

**Efficacy of Stypticin in Arresting Uterine Hemorrhages.**—Stypticin possesses no oxytocic properties, but it has been found very valuable in arresting uterine hemorrhages, climacteric, uncomplicated and after retroflexio uteri. No inconveniences followed its use. It resembles hydrastinin in its chemie composition.—*Wien. Klin. Rundsch.*, August 2, from *Therap. Monatsh.*, No. 2.

**Treatment of Hand Injuries.**—Dr. William P. Nicolson says the beauty of an operation should be sacrificed to the more practical work of conservatism. Cut away with scissors such tissue as may be hopelessly destroyed, leaving whatever shreds of skin remain to cover stumps, even though skin may slough afterward. If a finger has been crushed completely off, remove projecting point of bone with forceps, covering the end, if possible, by means of any remaining shreds of skin. After securing fragments of fractured bone as nearly in position as possible and inserting sutures absolutely necessary, he treats practically all hand injuries by saturation, under rubber tissue, with listerin, camphorated phenol or similar antiseptics.—*Atlanta Med. and Surg. Jour.*, August.

**Further Success with Serum Treatment of Syphilis.**—Boeck of Christiania reports seven cases of recent syphilis cured by hypodermic dorsal injections of serum from a tertiary hydrocele. The effects were most favorable; the primary manifestations rapidly passed away, and the secondary period was shortened and attenuated much more than is the case with mercury or iodine although the latter are more effective in the primary stage. The amount injected at one time averaged two to three grams a day or every other day, with a total of 32 to 92 grams in each case, although one received a total of 300 grams. There was no other medication. Experiments five years ago with serum from a patient in the secondary stage failed entirely.—*Semaine Méd.*, July 15.

**Cysticotomy, the New Operation.**—In the *Progrès Méd.* for July 25, Baudouin describes what he calls "the new operation with a future." cysticotomy, which is for the cystic duct what choledochotomy is for the common bile duct, and requires the same technique. Only one of the ten observations reported resulted fatally, and that was accompanied by cholecystectomy. The indication is a large calculus engaged in the cystic duct, which it is impossible to dislodge by manipulation, or to crush without injury to the walls of the duct. The retention is sometimes due to a stricture. The abdomen opened, adhesions released, the duct well in view, the calculus under the finger, the cystic duct is slit lengthwise above the calculus, and the opening made large enough to extract it without tearing the edges, as the walls are generally inflamed and easily lacerated. The only question is whether to drain or not, in a simple cysticotomy, when the adhesions have not been numerous; of course a complicated operation requires draining and even tamponing. The operation is usually simpler than choledochotomy on account of the more accessible position of the duct. The operation is new to France, the observations being gathered from English, German and Belgian sources.

**How to Sterilize Instruments without Danger of Rust.**—Iron, steel and nickel only rust when exposed to the combined action of carbonic acid, moisture and oxygen. If any one of this triad is absent or neutralized the metal remains unaffected. Certain alkalis neutralize the carbonic acid in water, and when this is neutralized no rust forms on metals when immersed in it. After careful experiments, Lévai has found that the best alkali for the purpose is natrium hydroxydatum causticum (NaOH). He adds a small quantity of the crystals to boiling water, and after they are entirely dissolved and mixed, he immerses the instruments and boils them *ad libitum*, with never a trace of

rust nor tarnish when they are taken out. One-fourth of 1 per cent. or even less of the natrium is sufficient, but it must be pure, with no sulphur, as this causes rust. If knives and scissors are wrapped in gauze to protect the edges, they can be effectively sterilized in this way without the slightest injury of any kind. It is equally effective and non-injurious for drainage tubes, etc., but it is not adapted for aluminum nor silk and it softens brushes. If the instruments are left afterward wet and exposed to the air rust will form, but they can be kept several hours, if necessary, in sterilized water to which 1.5 to 2 per cent. of the natrium has been added.—*Wien. klin. Rundschau*, August 2.

**Malignant Orbital Tumors.**—Dr. C. S. Bull's conclusions in regard to their course and prognosis, as influenced by surgical operations for removal, are as follows: 1. The prognosis of all forms of malignant orbital tumors, whether primary or secondary, is unfavorable; and if the tumor be primarily in one or more of the deep facial bones or their sinuses, the prognosis is positively serious. 2. Except in the case of encapsulated tumors of the orbit, surgical interference is almost invariably followed by a return of the tumor, and the growth of the secondary tumor is more rapid than that of the primary lesion. With each succeeding operation the period of quiescence in the return of the tumor grows shorter, and the rapidity of the growth increases. 3. The patient's family, and in certain cases the patient himself, should be told of the serious nature of the trouble and be warned that complete removal of all the disease germs is an almost hopeless task. The burden of the decision as to surgical interference must rest upon the shoulders of the patient. 4. Repeated operations in these cases undoubtedly shorten the life of the patient. While it is our duty to operate in order to relieve severe or unbearable pain, we should be slow to operate merely for the sake of relieving temporarily physical deformity, especially if we are convinced that by so doing we shorten the life of the patient, even if that shortened life is rendered more bearable.—*Am. Jour. of Ophthalmology*, August.

**Two Tumors on the Head of an Infant.**—The *Clinical Journal*, June 3, has remarks on the above subject, made before the North West London Clinical Society by Mr. Jackson Clarke. He showed an infant with two tumors on the left side of its head. The child was brought to him in the out-patient department, and its functions appeared quite normal. The tumors were situated over the upper part of the squamous suture. One measured 1 by  $\frac{3}{4}$  inch, the other  $\frac{3}{4}$  by  $\frac{1}{2}$  inch. Three possibilities arose in cases of congenital tumors of the scalp, viz., meningocele, encephalocele and dermoid tumor. Dermoids were generally single and subcutaneous, although often connected with the dura mater. It was necessary to remember that the brain was merely an epidermic structure, and that some dermoids were quite shut in by the skull and dura mater, lying occasionally in the substance of the brain. Meningocele ought to be more or less completely reducible within the cranial cavity; but in the child before them that was not the case. Moreover, meningocele, being fluid, should fluctuate, and should become tender when the child cried. This child's tumors were firm, and the skull appeared deficient at their bases, while a piece of cartilage or bone covered the convexity of the tumor. The only fluctuating spot was at the back part of the larger and anterior tumor. The tumors did not pulsate, therefore he had concluded that something had formed under the skull and elevated up what could be called normal Wormian bones, and there was a gap in the skull where that bone would have fitted in had it not been so elevated. Probably the source of the displacement was the growth of a meningocele, but the two other kinds of tumor he had mentioned could not be excluded, because the Wormian bone would mask any pulsation. The tumors were not due to the use of

instruments at birth, the labor having been a natural one. Cephalo-hematoma in a newborn baby was generally subperiosteal, and followed the shape of one of the bones, stopping at the sutures. In the child exhibited, not only was a margin felt in the skull, which might be simulated by hematoma, but there was a definite cap of bone to the swelling. Mr. Clarke said that the treatment was, in the main, on the expectant plan. He would watch the progress of the case, instructing the mother to prevent the child receiving knocks or bumps on the head. If his view was correct, he hoped the Wormian bone would spread out as the child grew, and the gap thus become sealed up by the bone.

**Injections of Salts of Iron in the Treatment of Anemia.**—Riva Rocci of Turin, has a careful study of this subject in the *Polieinico* for May. His conclusions are that injections of the salts of iron produce improved conditions in anemia, but they do not cure it. They affect the consequences of a pathologic process, but not the process itself, and the anemia returns if they are discontinued. They stimulate the reformation of the active principles of the blood, and also excite a hyperemia more or less transient, in various organs, which is the greatest danger from their use. The dose varies according to the case and the preparation used. The possible inconveniences that may result are, in the order of their frequency: nausea, vomiting, cephalgia, fever, diarrhea, albuminuria, cylindruria, hemoptyses, lypothymia and syncope. They are indicated whenever there are anemic conditions, when the anemia itself is of long standing, and other means have been tried and exhausted, when the condition of the alimentary system forbids the probability of successful internal medication, and also when it is urgent to have the anemic condition terminated as soon as possible. The injections are contraindicated when they produce gastro-intestinal disturbances, or symptoms of nephritis, or excessive fever, or when there is danger of hemoptysis.—*Revue Int. de M. et de Chir.*, July 25.

**First Trials of Frigor Therapeutics.**—The results of these new experiments with the excessively low temperatures secured by Professor Pictet of Geneva are paradoxical and inexplicable. The patient is lowered into a well in which the temperature is 105 to 110 degrees below zero, centigrade. It is not quite two meters in depth, and is about 65 c. in diameter. He retains his clothing and remains in the frigour bath ten minutes, his head uncovered and a warm covering about his shoulders to prevent the escape of the cold air and to protect his lungs. The sensation of this extreme cold is merely a refreshing stimulation, similar to that of a tepid bath, with an afterglow that lasts several hours. Instead of an increased dis-assimilation the quantity of urea was diminished 24 grs., 15 to the liter. The amount of uric acid fell from 0.52 to 0.33; of phosphoric acid from 4.9 to 2.1, the phosphates from 9.1 to 3.9; while the temperature in the mouth rose from 36.5 (normal) to 37.4 degrees. The pulse increased (one observation) from 87 to 102 in three minutes. In every case the temperature rose more or less, and the refreshing sensations with warmth and invigoration were experienced. Five baths cured Cordés of his gastralgia, improved his appetite, stimulated the functions of the skin and improved a tobacco bronchial cough. In one experiment the bath was not as cold as usual, and rose to -40 degrees during the ten minutes. The sensations were entirely different from those of the other baths and the cold seemed intense, possibly owing to the fact that there was more humidity, and the skin therefore more susceptible. Further reports are awaited with interest—*Jour. de Méd. de Paris*, July 26.

**Reported Rapid Recovery from Phthisis Under the Maragliano Serum.**—The London *Lancet*, July 4, reports through the medium of its correspondence from Rome that one of the early cases of the above kind and treatment has been progressing most favorably. The report in part is as follows: An authentic, well-

certified case of treatment of tuberculosis by the Maragliano-method comes from Spezia. A native of that seaport, A. B., aged 21 years, an able seaman by occupation, had since 1893 been suffering from phthisical symptoms, and on examination was found to have both pulmonary apices infiltrated with tubercle. The disease was not largely diffused, but it made steady progress, and by the beginning of 1894 the area of destroyed tissue was considerably increased. Both lungs were very seriously affected and A. B. was placed under Maragliano's treatment in the clinical wards of the Genoa Hospital. The injection of the serum was practiced continuously for two months till the close of Maragliano's summer course, by which time the patient had so far improved as to return to his native place. Convinced of the benefit he had received he returned to the ward as a patient in November of the same year and was once more subjected, under Maragliano's care, to the serum treatment. The case, though the progress of the malady had been arrested, was still a very serious one, and it was not till the close of July, 1895—eight months from the resumption of treatment—that substantial cure was effected. Several hundred injections had been practiced, and in the latter weeks of the treatment it was evident that A. B. was conquering the malady "hand over hand." He left the hospital at the end of July, as has been said, absolutely cured and since then has for six months been regularly on duty in the service of the royal navy. At present he is at Spezia, the object of no little professional interest, and described by the physician who last saw him as "sano come pesce." Maragliano has some severe critics among his compatriots, chiefly of the Neapolitan school. But is fair to add it that even in that quarter testimony in favor of his treatment is gaining in volume and authority.

**Bacterial Diarrhea of Children.**—Dr. L. E. Rardon of Cincinnati, in the *Lancet Clinic* thus refers to the summer diarrhea of infants: Astringents formerly extensively used have very properly been relegated to the waste dump as useless. 1. Summer diarrhea is caused largely by improper and unclean feeding, and is usually preventable. 2. Bacteria play a very important part in its development. 3. Hot weather has to do only in an indirect manner, as it promotes the growth and development of bacteria in the food supply. 4. Treatment consists, first, in eliminating all decomposing food from the bowels by cathartics, lavage and colonic irrigation. 5. Drugs judiciously administered are of great value, but are secondary in importance to prevention and management.

**Gastro-intestinal Catarrh.**—In the treatment of cases of acute gastro-intestinal catarrh, due to indiscretions in diet, and attended especially with nausea, vomiting, diarrhea and abdominal pain, good results are secured in the clinical service of Dr. Eshner from the employment of the following formula:

R Extract of hematoxylon . . . . . 8.0  
Aromatic sulfuric acid . . . . . 8.0  
Camphorated tincture of opium . . . . . 96.0

Dose: A tablespoonful every three hours if the bowels are moved that often; at longer intervals if the bowels are moved less often.—*Phila. Polyclinic*, August.

**Intestinal Fermentation with Constipation.**—

R Ext. aloes. . . . . gr. vi  
Pulv. rhei . . . . . gr. vi  
Benzosol . . . . . gr. ix  
Ext. hyoscyami. . . . . gr. vi

Misce ad ft. Caps. No. xii. Sig. One after meals.—Thos. Hunt Stuckey, M.D., in *Am. Therapist*, August.

**Beri-Beri.**—

R Aquæ. . . . . 150.0  
Tinct. scillæ. . . . . 8.0  
Tinct. digitalis. . . . . 2.0  
Syr. quiniæ. . . . . 30.0  
Ammoniaci (liquid). . . . . gtt. xii

Misce. Sig.—Two tablespoonfuls in water every three hours.—J. Dias Ribeiro, M.D., in *Dunlison's Coll. and Clin. Rec.*, August.

THE  
Journal of the American Medical Association  
PUBLISHED WEEKLY.

SUBSCRIPTION PRICE, INCLUDING POSTAGE:

Per Annum, in Advance . . . . . \$5.00  
Single Copies . . . . . 10 Cents.

Subscriptions may begin at any time and be sent to

THE JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION,  
No. 61 Market Street (Occidental Buildings), Chicago, Illinois.

MEMBERSHIP IN THE AMERICAN MEDICAL ASSOCIATION.

This is obtainable, at any time, by a member of any State or local Medical Society which is entitled to send delegates to the Association. All that is necessary is for the applicant to write to the Treasurer of the Association, Dr. Henry P. Newman, Venetian Building, Chicago, Ill., sending him a certificate or statement that the applicant is in good standing in his own Society, signed by the President and Secretary of said Society. Attendance as a delegate at an annual meeting of the Association is not necessary to obtain membership.

On receipt of the subscription the weekly JOURNAL of the Association will be forwarded regularly.

Gentlemen already members of the Association should send their annual subscription to the Treasurer, or direct to the JOURNAL office.

All communications and manuscript of whatever character, intended for publication in the JOURNAL, should be addressed to the Editor, and all communications relative to the business of the JOURNAL, proof sheets returned, or in regard to subscriptions, should be addressed to THE JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION, 61 Market Street (Occidental Buildings), Chicago.

Original communications are only received with the understanding that they are exclusively contributed to this JOURNAL.

INFORMATION WANTED.

It would greatly facilitate the prompt delivery of the JOURNAL to those members of the Association living in large cities, if they would kindly furnish this office with their street address in those cases where it is omitted from the wrapper of their JOURNAL, as we have been notified by the postmasters of the larger cities that second-class mail matter not having street address, would be placed in the general delivery to await call.

SATURDAY, SEPTEMBER 5, 1896.

THE U. S. MEDICAL PROFESSION AND THE MONTREAL MEETING OF THE BRITISH MEDICAL ASSOCIATION IN 1897.

The British Medical Association will meet in 1897 in Montreal. At once upon learning the fact, there will arise in the mind of every member of the medical profession of the United States the thought: What can we do to make the visit to America of our English confrères more enjoyable and useful, and to aid in deepening the professional unity, respect and affection which these two parts of our guild entertain for each other? Two things are prerequisite: The first is the establishment of a committee to take in charge the entertainment of our British and Canadian friends, and the second is the securing of funds to defray the necessary expenses.

To this end we suggest that the proper officers of the AMERICAN MEDICAL ASSOCIATION at once appoint three members from the ASSOCIATION to act with three members to be appointed by the Executive Committee of the Congress of American Physicians, the six to organize themselves as they may deem best and to have entire charge of the collection of funds and the plans and execution of the same for the entertainment, etc. As to the subscription we have no doubt sufficient contributions can be obtained from the various medical organizations of the country or even from private persons (the writer will give \$25). We should be moved by every honorable motive to make the American tour of our visitors one of the most enjoyable and profitable for all concerned. But there should be no delay in getting to work.

THE USE OF PUBLIC MEDICAL SOCIETIES TO PAY PRIVATE GRUDGES.

Many years ago we knew of the following case: A physician of the best standing applied for membership to the principal medical society of the town. He was vouched for and recommended by the best members; there was absolutely nothing said or to be said against him as a reputable physician; no objection was made to him; he had in many ways shown himself strictly ethical in professional and private life, and his scientific ability was certainly equal to that of the average of the members. And yet he was "blackballed." Three members came—were careful to come!—sat silent when objections should have been raised, sat silent when the balloting went on, and voted against the admission of the candidate proposed. By the antiquated rules of the society three members were sufficient to exclude, although a hundred should vote in favor of admission. By one of the old-time fictions of the society, it should be said, the candidate did not ask for membership, was not allowed to apply—that would be beneath the dignity of the body—but instead of this simple, frank method, he asked his friends to sign his application, or if fully wise, asked some friend to get the signatures of others, and then asked the friend to present it. The applicant was supposed to be in profound ignorance of the desire of his friends to make him one of their corporate number. It thus came about that the three blackballers "turned down," not the applicant, but his fellow members who wished the applicant admitted. By another figment of the corporate machinery the ballot was supposed to be thoroughly secret, but in reality it was not so, and the three dissenting balloters were at once known not only to all the society's members, but to the applicant, supposedly in complete ignorance even of the fact that he had been proposed; and not only to them and him, but of course to all professional brethren, and finally to the lay public. This old individual case we are using only as a text and type of more general principles, but in passing it may be added that the motives of the blackballers soon became evident. They were recognized as unsuccessful rivals of the candidate in a private occupation, and were simply jealous of the candidate's success in the private work, and they determined to injure him by their secret ballot. These poor dupes of their own envy had used a public medical society to settle private scores. They cared nothing for the injustice to the individual or of the wrong to the society.

But what of the rules of the society that permitted such proceedings, and what of the plan of using an organization presumably founded and existing for strictly professional and scientific purposes? If the example we have used to typify a method were single or rare, or existed only in prehistoric ages, there would be nothing to say, but to any one familiar with medi-

cal politics and organizations it is a well-known fact that similar practices are by no means unknown in our modern world. It is possible that the antiquated rules governing present-day medical organizations have not been abrogated, and that self-seeking members, in many ways, use them and the societies they control for their hidden schemes.

If the fanciful figments and supposed ignorances, and presumed confidences or secrets of the council chambers and boards of censors were not the shams they are, it would be a very different matter. But who does not know that they are most ludicrous farces? The candidate hears, sees, feels forever the fact that he has been considered unworthy of membership, and his professional and public reputation is injured. If he is of a sensitive nature, the fact can not help harming his own character, rendering him morbid, perhaps, and in various ways preventing the best purposes and realizations of his life. If he "braves it out," he becomes unduly callous, and perhaps this injury is greater than the other. Possibly he may be strong enough to recognize the true status, and large-minded enough to prevent his indulging in anything but pity and a good-humored contempt of the foolish performance. This is the proper course, but it may be doubted if it often results so. He may even find not a little pleasure in the boomerang his unwise enemies prepare for themselves, and laugh at the fact that one prominent member advises him, after the custom of the French Academy, to call on the members of the committee or board of censors having his application under advisement, while another member vows if there is any such "solicitation and advertisement" he will surely blackball him. He may even enjoy the feeling that he is barefoot and attempting to walk a floor strewn with needles and tacks. But we question his enjoyment!

But if he has any innate sense of dignity and worth, he will have a disgusted contempt for the imaginary figments and open secrets of the guarded portals. Every member knows that he applies, and if he gets in at all, he does it by "politics" that all ignore and are supposed to despise. No single word of recognition or official reply comes from his application, and the irony of the situation is heightened by the fact that the society hugs its pompous "dignity" in silent satisfaction while proceeding to the utmost length of impoliteness and discourtesy. A society or a man has no genuine dignity without just as genuine courtesy and kindness, and when these latter qualities are wanting, a man of innate dignity may wisely reason that the assumed dignity of the society is—*assumed*. Discourtesy is undignified, and corporate discourtesy is none the less so because, as SIDNEY SMITH said, the corporation has neither body nor soul for proper treatment. It is just as incumbent upon an organization to be dignified to an applicant (or supposed appli-

cant) as it is for the applicant to respect the corporation. It would be infinitely more manly to have the application made openly and frankly, and if it is refused to say so officially. A *no*, ever so blunt and brutal, is in every way superior to the savagery of no reply whatever to an inquiry.

And societies are none the less absolved from the duty of justice! Every member knows the blackballing becomes at once common talk despite the hundred fictions of assumed ignorances and secrecies. The machinery of these circumlocutions and mysteries and "supposed" is arrant nonsense, and deceives nobody. It would not be an absurd thing if some day some indignant candidate should enter suit for damages against the organization that had refused him membership without a single objection raised or exposed, and thereby injuring his professional and social reputation. To be sure, no large-minded man would care enough for the affair to do so, but all men are not so strong in the estimation of the public or of themselves to thus contain themselves.

It would appear that some of the rules of some medical societies need thorough overhauling; that manly, truly dignified frankness displace sham and pomposity and a silly secrecy; that societies be as jealous of their justice and kindness, as of their "dignity;" that they think what effect their action and manner of action may have upon the candidate by refusal of membership, as well as of their own rights and privileges; that they devise methods of preventing the use of the organization by greedy, cranky or stupid members for paying private debts and grudges; or, of punishing such when obviously guilty. The welfare of the profession stands above that of societies, and the welfare of the society must be placed above that of the piques and bickerings of its members.

We by no means argue against care in the admission of new members to a society. We advise greater care. Objections to a proposed man should be brought out and discussed, not hidden; blackballers and cranks who fraudulently use the society in secret ways to settle personal or clique enmities should themselves be blackballed before they get in; if the figment of the society that it *chooses* and elects its new members is to be any longer worshiped as a fetich, the society should see to it that there is no wily and sneaky "politics" upon the part of members or applicants in getting in. (In the illustrative example we have used, the candidate could have easily "blocked" or neutralized the scheme of his blackballing friends if he would have stooped to something like their methods.) In these days of specialism, it may also be noted, the profession in a city is divided up into cliques and parties, and the hatreds and deep grudges and jealousies of rivals often become so intense as to override all sense of decency or justice, and men thus actuated

should not have it in their power to exclude and injure one they hate or fear. The envies and hatreds of rival medical schools, or the infinitely worse ones of rival professors in the same school, accentuate these inter-necine quarrels, and often reduce the general medical society of the place to a simple stamping and fighting ground where men may come to battle out their wraths, but with which the society should have nothing to do. There is room for much amusement and irony when a blackballed applicant is told by *these men* that he is unworthy their professional company!

#### THE BACILLUS OF PARESIS.

That parotic dementia, or, as it is more commonly designated, paresis, has in the vast majority of cases syphilis as its antecedent, is coming to be a generally accepted fact. The exact relation of the two disorders to each other are, however, still in question, and the syphilitic or parasyphilitic nature of paresis is maintained by some and as strongly disputed by others. If the infection of syphilis were as definitely known as is that of some other diseases, tuberculosis for example, the question would be more simple; we could search for the specific microbe, and if found the identity would be established. Other like questions have been settled in this way; the failure to find HANSEN'S bacillus in syringomyelia has been considered as conclusive against ZAMBACO'S theory of its identity with leprosy, and still other instances could probably be cited. With the present uncertainty as to what is the real nature of the syphilitic infection, there is no possibility of a definite conclusion as to the identity of it and that of paresis on purely bacteriologic grounds, but a very recent Italian contribution is very significant and suggestive. In the latest issue of the *Annali di Neurologia*, Dr. PICCININO, one of Professor BIANCHI'S assistants, reports the results of a bacteriologic study of paresis in the laboratory of the Istituto Psichiatrico of the University of Naples. He examined the cortex in five cases, some of them with clearly syphilitic histories, others with it suspected or denied, using all antiseptic precautions and taking the specimens through openings made in the skull by trephining before the removal of the calvarium, as an additional security. Culture experiments and the usual staining methods gave only indeterminate or negative results; nothing very characteristic or noteworthy was discovered. The use, on the other hand, of a staining method only slightly modified from that of LUSTGARTEN for his syphilis bacillus, revealed a great abundance in all the tissues, and especially in the pericellular spaces, of a form apparently not very different from that described by the above author. The same method was tested as a control experiment in other brains than those of paretics, but with a uniformly negative result, and it was only by this staining reaction that these bacilli could be detected in the paretic cortex.

This paper has a special importance, in view of the question of the parasyphilitic nature of paretic dementia, and reflexly, as it were, also on that of the value of LUSTGARTEN'S discovery. It is a little remarkable that the research had not been made before. Had there been more faith in LUSTGARTEN'S bacillus as the cause of syphilis, or had the notion that paresis is only a late manifestation of that disease been earlier accepted by physicians, the very obvious suggestion of this special investigation would undoubtedly have been sooner taken up. It will be in order now to repeat PICCININO'S observations and to prove their value by widespread and careful investigations by our asylum pathologists.

#### STRENGTHEN THE ASSOCIATION.

The great increase in the membership last year should be only a beginning. We appeal to each member to use his influence to secure a new member by application. Let the good work go on until every regular physician in the United States is enrolled in the membership. Of this issue we print 9,000 copies and it is contemplated to continue to print not less than that number each week. The extra numbers will be sent to physicians who are eligible to membership in our ASSOCIATION in the hope that they may join us. Secretaries of local medical societies in affiliation with the AMERICAN MEDICAL ASSOCIATION, are requested to use their influence to increase the numbers of the great representative organization. Blank applications for membership will be furnished in any desired quantity on application.

The great improvement in our JOURNAL is solely due to the increasing interest taken by the members in making it better and to the large additions that have been made to the membership.

The object lesson furnished by the success of our JOURNAL, should be a sufficient demonstration of what it means to increase the number of members of the ASSOCIATION and the readers of the JOURNAL. Let us unite to make it the greatest medical weekly on the habitable globe. We have reason to be proud of the advance made in the past, but let that be as nothing to the improvement in the future. It could be made the greatest medical weekly in America in one week, if every present member would secure one additional one; and if that process were repeated the next week, the JOURNAL would in two weeks have the greatest subscription list of any medical weekly in the world. Will you, dear colleague, favor the ASSOCIATION in this way? Cut out an application blank from the advertising page of your JOURNAL and get your medical friend to sign it and send it on with the fee to Treasurer Newman and the object will be gained. Try it and let the semi-centennial report at Philadelphia next year show more than 10,000 actual members. It can be accomplished easily, will you do it?

We may strengthen ourselves and improve our JOURNAL by strengthening the ASSOCIATION, than which no organization ever had nobler aims or purposes, and every member will feel happier when he can truthfully say that he has done all he could to bring the whole profession in line under the banners of our ASSOCIATION, marching shoulder to shoulder in the sacred cause of humanity and science, and keeping step to the music of fraternal sympathy.

## CORRESPONDENCE.

### Unilateral Orchotomy.

NAVASOTA, TEXAS, Aug. 4, 1896.

To the Editor:—I herewith give in brief the history and operation of two cases of castration: C. S., aged 15 years; contracted continued malarial fever, which continued with no peculiar history until the third week, when orchitis developed in both testes without any disease of the genito-urinary organs, either during this attack of fever or previously. Later, it became complicated and terminated in orch-epididymitis, becoming exceedingly painful. During the fourth week I was called in consultation, finding the morning temperature ranging from 102½ to 103 degrees; evening from 103 to 104 degrees, with considerable tympanitis, great emaciation, prostration, intense suffering, a suppurating testicle of left side and the right one enlarged and painful. Castration being determined upon, antiseptic precautions were rigidly enforced. Patient being anesthetized I cut away the suppurating portion of the scrotum, turned out the testes and ligated the spermatic cord, nerve and vessels in mass with catgut. All capillary oozing was then arrested by hot compresses and the wound closed with silk sutures, leaving no drainage. The wound healed by adhesion, the other testicle rapidly improved, temperature declined and general convalescence followed.

A. M. C., aged 65 years. Gave history of slight hydrocele from boyhood, very gradually increasing. Patient contracted gonorrhoea, which gave him no little trouble, but finally terminating in orchitis, which kept him confined to bed for about three months; during which time he became very weak and emaciated. Temperature ranged from 101 to 103 degrees, due to pathologic condition of the right testicle. At the end of third month I was called in consultation. Removal of the diseased organ was decided on. The cystic portions of the testis was relieved by the use of the trocar. Then the scrotum was laid open and the testicle dissected out, as there was almost a continuous adherent tubercular attachment existed between it and the scrotum. The spermatic plexus was considerably enlarged and indurated, containing small cysts of pus. The cord and vessels were ligated as in first case, though much higher up above the tubercular tissue. The scrotum was then closed with silk sutures. No drainage was established, no suppuration followed; temperature declined and in ten days patient was able to be about his business.

D. F. PEEPLES, M.D.

### Dr. Carl Wagner Disclaims Connection with the "Milwaukee University."

CHICAGO, Aug. 28, 1896.

To the Editor:—In regard to the article in the JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION of Aug. 22 ("Another Diploma Mill in Wisconsin") I would like to state the following:

On August 19 an article came to my hand which contained my name in connection with an *unlawful* institution called the Milwaukee University. I immediately sent a letter, of

which I enclose a copy, to the said corporation. I also sent on the very same day letters to the States Attorney of Wisconsin, to the Secretary of the Board of Health of Wisconsin and to Dr. McDill, a prominent physician of Milwaukee, saying that I had nothing to do with that institution whatsoever, and asked the latter to make this known to his friends as far as lay in his power and to the medical society at large as far as possible; which he kindly promised to do. Then I begged the aforesaid parties to kindly inform me what means I should take to protect my reputation. I need only add that I will be pleased to appear in court to testify whenever I am summoned.

Very respectfully, CARL WAGNER, M.D.

[COPY.]

To the Milwaukee University: Gentlemen—Having learned that you used my name in your announcements as a director of the Milwaukee University, I ask you to withdraw my name from the list of your members immediately. I have never given you my consent to what you have done. I demand that you take all means within your power to see that my name in the future will be in no way connected with your enterprise, and also demand that all legitimate means be employed to recall the announcement already issued containing my name. If the above request is not complied with, I will instruct my attorney to proceed against your institution. Respectfully,  
Aug. 20, 1896. DR. CARL WAGNER.

## PUBLIC HEALTH.

**Medical Inspector for Schools.**—The Macclesfield (Eng.) School Board has passed the following resolution in regard to the question of medical certificates: "That, with a view to secure the more regular attendance of children at school, on the one hand, and to avoid unnecessary prosecution of parents on the other, a medical officer be appointed, whose duty it shall be to examine all children sent to him by the clerk, and to report as to their fitness or otherwise to attend school; and that the clerk keep a counterfoil record of children so sent; and that the medical officer be paid half-yearly at the rate of one shilling for each child so sent."—*Brit. Med. Jour.*

**A Quaint Hygienic Decalogue.**—The *Medical News* attributes to the late Dr. Frank H. Hamilton, of Bellevue Hospital Medical College, the following decalogue of health precepts: "1. The best thing for the insides of a man is the outside of a horse. 2. Blessed is he who invented sleep—but thrice blessed the man who will invent a cure for thinking. 3. Light gives a bronzed or tan color to the skin; but where it uproots the lily it plants the rose. 4. The lives of most men are in their own hands, and, as a rule, the just verdict after death would be—*felo de se*. 5. Health must be earned—it can seldom be bought. 6. A change of air is less valuable than a change of scene. The air is changed every time the wind is changed. 7. Mold and decaying vegetables in a cellar weave shrouds for the upper chambers. 8. Dirt, debauchery, disease and death are successive links in the same chain. 9. Calisthenics may be very genteel, and romping very ungentle, but one is the shadow, and the other the substance, of healthful exercise. 10. Girls need health as much—nay, more than boys. They can only obtain it as boys do, by running, tumbling—by all sorts of innocent vagrancy. At least once a day girls should have their halters taken off, the bars let down, and be turned loose like young colts."

**Attempt to Copy Michigan's Progress.**—In the *British Medical Journal*, August 8, is a short article by James Adam Dick, M.D., vice-president Eastern Suburbs Medical Association, Sidney, New South Wales, relative to "An Experience in the Voluntary Notification of Diseases in Sidney." He says: "Having observed in the pages of the *British Medical Journal* since August 31, 1895, the accounts of the movement to establish a national system of registration of sickness in Great Britain initiated by Dr. Arthur Newsholme, the Medical Offi-

cer of Health of Brighton, it occurred to the writer that a brief note describing an effort made in the same direction at the antipodes, might be of interest to those who are working at this most important subject. . . . The movement in Sidney had for its origin the example of the sickness statistics of that progressive body, the State Board of Health of Michigan, U. S. A. Correspondence was entered into with the secretary at Lansing, Mich., who very kindly supplied several valuable pamphlets and books. The Eastern Suburbs Medical Association of Sidney resolved to initiate a scheme for the voluntary notification of those diseases causing sickness in the area comprised by the association." Instead of having weekly reports, as in Michigan, the attempt was made to get monthly reports. This was unsuccessful because, while it is quite possible for a physician to remember to make a report every week, it will generally be found impossible to remember to make a report at a given time after a much longer interval; therefore, unless a central office regularly notifies all the observers at the time the monthly report is due, there is a probability of a general failure. And, in Michigan, what was commenced made successful for a time as a voluntary service by leading physicians, has since been supplemented by weekly reports required under the law to be made by local health officers; and in recent years more attention has been given to the securing of such official reports than to those by volunteer physicians. The writer hopes that the discouraging experiences in Sidney may not tend to abate the enthusiasm with which Dr. Newsholme has taken up this subject. This important scheme is one that the British Medical Association should again take up earnestly and urge its adoption upon parliament.

**Difference in the Death Rates Between the Sexes.**—Tables made up from Massachusetts census reports, covering a period of more than a quarter of a century, show that from birth to 10 years of age the male death rate is in excess of the female. From 10 to 40 the female death rate is in excess of the male, while the next ten years the rate is about the same. From 50 to 60 the percentage of deaths is largest with the males, while beyond that time the excess is with the females. Among insurance companies men over 50 are regarded as better risks than women of that age, and a strong man of 50 is preferred as a risk to an equally strong woman of 45. Dr. J. M. French, in the *Medical and Surgical Reporter*, May 9, calculates that out of 1,000,000 persons born 511,745 are males and 488,255 are females, making an excess of 4.81 per cent. of males. Of this number he estimates that 83,719 males and 65,744 females die during the first year, which would reduce the per cent. of excess males to 1.31. At 8 years of age the per cent. of excess has been reduced to 1 per cent. From then to 18 years of age the male excess increases to 1.18, at 39 to 2.08, while at 50 the excess has declined to 0.93 per cent. At 53 the number is equal. It is believed to be proved by statistics that while more women than men reach old age, there are more men than women reach the century mark. In Massachusetts between 1880 and 1890 there were 203 deaths of persons over 100 years of age, and of these 153 were men and 50 were women. Thus it seems that while more males than females are born, and while more males die between certain ages, the percentage is yet in favor of the males. The fact that men go to sea and to war, that they engage in more hazardous vocations than women and are more exposed is urged as an explanation for the greater death rate between certain ages. The fact also that women suffer from want of exercise, impure air and faulty modes of dress is cited to show why more women than men die at some ages.

**An Epidemic of Enteric Fever Among Children.**—Dr. A. K. Bond of Baltimore contributes to the *Virginia Medical Semi-Monthly* a brief report of "an epidemic of twelve cases of enteric fever which occurred in a home for destitute children in Baltimore.

The patient's ages in years were, respectively, 12, 7, 9, 3, 8, 4, 5, 7, 4, 4, 5, 19. The fever lasted from fourteen to eighteen days in the five youngest, whose ages ranged from 3 to 5 years. The temperatures ranged between 102.3 and 103.5 degrees. In the next older group it ranged between 104 and 105.5 degrees. Headache was a frequent symptom at the beginning. There was no delirium worth noticing, only one or two patients wandering in thought a little at night. The hearing of several patients was temporarily dulled while in bed. Nosebleed occurred in several cases at the onset of the disease. Rose spots were observed in all but three cases. They came in successive crops, and were very well marked even in the little boy, aged 3 years, who for five days had from two to three spots, old and new, upon the abdomen. The abdominal walls in all twelve cases were usually natural to sight and touch; tympanitic tendencies, as well as gurgling and pain in the right iliac fossa, being found only for a short time in two or three cases. There was a strong odor about the bodies of several of the patients, suggestive of intestinal fever. The bowels were not decidedly loose nor costive. In only a few instances were characteristic typhoid stools observed. Enlargement of the spleen so that it reached beyond the ribs was evident in only one or two cases. The following conclusions were drawn: That children often bear high temperatures well in this disease; that full baths should be very carefully and judiciously applied, if at all; that the disease in children under 5 years of age may easily be mistaken for other digestive disorders or for bronchitis; that albuminuria coming on during the fever does not necessarily lessen the chances of recovery; that gangrene of the mouth, if superficial, may in some cases be cured by permanganate of potassium washes, without caustics."

**Prevention of Measles.**—Dr. F. J. Waldo, the Medical Officer of Health in the St. George's, Southwark, London, district advises the use of more strenuous measures for the prevention of measles. He writes: "Medical science has not discovered any means of special protection against measles. Judging from the signs of the times, however, it seems not unlikely that some means of conferring in unity against the disease may be attained in the near future. Such a discovery, by striking at the root of the evil, would do much to lighten the labors of the sanitary reformer." The foregoing passage was written in 1890, and three years later we find the following important counter statements from Dr. Armstrong, of Newcastle, a leading authority in all health matters. In his 1892 report he writes: "By early knowledge of first cases in an outbreak we shall be enabled to check the spread of measles and whooping cough in schools, by preventing children of infected houses from attending school. Cases of measles would, wherever possible, be removed to hospital. The fact that measles is infective during the pre-eruptive period is no argument against the necessity for taking active preventive measures for the three or four weeks following, during which time infection still continues. The magnitude of the existing epidemics of measles and whooping cough and possible expense incurred in notifying those diseases in future, is surely no reason for turning our backs on this most important subject. The same argument would have applied with equal force to scarlet fever, smallpox, and typhus fever in 1882, when the question of notification was under your consideration. That argument, if it had been admitted, and acted on then, might perhaps have prevented the reduction of the mortality from smallpox to nil; that from scarlet fever to about one-fourth; and that from typhus to one-eighth of their magnitude; . . . which has followed the notification of these diseases in Newcastle." In conclusion, it is not too much to say of measles and its death toll that the question is one of national importance. Its satisfactory solution is one of the great problems of latter-day preventive medicine. Whether it is to be let alone, as heretofore, or to be

dealt with in a manner worthy of this scientific and progressive age, must to a great extent be decided by the verdict of educated public opinion. Experience has shown again and again that the health reformer can not travel far beyond the popular standard of enlightenment in these matters. That general rule holds good even in a matter so closely affecting the common welfare as the control of measles, one of the most deadly of the preventable diseases that devastate the populace of Great Britain. See the *Sanitary Record*, London, July 24, 1896.

**Excessive Mortality by Measles.**—The *Medical Press and Circular*, in its editorial columns, emphasizes the fact that measles is not a trivial disease, but on the contrary is the disease first, after tuberculosis, demanding the attention of the sanitarian. The editor says: "Among the preventable causes that swell the mortality rates, and are at present practically unchecked, measles and whoopingcough take the foremost place. The question of the prevention of measles has been discussed in the current number of the *Nineteenth Century* by Drs. Waldo and Walsh. They estimate that the case mortality from the disease in a poor district of the metropolis averages about thrice that of a rich quarter. They point out that in 1894 measles headed the zymotic death rate in London with 3,293 deaths, as against 2,670 due to diphtheria, and 2,097 to whoopingcough. But their chief emphasis is laid on the remarkable statistic deduction that during the year mentioned measles killed in the metropolis nearly twice as many persons as scarlet fever, fevers generally (including typhoid) and smallpox put together. In considering whether or no the disease should be made notifiable they pertinently remark: 'The wisdom and necessity of these (preventive) measures have been admitted in the case of smallpox, of diphtheria, of scarlet fever and other specific fevers, and of erysipelas. It seems illogical to exclude measles, which has been shown to cause a greater mortality than any of the diseases named. . . . Why it should be right to notify and control, or attempt to control, diphtheria, while measles and whoopingcough are left untouched, is somewhat of a mystery.' About the main facts advanced in this timely article there can be no dispute, any difference that may arise will be on the main conclusion that measles should be added to the list of notifiable diseases. As to this important question, it may be broadly stated that if it is the duty of the legislature to endeavor to prevent the loss of life by preventable causes, such as scarlatina and smallpox, it is difficult to see why a similar obligation should not apply to measles and whoopingcough. The cost of preventive measures in the case of measles would be, on the face of it, enormous. An outlay of this kind, however, many economists regard simply in the light of a national insurance. So far as the people who die and the folks who pay the direct and indirect costs of sickness are concerned, it matters not one jot whether the destroyer comes in the shape of cholera or smallpox, or the more homely, but far more fatal, measles. Whatever views be taken upon the advisability of notification, every one must agree with the concluding remarks of the authors above quoted. 'In conclusion,' they write, 'it is not too much to say of measles and its death toll that the question is one of national importance. Whether it is to be let alone as heretofore or to be dealt with in a manner worthy of this scientific and progressive age, must to a great extent be decided by the verdict of the educated public opinion. Experience has shown again and again that the health reformer can not travel far beyond the popular standard of enlightenment in these matters. That general rule holds good even in a matter so closely affecting the common welfare as the control of measles, one of the most deadly of the preventable diseases that devastate the populace of Great Britain.'"

**Disinfection Difficulties at Cairo.**—According to the *London Lancet*, Cairo and Alexandria with their hopelessly ignorant public, a virulent epidemic and a government not habitually

accustomed to repressive acts at variance with the habits of the people, have all the elements necessary to hamper the work of sanitary officials. The first instance of rebellion was an attack in Alexandria upon a cholera ambulance wagon, and a free fight at old Cairo between an Italian disinfectant and a hostile mob. Fortunately, the native court of justice sentenced six men to prison for periods varying from two to six months for this attack. Then came the revolution of about 500 Syrian students in the crowded and very sacred university of El Azhar with its 12,000 graduates, of all ages from early manhood to gray old age. A Syrian from this turbulent section was attacked by cholera and removed to hospital, where he shortly died. The old myth was at once started that the doctors had poisoned him, and when a second case occurred the doctor was not allowed to remove him. The sheikhs of the mosque were all absent, and refused to come when invited by the police to quell the riot. Both doctors and police seem to have behaved with the greatest moderation, and fortunately they were all Mussulmans, but when they found that the governor, who very pluckily went alone to expostulate with the rioters, was severely stoned, it was obviously time to put an end to the disturbance. Coles Pasha arrived with twenty picked men with loaded rifles and vainly essayed to open the mosque door, exposed to a storm of paving-stones from the windows of the precincts. He got the door slightly ajar and then fired into the mosque over the heads of the crowd. This was answered by yells and stones, and reluctantly the order was given to fire at the crowd. This produced an immediate dispersal and the Syrians fled to their bedrooms to hide. The police dragged them out, arrested about 500, and marched them at once to prison. The next day the bulk of them were released, sixty-five are now being exiled, and fifteen are going to be brought to justice. The Khedive has, moreover, decided to close the Syrian section of the university for one year. The greatest credit is due to both Coles Pasha and the governor for a successful ending of a very dangerous episode, and they have both been publicly thanked by the Egyptian government. Since that day there has been no interference with sanitary officers in Cairo. "In order to make thoroughly understood the serious and regrettable side of this incident, we must remind readers that the Theological university of El Azhar is the most renowned in all the East—for the pious a Rome and Jerusalem combined. A hundred years ago no Christian was allowed even to pass before its door, and one of the most hated incidents of the hated French occupation of this country was that Bonaparte converted the mosque into a temporary stable. It is difficult to believe that we shall not hear of this incident again. A very widespread belief is, unfortunately, current in both Cairo and the provinces that low-class Europeans are going about with sweetmeats to poison the faithful, and that this instead of cholera is the real cause of the epidemic. One despairs of finding any method to counteract an unfounded belief of this kind. With the exception of the English workers nearly all sanitary officers are Mohammedans, and the greatest care is being taken to avoid offending any religious feelings."

**Health Report.**—The following reports of mortality from smallpox, yellow fever and cholera have been received in the office of the Supervising Surgeon-General U. S. Marine-Hospital Service:

SMALLPOX—UNITED STATES.

Tennessee, July 1 to 31, 13 cases, 2 deaths.

SMALLPOX—FOREIGN.

Alexandria, Egypt, June 11 to 17, 3 deaths.

Bombay, India, July 21 to 28, 4 deaths.

Cairo, Egypt, June 11 to 17, 6 deaths.

Guantanamo, Cuba, July 1 to 31, 43 deaths.

Licata, Italy, August 1 to 8, 3 deaths.

Liverpool, England, August 8 to 15, 1 case.

London, England, August 8 to 15, 2 cases.

Madras, India, July 17 to 24, 1 death.  
 Madrid, Spain, August 4 to 11, 28 deaths.  
 Nantes, France, July 1 to 31, 2 cases.  
 Naples, Italy, August 1 to 8, 8 cases, 5 deaths.  
 Odessa, Russia, August 1 to 8, 18 cases, 2 deaths.  
 Osako and Hiogo, Japan, July 11 to 26, 78 cases, 25 deaths.  
 Paris, France, August 1 to 8, 1 death.  
 Pernambuco, Brazil, August 4 to 13, 362 cases, 58 deaths.  
 Prague, Bohemia, July 31 to August 7, 4 cases.  
 Rio de Janeiro, Brazil, July 18 to August 1, 27 cases, 4 deaths.  
 St. Petersburg, Russia, August 1 to 8, 7 cases, 1 death.  
 Tuxpan, Mexico, August 1 to 8, 1 death.  
 Warsaw, Russia, July 25 to August 8, 7 deaths.

## CHOLERA.

Alexandria, Egypt, June 11 to 17, 16 deaths.  
 Bombay, India, July 21 to 28, 17 deaths.  
 Cairo, Egypt, June 11 to 17, 91 deaths.  
 Calcutta, India, July 11 to 18, 10 deaths.

## YELLOW FEVER.

Fort de France, Martinique, W. I., August 3 to 6, 2 deaths.  
 Guantanamo, Cuba, July 1 to 31, 13 deaths.  
 Matanzas, Cuba, August 12 to 19, 29 deaths.  
 Manzanillo, Cuba, July 15 to 31, 8 deaths.  
 Sagua la Grande, Cuba, August 8 to 15, 85 cases, 11 deaths.  
 Vera Cruz, Mexico, August 13 to 20, 3 cases.  
 Rio de Janeiro, Brazil, July 18 to August 1, 8 deaths.

## NEW INSTRUMENTS.

## A NEW SUTURE NEEDLE. MODIFICATION OF THE HAGEDORN.

BY J. A. DIHRELL, JR., M.D.

PROFESSOR OF ANATOMY, ARKANSAS INDUSTRIAL UNIVERSITY,  
LITTLE ROCK, ARKANSAS.

A great number of forceps have been devised during the last few years. The almost endless variety seem to have grown largely out of attempts to adapt them for the use of both the

The above cut illustrates the modified needle as correctly made for me by Tiemann & Co., of New York City.

ordinary and Hagedorn suture needles. But in this respect all of them seem to be, to a great extent, failures. The transverse and oblique grooves in forceps for the flat Hagedorn needle, require both of one's hands for its accurate adjustment, and when this is done, the needle generally turns or rolls much to the annoyance of the surgeon. I have endeavored to obviate this difficulty and the necessity for so many needle forceps, in changing somewhat the form of the Hagedorn needle, which many surgeons prefer to all others, and at the same time I think, without impairing its usefulness, so that it may be used in almost any holder.

Simple as is the change in its form, I have had much trouble in getting it properly made, and then only after numerous trials by instrument makers in this country, and by one in Vienna.

The needle has given satisfaction in my own work, and to professional friends who have used it.

I have persisted in having it made for this reason, and because I have been informed on extended inquiry that no needle like it had been made, or is to be found in the market.

It has the Hagedorn point, but unlike that needle, is not "curved on the edge," but is flattened in the antero-posterior direction like the ordinary suture needle, from near the point to, and beyond the eye, which is in the same direction, and not on the side, as in the Hagedorn.

This flattened surface on the shaft, enables one to seize the

needle firmly at any place, except near the point and at the eye.

The cutting point being exactly like the Hagedorn, the wound made with it is the same, and is not altered in form by the non-cutting portion of the needle behind the point. It also appears to penetrate the tissues with as much ease as the Hagedorn.

The needle can be made in any of the usual sizes or curves.

Most of the needles sent me by the instrument makers, for approval, were entirely too heavy, contained too much metal, with the cutting points unnecessarily large, and the eyes too small.

## NECROLOGY.

WILLIAM R. CAMPBELL, M.D. (Starling Medical College, Columbus, Ohio, 1863), at Vanceburg, Ky., of rheumatism, August 19, aged 58 years. He served as a soldier during the civil war.

LUCINDA KEY, M.D., one of the leading women of the colored race and the second woman graduate of the Tennessee Medical College, at Shelbyville, Tenn., August 27. She was a successful practicing physician of Chattanooga.

THOMAS KILLOUGH, M.D. (Northwestern University Medical School, Chicago, 1873), at Hanover, Ill., August 25.

PROFESSOR PAJOT of Paris, aged 80; retired ten years ago. Founder of the *Annales de Gynécologie* and the first president of the Société d'Obstétrique et de Gynécologie.

J. C. WORTHINGTON, Surgeon, U. S. A., long stationed at Fort Thomas, Newport, Ky, died at Louisville, August 11. He was in strong affiliation with the profession of the neighboring cities and left a large circle of friends.

ARGYLE MACKEY, M.D., of Washington, D. C., at the City Hospital, Baltimore, Md., August 28, from a self-inflicted pistol-shot wound. To the physicians he explained most minutely the character of his wound and the causes that were leading to his demise. He even tried to feel his own fluttering pulse. He repeatedly felt the tips of his fingers and noted the slowly decreasing power of circulation and the peculiar sensations of approaching death. He was as calm as if he had been one of the professors of the hospital delivering a clinic lecture at the bedside of a dying patient. He graduated from the University of Maryland School of Medicine, Baltimore, in 1890.

GEORGE D. HOLSTEN, M.D., at New York, August 21. Dr. Holsten was born in New York in 1857, entered the University of New York in 1879, and was graduated in 1882. Subsequently he became a specialist in dermatology, and won much success in his chosen line of work. He was president of the Brooklyn Dermatological Society and editor of a paper devoted to the interests of the science. Dr. Holsten was at different times connected with the Eastern District and Brooklyn Throat Hospitals. He was also a member of the Long Island Medical Society, Alumni Association and Amphion Musical Society.

E. M. NELL, M.D., warden at the State penitentiary at Frankfort, Ky., at that place August 21, aged 49 years. He had been ill about three weeks with typhoid fever. He was born in Adair county near Gradyville and received his early education in the common schools. At the age of 17 he entered the Union Army, serving about two years in the Thirteenth Kentucky Cavalry. He graduated at the Nashville Medical College, and soon had a large practice. He entered politics in 1885, when he was elected as representative. When he was appointed as warden of the State penitentiary he was serving his first term as State senator. Dr. Nell in the short time he was warden had made many friends at the capital, and proved himself extremely efficient as an official.

ELSWORTH F. SMITH, M.D., of St. Louis, Mo., at Fort Missoula, Mont., August 19. Dr. Smith was born in St. Louis

seventy-three years ago. His early education was obtained in a college in St. Charles County, Mo., from which he graduated and went to St. Louis. In that city he entered the St. Louis University, and, after graduating, attended the St. Louis Medical College, from which he graduated in 1848. He went abroad to complete his medical education, and spent four years in Paris. On his return to St. Louis he began the practice of medicine. Through the smallpox and cholera sieges he manifested great courage and indomitable perseverance, and won golden opinions from hosts of grateful citizens. In 1852 he received the appointment as health officer, and four years later was offered and accepted the chair of physiology in the St. Louis Medical College, which he held until 1870. He was a member of the AMERICAN MEDICAL ASSOCIATION, St. Louis and City Hospital Medical Societies.

JACOB ROSENTHAL, M.D., of Chicago, after an operation for appendicitis, August 24. Dr. Rosenthal was born at Philadelphia, Dec. 7, 1862, the third son of Morris and Jenetha Rosenthal. He received his education at the public schools of Philadelphia, graduating with highest honors from the Central High School in the class of 1878, being of the few awarded the teacher's certificate for high average. In 1882 he received the degree of M.A. while a student of the Jefferson Medical College, Philadelphia, from whence he graduated with honors in 1888. After graduation he began practicing medicine in Chicago, and in 1891 stopped practice to take up special courses of study in gynecology and obstetrics, spending considerable time at various universities of Germany and Austria, especially with Leopold of Dresden. He returned in 1893 and renewed his practice in Chicago. Dr. Rosenthal was a member of several medical societies and fraternal organizations. He was attending gynecologist at the Cook County Hospital, advisory surgeon of the Standard Accident Association of Detroit, physician to the Hebrew Charities and attending physician at the Jewish Orphans' Home. He has written extensively for medical journals here and abroad, and was generally beloved by his colleagues in the profession. A host of friends mourn his loss.

## BOOK NOTICES.

**Proceedings of the Nebraska State Medical Society.** Twenty-eighth Annual Session, 1896. Pp. 344, cl. Published by the Society. It contains thirty-five carefully prepared and interesting articles, and is embellished by the portrait of J. E. Summers, Jr., M.D., President of the Society for 1895-96.

**Transactions of the American Academy of Railway Surgeons.** Annual Meeting, 1895. Vol. II. Edited by R. HARVEY REED, M.D., Columbus, Ohio. Pp. 221, cl. American Medical Association Press. 1896.

President C. K. Cole, in his address, congratulates his associates on the evidences of the success attained by the Academy in the short period of one year. There are nineteen carefully written articles on injuries, sanitation and medico-legal subjects. It contains numerous fine illustrations, including portraits of the officers of the Association and views of the Plant System hospital car.

**Eleventh Annual Report of the State Board of Health and Vital Statistics of the Commonwealth of Pennsylvania,** 1895. Pp. 729, cl. Printed by Clarence M. Bush, State Printer. 1896.

President of the Board, Pemberton Dudley, M.D.; Secretary, Benjamin Lee, M.D., Philadelphia. It contains the report of the Secretary, minutes of the meetings of the Board, reports of inspections, quarantine, disinfections and epidemics; reports of conferences and conventions; circulars and forms in use; organization, by-laws and regulations of the Board; laws of the State relating to the protection of life and health, passed in 1895, etc. It is illustrated with numerous drawings show-

ing drainage and water supply of various towns, maps prepared by the State Weather Service showing mean temperature, rainfall and prevailing direction of the wind for each month, plans of the hospital for contagious diseases at Harrisburg, etc.

## SOCIETY NEWS.

**Pennsylvania and Maryland Union Medical Association.**—The ninth annual reunion took place at York, Pa., August 27. The following officers were elected: President, Dr. Joseph Price, Philadelphia; vice-presidents, Drs. C. A. Rahter, Harrisburg; Charles G. Hill, Baltimore; secretary and treasurer, Roland Jessop, York.

**Sheboygan County (Wis.) Medical Society.**—The annual meeting was held August 24 at Sheboygan Falls. Dr. H. Reineking of Sheboygan read a paper on aseptic surgery, and there was a general discussion on tuberculosis. The officers elected for the ensuing year were: President, C. W. Pfeifer; vice-president, Charles Schaper; secretary and treasurer, O. B. Bock. The next meeting will be held at Plymouth.

**Society of Doctors and Lawyers.**—The Medical League Society of Indiana was organized August 28 at Indianapolis by a number of physicians and attorneys from various sections of the State. The object is mutual interest and the avoidance of friction between the two professions in the giving of expert testimony. Major C. L. Holstein of Indianapolis was elected president; Dr. J. F. Hibbard of Richmond, Judge Cyrus F. McNutt of Terre Haute, Dr. G. W. McCasky of Fort Wayne, John B. Cockrum and Dr. M. V. B. Newcomb of Indianapolis, vice-presidents; Dr. J. F. Hodges, Anderson, secretary; Dr. A. E. Sterne, Indianapolis, treasurer, and John B. Elam, Indianapolis, heads the executive committee. A committee reported constitution and by-laws, which will be still further revised at a meeting to be held in Indianapolis the first Tuesday in December.

**Transportation Arrangements for the Pan-American Medical Congress.**—Dr. H. L. E. Johnson, 1400 L Street N.W., Washington, D. C., has been elected chairman of the Special Committee on Transportation. All communications relative to rates, reservation in the special trains, etc., should be addressed to him. A rate of one fare for the round trip has been secured between St. Louis, New Orleans and trans-Mississippi points and the City of Mexico. It is confidently expected that this rate will be extended over the entire territory of the United States. Arrangements are in progress for a splendidly equipped special train of sleeping and observation cars, with first-class dining-car service. Dr. Johnson will presently be in position to announce a rate which will include railroad fare, sleeping and dining car service both ways and in the City of Mexico, and covering the expense of various side trips to the most important historic points in the Republic. Charles A. L. Reed, M.D., Secretary International Executive Committee.

**American Association of Obstetricians and Gynecologists.**—The ninth annual meeting of this association will be held at Richmond, Va., Sept. 22-24, 1896. The following papers will be read: "Principles and Progress in Gynecology," president's address, Joseph Price, Philadelphia; "Vaginal Hysterectomy by the Clamp Method," Sherwood Dunn, Los Angeles; "Further Experience with Appendicitis," A. Van der Veer, Albany; "Relation of Malignant Disease of the Adnexa to Primary Invasion of the Uterus," A. P. Clarke, Cambridge; "Treatment of Puerperal Septicemia," H. W. Longyear, Detroit; "Treatment of Posterior Presentation of the Vertex," E. P. Bernardy, Philadelphia; "Relation of Local Visceral Disorders to the Delusions and Hallucinations of the Insane," W. P. Manton, Detroit; "Differential Diagnosis of Hemorrhage, Shock and Sepsis," Eugene Boise, Grand Rapids; "Movable

Kidney; Local and Remote Results," A. H. Cordier, Kansas City; "Pathology and Indications for Active Surgical Treatment in Contusions of the Abdomen," W. G. Macdonald, Albany; "Some Causes of Insanity in Women," George H. Rohé, Sykesville; "Shall Hysterectomy be Performed in Inflammatory Diseases of the Appendages," L. H. Dunning, Indianapolis; "Dynamic Ileus; with report of cases," J. W. Long, Richmond; "Faradic Treatment of Uterine Inertia and Subinvolution," Charles Stover, Amsterdam; "A Plea for Absorbable Ligatures," H. E. Hayd, Buffalo; "Treatment of the Stump," J. F. Baldwin, Columbus; "Limitations in the Teaching of Obstetrics and Gynecology as Determined by State Medical Examining Boards," William Warren Potter, Buffalo; "The Philosophy of Drainage; Treatment of the Pedicle in Hysterectomy or Hystero-myomectomy in the Abdominal Method," George F. Hulbert, St. Louis; "Removal of the Uterine Appendages for Epilepsy and Insanity; a Plea for its more General Adoption," D. Tod Gilliam, Columbus; "Albuminuria of Pregnancy," A. Fr. Eklund, Stockholm; "Unnecessary and Unnatural Fixation of the Uterus and its Results," James F. W. Ross, Toronto; "Sarcoma of the Urethra," Charles A. L. Reed, Cincinnati; "Appendicitis as a Complication in Suppurative Inflammation of the Uterine Appendages, L. S. McMurtry, Louisville; "Gunshot Wounds of the Abdomen with the New Gun," J. D. Griffith, Kansas City; "Tubo-ovarian Cysts with Interesting Cases," A. Goldspohn, Chicago; "Obstruction of the Bowels Following Abdominal Section," George S. Peck, Youngstown; "Memorial of Dr. Hiram Corsen," Fraill Green, Easton.

Papers are also promised by John Milton Duff, Pittsburg; Rufus B. Hall, Cincinnati; George Ben Johnston, Richmond; Walter B. Chase, Brooklyn; Lawson Tait, Birmingham; Walter B. Dorsett, St. Louis; W. E. B. Davis, Birmingham; E. Arnold Praeger, Los Angeles. Dr. George Ben Johnston, 407 E. Grace street, Richmond, Va., is chairman of the Committee of Arrangements, who should be addressed in regard to hotel accommodations and railway fares. Joseph Price, president; William Warren Potter, secretary.

## MISCELLANY.

**Appointment.**—Dr. S. S. Bond of Washington, D. C., was selected as surgeon general of the Union Veterans' Union, at its meeting held in Binghamton, N. Y., August 20.

**The House of Mercy Hospital,** Springfield, Mo., has received a handsome gift from Garratt Barry, for the equipment of a surgical ward of five beds. The ward will be for men, for general operations.

**Fruit Seeds in Appendicitis.**—Only two fruit seeds were found in the appendix in the course of 200 operations by Roux for appendicitis. Sixty-five calculi of fecal origin and concentric formation were found, their peculiar shape showing that they had developed in the appendix.—*Cbl. f. Chir.*, August 1.

**Infection by Pets.**—Cats have been suspected of conveying the infection of diphtheria, and scarlet fever has been traced to them. To this may be added the unwelcome news that a health officer has reported a case of smallpox which has been brought about in the same way; that is to say, by a cat from an infected house entering a neighbor's.—*Pop. Science*, September.

**A Vegetable Meat.**—In Japan they have what may be called vegetable meat. The substance is called in the vernacular "torfu." It consists mainly of protein matter of the soya bean, and is claimed to be easily digestible and as nutritious as meat. *Torfu* is as white as snow and is sold in tablets; it tastes somewhat like fresh malt.—*Popular Science*, September.

**St. Margaret's Memorial Hospital,** Pittsburg, Pa.—Ground was broken August 25. The buildings which will form the hospi-

tal are located on Forty-sixth street, between Lawrence and Davidson streets. The front elevation will be 350 feet and the depth 100 feet. The cost \$200,000. The hospital was provided for in the will of John H. Shoenberger. It is to be a memorial for his wife.

**Unusual Case of Syphilitic Infection.**—The *Annales de Derm. et de Syph.*, July, describes a case of syphilitic infection which, starting from the initial chancre, produced in turn pleurisy, icterus, phlebitis, acute rheumatism and dermoneuropathy, all in the course of four months, and only yielding to mercurial treatment.

**Elect the Doctors.**—The profession throughout the State should see to it that every physician who is a candidate for the next legislature is elected this fall. Dr. Yett, the nominee for the senate, and Dr. Hill, nominee for the house, from the Austin district, will be elected without doubt.—*Texas Medical News*.

**Ditte's Method of Elastic Ligatures of Hemorrhoidal Nodules.**—The *Wiener Med. Presse*, No. 20, reports the invariable success of this method in 269 cases treated. Average length of treatment, twelve days. The nodules dropped off with the ligatures in five to twelve days. If the surrounding skin can be left out of the ligatures, the pain is slight, otherwise local anesthesia may be required.—*Cbl. f. Chir.*, August 1.

**A New Parasite.**—A gentleman residing in a comfortable country home in France, exceptionally careful of his person, has been infested with a parasite since his return from a short trip in 1891. It seem to belong to the genus *seira*, but is not identical with any of the species described in the text-books. It does not produce any lesions of the skin, but merely annoys by its presence in the hair and by crawling around on the neck and body. It disappears in the winter, but reappears each spring in spite of the most determined efforts to exterminate the pest. It is confined to the gentleman himself, the servants being almost completely exempt.—*Union Médicale*, August 1.

**The Asiatic Ant a Surgical Adjunct.**—According to the *Independent*, Dr. Miltiades Issigonis, of Smyrna, a Greek naturalist, has sent a paper to the Linnean Society of London, on a remarkable use of ants in Asia Minor. It was stated that the Greek barber-surgeons of the Levant employed a large species of ant (*camponotus*) for the purpose of holding together the edges of an incised wound. The ant, held with a forceps, opens its mandibles wide, and being then allowed to seize the edges of the cut, which are held together for the purpose, as soon as a firm grip is obtained the head is severed from the body. The author had seen natives with wounds in course of healing with the aid of seven or eight ants' heads.

**Treatment of Malignant Tumors with Toxins of Erysipelas and Prodigious.**—Dr. William B. Coley has reported 160 cases treated, extending over a period of four year: Total number of cases of sarcoma were 93; carcinoma and epithelioma 62; sarcoma or carcinoma 10; tubercular 2; fibro-angioma 1; mycosis fungoides 1; goitre 2; keloid 1. Of the cases of sarcoma nearly one-half showed more or less improvement; the variety that showed the greatest improvement was the spindle-celled; the melanotic showed the least. Next in order of benefit was the mixed celled—round and spindle; then round-celled, while osteo-sarcoma closely approached the melanotic in showing but little change. In a series of nine cases of melanotic sarcoma no improvement was noticed in six; very slight in three. Most of the cases of osteo-sarcoma failed to respond to the treatment; many showed slight improvement, and one case, a very large osteo-chondro-sarcoma of the ilium, apparently disappeared and the patient remained well for nearly a year, when a recurrence occurred. One case of round-celled sarcoma of the neck of very rapid growth showed very marked decrease during the first week's treatment, after which

time it continued to grow in spite of large doses of the toxins. He was of opinion that a series of upward of twenty successful cases of inoperable sarcoma (four of which had remained well upward of two and one-half years), the diagnosis of which had been established beyond question according to accepted methods of diagnosis, ought to be sufficient to demonstrate the real and positive advance that had been made in a field which, up to this time, had been regarded as absolutely hopeless.—*Johns Hopkins Hos. Bul.*, August.

**Laughter as a Symptom of Disease.**—From Austria comes a curious account of a man suffering from a nervous disease that manifested itself in paroxysms of laughter. The patient, whose case was described before the Psychiatric and Neurological Society of Vienna, was 30 years of age, and had been subject for three years to fits of laughter, which occurred at first every two or three months, gradually increasing in frequency to a dozen or more a day. The attacks occurred especially between 9 P.M. and 6:30 A.M. Some occurred also during the day, however the patient happened to be occupied. In the intervals between the attacks, and immediately before and afterward, the man appeared perfectly well. The attacks commenced with a tickling sensation arising from the toes of the left foot, and the patient would fall to the ground unless he could reach some place to lie down. When this feeling reached the level of the left nipple the patient lost consciousness for a few seconds. Often the patient lay upon his face. The mouth and eyes were closed spasmodically, the eyeballs turned upward; the pupils were dilated and unresponsive to light. At the height of the attack the patient at first smiled, and then laughed aloud without other sign of merriment. The entire attack occupied about two minutes. On two occasions there was protracted loss of consciousness.—*Pop. Science*, September.

**Permanent Baths.**—The *Journal de Méd.*, August 2, contains a description of the permanent baths at the General Hospital at Vienna, for the treatment of various skin diseases and cases of extensive destruction of the epidermis. The baths are of copper in a thick wooden case, and the patient is kept completely submerged, floating beneath the surface of the water, sitting up or reclining on a covered trellis, which can be raised and lowered at will. He remains in this bath day and night for weeks and months, and is only lifted out to attend to the calls of nature. Some patients were observed who had been in the bath for two years. The temperature of the water is the same as that of the body; medicaments are added as indicated. The functions of the organism do not seem to be affected by this prolonged soaking. The palms and soles swell and wrinkle at first, but the rest of the sound skin is not altered, except in rare cases an eczema is produced on the arms or throat. Where there is great loss of epidermis, as in dermatitis exfoliacea and pemphigus foliaceus, extensive burns and suppurating wounds, the water takes the place of the numerous bandages required, which would fatigue and weaken the patient. It keeps the surface moist and disinfected, and forestalls complications. It also soothes or prevents the pain when the papillæ are exposed. Similar results are obtained in gangrenes, fistulas, syphilis, cutaneous tuberculosis, psoriasis, lichen ruber, pityriasis universalis, ichthyosis, etc. No other means can be compared to the permanent bath in the prompt relief afforded, the rapidity with which the necrosed tissues are thrown off, inflammation, pain and fever subdued and granulation and cicatrization accelerated. Erysipelas is the only skin disease which it does not seem to benefit.

**A New Question to be Decided.**—According to the *American Law Review*, an action at law is pending in the circuit court of the city of St. Louis, involving a new question of law, which is of importance to the teaching medical profession. The action, it says, was brought by Anita May George, an infant, by her next friend, against Dr. Augustus C. Bernays, a very eminent sur-

geon of that city. The plaintiff, when two years of age, had swallowed a quantity of concentrated lye, by reason of which the esophagus became closed, so that for four years she received her nourishment through rectal injections and through a fistula established by a successful operation of gastrotomy. The defendant then took the child into his charge and succeeded in opening the esophagus, and enabling her to take her nourishment in the natural way. His principal operations were performed at the Marion-Sims College of Medicine, in the presence of a number of surgeons and medical students, as well as of the mother of the child. And he afterward published a description of these operations, accompanied by a photograph of the child stripped to the waist, showing where the various incisions in her body had been made, and illustrating the printed description given of the operations; but he did not give the name of the child in the pamphlet, using instead false initials. Now the mother of the child has taken it into her head to try to recover heavy damages for the latter, on the ground that the defendant violated her right of privacy in two particulars: 1, in allowing outside parties to witness the surgical operations which he performed upon her; 2, in publishing in the pamphlet in question a description of the operations, together with a photograph of the patient. The result will be awaited with interest, and it is to be hoped that the case will not be allowed to rest until it is finally passed upon by the supreme court of Missouri. Upon the foregoing meager statement of facts it hardly seems possible that it can be anything but a judgment for the defendant. At the same time it will be a decided advantage to have the law on the subject authoritatively laid down.

**Experimental Explorative Operations on the Brain.**—A series of experiments in cerebral explorations for diagnostic purposes has been recently conducted at the Albert Clinic at Vienna, which are described in detail in the *Cbl. f. Chir.* of August 1. The subjects were dogs, and the instruments used were an improved drill, the point forming an angle of about 100 degrees,  $1\frac{1}{2}$  to 2 mm. in diameter, with a gauged guard to prevent its penetrating too far; a double spoon harpoon, closed to a small point or spread apart at will, and the usual Pravaz' needles, harpoons, etc. The object of the experiments was to determine whether and how far it is possible to explore accumulations of fluids in the substance of the brain or under the membranes, without injury to the patient, and also to secure portions of the brain and fluids for histologic investigation, through the smallest possible opening. After narcosis, the skull of the dog was drilled through in several places, and portions of the dura mater and cerebrum brought up by means of the spoon harpoon or needles, curved and straight. The operations were successful in every case; there was no hemorrhage, and the small drill holes in the bones and soft parts healed perfectly without inflammation. None of the dogs showed the slightest symptoms of cerebral disturbance, but were as lively and hungry the next morning and afterward, as if nothing had happened. Those killed later showed that the wounds had healed by first intention in both bone and tissue, and that there had been no bleeding and no adherences. Roser and Braun have asserted that lack of pulsation in the dura mater usually indicates an accumulation of pus or a splinter of bone, under or near it. By means of a small glass tube inserted in the hole drilled, and half filled with water, the pulsations of the dura mater were distinctly perceptible as they were communicated to the water. This effect was also obtained by a closed glass tube, with the upper end drawn out into a delicate glass thread at right angles to the tube, which vibrated with the pulsations of the dura mater.

**A Remarkable Operation in Intestinal Surgery; Recovery.**—An article headed "The resection of ten feet of the small intestine of a small boy," by Dr. Guiseppe Ruggi, in *Il Policlinico*,

Rome, will attract attention. The patient was a lad of 8 years, who received his injury by being accidentally but violently struck on the abdomen. The abdomen being opened, a loop of intestine was found constricted by a bridle of the omentum. This was divided, and the gut being apparently uninjured, the wound was closed. For a few days the boy did very well, but then all the symptoms of obstruction returned in aggravated form. One week later the wound was reopened and the intestine was found to be stenosed at the point where the constricting band had been divided. The intestine was incised longitudinally for a distance of 6 or 7 centimeters, freeing the stricture, and an anastomosis was effected. For some time after this the child did well, but complained, as he had before the first operation, most bitterly of hunger during night and day, in spite of the facts that large amounts of food were given, in addition to rectal feeding. But in two weeks the meteorism, pain and other signs of intestinal obstruction returned, and it was determined to open once more the abdomen. A large mass of the small intestine was found agglutinated together and adherent to the abdominal wall. On attempting to break down these adhesions it seemed to be effected with comparative ease, but it was soon seen that the freed parts were deprived of their mesenteric attachments. Instead of closing the abdomen as had been done in similar cases, Dr. Ruggi determined to resect the injured part. He removed successively three portions of the gut, the entire length being ten feet, nine inches, until sound gut above and below was reached. The lower incision was six inches from the ileo-cecal valve. The extremities of the intestine were united by silk sutures. There were no bad symptoms after the operation, and within a few days the boy was again crying for food. For three weeks, in spite of many imprudent concessions being made to him, the boy was teasing night and day for something to eat. Gradually, however, the food taken seemed to afford some nourishment, and five weeks after the last operation the child was discharged perfectly well. At the time of the report, fifteen months later, he was in perfect health.

**Character of Locality Considered.**—The supreme court of Michigan thinks that it may reasonably take judicial notice that a surgeon's skill depends somewhat upon his experience and opportunity for witnessing operations, and it is to be expected that the degree of surgical skill met with in different localities will be affected by these things. However, a man with no skill, or inconsiderable skill, should not shelter himself behind the claim that he is the only practitioner in his neighborhood, and therefore that he is possessed of the ordinary skill required, although shown to possess less than the ordinary skill to be met with in such localities, or, as the books sometimes say, in the general neighborhood. And, recognizing that the character of the locality has an important bearing upon the degree of skill requisite, the court holds in the case *Pelky v. Palmer*, decided June 2, 1896, that while the instruction of the circuit judge, taken abstractedly, that a physician charged with malpractice was bound to use only such care, skill and diligence as physicians and surgeons in the neighborhood where he resided and practiced, and who were engaged in the same general line of practice, ordinarily have and exercise in like cases, was perhaps not strictly accurate, yet, in view of evidence showing that the physician in question resided in a city where there were other physicians, presumably of average ability, when compared with similar localities, the party suing was not thereby injured so as to entitle him to a reversal of a judgment in favor of the physician. There was also an instruction in this case that the plaintiff could not recover unless he showed, by a preponderance of the evidence, a state of facts from which no other rational conclusion could be drawn that the defendant was unskillful and negligent, which was the proximate cause of producing the result complained of; and that it was not enough to show a state of things equally con-

sistent with unskillfulness and negligence or the absence of them. The latter part of this instruction, the supreme court holds not objectionable; for, where the inferences to be drawn from the facts proved are as consistent with skill and diligence as with unskillfulness, the plaintiff should fail. But it can not properly be said that the plaintiff can not recover where it is possible to draw a rational, or reasonable conclusion other than that of negligence. Therefore, because the language in the first part of this instruction excluded probability, and required too high a degree of proof, the court directed a new trial.

**Breaking Up of One of the Hospital Corps Companies, U. S. Army.**—

One of the results of the recent tour of inspection of Surgeon-General Sternberg among the Western military posts has been the breaking up of the company of instruction at Fort Riley Kas., and the distribution of the men in small detachments at some central post in each of the military departments west of the Missouri River. In 1891 schools or companies of instruction were established at Fort D. A. Russell, Wyo., Fort Riley, Kas., and at Fort Keogh, Mont. The intention was to train men for service in the corps by instructing them in all duties which the non-commissioned officer or private is liable to be called upon to perform, such as nursing, first aid and hospital corps drill, dispensary work, cooking, mess management and the preparation of official papers pertaining to the hospital. The organization proposed for Fort Keogh was not completed, but companies were formed at the two other posts which did excellent educational work and kept at the disposal of the surgeon-general for an emergency a number of men who could be cut loose from their school duties until the emergency was passed. During the railroad strikes of 1893 men were detailed from these schools for duty with the troops on active service. Later, a hospital corps company was formed at Washington Barracks as of value in connection with the army medical school recently established in Washington, D. C., and as a suitable center for the distribution of trained men to posts in the Department of the East; and the company at Fort D. A. Russell was permitted to lapse by failing to recruit it. For the past two years the centers of Hospital Corps education have therefore been Fort Riley and Washington Barracks. The great objection to the continuance of the former company appears to have been the expense of transporting men from it as a center to posts on the Pacific coast and in the far north. This was so great as practically to debar those distant posts from participation in the benefits to be derived from the system of instruction. By breaking up the company into detachments and attaching these for instruction to the hospital department at certain large posts well scattered over this large territory it is proposed to retain the advantages of the school method and have spare men in each military department available for assignment in emergencies without involving so much expense as heretofore in getting them where they are wanted.

**Nurses as Non-Experts.**—In the case of *American Accident Co. v. Fidler's Administratrix*, which was an action on a policy of insurance against death by accident from external causes, the main question was whether the insured died from typhoid fever or whether his death was caused by his body coming in contact with a telephone wire that threw him some ten feet on his back and seriously injured him. The case was twice before the court of appeals of Kentucky, May 12 and June 17, 1896. On the first occasion it reversed a judgment for the plaintiff, because of the admission of testimony of non-experts to prove that the deceased died from the effects of the fall, and not from typhoid fever, as the attending physician and other medical men testified; and on the second a petition for rehearing was overruled. It seems that the widow of the dead man, her sister and mother and also another party were permitted to testify, not only to the symptoms of the patient such

as would necessarily come to their knowledge when nursing him, but from those symptoms, to give it as their opinion that the deceased did not have typhoid fever. They did not pretend to be experts in medical science or to have nursed more than two or three typhoid patients. The symptoms manifested by the patient from day to day and such as one of ordinary observation could detect, the court says, were properly allowed to be detailed by the witnesses and to go to the jury as evidence. And on these statements a hypothetic case could be, as was done in this case, presented to those skilled in the character and treatment of diseases and their opinions given as to the cause of death; but the court holds that these four witnesses mentioned were clearly not entitled to express any opinion on the subject, though it cites the case where the opinion of one who had been a professional nurse for half a century and his familiarity with the disease was unquestioned, was received as entitled to great weight. On the rehearing the court said that the opinion of one having no experience in the science of surgery should have no weight when eminent surgeons are present and have testified that a limb was improperly amputated, or that it was not necessary to save the life of the patient; nor, where the disease is pronounced to be typhoid fever by educated physicians, is it competent to prove by one inexperienced in the treatment of diseases, and who had never made a study of medicine, that the physicians were mistaken.

**Water Famine Among the East London Poor.**—The water famine in the East End of London has become a great source of complaint. Many children, it is said, have died, others are sick and others are becoming ill owing to the scarcity of water. Few houses are allowed a supply of more than an hour daily, and the water furnished has an unpleasant deposit. The result is that scarlet fever, diphtheria and other diseases caused by uncleanliness have seriously affected the section. While the East End has thus been deprived of water, the fountains in the West End, or fashionable part of London, have been running, thereby wasting water which would most likely have saved the lives of many poor children in the unaristocratic portion of the metropolis, although this must be remembered that the companies that have the water rights in these different sections are not the same.

**Medical Longevity.**—The London *Lancet* for June 20 states that Dr. Salzmann of Esslingen has recently devoted his attention to determining the average duration of life among members of the medical profession. After an exhaustive examination of all accessible archives referring to the last four centuries, the following are the results arrived at by the zealous antiquarian. The average duration of a medical man's life during the sixteenth century was 36 years, 5 months; in the seventeenth century it was 45 years, 8 months; in the eighteenth century 49 years, 8 months, and in the nineteenth century 56 years, 7 months. It would appear from these data that, whether the survival be of the fittest or not, the duration of medical life has been increasing in a marvelous manner. Should the same rate be maintained practitioners of medicine may ere long all look forward to centennial honors, by no means a rosy prospect from the point of view of the neophyte who, as it is, finds it sufficiently hard to make good his footing within the densely crowded ranks. According to Dr. Salzmann the addition of over twenty years to the average medical lifetime is due to the advance in medical science, preventive and curative; so the ironic apophthegm, "physician, heal thyself," can no longer be launched with any effect. In a speech delivered some time ago the present leader of the House of Commons alluded to the possibility of normal human life becoming extended "to the patriarchal term of 120 years."

**Alleged Medical Hardships in Russia.**—The London *Lancet* refers to the hard lot of the profession in Russia, and to the many cases of suicide among the physicians in that land.

Italy in suicide, as in homicide, maintains a bad preëminence; but in professional suicide, in the self-destruction of votaries of the liberal arts, particularly medicine, she would appear to be out-distanced by Russia. From a statistical return lately published, suicide among the practitioners of the healing art in Russia has reached alarming proportions—a distressing feature of the return being the comparative youth of the victims. The majority of them average between 25 and 35 years of age—all of them in the prime of life and full flush of their powers. An explanation of the phenomenon is sought in the fact that the Russian medical man's lot is a particularly hard one. As in Italy the profession is vastly overstocked in all the cities of the empire, and in consequence competition is exceptionally severe—so severe that a physician has been known to hold consultations from 8 A.M. to 11 P.M. in order to gain the reasonable income of 600 rubles a year. Besides the Russian municipalities, seconded by the lay press, have instituted gratuitous consultations in public ambulances, by which the wealthy city of Kiev, for example, withdraws from the legitimate fees of the profession as much as 27,000 rubles per annum. There the poverty of the practitioner is such that he has been known to give advice for 20 kopecks (8d.) for each consultation.

**Hippocrates the Founder of an Enduring Ethical System.**—It can not truthfully be said of the Father of Medicine that he is a "back number." On the contrary a perennial bloom graces all his decisions about the medical life. Men may come and men may go, but his wise eloquence flows on forever. The editor of the *Scalpel* enlarges upon this thought as follows: "The Father of Medicine, Hippocrates, has laid down our ethical code for all time. It is the only one we can recognize and have recognized. It over-rides all modern definitions, whether framed by colleges or leading members of the bar. It is not a question of *autres temps autres mœurs*. This old Pagan knew his duty, and his words, sounding along the corridors of time, appeal to us to-day with all their freshness, because at the root of his words there is the one great element which makes all words valuable and vitable, viz., their truth. The practice of medicine in ancient times was much as it is in the present day; human nature has been much the same in all ages, especially where sex is concerned. Hippocrates knew probably just as much as the College of Physicians of London about abortion and about all the secrets connected with it, and not only about abortion but about the thousand and one secrets which are brought under our notice, for the life currents have hardly changed; the same fears are here, the same weaknesses, the same suffering, the same vices, the same repentance, and the physician who hears all the sad stories of human frailty is still the same. We have followed the teaching of Hippocrates and not of modern men and modern manners; we intend to follow it, and we strongly advise all younger members of the profession to read the Hippocratic oath and to adopt it. Hippocrates said: 'I swear whatever in connection with my professional practice or not in connection with it, I see or hear in the life of men which ought not to be spoken of abroad, I will not divulge, as reckoning that all such should be kept secret. While I continue to keep this oath unviolated may it be granted to me to enjoy life and the practice of the art respected by all men and in all times, but should I trespass and violate this oath may the reverse be my lot.' The word 'men' here is used in the generic sense and also includes women, and the word abroad also admits of definition, for Hippocrates did not say anything of the law which even in his time demanded civic duties of the doctor. In France, Germany and all civilized countries, the professional secret is not only privileged but sacred. In England, with the old school of practitioners, we have been brought up in the same traditions. There may be a younger school, but we hope it is a very limited one, holding different tenets."

**Practice of Medicine in West Virginia.**—Section 9 of chapter 150 of the code of West Virginia was amended in 1895, so that the following persons, and no others, shall hereafter be permitted to practice medicine in that State, viz.: 1. All such persons as were legally entitled to practice medicine in that State Feb. 22, 1895. 2. All such persons as shall pass an examination before the State board of health and shall receive certificates from such board, as provided. The State board of health, it is further enacted, shall, at such times as a majority of them may deem proper, hold examinations for the licensing of practitioners of medicine. Such examinations shall not be less in number than three during each year and shall be held at such points in the State as shall be most convenient to those presenting themselves for examination or to the State board of health. At such examinations written and oral questions shall be submitted to the applicants for license, covering all the essential branches of the sciences of medicine and surgery, and the examination shall be a thorough and decisive test of the knowledge and ability of the applicants. The president and secretary of the State board of health shall issue certificates to all who successfully pass the said examination, and such certificates, after being duly recorded, shall be deemed licenses to practice medicine and surgery in all their branches in West Virginia. The State board of health shall give timely notice of the time and place of holding each such examination, by publishing such notice in at least three newspapers of general circulation in the State, and all persons wishing to present themselves for examination should notify the secretary of the State board of health to that effect. No applicant for a license to practice medicine in West Virginia shall be rejected because of his or her adherence to any particular school or theory of medicine. The State board of health shall call to their assistance, in the examination of any applicant who professes the homeopathic or eclectic school of medicine, a homeopathic or eclectic physician duly licensed to practice medicine in the State, and such homeopathic or eclectic physicians so called to the assistance of the State board of health, shall be allowed per diem and actual expenses incurred as allowed to regular members of the State board of health; provided, however, that the provisions of this and the preceding section shall not apply to physicians living in other States and duly qualified to practice medicine therein, who shall be called into consultation into West Virginia, by a physician legally entitled to practice medicine in West Virginia under these sections. Section 17 of the same chapter of the code is amended so that all moneys received from the State board of health as fees for examination, under section 11 thereof, shall be placed to the credit of the State board of health by the treasurer of the State, and shall, with other moneys appropriated to the said State board of health, be used to defray the expenses of its meetings, examinations, etc.

**Changes in Virginia Health Law.**—Sections 1714, 1715, 1717, 1724 and 1725, code of Virginia, were amended and reenacted by an act approved March 3, 1896. The provision, in original section 1714, that the State board of health should not in any way be a charge upon the State, was dropped. Section 1715 had introduced into it a provision that the board shall have power and authority, as further directed, to adopt such rules and regulations, and issue such orders as may be necessary to prevent the spread of contagious or infectious diseases, and to confine persons infected therewith or who may have recently been exposed to the same, within prescribed limits. Section 1717 had the provisions added that the salary of the secretary shall be fixed by the board and that the other members of the board shall receive no salary, but shall be paid the sum of \$4 per day while engaged in the discharge of their duties, and their traveling expenses incurred while so employed. The expenses of the State board of health, which shall not in any one year exceed

the sum of \$2,000, shall be paid by warrants drawn on the auditor of public accounts, signed by the president of said board, and countersigned by the secretary, out of any money in the treasury not otherwise appropriated. Section 1724, as now amended, provides that if any member of the State board of health or a justice of any county shall have complaint, on oath, made to him, or if he shall have reason to think that there is on any lot, tenement, or plantation, or on board any vessel in said county, any person infected with smallpox, or other dangerous disease, it shall be the duty of said member of the board of health, or of said justice to issue a mandate in writing, addressed to two physicians of said county, requiring them to go to the place so suspected and to examine the persons diseased, if any, and to report in writing their opinion of such disease, and whether the public's interests require any action. If it appear to said board of health or said justice from said report that such person or persons are infected with smallpox or other dangerous disease, then said board of health or justice, whichever has first taken cognizance of the case, shall prescribe such rules and regulations as may be deemed necessary to prevent the spread of such disease; but the action of said justice shall be subject to the review of the local board of health, and for this purpose said board of health or justice may establish a quarantine at the place or places where such disease exists, and inhibit any ingress or egress to or from the same. They may, by proper orders, prevent any railroad train, steamboat or other conveyance from taking on or putting off passengers or freight at any point or points in or near the infected district. For the services required of the physicians under this section, a reasonable allowance shall be made to them by the board of supervisors at the next county levy thereafter. Section 1725 is amended, extending power to the State board of health to have infected persons removed to a hospital or other proper place.

**Lord Walseley on the Army Medical Officer.**—It may be remembered that six months ago at the close of the 71st session of the Army Medical School, Netley, England, the speech of Adjutant General Sir Redvers Buller to the graduating class created much dissatisfaction in medical circles, civil as well as military, on account of the low place which he gave to the army medical officer in the military hierarchy, defining his duties as those of the doctor merely and overlooking those of the sanitary officer, although speaking under the roof of the medical school and in the presence of the faculty instituted to teach the young officer these very duties. The impressions created by that speech can not be effaced by the spirit of comradeship evinced by the Commander-in-Chief, Lord Walseley, in his remarks on distributing the prizes, July 31, at the close of the 72d session. He eulogized the medical department and raised the army medical officer officially and socially to his proper plane. According to a summary in the *Lancet* of August 15: During the course of a long military career he could most conscientiously say that some of the greatest friends he had had in the army had been medical officers. . . . As they (the young officers) went out to their duties he could assure them that they would find that no man appreciated the services of officers—certainly of the medical officers—of the army more thoroughly than the private. He was extremely grateful for every kindness; and he would remind them that no body of men in the army were more capable of doing acts of kindness than the medical officers of Her Majesty's service. When he thought of that building (the Royal Victoria Hospital) he could not help remembering the two men to whom he thought they were mostly indebted for it. He knew them both well and had the greatest admiration for them. He was referring to Dr. Parkes and Sir Thomas Longmore. The name of Dr. Parkes called to his mind the book which he wrote on Hygiene, which when it first appeared created quite a revolu-

tion in that science not only in the medical service but throughout the various parts of Her Majesty's dominions. It was their duty not only to heal disease, but to do their best to prevent it, and Dr. Parkes was the first man to show them how disease might be kept away from their barracks. Dr. Parkes had passed away from them, but his memory would always be fresh in the minds of those studying there, and his name would be remembered in the army so long as the hospital continued to exist. Members of their profession had not only been distinguished for their medical services. He had on many occasions seen some of the greatest acts of heroism performed by gentlemen of the department; and if he was asked to name a dozen of the very bravest men he had ever met he should have to include two or three who had been in the medical department. He would name one at once, because he saw him, quite lately. Perhaps they had heard of Sir Robert Jackson. He was with him for a long time; and if he had to lead a storming party to-morrow he did not know any man he would sooner have with him than his friend Dr. Jackson. He went to Lucknow with his regiment, and the senior medical officer of the battalion was equally brave and won the Victoria Cross on the occasion. There were many acts performed by medical officers which deserved to be recorded on any pages of history devoted to heroism. He related the dying act of Surgeon-Major Landon, who, when lingering under what proved to be a fatal gunshot wound, asked the enemy, into whose hands a batch of wounded had fallen in an unfortunate expedition, to prop him up while he injected morphia into a soldier who had been seriously wounded in order to relieve his suffering. After which service he fell back and expired in half an hour. Such an act as that should be talked of and read of in the medical school and should be known throughout the army. In conclusion he begged to wish them the best fortune in the profession in which they had embarked and to hope that he might have during the remaining portion of his life many opportunities of meeting them again.

**Gleanings.**—Fatal pneumonia immediately following a fall into water; pneumococci must have been inspired into the lungs with the water. Finkelstein ascribes follicular enteritis to a new bacillus he has discovered. (*Therap. Woch.*, July 25.)—Query whether the "ainhum" of the negroes and some cases of syringomyelia, sclerodactylia, etc., may not be forms of leprosy. Cancer of the stomach arrested and pains and cachexia cured by exposure to the Roentgen ray half an hour, twice a day for a week, supplemented by milk diet, condurango and injections of artificial serum. Absolute cure of congenital incontinence of urine (age 22 years) by inductive static current (Morton's current, six to eight sparks a second) introduced with a bougie into the urethra to the vesical sphincter. (*Sem. Med.*, July 29.)—Acute appendicitis treated with opium and ice; fifth day the appendix was passed entire in the feces, with evidences of a circular abscess where it had been joined to the intestine; recovery. (*Wratsh.*, No. 22.)—Fatal peritonitis; two pins found in appendix. (*Cbl. f. inn. M.* No. 20.) Goitre experimentally produced by water from the beautiful Vale of Aosta, noted for its many cases of endemic goitre. (*Wien. Klin. R.*, July 23.)—Four grave cases of infective disease cured by letting out blood and substituting in its place an equal amount of serum. (*Bull. de l'Acad. d. M.*, July 21.)—Arnheim reports sanoforn (di-iodin-salicylic acid methyl ether,) non-toxic and fully as effectual as iodoform; 72 ulcers, etc., treated; used as powder, gauze, salve and colloidum. (*Cbl. f. Chir.*, July 11.)—Borger has invented a thyroid gland hook to simplify tracheotomy. (*Zeit. f. prakt. Aerzte*, No. 8.)—As a means to prevent adulterations it is proposed to hang up in a prominent place in an offender's establishment the analysis of the article adulterated, with a notice calling customers' attention to it. (*St. Pet. Med. Woch.*, July 18.)—The healthy

skin and vagina do not absorb medicaments added to baths; erythema of the surface must first be produced by chemic or mechanical means before there is absorption. (*Nouveaux Remèdes*, July 18.)—Experimental "washing" of the blood (dogs), leads Bosc and Vedel to conclude that the action of the intravenous injections of 7 per cent. salt solution is by the osmotic action of the NaCl, by the diuretic action of the salt, direct and indirect, and by elevation of the pressure of the blood; it also acts on the red corpuscles, promotes the nutrition of the organism, and diminishes the globulicidal power of the pathologic serum; a medium dose injected at the first symptoms of infection promptly cures; large doses resulted fatally; the preventive action of early injections suggests the existence of a superactivity of the organism, revealing itself in reactionary phenomena, already noticed in normal dogs, resembling a natural crisis reaction. (*Bull. Méd.*, July 29.)

## THE PUBLIC SERVICES.

**Army Changes.** Official List of changes in the stations and duties of officers serving in the Medical Department, U. S. Army, from Aug. 22 to Aug. 29, 1896.

A board of medical officers to consist of: Col. Dallas Bache, Asst. Surgeon-General; Lieut.-Col. William H. Forwood, Deputy Surgeon-General; Lieut.-Col. David L. Huntington, Deputy Surgeon-General; Major Walter Reed, Surgeon; Capt. Charles M. Gandy, Asst. Surgeon, is constituted to meet at the Army Medical Museum Building on Wednesday, Sept. 23, 1896, at 10 o'clock A.M., for examination of candidates for admission to the Medical Corps of the Army.

**Navy Changes.** Changes in the Medical Corps of the U. S. Navy for the week ending Aug. 29, 1896.

Medical Director David Kindleberger, placed on the retired list September 2.

Asst. Surgeon H. La Motte, ordered to the naval hospital at Norfolk.

Surgeon C. Biddle, detached from the "Monongahela" and placed on waiting orders.

Medical Inspector J. C. Wise, Surgeons J. C. Byrnes and C. Biddle ordered as a board to convene at Annapolis September 3, to examine candidates for admission to the naval academy.

### Change of Address.

Durant, G., from Branford, Conn., to 12 W. 46th St., New York, N. Y.  
Earles, W. H., from 655 3d St. to 259 11th St., Milwaukee, Wis.  
Fraser, J. N., from 3100 Wentworth Av. to New Era Bldg., Cor. Blue Island Av. and Harrison St., Chicago.  
Hagens, G. J., from 6058 S. Halsted St. to 6053 S. Halsted St., Chicago.  
Jones, W. A., 630 Walnut St. to 221-222 Spitzer Bldg., Toledo, Ohio.  
Kober, G. M., from Winchester, Va. to 1819 Q St., N. W., Washington.  
MacDonald, Chas. E., from Liberty Falls to St. John's Hospital, Long Island City, N. Y.  
Niles, J. W., from 355 Dearborn Av. to 390 N. Clark St., Chicago.  
Penton, A. B., from 275 Harrison St. to 134 Ash St., Detroit, Mich.  
Percy, J. F., from Mantorville, Minn., to Galesburg, Ill.  
Smith, S. L., from Chicago to Neenah, Wis.  
Simpson, Irwin, from Anamosa, Iowa, to 5064 Washington Av., Chicago.  
Watts, G. W., from 361 W. 65th St. to "The Yale," Station O, Chicago.

CHICAGO, ILL., SEPTEMBER 12, 1896.

No. 11.

## ADDRESSES.

### CHAIRMAN'S ADDRESS.

Delivered before the Section on Ophthalmology at the Forty-seventh Annual Meeting of the American Medical Association, at Atlanta, Ga., May 5-8, 1896.

BY LUCIEN HOWE, M.D.

BUFFALO, N. Y.

It is one of the duties of the chairman of each Section of this ASSOCIATION to present an "Address" at the opening of the session in his department.

Perhaps this custom would be more honored in the breach than the observance and in the present instance the time would be better employed by proceeding at once to the inviting list of papers which the Executive Committee has prepared. But when one has been complimented by election to the chairmanship of the Section which is generally conceded to be the most active of all the Sections in this ASSOCIATION, it ill becomes him to avail himself of any excuse and fail to acknowledge the honor thus conferred upon him.

Indeed, he assumes a definite responsibility in accepting this position. For while it is manifestly impossible for him to present the barest outline of the year's advance even in this one small corner of the field of medical science, still, it is his duty to observe the trend of ophthalmologic thought, to point out, if he can, the directions in which the lines of progress may be advanced, or, what is yet more important, to sound the alarm if there is danger of any in our ranks going so far and so fast in their eagerness for achievement as to overstep the limits of scientific accuracy, with the inevitable result of retreat, in confusion and in shame, to a more moderate and secure position. With this in view, I feel impelled to ask your attention, very briefly, to a growing tendency among us to regard difficulties of the accommodative and muscular apparatus as entirely local. I would fain say a word for that nearly forgotten factor, the "general health." This introduction again of a threadbare subject almost demands apology, especially as, for the sake of clearness later, it is necessary now at the outset to repeat definitions which have been agreed upon long ago. Thus, when we say that the pathologic conditions above mentioned produce asthenopia, it is essential that we remember not only what that means, but also the three shades of its meaning.

We must remember that asthenopia is simply the name of a certain group of symptoms, namely, difficulty or discomfort when attempting to use the eyes for near work, occasionally a little redness or smarting of the conjunctiva, and nearly always headache—then called ocular headache. Moreover, we must remember that this group of symptoms may be dependent upon at least three distinct causes. These we have long ago recognized as:

1. Accommodative asthenopia, which, being due to

some variation from the normal shape of the typical eye, as near- or far-sightedness, or to astigmatism in some form, necessitates an unusual action of the ciliary muscle and is, of course, to be corrected with a concave or convex glass.

2. Muscular asthenopia. While this is often associated with the accommodative form, it may occur when the globe is perfectly normal. It is due to an unnatural action of the muscles on the outside of the eye, to the recti and possibly to the oblique; it is recognized by the various tests for unequal muscular balance, and is corrected by means of prisms, by tenotomies, partial or total, or by muscular advancement.

3. Central or neurasthenic asthenopia. In this condition no variation from the normal standard can be discovered either as regards the action of the ciliary muscle or the recti or oblique muscles. Or, indeed, if any such abnormal condition did exist, the asthenopia persists after the patient has received full correction of the difficulty by means of glasses or otherwise.

While it may appear puerile to repeat elementary facts at a meeting of ophthalmologists, it is better to err in that respect than to risk the confusion that arises from nebulous ideas defined in vague terms.

This, especially for the reason that, in order to establish the point in question, it is more important to arrange in proper sequence a few facts already well known than to bring forward any that are new.

Now, the object of this paper, as above stated, is to call attention to the too great tendency with most ophthalmologists to consider their cases of asthenopia as belonging to the first or second class. In other words, we look upon the causes of the symptoms as more local than general, as is natural enough with those who, like ourselves, are obliged to focus their entire attention upon a small field of practice. Especially is this true because we naturally see a large proportion of cases of asthenopia which do require only local treatment. Indeed, in a few rare instances, ametropia or a faulty muscular balance may produce by reflex action pathologic symptoms in distinct organs, which symptoms have apparently been relieved by the use of suitable glasses. But let us ask ourselves more exactly concerning accommodative and muscular asthenopia and it will be evident, I think, how often we deal with the third form, how often this becomes in the history of the case what the *Tiers Etat* was to the French Revolution, the element unrecognized or reluctantly acknowledged at first, but dominant in the end.

Take accommodative asthenopia first. In high degrees of far-sightedness or especially of astigmatism, we learned long ago to expect ocular headaches or their allied symptoms. We have prescribed suitable glasses and the asthenopia vanished, as if by magic. Then, later, we learned that in certain individuals lesser degrees, even very minute degrees, of variation from the normal type also gave rise to the

same symptoms, and required likewise to be corrected with glasses. This is the positive evidence. But we should look at the negative evidence as well. For if these same anomalies, which are mathematically definite, produced invariably the same effect, as we ought to expect if the asthenopia springs from local causes, then there would be but very few men, women or children not wearing glasses. I know of no figures more instructive on this point than those obtained by Roosa in his examination of the refraction of a hundred persons who supposed their eyes to be perfectly normal. These individuals, it will be remembered, were of various ages and occupations, and no person had both eyes absolutely perfect, as shown by the combined tests of the ophthalmometer, ophthalmoscope and test glasses, while only 1 per cent. had one eye in that condition. Among them, too, several persons were found having as high as one and one-half or two dioptries of either myopia, hypermetropia or astigmatism, who were blissfully unconscious of their defects.

While thus on the one hand, we find constantly such variations from the normal standard to exist without headache or any symptoms of accommodative asthenopia, so, on the other hand, are we unfortunately familiar with the fact that when the very best and most exact corrections have been made, even under atropin, this asthenopia obstinately persists in almost as great a degree as without the correction.

Next, let us glance at the state of our knowledge concerning muscular asthenopia and arrange before us, in similar sequence, a few well-known facts. We can formulate these in the same manner by saying that while asthenopia usually exists with unequal muscular balance, the same symptoms also frequently persist when that fault can not be detected by any methods of measurement now at our command, or when, having been present formerly, it has been corrected. On the other hand, eyes which have always been considered perfect, which never gave their owners a suspicion of asthenopia, have occasionally been found, on examination, to be in a state of exceedingly unequal muscular balance. In these cases, even though exceptional, of course, I am careful not to include those in which any existing error of refraction had not been previously fully corrected under a mydriatic, no matter how slight that variation from the normal had seemed to be. Moreover, in this connection, I do not ignore at all that very important distinction which I think should always be made between the sthenic and asthenic varieties of muscular asthenopia.

In other words, we have for muscular asthenopia just what we found before for accommodative asthenopia, namely, that some considerable variations from the normal type, which theoretically should be corrected, do not demand that, the owners of these eyes being perfectly comfortable without glasses. And on the contrary, in many individuals when the variations from that type are very slight, indeed, practically not measurable, the asthenopia continues in spite of every effort, the patients wandering from one office to another in a vain search for relief.

Now, the question naturally arises, why are we obliged to make such an exact adaptation of glasses, or to correct the muscular condition so carefully, with one class of individuals, and not with the other? Under these circumstances we fall back upon our third factor, so conveniently indefinite just then, by

saying that the difference is in the "accommodative power" of the individuals, or in the "strength of the muscles" or "*vis a tergo*," as we variously term it. Evidently, though, this is simply using a phrase to cover our ignorance.

In this dilemma, unfortunately too common, we must simply ask ourselves honestly what other condition exists, or what conditions combine, in that individual, to produce the asthenopia? This is a branch of pathology which, as I said at the outset, is too much neglected, and in regard to which I venture to speak only with caution, but it seems safe to say that what we understand in general as anemia, as imperfect assimilation and as nerve exhaustion, are three important elements which, in varying degrees, separately or together, produce central asthenopia.

Several years ago I measured, with the spectroscopic bands, the amount of hemoglobin present in individuals suffering from certain forms of eye disease, a portion of the results being published then in the Transactions of the Medical Society of the State of New York. It was quite surprising to observe how frequently improvement in these cases corresponded with a return to the normal condition of the blood. I can speak with no such certainty concerning the relation between the condition of the blood and central asthenopia, but it is fairly reasonable to infer that the pallid specimens of humanity who come for glasses and who find relief from a half or possibly a quarter of a dioptre, or from correspondingly weak prisms, would have strong eyes if they had also more nearly normal blood.

Next, as to imperfect nutrition. There is but little doubt that this also plays an important rôle in aggravating the asthenopia in certain individuals. In order to test this, about three years ago I placed in a corner of my office a pair of the small size Fairbanks scales, noting the weight of those patients to whom very weak glasses proved beneficial, and was not surprised to find that as appetite improved and weight was gained, the glasses could often be dispensed with.

Finally, as to the effect of the so-called "nervous" condition of the individual. It would require too long a digression to discuss that in any detail, nor is it necessary, as I think it will be admitted that this is one element, and an important one, in relation to asthenopia. In this connection the so-called psychic effect of glasses, of manipulations or of "operations," can not honestly be passed by without some notice. It is probable that the mere wearing of a pair of spectacles with simple plane glasses has an effect upon the minds of certain individuals, similar to that produced by a hypnotic suggestion. This observation was made by Dr. Holt at a recent meeting of the American Ophthalmological Society, and acting on this hint I provided myself with a number of pairs of plane glasses. These have been lent to those who imagined they should have spectacles, or have been exchanged for weak glasses before prescribed, in a sufficient number of instances to prove beyond question this psychic element. Moreover, I have yet to meet with the person who fails to appreciate the advantage of such a trial, or one who is not glad to be rid of any glasses, when the reason for the experiment has been frankly and fully explained. Most practitioners also have heard reports of improvement from their imaginative patients almost before treatment was begun, and certainly the results from some of the methods of making partial tenotomies, can be

accounted for more rationally in this way than in any other.

There are, of course, other general causes tending to produce central asthenopia which might be considered in this connection, but which must of necessity be omitted. It should be noted, however, that while the error of refraction which produces accommodative asthenopia remains nearly the same through life, and while, also, the unequal balance belonging to muscular asthenopia varies comparatively little, on the other hand, those conditions of the general health which accompany central asthenopia do change readily. The application of this fact is practical and familiar. Convex glasses or prisms which once gave the patient relief can be changed for those which are weaker, or are voluntarily laid aside altogether when the health of the patient has improved. In certain cases after we have gone through the usual exact routine with ophthalmoscope, ophthalmometer and various muscular tests, it is true we do succeed in detecting some slight anomalies which have existed perhaps for years, and which are aggravated only temporarily by some such fault in the general condition as has been indicated above, and which the family physician himself has overlooked. Under such circumstances if we then also neglect the general health of the patient and set ourselves at work to correct only the error of refraction or the muscular balance, we may be sure of obtaining little or no improvement at first. But as the patients are patient, and consent to rest, or to exchange a sedentary life for fresh air, or a life of hard work for one with more relaxation, in such cases relief does come, but comes very gradually, and this improvement must be accredited more to nature's tonics and time than to any skill in prescribing glasses or to "exercises," or to any of those measures which in other individuals are undoubtedly of benefit.

I know that this will be considered by many as heresy, but it is none the less the truth. It behooves us to recognize it frankly and to be on our guard accordingly.

We have reason to congratulate ourselves upon the advances made during the last few years, especially in America, in the methods of determining and of treating accommodation and muscular asthenopia. But let us beware of rapid progress in these two lines, at the neglect of a third often equally important.

To avoid that, for our own credit, and for the greater comfort of our patients, I venture to recall these facts, already familiar, concerning the relation of the general health to asthenopia.

#### CHAIRMAN'S ADDRESS.

Read in the Section on Laryngology and Otology, at the Forty-seventh Annual Meeting of the American Medical Association, at Atlanta, Ga., May 5-8, 1896.

BY G. V. WOOLEN, M.D.  
INDIANAPOLIS, IND.

*Gentlemen of the Section:*—It is especially pleasing to me to meet so many of you again, and in this fair city of the South already noted for its activity in promoting the general welfare of mankind.

I again wish to express to you my sincere thanks for the high honor conferred in selecting me to preside over this part of our work so dear to us all. Whatever may be our ideas relative to specialties and the organization of special societies, it must be conceded that the unity of the profession must be preserved, and that much of our best work should be per-

formed in connection with the meetings of this ASSOCIATION. It is, therefore, fitting that we meet annually with the profession for special as well as general work, and the consideration of matters pertaining to the general welfare of the fraternity.

It will be a sad day for specialists when this is neglected. We can not afford to ignore these claims and I am persuaded that it is the purpose of you who have helped to further the interests of this section from its beginning to have no thought of forgetting this AMERICAN MEDICAL ASSOCIATION, now old and honored in its usefulness.

In view of the length of our program, and the desire of your Chairman that a full discussion of its merits may be secured, without which our meeting will be robbed of much of its interest and profit, it is not his intention to furnish an extended address. In this respect, and in the preparation of the program it is desired to depart from former customs somewhat, hoping thereby to increase the interest of our meeting.

By collecting papers on allied subjects for individual sessions and following them with a speaker specially chosen to open the discussion it is hoped the interest will be direct, and much useful information secured, and thus justify the departure. Indeed it has been a question with me if this department might not be extended by the selection of a single individual to furnish a paper for each session of our future meetings and of one or more to open the discussion and so confine attention, thereby securing more exhaustive work than can be had by our present methods.

Our specialty is young, but its field is broad, vastly more so than the uninitiated can know, and our very best endeavors should be given to bring it up to the high plain of its importance, and not the least of these efforts should be put forth annually in this section here in close contact with our fellows of the other departments.

#### ORIGINAL ARTICLES.

##### SUBCONJUNCTIVAL INJECTIONS.

Read in the Section on Ophthalmology at the Forty-seventh Annual Meeting of the American Medical Association, held at Atlanta, Ga., May 5-8, 1896.

BY EDWARD J. BERNSTEIN, M.D.  
BALTIMORE, MD.

Like all other remedial agents, subconjunctival injections must run the gauntlet of ill-considered judgments, both favorable and adverse, until its place shall have been firmly assigned.

Few men, like Abadie, Darier, Deutschmann, Gepner, Schmidt-Rimpler, Pflueger and Zossenheim have yet had sufficient personal experience to entitle them to give conclusive verdicts. In the main, these men assert, we have in this method a means at our hand, swift, sure and intense, which under proper precautions and indications should stand us in good stead, whether employed alone or in conjunction with general treatment.

That it is a panacea or infallible, not even an enthusiast will contend. Much adverse criticism comes from those who declare that we have no precise indication for its employment. Certainly we must, *in part*, admit this contention, but should one expect a hard and fast demarcation in a method so novel?

Even Darier, who has been working in this line since 1888, admits that he must still often work in the dark. But are we uniformly successful with opium, quinin, or the bromids? Shall we give up the use of the Eustachian catheter because of discouragement and occasional failure?

Though Rothmund, in 1866, and Segondi, in 1871, were the pioneers in the use of subconjunctival injections, it is to the persistence and zeal of M. A. Darier we owe the present status of the question.

Though rather unfavorably impressed with the method when I observed it in the fall of 1891 under Darier, that opinion has been greatly modified during the past sixteen months. My task shall be to supplement the work of Valude (*Annales D'Oculistique*, August, 1893) and to record my own experience.

Upon technique I shall only touch, referring for more complete data to the original articles and the many translations, but the following points are worthy of consideration:

1. Observance of every practical aseptic precaution—sterile ground, solution and instruments.

2. Thorough anesthesia of conjunctiva with 4 per cent. (sterile) cocain solution.

3. Use of cyanid of mercury instead of sublimate. Cyanid hydrargyri is compatible with cocain muriate. Adding 1 per cent. of cocain increases anesthetic effect. Cyanid is less irritating than sublimate, and is taken up as such by the tissues instead of being converted into the slowly soluble albuminate.

4. The injection is to be made *subconjunctivally*, and as far as possible at a tangent with the globe, and *not* under Tenon's capsule.

We can avoid the larger vessels by simply rubbing the lid over the eye once or twice, when they become visible, and one can readily choose a clear spot. We are not so fortunate with the fine nerve twigs, and should we puncture one of these pain will be quite severe for twenty-four hours.

Muttermilch (*Annales D'Oculistique*, September, 1894) asks: "Why resort to injections when we know that fluids reach the interior of the eye by simple instillation into the sac?" Even if sublimate so given were absorbed, which he questions, basing conclusions on Tichomoroff, the dose would be so infinitesimal that its effect would be *nil*. "Say you inject one-twentieth mg., the beginning dose, two-thirds of the fluid is lost (?) in the conjunctival sac, leaving but one-third, or one-sixtieth mg. (0.000017), to enter the eye. Now reckon the volume of the eye at 7 c.m., you then obtain a dilution of 1 to 400,000 which can hardly be called an antiseptic solution." Furthermore, he believes whatever good results is from suggestion.

To these we may reply that the action of drugs injected is intensified, and it is a more exact method of dosage. Pflueger converted the crystallin lens into an emerald mass by so injecting solution of fluorescein. Cocain thus used produces a rapid and thorough anesthesia of the iris, which simple instillation does very unsatisfactorily, if at all. But it is objected that this does not hold true for sublimate, which is converted into the slowly soluble albuminate in the body. Does this latter not apply equally as well to its hypodermic use, and who can gainsay its superiority in accuracy of dosage, rapidity and intensity of action over the administration per ora? Yet here we use the cyanid, which is not, or but feebly so, transformed. Admit even that all the mercury is so changed, it will none

the less be absorbed. Bocchi demonstrated microscopically the presence of mercury in the tissues after injections under the conjunctiva.

The assertion that but one-third of the fluid injected enters the eye is a flight of the imagination and not founded on fact. Let us even admit this to be true, yet are his calculations and conclusions erroneous.

Say we inject hypodermically 0.01, the usual dose, of HgCl<sub>2</sub> for a person of 60 kgm. Remember much of the hydrargyrum is carried off by the excretory organs; the liver takes up and retains a larger proportion; then come the other glands, especially the salivary glands; next, the skin, and finally the other organs and tissues. Now, how much of this 0.01 goes to the eye? And have we not all seen specific lesions actually melt away under its influence? Does it not look on the face of it that a larger proportion of hydrargyrum enters the eye by this means than by systemic medication? And is it not also likely that hydrargyrum acts in a much smaller dose than we generally credit? You can not estimate the quantity, as you see, by saying, "If the eye weighs 6 gm. and the body 60 kgm. then one-ten-thousandth goes to the eye."

I propose during the summer to make the actual experiment, using some such method as suggested by Dr. Rudolph Winternitz, and promise to report later.

Are we at all sure that drugs injected subconjunctivally enter the eye? Of this there can be no doubt. "Let us inject a solution of K<sub>2</sub>FeCy<sub>3</sub> subconjunctivally, and after a short time enucleate the eye and fix the eye in an alcoholic solution of ferric chlorid (Fe<sub>2</sub>Cl<sub>6</sub>). On making sections we can show that the first solution entered by way of the lymph channels, for these show colorless on a blue background. The connective tissue retains the K<sub>2</sub>FeCy<sub>3</sub> with great tenacity" (Schwalbe, *Anat. Des Auges*). Ovis and Pflueger have demonstrated China ink—in the lymph channels—which had been previously injected under the conjunctiva.

As several writers contend that the main action of subconjunctival injection is limited to the anterior portion of the eye, and therefore preferred to inject, if at all, under the capsule of Tenon. Carl Mellinger and Domenico Bossalino determined to find out just how far fluids so injected would enter the eye and its neighborhood; they made a series of injections with sterilized mixtures of China ink. These were well borne and produced no inflammatory reaction. The staining particles were found in the lymph channels, the leucocytes could not be demonstrated as charged with the material to any considerable extent. They showed that the particles did follow the large lymph channels of the whole globe and optic nerve, and that not only was the eye and nerve surrounded by such, but the supra-choroidal spaces (by smaller communicating channels) and the intervaginal spaces (Zwischenscheidenraum) as well.

Sublimate thus injected entered the eye as albuminate. Neither Bach nor Hess could discover any sublimate in the interior of the eyes they experimented on, though Bocchi, Brugnietelli, Gallemaerts and Jolly always recovered small quantities by electrolysis.

Pflueger employs solution trichlorid of iodine (1 to 1,000). His results in general are not so good as those obtained by the use of hydrargyrum. Still in retinal detachment, macular retino-choroiditis, he reports good results where others meet failure with hydrargyrum.

Is it not likely an indication to employ iodine trichlorid in some of these cases and hydrargyrum in others? Or are they not at least worthy of trial? Marti following in the line of Mellinger found equally good results from the use of weaker solutions of hydrargyrum. He declares that subconjunctival injections act not through any germicidal influence, but by action on the lymphatic circulation (stimulating its rapidity) thereby causing resorption and elimination of pathologic products, thus hastening healing. That his results with salt were equally as efficacious as with hydrargyrum, with the advantage of greatly diminishing pain, and furthermore avoiding the adhesion of the conjunctiva to sclera at site of puncture

To this Darier replies that adhesions only occur when puncture is made too near the limbus or too deep under the conjunctiva. Pain is a variable quantity even in the same individual. Sometimes in one patient an injection will be perfectly painless, while the next time it will be excessive. He had one patient who went through a whole course of hydrargyrum injection without pain, and who complained bitterly when he once injected distilled water. Darier had tried salt solution, iodine trichlorid, soda salicylate and various other drugs, but is convinced that hydrargyrum is most reliable in his hands.

As soon as Mellinger, Pflueger and the rest prove their assertion by an array of sufficiently conclusive observations, Darier says he will be among the first to admit their utility, and will follow their lead. At any rate, these men obtain good results from this procedure, and this is a gain in the right direction. We must not forget that it is not intended to do away with general treatment; all that is claimed for it, is that it intensifies the action of hydrargyrum and hastens cure.

Mellinger declares the action of subconjunctival injections to be alterative; possibly hastening the flow in the lymph channels, thus carrying infectious particles away more quickly. Gepner is satisfied that it is the hydrargyrum which is beneficial, because in two instances he used salt solution with no result; improvement began immediately after substitution of hydrargyrum.

Gutman condemns the method. He says it is not only painful and gives no good results, but often works positive injury. He characterizes Darier's work as insufficient and inaccurate. No one who has observed Darier will question his accuracy or sincerity. As to insufficiency, this is in a measure true, as Darier admits, but consider that under his hands, the work has gone on steadily since 1888, that Deutschmann has made some 2,000 injections, that between Gepner, Peunow, Picunoff, Bergmeister, Schmidt-Rimpler and Grossman some three hundred cases and more are reported, and we must admit that it is not wholly an untried experiment.

Yet, Gutman, from the standpoint of experience gained in twelve cases, would sweep away this whole structure. Let us examine his own report, and we see that his results are better than his conclusion, and that they bear out the utility of this method. He obtained good results with iodine trichlorid; had he continued this remedy doubtless his results would have been better; at any rate we will await the results of his experiments with NaCl. solution and trust they will be more extensive, and that he will come to modify his former opinions.

Gallenga found that corneal ulcerations artificially produced in rabbits' eyes were quickly healed by subconjunctival injection. This, Muttermilch declares is without significance, as such heal quickly when nothing is done, and were it really due to hydrargyrum, he might have obtained equally good results from simple instillation.

According to Muttermilch, "Should one use this treatment for sympathetic ophthalmia, one would make the double mistake of using an innocuous means against a microorganism which does not exist (proceeding from the standpoint of Deutschmann), for he says the microbial theory is not alone not proven, but every pathologic and physiologic experiment, as well clinical experience, is against such a theory. In reference to the two cases myopic choroido-retinitis reported by Gepner as benefited, he is of the opinion that the rest which the patients obtained in the hospital would have done the same. As to prevention of post-operative purulent infection, he has the greatest doubts, for we know even without this new treatment few wounds now suppurate, and that it is rare for iritis to be transformed into irido-choroiditis." In these latter he is in a measure correct, but when purulent infection does start often sad havoc is caused before its progress is checked, and it is right to be on the safe side. We know Jaeger and Arlt had a percentage reaching 95 and 97 in their cataract extractions in pre-aseptic days. Does this release us to-day from taking the most stringent precautions? As a matter of fact, his whole criticism is based on an experience gained in three cases: One ulcer serpens cum hypopyon, one kerato-iritis traumatica and one of ophthalmia sympathetica. In his ulcer serpens case he ruptured the cornea, most likely because he did not observe the rule not to inject too near the limbus, and in the other two he desisted on account of pain. He further attributes many of the reported cures to suggestion. The pain induced and a glance at the list of cases reported cured by this treatment is sufficient to negative any such theory. A criticism based on so wide (*sic*) an experience can hardly be upheld in the face of so much positive clinical proof to the contrary. My own personal experience was gained from seven cases.

*Case 1.*—Hypopyon keratitis; J. S., 20; recent injury, his anterior chamber one-fifth full of pus; marked photophobia; much ciliary pain; lachrymal ducts normal. Typical case. Patient has been under atropin, pressure bandage and iodiform treatment for sixteen days; is worse and in more pain. Under these circumstances injected one portion of a Pravaz syringe full cyanid of mercury (1-3000); continued the pressure bandage. Next day hypopyon had decreased and he had the first night's sleep since his present illness began. Four days later repeated the injection and four days thereafter the third, when ulcer was covered with epithelium and case went on to recovery under simple bandage.

*Case 2.*—April 2, 1894, M. L., age 26. Keratitis ulcerativa cum hypopyon. Typical case, in a very much reduced individual. Resulted from having baby stick finger-nail into cornea. Case progressing very unfavorably for eighteen days. Hypopyon beginning; whole cornea cloudy; injection of cyanid on April 20, followed by three more at intervals of five days. Recovery began from the first injection. Cloudiness clearing up from day to day. Cure with small peripheral macula of cornea.

*Case 3.*—J. W. Had had several attacks of iritis in each eye; no luetic history; both irides bound down by many adhesions, the right one almost completely. Could allay pain and inflammation, but could not break up synechia, so performed iridectomy on right eye. Was told to return immediately if any symptoms of trouble in left eye. In six months some exposure brought on another attack of iritis. In the face of his old synechia I feared a total occlusion and offered the alternative of iridectomy or subconjunctival injections. The latter was

accepted, and as result of four injections the old adhesions yielded to the atropia and his pupil is now round.

*Case 4.*—Keratitis punctata. W. T., aged 30. Typical case of acquired luetic keratitis punctata. Had been under care some three weeks and was progressing very slowly. Suggested subconjunctival injections, which were accepted. After five injections at intervals of five or six days, patient could return to work. In this case I can only claim that the injections hastened the progress, as it was beginning to show signs of recovery when I began.

*Cases 5 and 6* were cases of optic nerve trouble. One, H. J., positive luetic history. Came when vision of right eye was reduced to light perceptions, of left eye to counting fingers at 6 m. Field of vision narrowed and contracted; color sense also very defective for blues and greens. Typical atrophic discs in both eyes, showing lamina cribrosa. After routine treatment had been instituted for more than six weeks, subconjunctival injections to the number of twelve were administered, but, except for a light transitory improvement, to no avail.

*Case 6.*—Typical tobacco amblyopia, in which cure was hastened by seven injections and the length of treatment reduced to six weeks.

*Case 7.*—Is a case of old choroiditis disseminata in left eye, with total loss of vision, and detachment of retina in right. This case is being treated with iodine trichlorid and result will only be known in the future.

Let us now turn to special indications for the employment of subconjunctival medications and see when and by whom they are endorsed.

In keratitis parenchymatosa general treatment is the first and most constant indication. Above all hypodermic injection of sublimate, not neglecting atropin, warm compresses, etc. Special indications calling for subconjunctival injections are keratitis benigna, keratitis circumscripta, keratitis atonica or at least with a very moderate reaction; here the results are absolutely marvelous; with each injection one often sees the gradual recession of the area of infiltration. When limited to the center of the cornea massage with lanolin ointment of mercury produces active resorption of old maculae. (This I have tried in a number of cases with most excellent results.) At the period of decline, when the bulbar conjunctiva has regained its normal state, these injections will often clear up in a few days what would otherwise have taken months. In the acute, violent pannus of keratitis parenchymatosa all local irritating treatment is absolutely contraindicated, and this is also true wherever there is stasis of the ocular circulation.

Deutschmann and Zossenheim (Beitraege zur Augenh. XV, 1894) agree "that we can often shorten the treatment to four weeks, while it usually takes twice or thrice as long."

Gepner would expect good results, though must acknowledge one of nine cases was cured, the other eight merely benefited.

Peunow treated twenty-three cases with good results, best however in those of specific origin.

Picounoff treated between twenty and thirty; commends treatment under above conditions.

Veasey treated two cases. Cured one, stopped treatment of the other on account of pain.

Abadie endorses all Darier says in this regard.

Chibret, Mellinger and Gosetti have used the method and approved of it.

Motais was "impressed by the rapidity of recovery."

Gerasimos Materangos treated a number of cases of traumatic and infectious keratitis in conjunction with general treatment, best results.

Schmidt-Rimpler treated nine cases, and does not recommend.

Haab, ten cases, no result.

*Keratitis ulcerativa cum hypopyon.*—Its utility is

here questioned because it has not been applied with sufficient discernment.

In mild cases, it will produce cures quicker than by the classic treatment. In those of average intensity the galvano-cautery to the edges of the ulcer is the first indication together with antiseptic dressing. In grave cases where the globe or cornea is threatened Saemisch incision or galvano-cautery, or both are necessary. Cure is hastened when followed by subconjunctival injections (five to ten divisions of the syringe) made as far as possible from the cornea and above all not under Tenon's capsule. In great hyperemia the artificial leech applied to temple helps.

Failure to observe these points produced rupture of cornea in Muttermilch's case. Any such formula as "ulcer of cornea, subconjunctival injections" will result in numerous failures, while observance of the above indications will hasten cure.

Gepner "employs it most frequently in ulcerative forms of keratitis and with best results."

Gagarin—"Good and rapid results up to the clearing of hypopyon; after this not much further improvement is noted."

Peunow—"Considerable help, but does not neglect routine treatment."

Veasey—"As good as other methods."

Abadie—"Highly extols."

Mellinger had brilliant results.

Bocchi—"First injection brought process to a halt."

Gosetti—"Very efficacious from the first injection." Grossman and Rogman and myself had excellent results.

Chibret—"Results doubtful."

Masselon—"Altogether negative."

Schmidt-Rimpler—In thirteen cases of ulcerative keratitis hypopyon. Good results in three. Questionable in eight. Two of simple ulcerative keratitis gave negative results. He thinks very little of it in this latter and hypopyon keratitis.

Deutschmann prefers galvano-cautery, which in his hands works surer and quicker.

In keratitis lymphatica, Darier, Doufer and Segondi coincide that the yellow ointment fills every indication except in grave cases, when the new method gives good results.

Coppez and Gallemaerts give preference in vascular keratitis to subconjunctival injection of potassium iodid solution.

In iritis the indications and the contraindications are very subtle. While in many the results are beneficial, in others it is not only useless, but positively harmful. Whenever iritis is lighted up with violence, and is accompanied by brisk reaction (deep pericorneal hyperemia, chemosis, photophobia, etc.) an energetic antiphlogistic treatment is the first indication in connection with general treatment of the proper character. Only after the violence has abated is subconjunctival injection indicated. Failure to observe this might provoke an aggravation of symptoms in an eye already inflamed, and is no doubt, the cause of much of the reproach heaped upon this method and the consequent ill success, whereas those who have instituted treatment in relatively benign cases, either at their beginning, their relapse or their decline have according to Darier obtained conclusive evidence of its efficacy, but in benign cases, the older methods are less annoying and often equally as satisfactory.

I coincide with Gepner, who finds its main indica-

tion in assisting to break up old iritic synechiæ, or in the very beginning of the malady, for as Zossenheim says it cures so quickly that complications have no chance to manifest themselves. It may be used with advantage according to both these men in occlusion of the pupil and where we find hypopyon in the anterior chamber. Peunow treated twenty-eight cases with good results. Picounoff also had the same uniformly good results in a large number of cases. Veasey seven cases, prompt and effectual results in all, as also in cases of chorio-retinitis.

Schmidt-Rimpler nine cases. Cured two cases of plastic iritis, other results divided as follows: One cured after thirteen injections; four relatively good results; two slightly benefited; he recommends further use of this method in iritis and irido-choroiditis.

Grossman, Alt and Mellinger also commend its use.

Bergmeister two cases. Both cured after the fourth injection.

Bocchi and Masselon do not recommend it in iritis.

*Irido-choroiditis.*—What applies to iritis applies with greater force in this. In a disease so difficult to treat and holding out such poor promise, we often proceed as though groping in the dark, for at times we see one of those eyes apparently quiescent, react with an extreme violence to the slightest local irritation. These are the cases in which we are often led to prematurely perform iridectomy.

With injections one is often surprised to observe not only amelioration, but at times cure, where one would not expect such. In certain grave cases, we are obliged to keep the patient under continuous treatment, often alternating between general and local, so as to give the patient a relative rest.

Grossman treated two cases with good results. Alt also reported success. Pflueger treated his cases with iodine trichlorid and reports: one case of serous iritis, result beneficial; in another no effect; in a third stopped on account of pain and increasing intra-ocular tension.

Matarangas—Good results in conjunction with general treatment.

Deutschmann—Iritis specifica, as well as non-specifica, this method was at its best. He uses no atropin. Posterior synechia disappeared, and in four to eight days the pupil was quite round, dilating and contracting freely and the eye quiet. Saw no recidives; completed the treatment with mercury internally.

*Choroiditis and retinitis.*—When structural lesions have occurred, it is impossible to speak of cure in the sense of complete restoration. Much can be done for those who seek our aid early, to avoid such destruction by active and prompt methods, among the foremost of which stand subconjunctival injections.

Often an appreciable effect is noted from the first or second injection, and again not until a great number have been made. In macular choroiditis before central vision has been irremediably destroyed, we can restore if not normal vision, at least bring a considerable amelioration, and in so short a time there can be no doubt of the relation of cause and effect. Darier claims favorable result in at least 25 per cent. of his cases, and in 10 per cent. a result which "I can call surprising."

Abadie claims its efficacy in all degrees of chronic chorio-retinitis. He condemns the use of potassium iodid alone or with mercury as manifestly injurious. Injections of pilocarpin had no effect except when due to myopia; certainly not in infectious forms. In obsti-

nate cases he uses subcutaneous injections in addition.

Venneman—Results excellent.

Grandclermont—Best effect in serious or desperate affections of middle (vascular) coats of the eye. Above all in irido-choroiditis.

Gepner—Improvement in many cases of chronic choroiditis. Decided in two cases of myopic choroiditis.

Peunow—Thirty-one cases choroiditis cured by these means.

Deutschmann—Especially good results in specific chorio-retinitis. In non-specific choroiditis best results from potassium iodid kept up for months.

Schmidt-Rimpler—One good result in choroiditis; two doubtful in chorio-retinitis; thinks this is one of the conditions in which it is worthy of further trial.

Bergmeister—Not specially praiseworthy but recommends further trial.

Alt—Good results in choroiditis exudativa and centralis.

Bocchi—No specially good results; in this he is sustained by Masselon, Lacquer, Dianoux.

Bull—Positive effect in allaying severity of symptoms, and shortening the duration of acute irido-choroiditis non-specifica.

Seggel reports a cure in irido-cyclitis.

*Optic Nerve.*—Darier says in all infectious inflammations of the nerve, results are encouraging often after classic treatment proves unavailing. In retro-bulbar neuritis often excellent results, though in hereditary form we secure neither better nor worse results than by other means. Does not include tobacco and alcoholic amblyopia which tend to recovery *sublata causa*. Where actual atrophy of nerve fibers has set in it is useless to expect results. In retro-bulbar neuritis of rheumatic (?) origin, better results than by salicylates or mercury.

In compression neurites, obtained very rapid cure. In specific neuritis, and in one secondary to chorio-retinitis greater amelioration than by old method.

We may expect good results in recent infectious inflammations.

"No results to be expected in gray atrophy of tabes, in white atrophy following old inflammatory processes occasionally a slow increase of vision is manifest, but generally only transient."

Grossman, De Wecker, Lindsay Johnson and Matarangas corroborate these opinions. Deutschmann's results negative in every case. In commenting on this in his journal, Hirschberg reports a good result in chronic optic neuritis, also in one of recent origin.

In sympathetic ophthalmia, Darier found subconjunctival injections available in a number of cases characterized by uveitis.

Abadie says: If the injury is not so serious as to preclude all possibility of recovery, the surface of the wound should be touched with the galvano-cautery, and hydrargyrum bichlorid injected under the conjunctiva. It is often thus possible to arrest sympathetic ophthalmia already declared in the other eye, but if the traumatism is such that there is no hope of saving, or if disorder continues in spite of all these means, we should enucleate the offending eye. The other one will be benefited by the injections. Personally, I should hesitate to temporize with an injured eye which is likely to cause sympathetic ophthalmia. We all know how many such eyes may remain quiescent for as long as fifteen or twenty years, to suddenly light up inflammation in the other eye.

Gosetti reports remarkable success in a severe and recurrent case.

Deutschmann also reports good results in a number of cases.

Picounoff especially recommends it, here, where we can usually avoid enucleation.

In *scleritis* De Schweinitz, Bull, Veasey and others report some good results among a number of negative ones.

Many, Abadie and Coppez among the number, declare that they have thus avoided panophthalmitis in many cases of cataract and iridectomy operations, and indeed have checked the disease when it had actually begun. Rogman corroborates this latter statement.

Gepner says he resorts to subconjunctival injections in all cases of serious injury where there is still hope of saving the globe, for two reasons: 1, because we can not foretell where we have wound infection before we see our patient; 2, because in every deep injury we can not foretell whether sympathetic ophthalmia will result. Germicidal agents in the lymph channels lessen that danger. Seggel reports cure of suppuration of vitreous after cataract extraction, one case of threatened destruction of the whole cornea and vitreous from infected wound with prolapsed iris, and also cure of a case of orbital phlegmon.

Deutschmann says: "As a preventive of post-operative infection it is of a special utility. Cases that usually resulted in loss of the eye were by this means saved useful vision." In this he is upheld by Gepner and others. He further says: "We can not compare results of experiments made on animals to clinical results in man. In animals large deposits are at once introduced into the eye, which condition bears no relation to that in post-operative infection."

#### DISCUSSION.

DR. G. E. DE SCHWEINITZ, Philadelphia—I have used the subconjunctival injections since 1892 and also advised my chief of clinic, Dr. C. A. Veasey, whose results have been quoted, to employ them. My experience is that exactly the same results are obtained whether the bichlorid of mercury or the physiologic salt solution is used, each being equally efficient in suitable cases. I have secured good results in iritis, no matter what its type, provided there is no high inflammatory action. Good results were also obtained in episcleritis and some types of keratitis. I have failed, however, to secure good results in corneal ulcers and in diseases of the deeper coats, *e.g.*, choroïditis. I would call attention to the promptness with which these injections, either salt or mercuric, relieve pain and advance resolution in certain cases of inflammatory disease of the iris and episcleritis, but would also suggest that a relapse is more likely to occur than when ordinary constitutional measures are thoroughly employed. I believe that subconjunctival injections deserve a permanent place in ophthalmic therapeutics, but not to the exclusion of constitutional measures.

*Case 1.*—A. M., a male Italian, about 40 years of age, presented himself at the eye dispensary of the Jefferson hospital for treatment of sore eyes. Upon examination he was found to have a double syphilitic iritis, plastic in character, the initial lesion having been present four months. There were present the usual symptoms of marked pericorneal injection, intense pain, photophobia, lachrymation and a contracted pupil with posterior synechia, these symptoms having been present, according to the patient's statement, for four days. In the right eye the iris is attached to the lens capsule by its entire pupillary border, except a small portion in the upper and outer quadrant, this being the only part that would dilate with atropin. The media were hazy, and there was an indistinct view of the fundus which showed an oval disc, with rather large veins, filled with dark blood, but there were no gross lesions. In the

left eye there was also almost complete annular attachment of the iris, there being a small free portion on the temporal side, while the ocular fundus presented practically the same appearance as the other eye. His vision was 10-200 in each eye. Atropin was instilled for twenty-four hours without any improvement in the pain, and with very limited dilatation in the pupils. He was then given a subconjunctival injection of mercuric chlorid (5 minims of a 1 to 2,000 solution) in one eye, and a subconjunctival injection of sodium chlorid (2 to 10 of a 1 per cent. solution) in the other eye, and returned on the following day with the pupils dilated ad maximum, the pain entirely gone, and said that he had spent the night free from pain, the first for about a week. There was absolutely no difference to be detected between the effect on the two eyes. This treatment was continued, he being given an injection of mercuric chlorid in one eye and sodium chlorid in the other, at intervals of two or three days, until he had received five injections of each, no other medication being employed except the solution of atropin. At the expiration of this time the pupils were completely dilated, there had been no pain since the first injection, and it was impossible to say that there had been the slightest difference in the results of the two solutions. His vision was 20-30 in each eye, there being some pigment on the capsule of the lens where the iris had been attached.

*Case 2.*—C. B., a male, aged 35 years, came to the eye dispensary of the Jefferson Medical College Hospital complaining of sore eyes that had been present for two days. Upon examination he was found to have a syphilitic plastic iritis in the right eye, the initial lesion having been present about six months. There was a small synechia up and out, the vision was 20-100 and there were the usual symptoms of the disease present. In the other eye there was a slight conjunctivitis, the vision being 20-20. He was suffering from severe pain and was given an injection beneath the conjunctiva of the solution of sodium chlorid; atropin was instilled into the eye, and he returned on the following day entirely free from pain, the pupil dilated, the peri-corneal injection much less and the photophobia less severe. He was given similar injections on alternate days until he had had four, no other treatment being employed beyond the instillation of the atropin solution, when the inflammatory condition of the eye had entirely disappeared. No difference could be observed between the promptness with which the disease yielded to the injections of sodium chlorid and the promptness with which other cases had yielded to the injections of mercuric chlorid. The vision in this case returned to the normal.

*Case 3.*—H. F., male, aged 31 years, consulted me in February of this year for a rheumatic iritis. There was no specific history, and he had had several attacks of the same character before, each time being treated by a competent ophthalmic surgeon who had pronounced it rheumatic in character and relieving it each time by the use of the salicylates, in addition to other treatment. The pain was intense, and desiring to see what effect an injection of salt solution would have, one was made at once, and other treatment, excepting the instillation of atropin, withheld. On the next day he returned with a complete cessation of pain, except when exposed to bright light, the pupil entirely dilated and a marked reduction in the inflammatory condition. He was given five other injections, after which the iritis was practically well, when he was placed on the anti-rheumatic treatment. Other cases of iritis, syphilitic or rheumatic, treated by myself with injections beneath the conjunctiva of mercuric chlorid, have not shown any advantage over the injections of the solution of sodium chlorid. Indeed, it is my experience that the latter causes less pain, and relieves the pain of the iritis just as speedily, if not more so, than the injections of the mercuric chlorid.

DR. G. C. SAVAGE, Nashville—I have used only the bichlorid, but found it too painful. When opportunity offers I shall use the cyanid of mercury. I wish to condemn the practice of not using atropin in iritis, although subconjunctival injections of cyanid of mercury may be capable of accomplishing much. Atropin should never be omitted in the treatment of iritis, whatever else may be done. I want to go on record as believing that it would be a grave error to neglect bringing the iris under the influence of atropin, whoever may recommend to the contrary.

DR. D. S. REYNOLDS, Louisville—I am not persuaded that any local method of treating iritis, except the persistent use of an efficient mydriatic, has ever accomplished any desirable result. The subconjunctival injection of a solution of chlorid of sodium in cases of synechia following iritis from all causes

is undoubtedly valuable, but I should certainly avoid the use of any subconjunctival injections during the active stages of any form of iritis.

DR. A. W. STIRLING, Atlanta—I watched the use of this method in a fair number of cases in London and Paris and have tried it myself, but gave it up because it was so painful. It will not take precedence over the older methods.

DR. A. R. BAKER, Cleveland—Having used the strong solutions of bichlorid of mercury and found the injections painful, I estimated the amount of mercury which would reach the eye from a subcutaneous injection as generally used, and determined that a much weaker solution would probably prove efficient, I tried a 1 to 10,000 solution with excellent results in a large number of cases, notably interstitial keratitis and central choroiditis. The injections were never painful and the results appeared as good as from the stronger solution. In private practice it has been found necessary to combine its use with the accepted methods of treatment, but with more rapid recovery than when its use is omitted.

DR. DUNBAR ROY, Atlanta—I use the method largely in my clinic, where the patients consist largely of the colored race, who have a great deal of corneal trouble. In ulcers of the cornea I have had good results, but no better than when I use hot fomentations and iodoform. In post-suppurative trouble and panophthalmitis and in cases of suppurative iritis I have used it with success. I have used 1 to 1,000 bichlorid with an ordinary hypodermic needle, sterilizing both the instrument and the field before the operation. In iritis I have not seen adhesions break up and have had no results in choroiditis, but my experience leads me to say that in ulcerative and suppurative forms of conjunctivitis or keratitis the results are as good as those obtained by other methods.

DR. E. J. BERNSTEIN—I have no experience as yet with relapses, but one must not forget that neither atropin nor general treatment are to be neglected in iritis. As to pain, my patients had none, or very little, as the result of subconjunctival injections. I am now treating a case of detachment of the retina by this means without much hope of cure, but because no other treatment has availed. I believe no one should follow Abadie in not using atropin in iritis. I should hesitate too implicitly to follow his lead. In phlyctenular keratitis I should not think of using this method, as I believe most men agree that the yellow ointment is all that is needed.

## EXTRA-DURAL ABSCESS FROM MASTOID EMPYEMIA.

Read in the Section on Laryngology and Otology at the Forty-seventh Annual Meeting of the American Medical Association held at Atlanta, Ga., May 5-8, 1896.

BY B. ALEXANDER RANDALL, M.D.

PHILADELPHIA, PA.

When the presence of a "mastoid abscess," declared by the occurrence of a fluctuating collection of pus on the surface of the skull behind the ear, only caused the surgeon to incise and evacuate the abscess, we heard little of extra-dural or cerebral abscess except as a curiosity of the postmortem room. Even when the farther step of opening the mastoid became more common, it was so often merely in the interest of better evacuation and drainage that exploration for the remoter extensions of the lesions was rare. It is only since we have more generally adopted the idea urged by all experienced operators, that every possible trace of the pathologic condition shall be extirpated at the operation in the effort to secure immediate cure, that the relative frequency of extra-dural abscess has been recognized. The earlier operators looked upon the middle cerebral fossa and the sigmoid sulcus as regions dangerous to approach, and perhaps held

their hands as they followed some purulent track lest it should lead them into these dreaded cavities. The impetuous entered them oftener than they meant, and the careless oftener than they knew, while the careful and conscientious surgeon was gradually learning the innocuous and beneficent effect of hunting down the disease even into these and deeper regions. With the abandonment of the trephine and drill in favor of the gouge and spoon, much of this fear has died a natural death. There is less chance of unintentionally and blindly penetrating the inner table of the mastoid and wounding or infecting the important structures within. Mastoid anatomy is being better learned and the rule has grown more common to operate in each case as though the relations were the most disadvantageous possible, and to assume no safety that has not been demonstrated. And with this knowledge that the middle lobe of the brain may extend down as low as the upper margin of the meatus and the lateral sinus be separated by hardly a film of bone from the back wall of the canal or the mastoid surface at the usual point of attack, there has grown a proper confidence in the wisdom of opening the intracranial cavity in appropriate cases. It should always count as a bungling step when accidentally these cavities are opened, or an officious one when needless; but the futility of half measures grows more evident with experience. One who formerly looked askance at the radical procedures and views of Schwartze and others who chisel open the mastoid in scores of cases yearly, finds his tendency to follow this lead to be limited principally by his lack of a like material. And since the grippe epidemics few of large aural practice but have had growing opportunities to learn the need of such measures.

We can no longer look upon "mastoid trephining" (as we may still call the operation whether done with chisel, burr or spoon) as permissible only as a life-saving step; nor can we rest content to leave to long after-treatment the completion of the cure which might have been more safely as well as more quickly secured by more heroic thoroughness. It is to be hoped that American aural surgeons will continue truly conservative in their choice of cases, methods and efforts after thoroughness, eliminating all cases that might be cured by less radical procedures and sacrificing to brilliancy of immediate result no function that patience might have saved; but it is also to be hoped that they will give little basis to the charge sometimes made by the surgeon, that they are too timid in their work and shrink from doing their full duty when half measures are insufficient.

The past decade has seen the publication of hundreds of cases in which there has been extension of caries from the tympanic inflammation to the dural surface of the temporal bone, with pachy-meningitis and outpouring of pus between the bone and dura. In itself it constitutes no great menace to life, and the prognosis after drainage is generally excellent. So little may be the head symptoms caused by it that its presence is a total surprise to the operator; and one marvels that lesions so extensive may be wholly undeclared by the usual signs.

Surprisingly innocuous as the extra-dural abscess has generally proved if drained outward by nature or art, the story is wholly different in no small group of cases. Most of the thrombotic lesions of lateral, petrosal or cavernous sinus have been secondary to extra-dural abscess. Many cerebral and cerebellar

abscesses are due to the previous existence of pus outside of the dura. Raised here above the normal level, the dura may present no visible farther disturbance in the form of injection, etc.; yet the overlying brain is apt to show a discolored depression with pial injection and commencing softening. Again there is ulceration of the dura with rupture of the pus either into the arachnoid space or through the agglutinated tissue into the brain substance. In other cases the exact path of the process can not be traced; yet the extra-dural abscess must be held responsible for the serious or fatal occurrence.

It is no new matter to point out the dangers of acute or chronic aural suppuration in these directions, although the importance can never be overstated in any truthful setting forth of the matter. It is not so generally known how rapid the process may be. A good illustration was met last year when a boy came to me with mastoid abscess, supervening upon a light blow on his chronically suppurating right ear. Nausea and general malaise immediately followed and persisted in less degree on the fifth day, when I first saw him. No changes were visible in the eye-grounds to suggest intra-cranial involvement; but fever was marked and operation promptly needed. This could not be carried out until the second day following, when the very hard mastoid was very freely chiseled open, all carious bone in the antrum and adjacent cells curetted away and smooth, firm walls left toward the middle and posterior cerebral cavities. His fever fell, to rise again almost immediately; pleurisy and then pulmonary inflammation quickly declared themselves, and he died on the sixth day after operation. Autopsy showed a septic pleurisy and pulmonary abscesses; while in the cranium a cerebellar abscess as large as a plum ruptured on removing the brain, at the point where it was adherent to the sub-dural collection which extended backward from the tegmen down upon the posterior aspect of the petrous. Section of the bone showed no microscopic connection of the intra-cranial collections with the tympanic spaces—the intervening bone being firm and intact, if not healthy. The nearly total destruction of the ossicles marked the otorrhea as of long standing; but all the other lesions had probably developed within the thirteen days after the aggravating blow. The parietal lobe, where it rested on the subdural collection was injected, depressed and softened and would doubtless in a few days have been the site of a cerebral abscess.

Numerous other instances have come to my knowledge, sometimes only on the postmortem table, rarely, I am glad to say, in my own patients. Of some thirty whose mastoids I have opened in the past year, nearly one-third have had caries which compelled me to uncover the dura, and in a number of them the granulations upon its surface, if not the gush of pus as it was exposed, revealed the fact that it had been separated from the bone by a layer of pus. In several cases what seemed at the time a complete operation left bone of too little vitality behind and a later operation had to be carried still farther under the dura; and in one there was death, probably from a cerebellar abscess which could not be found.

Doubtless other aural surgeons are meeting the same experience as myself in these directions and find their field extending inward deeper than they can cheerfully follow. The dangers and difficulties of brain surgery can try the stoutest heart and may

well appall the beginner. But we should not forget that the general surgeon has only recently entered this field and that his bravery is sometimes foolhardiness. No one should better know the territory to be invaded than the aural surgeon, who must often guide the hands that he has called in to wield his instruments. And if he does not feel equal to meet the exigencies of such intra-cranial work when first he encounters it, he will not generally be doing his full duty if he does not utilize every opportunity to master the technique of head surgery on the cadaver and on the living, and be prepared to act for himself unless a distinctly better man is at his side.

### PRIMARY INFLAMMATION AND ABSCESS OF THE MASTOID; REPORT OF CASE.

Read in the Section on Laryngology and Otolaryngology, at the Forty-seventh Annual Meeting of the American Medical Association, held at Atlanta, Ga., May 5-8, 1896.

BY DUNBAR ROY, A.B., M.D.

PROFESSOR OF OPHTHALMOLOGY AND OTOLARYNGOLOGY IN SOUTHERN MEDICAL COLLEGE.  
ATLANTA, GA.

Cases of the above pathologic condition are by no means frequent, hence my apology for presenting the following:

Mary H., colored, age 10 months, was brought to my clinic at the Southern Medical College on account of a swelling behind the left ear, which the mother said had been forming for the last five or six days. To all outward appearances the child presented a fairly healthy and nourished condition. The mother was very positive in her assertions that there had been no discharge at any time from the auditory canal. She was a strong, healthy woman, and with the exception of enlarged post-cervical glands, no abnormal condition could be found. The child presented numerous glandular enlargements over various parts of the body besides a well-marked case of "snuffles." No history of tuberculosis or syphilis in the family could be ascertained from the mother, as all the other children were healthy and the father could not be seen.

Nothing is more uncertain, however, than the histories usually obtained from the negro race, so that I rarely place any confidence whatever in their statements.

The child was very fretful, especially when the region of the left ear was touched. Behind the auricle and over the mastoid a distinct fluctuating tumor could be diagnosed. The auditory canal was freely patulous with no moisture upon its wall or any signs of a previous discharge such as a smooth, hardened condition of the dermoid layer. The drum membrane was clear and of normal reflex, showing absolutely nothing pathologic. The temperature was practically normal, which still further strengthened the diagnosis of the abscess being syphilitic or tubercular in its origin.

The treatment consisted of a thorough evacuation of the abscess by incision, followed with a curetting of the mastoid cells which communicated with the abscess superficially and which was undergoing a disintegrating process, packing the wound with iodoform gauze, and securing the whole with a protective bandage. Internally the child was put upon syrup ferri iodidi 5 m. three times daily. Under this treatment the wound healed perfectly in ten days, there was no rise of temperature and the child's general health was much improved.

Six months after the patient was again brought to the clinic with an abscess behind the right ear similar in all respects to the one which had occurred behind the left. The history was about the same as previously and absolutely no inflammatory signs could be seen in the auditory canal or upon the drum, nor any signs of a previous discharge. The treatment was the same with excellent results. Since that time the mother reports that the child has much improved and there has been no further trouble with the ears.

Perhaps no single bone in the body, if it may be so called, has received the attention from surgeons and anatomists in the last few years as the temporal bone, and especially that portion of it known as the mastoid. And justly has it deserved this attention on account of the frequency with which it is involved in all severe inflammations of the tympanic cavity, and its importance often in the future life of the patient. In inflammations of the tympanic cavity it is impossible to conceive of an absolute freedom on the part of the interior of the mastoid from the same inflammatory congestion on account of the close proximity and contiguity of the mucous lining. This participation of the mastoid in the inflammatory process of the tympanum may not always be recognized by objective signs, nay, even by the subjective symptoms, yet pathologic anatomy and operative procedures teach us that the interior of the mastoid did become affected simultaneously with this inflammation in the middle ear as is recognized by the obliteration of the pneumatic cells and hyperplastic condition of the antral mucous membrane. For instance, Zuckerkandl, in the examination of 250 temporal bones, found only 36.8 per cent. of the mastoids pneumatic throughout, in 43.2 per cent. he found the same partly diploetic and partly pneumatic, while in 20 per cent. of the total the mastoid presented fatty degeneration, diploetic or sclerosed condition of the bone substance itself.

So it happens that one can readily trace the origin of a mastoiditis or a mastoid abscess when there has been previously or at the same time a severe purulent otitis media, but when a mastoid abscess exists without any discoverable involvement of the tympanic cavity, the etiology is more obscure. Cases of primary mastoiditis or abscess of the mastoid are among the rarities, yet such cases have been reported and for this reason are never without interest.

When I say *primary* I mean an inflammation or an abscess originating in and confined exclusively to the mastoid process, when no inflammatory signs are discernible in the tympanic cavity either at the present time or any time previous which could give the existing process a causal dependence.

Politzer in his last most excellent text-book speaks of primary inflammation of the mastoid as among the rarest affections in aural disease. He divides the inflammation in this region as being limited either to the periosteum or to the pneumatic cells of the mastoid bone proper.

Primary periostitis is extremely rare and is observed more frequently among adults than among children. Such cases have been reported by Voltolini, Blake, Knapp, Jacobi, Turnbull, Swan Burnett, Hotz and Kirchner.

Dench, in his late text-book, speaks only of *primary mastoiditis* without any subdivision, as does also Blake in Burnett's System of Diseases of the Ear, while Politzer makes the more minute subdivision as stated above.

According to this latter author the most frequent causes of periostitis are cold and trauma, while occasionally no cause whatever can be discovered. The usual course and termination of this process is either for inflammation to reach its height in a few days, and the infiltrate be reabsorbed without pus forming or an abscess results with spontaneous bursting through the walls into the antrum, as observed by Roosa and Ely, Webster, Knapp and others, or the pus may find its way into the auditory canals as in a case reported by Burnett, or finally the inflammatory process may produce a painless carious condition of the superficial lamellæ of the mastoid to be thrown off with the evacuation of the abscess. The same author also recognizes a condition of primary abscess of the mastoid, and in addition to the causes already given mentions syphilis, but fails to mention tuberculosis, which must certainly be placed in this category.

Knapp has reported a case of "primary tuberculosis of the mastoid," where there was an abscess of the mastoid while both the canals and tympanic membrane presented a normal appearance. This writer in quoting Schwartz, who says that primary otitis and especially primary tuberculosis of the mastoid process is extremely rare, declares that "this assertion may be true in general, but on the other hand as far as bone tuberculosis of the temporal is concerned the rarity with which we diagnose this affection may be owing to the omission of special bacteriologic examinations of carious bones of the ears."

To my mind it would certainly be very difficult to tell whether the abscess thus discovered over the mastoid originated in the periosteum or in the bone proper, especially when upon opening the abscess you find the bone substance itself involved. In very young children, like the case reported by me, the communication between the antrum and the overlying superficial surface is much more pronounced than in adults on account of the semi-embryonic condition of the bone substance; hence in such cases it is almost a matter of impossibility to tell whether the abscess is of superficial or of deep origin. In the newborn, according to Hartman and Bezold, the mastoid process is a mere shell surrounding a large antrum, which shows the ease with which the walls would be broken.

My observation and opinion is that in primary inflammation limited entirely to the congestive period, its origin is most frequently in the periosteum; while in abscesses, especially those not manifesting any severe inflammatory swelling over the mastoid cells, I am in full accord with Clarence Blake who says that primary mastoiditis is exceedingly rare, and is usually the result of injury or exposure to cold, or may occur in the course of syphilitic diseases and, I may add tuberculosis. He believes that in the reported cases there has existed, some time prior to its appearance, an inflammation of the tympanic cavity. Yet it is conceivable, where the system is thoroughly impregnated with a specific poison, whether congenital or acquired, that there might be a primary mastoiditis just as an otitis is liable under the same conditions to occur in any other portion of the body. I believe that all primary mastoid abscesses are nothing more than an otitis the result of either syphilis or tuberculosis, and by close examination the histories will bear out this conclusion.

There is one especial point which I have noted in mastoiditis in children, and that is where the abscess

is due to syphilitic or tubercular otitis, the temperature has always been practically normal, while in those cases where the cause has been an extension of the inflammatory process from the middle ear to the mastoid cells, the temperature is usually elevated above the normal at some time during the inflammatory process.

Before closing I wish to mention similar cases which have been published by three American confrères: S. C. Ayers of Cincinnati has reported two cases of the so-called primary abscesses, but admits that there had previously existed an otorrhea, which to my mind excludes these from the cases of primary mastoiditis. Würdemann of Milwaukee has also reported two cases which were thoroughly cured by means of incision and packing. Connor of Detroit reports a case in a child 10 years of age. The drum presented a perfectly normal appearance, and there was no history of a previous discharge. The abscess was thoroughly opened, parts curetted with the final result of perfect healing.

In studying the literature of these cases my conclusions are as follows:

1. Primary abscess of the mastoid is more common than a periostitis.
2. That this pathologic condition is more frequent in children than in adults.
3. The most common causes are syphilis and tuberculosis, and the latter is much more frequent than the text-books would lead us to believe.
4. That the prognosis is nearly always favorable, and a full restoration of the parts is the usual result.

### CEREBRAL DISEASE FOLLOWING MIDDLE EAR SUPPURATION.

Read in the Section on Laryngology and Otology, at the Forty-seventh Annual Meeting of the American Medical Association, at Atlanta, Ga., May 5-8, 1896.

BY M. D. LEDERMAN, M.D.

LECTURER ON DISEASES OF THE NOSE AND THROAT, NEW YORK POLYCLINIC; ATTENDING AURAL SURGEON UNIVERSITY MEDICAL COLLEGE DISPENSARY; ASSISTANT AURAL SURGEON MANHATTAN EYE AND EAR HOSPITAL, ETC. NEW YORK.

Having lately observed three instances of fatal cerebral complications occurring in individuals suffering from suppurative disease of the middle ear, I accept this opportunity of narrating their histories, hoping they may prove of some interest.

When we recall the anatomic arrangement of this cavity, we are impressed with its immediate proximity to vital structures. The partition that separates the middle ear from the brain and its coverings, is but a thin portion of bone, with no diploe. Having little or no illumination, but being sufficiently supplied with heat and moisture, the middle chamber is an ideal incubator for the propagation of pathogenic microorganisms. Diseases of a suppurative character affecting this locality, have many factors to augment their vitality, but comparatively little resistance to limit their spread. It requires no stretch of imagination to picture a purulent inflammation extending through the roof of the tympanic cavity, and attacking cerebral structures.

Observers agree to three forms of pyogenic intracranial invasion arising from middle ear suppuration, *i. e.*, brain abscess, meningitis, and sinus thrombosis. According to Koerner,<sup>1</sup> almost all brain abscesses, originating from purulent aural disease, are situated near the primary collection of pus, in the ear or temporal bone. Jansen, however, could not discover an

extension of the disease from the temporal bone to the brain in any of the cases of abscess of the temporal lobe upon which he had operated, though the collections of pus were directly over the tegmen tympani. To reach them, the posterior and upper wall of the mastoid had to be removed. In 184 instances of intracranial involvement observed by Jansen, in three and a half years, at the Berlin Clinic, 148 were extra-dural abscesses, 35 were thrombosis of the lateral sinus, and only five were brain abscesses. In the extra-dural lesions, the purulent matter was more often found occupying the posterior cerebral fossa. He has observed that extra-dural abscesses are the most frequent complication of acute suppurative otitis media. In cases of doubtful diagnosis he recommends exploratory operations, and further remarks that deep seated collections of pus are best reached after removal of the entire posterior wall of the mastoid process.

It is not always a simple matter to differentially diagnose the presence of existing cerebral disease. When the abscess occupies the motor zone, the direct functional symptoms resulting, assist materially in arriving at a conclusion. If, however, this area is not involved, it requires careful observation to localize the seat of trouble. Picque<sup>1</sup> remarks, that a persistent cephalalgia, referred to a distinct region, with coma and slowing of the pulse, indicate cerebral suppuration. If the lesion points to an involvement of a motor zone, this locality should be trephined at first, and the mastoid opened later. If on the contrary, indistinct cerebral symptoms arise, the mastoid should be primarily attacked. Should the unpleasant symptoms still persist, further exploration must be carried out.

In endeavoring to illuminate the haze, which at times obscures a positive diagnosis in otitic-cerebral cases, a statement has been made that where bone conduction is present, the abscess is probably situated in the cerebrum; if the bone conduction is absent, the disease is presumptively in the cerebellum. This theory was deduced from the supposition that the pyogenic organisms reach the cerebellum by way of the internal ear. In this manner the infectious process spreading along the auditory nerve and its covering, abolishes bone conduction. Macewan<sup>2</sup> claims that as a rule, the cerebellar abscess arises from the disease extending from the sigmoid sinus, and not from the internal ear, so that the seventh and eighth nerves in the internal ear remain unaffected, and are capable of performing their function. If the mechanism of hearing is not disturbed, the auditory nerve will conduct sound both by air and bone, even though the cerebellar abscess exists. Should, however, the septic process extend to the cranial cavity through the internal ear, bone conduction may still be present. This fact was demonstrated by a case, reported by Macewan. In this patient auditory conduction was absent, but bone conduction was more acute on the affected side, than in the normal ear. Postmortem examination revealed extensive purulent leptomeningitis, chiefly marked in the posterior fossa, surrounding the right internal auditory meatus. The seventh and eighth nerves passing through the occluded internal auditory meatus, were swollen and compressed; while on the healthy side, the same nerves occupied only one-half of its caliber.

<sup>1</sup> Annals of Ophthal. et Otolaryng. Vol. IV. No. 4.

<sup>2</sup> British Med. Journal 1820-1895.

Both arial and bone conduction may be absent without being the result of cerebellar disease. This may occur if some affection of the auditory nerve previously existed. In such a case seen by Macewan, the brain lesion was found to be a cerebral abscess. From his observations he concludes that whether bone conduction be present or not, it is not a reliable sign in localizing the cerebral complication. These contradictory experiences clearly demonstrate that no symptom can be taken as a *vade mecum*.

Otitic-cerebral abscess is more apt to be the result of a prolonged suppuration and not of an acute affection. Eulenstein,<sup>3</sup> after collecting authenticated cases, could find but eighteen of brain abscess originating from acute disease of the temporal bone. To this number he adds one of his own, operated upon with a good result. In all these cases the cerebral disease was situated upon the side of the affected bone; the greater number being on the left. Koerner, on the other hand, found the right side to be most frequently attacked. In two of my cases the disease was on the right side. Of the eighteen cases above mentioned, thirteen abscesses were found in the temporo-sphenoidal lobes and four in the cerebellum; the situation of the other one is not given. Among the symptoms observed in connection with cerebral abscesses were: Irregular fever; persistent headache (being one of the most constant symptoms, due to intracranial pressure); retardation of pulse; choked disc; interference with speech (in the left-sided disease); paralysis (facial, hemiopia, ptosis, abducens on the same side). Other manifestations were, incontinence of urine, photophobia, increased tendon reflex, hemi-anesthesia and hyperesthesia. Eleven patients were operated upon. Of these, five died (two cerebellar, three temporo-sphenoidal); and six were successful (one cerebellar and five temporo-sphenoidal).

During past years there has existed a tendency to wait for pronounced symptoms before attempting to discover the cerebral complication. Clinic experience has shown us that temporizing under such circumstances is not only unjustifiable but frequently productive of fatal consequences. It matters not in what portion of the economy a septic focus exists, our efforts should be directed toward the prompt limitation of its activity. Accepting this axiomatic principle *pro vero* we should unhesitatingly attempt to check the stride of an infectious process when it has reached so vital a region. Under present antiseptic precautions, surgical treatment can be undertaken without much fear of external contamination. It is not my intention, however, to sanction hasty and premature operations in these cases, but rather to suggest the prompt employment of effective measures, when indications arise. Suppurative otitis media should not be treated (as is often the case) in a nonchalant manner. Its serious aspect should be vividly pictured to the patient, and the possibility of threatening dangers should be emphasized.

*Case 1.*—M. C., female, 8 years of age, had a chronic discharge from the ears for three years. Under local treatment the suppuration was checked and no further trouble was noticed. About two years after the cessation of the aural trouble the child fell and struck the back of the head with considerable force. At the time of the accident the child was unconscious, and on recovery complained of pain in the head. Three weeks elapsed before any further symptoms appeared. At this time the mother discovered that her daughter was not

feeling well and Dr. Charles Hoffman was called. As nothing definite could be found, the condition was treated symptomatically. Irregular temperature became apparent and some pain was complained of in the region of the left ear. Recalling the former otitic trouble, Dr. Hoffman asked me to see the case with him. No local signs of an inflammatory process could be seen. The temperature was 101 degrees F. rectum. No swelling or tenderness of the mastoid or jugular region existed at this time. Treatment was continued as before.

A few days later convulsive seizures together with a somnolent condition of the child was observed by Dr. Hoffman. Applications of ice were ordered to the head and neck. Drs. L. Weber, Hoffman and myself saw the case in consultation and agreed that meningitis existed, but that the character of the disease could not be definitely diagnosed. As no active ear symptoms were found at this visit, a tubercular manifestation was suspected. Temperature of a septic character persisted and the semi-stupor was rather more marked. Forty-eight hours after our consultation pressure over the mastoid revealed some tenderness. We decided to operate at once. The usual opening was made under ether. The cortical layer of the mastoid process was found sclerosed, but in chiseling more extensively some pus was discovered. The quantity evacuated was very little. Repeated hypodermic stimulation had to be given while the operation was in progress. The patient's serious condition at this time did not justify further exploration, so the wound was packed with iodoform gauze. On the following morning I trephined an opening into the middle cerebral fossa, three-quarters of an inch above the external auditory canal. The dura was bluish in color, but did not pulsate. A hypodermic needle was introduced and about a drachm of pus withdrawn. Two more buttons of bone were removed with the trephine, and the connecting bridges of bone were cut away with the rongeur. An incision was then made through the membrane, and fully three ounces of fetid pus escaped. Gentle antiseptic douching was carried out and the parts packed with gauze. As in the previous operation frequent subcutaneous stimulation was found necessary.

Paralysis of the right arm and leg had appeared. Pupils reacted to light in the evening of the day of the second operation. Coma continued, paralysis of the sphincters was observed, and on the following day dissolution occurred.

Case 1 is an illustration of the irregular course a temporo-sphenoidal abscess may run. Though previous ear trouble had existed, no symptoms pointed to this organ at the beginning of the fatal complication. The quantity of pus present in this cerebral abscess demonstrates that such a state of affairs may exist for some time without producing characteristic symptoms. It is possible that the traumatism in this case may have been an exciting factor. The question arises, whether we are justified in opening the mastoid process or cerebral cavity, in cases presenting a similar train of symptoms which give evidence of previous suppurative otitis media, though presenting no active manifestations.

*Case 2.*—F. M., aged 16 years, white, was admitted to the Manhattan Eye and Ear Hospital, Oct. 5, 1895, with the following history: For the past twelve months had chronic suppuration of the right ear, resulting from the measles. The discharge was not constant, but whenever it stopped severe pain set in, which ceased when drainage was reestablished. About three weeks before his appearance at the hospital, after an exposure, he was taken with severe pain over mastoid, in and around the ear. Pain had been constant since. At this time the external parts were considerably swollen and tender: temperature 100 degrees F.; pressure in front of tragus caused pus to flow freely. Under local treatment the patient progressed nicely until about 2 o'clock A. M., Oct. 6, 1895, when becoming delirious, he was then sent to the hospital.

Condition on admission: Delirious, restless and anxious expression. Temperature 104 F.; pulse 110. Right mastoid swollen; slight redness extending well down over neck. Marked tenderness over mastoid, front of ear. Decided pulsation in right cervical region. On slight manipulation with probe and cotton profuse offensive discharge came from ear. Meatus perforated in postero-inferior quadrant.

Patient was etherized and a mastoid operation done under strict antiseptic precautions. Small quantity of pus was found in cells. Wound cleansed with bichlorid solution and packed with iodoform gauze. Morphine hypodermic was necessary to quiet during night.

<sup>3</sup> Monat. für Ohrenheilk. 1895.

October 6. Very restless this A. M. Temperature 100 F., pulse 110; complains of sick stomach, but does not vomit; does not take nourishment.

October 7. Temperature 98 F., pulse 110; still restless; takes little nourishment.

October 8. Extremely restless; constant tendency to get out of bed. Temperature 99.6 F., pulse 110. Dressing removed. Considerable pus in canal and mastoid. Cleansed and irrigated with bichlorid solution, 1-10000; packed with gauze and bandaged, leaving external auditory canal exposed for douche, every two hours. Morphine to quiet; strychnin and spirits frumenti ordered to be given at the discretion of the house surgeon.

October 9. Still restless; temperature 100 F. Takes nourishment quite freely. Mastoid dressed as before. Wound clean and healing.

October 10. Temperature 98 F., pulse 110. Not quite so restless. Voids urine in bed.

October 11. Temperature 97 F., pulse 120; restless; no chills; stimulants increased.

October 12, 8:30 A. M. Some signs of left hemiplegia. Not so restless; breathing slightly stertorous; 9:30 A. M., will not take stimulants. Died with symptoms of compression at 12:15 P. M.

Postmortem examination showed an extensive cerebral abscess of the temporo-sphenoidal lobe. A large quantity of pus escaped after the dura was incised. Four finger tips could be readily introduced into the abscess cavity. The dura was thickened and on the cerebral surface of the tegmen a necrotic area was found. No involvement of the sinus was observed, the extension of the disease being by continuity of tissue, and not through the lymphatics.

On Oct. 11, 1895, the patient was doing so well, even though the temperature only registered 97 F., that further operative interference was contraindicated. Had an opening been made on this day into the middle cerebral fossa it certainly could not have saved the patient, as the disease had then assumed extensive proportions.

*Case 3.*—Phoebe B., deaf mute, 62 years of age, was referred to me at the Manhattan Eye and Ear Hospital, May 6, 1895, for mastoid operation, with the following history:

For past year has had pain in right ear, with scanty discharge. Three months ago, facial paralysis of right side occurred suddenly. The patient had been operated upon for aural polypi, which completely filled the external canal. There was a profuse and very offensive discharge from the right canal, which was somewhat benefited by the removal of the granulation tissue. These growths rapidly reappeared so that repeated attempts at their eradication had to be made.

On May 5 the mastoid process became boggy and very tender. Treatment failed to relieve the pain and swelling, so patient was turned over to me for operation.

May 6, 3 P. M. A Stacke operation was performed, together with the removal of almost the entire tip of the mastoid. The osseous destruction was very extensive, the dura being encountered on passing the probe upward. Thorough curetting of the posterior and inferior surfaces of the diseased tissue was carried out. Fearing perforation into cerebral cavity, gentle manipulation in the upper portion of the wound had to be observed.

May 7. Temperature 99.4 F. Patient doing well.

May 8. Temperature normal. Dressing removed. Some discharge from the canal which was not offensive. Otherwise wound clean. Packed as before and ordered cleansed with peroxid of hydrogen and corrosive sublimate solution.

May 11. Some slough on posterior wall of cavity. Discharge increased, with some odor. The slough was removed and Labarraque's solution ordered as a cleanser.

May 18. Improving; wound clean and rapidly filling. Temperature normal.

May 20. Granulations exuberant. Touched with caustic.

May 25. A small sinus was found on inner wall of cavity, filled with pus; probe showed necrotic bone. Sinus curetted, cleansed, and packed with gauze.

May 30. Improving; wound clean; slight odor from sinus.

June 9. Odor becoming offensive. Some débris curetted from the wound. Inability to move left arm and leg was noticed.

June 11. In the morning, a hemorrhage occurred from the mastoid, appearing through the ear, nose and throat, and saturating the dressings. 7 P. M. Severe hemorrhage through naso-pharynx. Post-nasal tampon applied. Source of bleeding could not be discovered.

June 12. Another hemorrhage, which was checked by tamponing mastoid opening. Hypodermic stimulation.

June 14. Patient gradually grew weaker from the loss of blood, and died at 6:30 P. M.

The autopsy revealed marked necrosis of the petromastoid portion of the temporal bone. The probe could be readily passed into the posterior and middle cerebral fossæ. Ulceration of the sinus was found to be the cause of the severe hemorrhage. Softening of the right temporo-sphenoidal lobe of the brain was recognized.

Owing to the congenital condition of the patient, subjective symptoms were not readily ascertained. There can be no doubt as to the chronic character of the destructive process, as the facial paralysis had occurred three months previous to the case coming under our observation. So extensive was the disease, that after the operation, a probe could be passed into the mastoid opening for a distance of almost two inches, measured from the external surface.

*Case 4.*—Though this case can not be positively classed as a cerebral involvement, nevertheless I mention its history for the purpose of emphasizing the difficulty we meet with at times, in arriving at a correct diagnosis.

James B., 34 years old, had scarlet fever twenty-five years ago, which resulted in a chronic suppurative otitis media, which has been more or less active ever since. During the past four years the discharge has been more profuse, and frequent attacks of severe pain have been experienced. Relief from the pain was noticed, whenever the discharge flowed freely. Blood was at times found in the discharge. On May 24, 1895, he was admitted to the Manhattan Eye and Ear Hospital, with intense pain in the left ear, from which a scanty flow of pus was observed. Some infiltration of the soft tissues of the external auditory canal existed. A small perforation in the postero-inferior quadrant could be seen on careful inspection. Anterior to tragus, the parts were tender, but no pain or swelling over mastoid.

*General condition.*—Patient is anemic, and seems to be suffering severely. Tongue heavily coated; bowels constipated; temperature 103 F.; pulse 140.

May 25. Bulging of membrane. Tympanum liberally incised. Hot douching every two hours, and boroglycerid tampons were ordered; also calomel, until bowels moved freely.

May 26. Slight improvement. Temperature 101 F. Some headache and pains in back of neck. Leeches applied. No definite conclusion could be reached.

May 30. Temperature still high. Gripping pains in bowels; calomel stopped. Marked tendency to constipation.

June 1. Great pain in back of neck. Temperature 102 F. Counter-irritation applied.

June 2. Pain somewhat less, but still present. Ice to neck ordered. Bromid was prescribed.

June 4. Considerable pain in neck. Peculiar discharge from bowels resembling that of enteric fever. Temperature 104 F. Our medical consultant examined the patient, and suspected thrombosis of the lateral sinus.

June 5. Chill lasting twenty minutes. Patient much exhausted. Strychnin and whisky freely administered. Temperature 104.2 F.

June 6. Chill lasting fifteen minutes. Quinin and fluid extract digitalis given continuously. Temperature 103 F. Dr. A. H. Smith advised surgical interference. At 8 P. M. I operated. Periosteum was detached from mastoid with great difficulty. The bone was found sclerosed throughout its entire extent. No pus was discovered. On opening into the lateral sinus, nothing abnormal was found. Sinus and mastoid were packed with iodoform gauze. During the operation patient received hypodermic injections of strychnin.

June 7. Recovered nicely from operation.

June 9. Symptoms of abscess of liver appeared, with great exhaustion.

June 12. Temperature still elevated. Occasional chill followed by pronounced depression, which finally terminated the patient's existence. Unfortunately no postmortem was allowed. We were inclined to believe that the liver symptoms were the result of metastasis. A cranial lesion in the form of a cerebellar abscess was suspected.

We must not overlook the fact that disintegration of osseous tissue may take place, without causing painful symptoms. This is especially characteristic

of a tubercular process; and in the region of the ear, marked destruction may occur without involving the integrity of the membrana tympani. Such a condition is more apt to affect children of a strumous diathesis. In such instances the ulceration may soften the roof of the tympanic cavity, and so attack the brain. It furthermore may generate miliary tuberculosis of the lung and other organs, by entering the circulation, through the antrum and mastoid cells, or by penetration into the jugular fossa or sigmoid sinus.

128 East 60th Street.

#### DISCUSSION.

DR. MAX THORNER, Cincinnati—The papers are of more than usual interest, because the question of operative interference and topographical relations are comparatively new. Ordinarily topography of the temporal bone is insufficiently treated in text books.

The antrum is ordinarily larger and the floor of it is so much below the level of the aditus that pus can not flow out according to the laws of gravitation. Thus it happens that in cases where the inflammation is violent, before we think it possible, we have the whole mastoid process converted into a pus cavity. It has often been said that the ordinary acute otitis media will, if attended to at once, never lead to serious complications. This is, however, not my experience. Sometimes serious complications will ensue in spite of all that we do.

Dural abscesses, the essayist stated, may exist some time without distinct symptoms. Only seven weeks ago I had a case of acute otitis media following influenza, which was very serious from the start. The temperature was never lower than 102 and the discharge was profuse for weeks. At the same time severe pain developed over the temporal bone. All the symptoms of a mastoiditis were present when, after six weeks' treatment, I opened the temporal bone. It was one large cavity filled with pus and granulations. When cleansed thoroughly I found that a small amount of pus had collected below the posterior and anterior wall of the enormously large antrum and the dura-mater. About five or six drops of pus escaped from this location, after enlarging the pin-hole opening which existed in the bone. The patient made an excellent recovery. I believe that in a case where we have mastoiditis, which is not primary, we can not cure it by simply making an incision through the integument, but only by entering the cavity and removing the pus. But in cases of primary or secondary periostitis of the mastoid process, without any accumulation of pus, I do not see why Wilde's incision should not suffice.

In regard to that part of the paper referring to cerebral abscesses as one of the possible complications, I will report one case which I had, only a few months ago, under my observation. It is interesting on account of the enormous size of the cerebral abscess. The patient had been in a comatose condition for three weeks when received at the Cincinnati City Hospital. The history was meager, but it was found that there had been suppuration for some time previous. It was stated by relatives that a little piece of bone had been discharged into the auditory canal. There was a profuse purulent discharge from the right ear which was exceedingly offensive; caries of the attic could be determined. Upon opening the antrum I found it filled with pus and granulations, and the tegmen tympani bare; in this a very small perforation was found, through which a few drops of pus escaped. This opening was gradually enlarged, when a great amount of pus, very offensive and of a green color, came out. The abscess cavity was large. After establishing thorough drainage the wound was closed. The patient recovered from the comatose condition, but died in thirty-six hours after the operation. It was the largest abscess that any one connected with the hospital ever saw, being about the size of a small orange and occupying the right temporo-sphenoidal lobe. The brain tissue

within one-fourth and one-half inch of the walls of the abscess cavity was softened and discolored.

DR. MYLES—My experience has taught me that nothing but frequent demonstration of these practical anatomic points will fix them permanently in the mind. The topography of the antrum and mastoid varies in different cases, and in different ages. The doctor has presented some remarkable specimens, but I would have presented them in a little different way. I leave all the external landmarks on the specimens, that will not be detrimental to them, as I find that in this way the mind is better enabled to grasp the situation. A complete analysis of the relation of every structure is essential in the proper comprehension, and in the teaching of this department. It is well to instruct the student so that he can operate safely, and without penetrating the lateral sinus under any topographic condition. One good rule in operating is to cut carefully and deliberately, and to start by chiseling a broad beveled opening rather than a round narrow hole. If he clings closely to the auditory canal, and cuts in a spiral direction upward, inward and forward, he will reach the antrum quickly and surely. If you wish to be a little more direct, you may start a little higher in the suprameatal triangle and chisel directly inward. The chief thing to avoid is injury to the facial nerve, which usually comes outward near the junction of the floor of the antrum and the posterior superior walls of the tympanic cavity.

In regard to children and to the paper of Dr. Roy, a great many cases of swelling posterior to the ear, and over the antrum or mastoid, can be cured by a Wilde's incision. In that class of cases where there is no pus discharge in the canal, it is usually due to periostitis or caries either of traumatic or tubercular origin, or extends through a small venous aperture from the antrum, and in certain cases the pus burrows from the attic along the external auditory canal, and causes local abscess on the roughened area of the mastoid process. A great many of these cases recover after simply incising and draining, without curettage or interference with the middle ear.

DR. FRANK ALLPORT, Minneapolis, Minn.—I must take issue with what has been said concerning the unnecessary frequency of such operations. My own tendencies are somewhat conservative, especially where serious operative procedures are contemplated, but in this line of cases I emphatically believe we do not operate enough. The history of the mastoid operation, and now the history of operations for otitic brain abscess, leads us through the uncertain maze of the past, when such procedures were regarded with mingled feelings of awe and aversion, to the triumphant place now universally accorded them in the modern annals of surgery, and I predict for them, and especially the latter, a much higher and more exalted position than that at present possessed. The time will come when the human brain will no longer remain a *terra incognita*, but will be successfully explored by the progressive modern surgeon.

No man should venture upon such surgery unless thoroughly prepared therefor by accurate anatomic, topographic and pathologic studies, both theoretic and practical; but when thus fortified, and then brought face to face with a case of this character, he should not hesitate. In a correctly recognized case of brain abscess there is no other course to pursue, and the patient may as well die from an unsuccessful operation as from a timorous and too conservative therapeutics. It is astonishing how much interference the brain will endure, as is instanced by a case I will briefly recite: The patient was a man injured in a trolley car accident, producing a basal fracture and bleeding from the ears, followed by some discharge. Cerebral symptoms ensued, and I was called to diagnose a mastoid abscess, which I could not do. The consulting physicians and myself thereupon diagnosed a probable brain

abscess and the patient was accordingly trephined. Thorough exploration was made in many directions, starting from the temporo-sphenoidal lobe, but no pus was found. The wound was closed and death speedily expected; but the patient quickly and completely recovered, whether from relief of pressure we do not know. So, death need not always be expected, even when an operation is made and no pus found. I do not repeat this instance to encourage reckless operating, but to endeavor to dissipate the reluctant attitude assumed by surgeons when cerebral operations are mentioned.

It is not necessary for a man to be an aurist to open the mastoid process. Any surgeon properly qualified may undertake it, but it should be remembered that the operation has developed from a mere gimlet-hole opening or vent to a thorough removal of the outside mastoid shell, and a conscientious following up of every pus avenue, *no matter* where it may lead. We never know, therefore, when we open a mastoid process, what may be the ultimate issue involved, and we should be prepared to meet and care for any and all emergencies; and to treat pus deposits in this locality upon the same general principles observed in other portions of the body.

In regard to the method of operating, I prefer the dental engine, with fresh, sharp burs. It is gentler, quicker and smoother than the chisel, and the field of operation can be observed with great accuracy.

Concerning Wilde's incision, I believe it to be indicated but seldom, but when used, unless a pus deposit upon the outside of the mastoid is evident, the incision should be made in the inner, upper and posterior portion of the meatus, as the mastoid cells are here much more in evidence than at the hard external mastoid plate. At best, however, the Wilde's incision is usually but a temporizing procedure, through which valuable time is lost; and still I can not say I have *never* seen benefit ensue through its agency.

DR. CLINE—I have seen some remarkable cases of mastoid disease and I have been fully persuaded that too many extensive operations are performed on these cases. I was called to see a man seventy years old who had a discharge of pus from his ear for ten weeks, and for eight days and nights could not lie down on account of pain. On making Wilde's incision the knife passed into the bone, which seemed soft and pulpy. Pain subsided immediately and he was able to lie down. A draining tent was introduced, and the second day there was a free discharge of pus. I prescribed iodid of potassium and he made a rapid recovery without any scraping or chiseling away of the bone.

In another case the ear had been discharging for fourteen weeks. The ear was very painful and over the mastoid the tissue was very much swollen and of a very dark purple color. His condition was such that, with his previous history, I considered an operation was indispensable. I directed him to return home and send for a surgeon in his town and have the operation performed at once. The doctor who took him in charge decided to wait a day or two before operating. He put him on ten-grain doses of iodid of potassium every two hours. The patient began to improve, in three days the pain had disappeared and in seven days the discharge from the ear ceased, and since then (two years) he has had no further trouble.

I might detail other cases but these will suffice for the plea for conservative, early extensive operating and the free use of the iodids in these cases.

DR. T. H. SHASTED, Galesburg, Ill.—I am inclined to believe that Politzer's ideas on this point are correct. He says that in the chronic mastoid troubles the thorough operation should be done. The antrum should be opened, and, if then found necessary, the tympanum also. In acute cases, however, the thorough operation is seldom necessary. The abscess usually lies in the vertical portion of the process and does not, as a rule, communicate with the antrum. If in such cases, we cut down to the

antrum, we shall infect those parts when there is no necessity for it. In those cases where the pus bursts through the cortex spontaneously, there is very little to be done. We can easily remove whatever comes away and that is about all there is to be done. It is seldom necessary in such cases to make a thorough operation on the ground of preventing chronic fistulous discharge. I have frequently seen such cases and they almost invariably do well in the course of two or three weeks at the longest.

Dr. Roy's case reminds me of my own, that of a lad about 18 years of age. There was no suppuration from the ear, nor sign or history of former suppuration. At the operation I found very little pus, but some carious bone. I had the case diagnosed as primary mastoiditis. But afterward I was somewhat surprised to receive from his parents a history decidedly different from what they had first given me. He had had a slight discharge of short duration some years before. No doubt in all these cases there has been previous tympanic trouble, of which the membranous signs have been effaced and the history forgotten.

DR. B. ALEXANDER RANDALL, Philadelphia, Pa.—I wish merely to refer to the point already made that these mastoid and tympanic cases are the hot-bed of tuberculosis. Cases that are not primarily tubercular are here transformed, and we have the tubercular infection passed into the whole body.

While I do not believe in Wilde's incision, I think the whole matter can be set down as largely one of technique; and the way in which we proceed will depend upon our instruments.

DR. EDWARD J. BERNSTEIN, Baltimore, Md.—I do not believe that the relative impunity with which one can enter the brain constitutes any warrant for the frequency with which some undertake these operations. I have operated a number of times with a good percentage of successes; on the other hand I have had cases, of late, where everything indicated the necessity for operation, and I plead with the patient for the necessary permission, but owing to their persistent refusal, I was forced to keep to less radical means. Many of these latter patients recovered and are apparently well. They are not safe from recurrences, as are those who submit to the radical procedure, but an immunity from attack for one or two years speaks well for their side of the question. I have never used Wilde's incision, because Leiter's coil, mercurial ointment, and other local applications have always served me where the regular mastoid operation was not indicated.

## ELECTROLYSIS FOR THE REDUCTION OF SPURS OF THE NASAL SEPTUM.

Read in the Section on Laryngology and Otology, at the Forty-seventh Annual Meeting of the American Medical Association, held at Atlanta, Ga., May 5-8, 1896.

BY W. E. CASSELLBERRY, M.D.

Professor of Laryngology and Rhinology in Northwestern University Medical School (Chicago Medical College); Laryngologist and Rhinologist to St. Luke's Hospital; Laryngologist to Wesley Hospital, etc.

CHICAGO, ILL.

A year ago I gave the results of recent experience with electrolysis for the reduction of spurs of the nasal septum, in a paper read before the section of Laryngology and Otology of the AMERICAN MEDICAL ASSOCIATION,<sup>1</sup> and later in another paper before the American Laryngological Association,<sup>2</sup> and it is not my purpose in this supplementary report to repeat the technical details of the procedure or to recite cases at length, but simply to formulate conclusions bearing upon the exact limitations of this method.

The bibliography having been presented in previous papers, will be omitted at this time; suffice it to

<sup>1</sup> JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION, 1895.  
<sup>2</sup> Transactions of the Am. Laryn. Assoc., 1895; New York Medical Journal Aug. 31, 1895.

say, that a few European operators have advocated the method and some have praised it with seeming extravagance.

Customarily spurs or excrescences of the septum narium are removed by surgical means, by the knife, saw and drill, and these are the methods employed by myself in the majority of cases. In skillful hands they are more rapid, more precise, and in the case of large, bony spurs, certainly more effective than is electrolysis. The surgical method, however, is more or less sanguinary and otherwise far from agreeable to contemplate or experience. In cases of major degree, where the excrescence is of bone and of large size, occasioning pronounced occlusion of the nostril, together, perhaps, with serious secondary catarrhal symptoms, pressure neuroses, middle ear affections, or impairment of the general health, one should not hesitate to sacrifice the spur and if need be by the surgical method. The operation, the discomfort subsequently for a few days of an iodoform gauze packing as a preventive to hemorrhage, and even the substitution for normal mucous membrane over the operated area of a cicatricial mucosa with its tendency to dry crustation, are but trifling inconveniences in comparison with the benefits conferred in properly selected cases.

But there are cases of minor degree, small spurs of cartilage or of cartilage and bone and thickened areas which seem scarcely deserving of surgical treatment, but which one would like to see resolved for the sake of the additional nasal space and better drainage which would thereby accrue to the patient. There are also patients of delicate physique and those of highly sensitive and uncontrollable nervous organizations, and bleeders, also, whom one hesitates to subject to the regular operation. And, again, there are patients who willfully refuse an operation, however needed or suitable the case may be.

To what extent can electrolysis be utilized for the relief of these subjects and what sort of spurs can be completely removed, and in which can reduction in size only be expected?

Concerning the physics of electrolysis it is only necessary to state that it is a process of chemic disintegration of tissue under the influence of a direct or galvano-electric current by which water and salts are separated into their component parts, oxygen and acids being attracted to the positive needle and hydrogen and the alkaline bases to the negative needle. With one exception I have employed the preferable bi-polar method by which two needles, one representing each pole, are inserted into the spur. My needles are made of irido-platinum, which is nearly as stiff and hard as steel, twenty millimeters in length, about one-half millimeter in thickness, soldered parallel three millimeters apart to copper bars, which run through a light handle. Steel needles are perhaps more commonly employed and I have used them somewhat.

The process of electrolysis is not to be confounded with galvano-cauterization. While fine electrolytic needles can be made to burn by a sufficiently strong current, my needles as used with a current adequate for the purpose of electrolysis do not cauterize. The current strength necessary for electrolysis of nasal spurs is from fifteen to forty milliampères, measured with the resistance of the spur in the circuit, and to supply this current from fifteen to twenty cells of a galvanic battery would ordinarily be used with a corresponding electromotive force of from twelve to

twenty volts or more. The inconvenience of this apparatus and especially its unreliability when called into use only at irregular and prolonged intervals, has deterred many from trying the electrolytic method. I sought to avoid these annoyances by adapting the Edison electric light circuit to the purpose by means of lamp resistance and the McIntosh current controller. It is as easy and readily applied as the galvano-cautery, except for the few minutes' additional time that its energy needs to accomplish the work. When used it is necessary only to adjust the milliampèremeter and insert the needles.

A current suitable for electrolysis should be characterized by moderately high tension or voltage and comparatively low current strength or ampèrage. The Chicago-Edison current has an electromotive force of 110 volts, which must be reduced by the current controller. During the last year I have used only eleven volts or less. The ampèrage depends on the amount of resistance in the circuit, but it also can be correspondingly reduced by the resistance of a lamp and the controller so that with the spur in the circuit it measures the requisite number of milliampères. The current controller was described at length in my preliminary report. It is designed only for the continuous current and can not be employed with the alternating for the purpose of electrolysis, nor is it adapted to electro-cauterization.

I now employ the controller with only one lamp [in series] as additional resistance in the circuit, which aside from the action of the controller reduces the initial electromotive force to fifty-five volts. During the year I have used a current of only eleven volts or less, secured by advancing the decimal slide of the controller to 1 before the needles are inserted into the spur, which removes coil resistance sufficient to provide one-tenth of fifty-five volts or five and one-half volts. Then, after insertion of the needles, the centesimal slide is advanced gradually, each point removing coil resistance in fractions of hundredths, which occasion little shock, until if need be ten one-hundredths, or another five and one-half volts are added. With this arrangement the meter will usually register from ten to thirty milliampères, which with an exposure of seven to twelve minutes is adequate.

The chief difficulty in the reduction of cartilaginous spurs is to determine exactly when sufficient destruction has been effected, and no rule of guidance in this regard can be formulated, experience and delicate judgment only being of service. Nor can one always foretell the range of action or distance from the needles in all directions to which the destruction will extend. The ideal action is to produce just enough disintegration within the spur to lead to subsequent absorption without total destruction of the surface mucosa, which will therefore be reproduced in the process of cicatrization more perfectly than is usual after the cutting operation. If, however, the action be more intense and the slough produced be large it will separate as a whole with corresponding complete destruction of the mucous membrane. In the same manner by too intense an action a slough extending through the cartilaginous septum can be caused and perforation result. This is especially apt to occur while electrolyzing a spur which surmounts the convexity of a bent or deflected cartilage.

A simple deviation or bending of the septum can not be corrected or straightened by electrolysis and its use in such a case can only result in perforation.

If in addition to the deviation there is also a spur, that is, conjoined deviation and excrescence, the thickening may be reduced or removed by electrolysis, but the deviation will remain. These distinctions should be held clearly in mind when considering in any given case the applicability of electrolysis. It is true that perforation is prone to happen when operating on similar cases by the surgical method, for it is not always possible to estimate exactly the degree of concavity of the opposite side, and a closely reduplicated deflected septum can be mistaken for a spur and perforation result on cutting it off. But with electrolysis, in addition to these there is the further uncertainty of being unable to tell in advance exactly how far the action will extend. A close watch should be maintained in the opposite nostril and the electrolytic action discontinued on the slightest mottling in hue or escape of gas from that side of the septum. But there is reason to think that too great destruction can be effected even short of the production of these danger signals and other safeguards, such as not inserting the needles too deeply or permitting the treatment to endure too long, should be kept in mind. The duration necessary depends somewhat upon the current strength, but with the meter registering from fifteen to forty milliamperes I have not found it necessary to exceed from six to eight minutes for the devitalization of cartilage. The continental authors mention fifteen to twenty-five minutes as the duration of their séances, which would seem unnecessarily long for a single insertion of the needle, although I sometimes, in order to act upon a larger area, make two insertions at one sitting, which must then endure for about fifteen minutes.

I have accidentally made one small perforation out of a total of sixteen cases treated by electrolysis. In nearly this proportion they will likewise happen from the surgical treatment. In this one case no appreciable harm resulted, although I object on esthetic grounds to perforations and think that all possible care should be taken to avoid them. Beside, by encouraging incrustation, they sometimes do occasion annoyance.

On the other hand, if one is too timid in the application of the remedy, inserting the needle too superficially, using too small a quantity of electricity and for too brief a time, one will accomplish little or nothing beyond occasioning a disagreeable inflammatory reaction for a few days. Pain during the treatment need be but trifling, but the sensation is peculiarly disagreeable and tends to cause syncope. This tendency might be avoided by making the application in the recumbent position. My arrangements have not been suitable for this.

As to whether large spurs or ledges of bone can be resolved by this process of electrolysis opinions differ. My own experience is decidedly in the negative. I have been unable to penetrate even by steel needles the bony parts of spurs and failed to cause their resolution, even when the needle could be forced into approximate position. This experience is confirmed by Newcomb,<sup>3</sup> Chiari cited by Lowman,<sup>4</sup> and others. On the other hand, Moure<sup>5</sup> and also Bresgen,<sup>6</sup> lead us to infer that they are successful with bony spurs, which contention is confirmed by Ballinger,<sup>7</sup> who, however, fails to give particulars in this regard. Bone differs

in degree of hardness and, also, it is quite conceivable that spurs, which consist chiefly of cartilage with small spicula only of bone running through the center, that in addition to the cartilage the bone, by having the needles run into its immediate proximity, may be devitalized; but large spurs which consist chiefly of bone, often of iron-like hardness, will certainly resist this method.

I have treated by electrolysis sixteen cases, and these may be classed in three types according to the composition and location of the spur and the degree of success attained. With the exception of a case representative of each type they will be tabulated without detail and with mention only of salient features:

#### TYPE I.—STRICTLY CARTILAGINOUS SPURS.

*Case 1.*—Mr. H. H. C. M., somewhat advanced in years. He complained of nasal stenosis and distinct paroxysmal asthmatic symptoms. Examination disclosed hypertrophic rhinitis, conjoined with a cartilaginous excrescence of the right side of the septum, well in front and sufficiently large to approach the collapsed ala. The galvano-cautery applied to the turbinated bodies restored the patency of the left nostril, but on the right side the spur interfered with the attainment of a perfect result and the symptoms in part continued. Feb. 10, 1896, electrolysis applied to the spur, thirty-five to forty milliamperes, for seven minutes. The result is very satisfactory. A slight prominence farther back remains, but the space gained by the reduction of the spur is adequate for comfortable respiration. It could be wholly removed by a second application, which, however, now seems unnecessary. He reports entire freedom from asthmatic symptoms, disposition to "colds" and nasal discomfort, and while this happy result can not be wholly attributed to the reduction of the spur, that was an essential part of the treatment. The case exemplifies a considerable class of individuals, who if the less formidable procedure of electrolysis were not utilized to reduce the excrescence, would continue indefinitely to bear with the discomforts incidental to the presence of a spur rather than undergo the surgical treatment. The surface shows cicatricial markings, but mixed with natural mucosa and there is no annoyance from crustation.

*Case 2.*—Mr. R., right nostril entirely occluded by a cartilaginous spur five or six millimeters in thickness, which is implanted upon a slight convexity of the quadrangular cartilage. Electrolysis, 40 milliamperes for eight minutes, when the larger part of the spur had assumed a mottled bluish and whitish aspect. The large slough separated in two weeks as a whole. This is the case referred to above, in which a small perforation ensued. The result was otherwise satisfactory.

*Case 3.*—Mr. A. G. M. The cartilaginous septum was deflected to the right and in addition, situated toward the base of the convexity was an excrescence which projected sufficiently forward to approach the partially collapsed ala and so close the nostril. Electrolysis was selected because of the nervous disposition of the patient, he having so little self-control that the surgical method might have involved unusual difficulties. Three treatments, fifteen to twenty-five milliamperes each, for six minutes were given, special care being taken to avoid a perforation. By the removal thus of the excrescence, the deflection remaining, enough space was gained for comfortable respiration.

*Case 4.* Mr. M. H. B., and *Case 5.* Mr. W. M., present few features not already noted in connection with the others; in one somewhat advanced age, and in the other trial purposes only were the reasons for the selection of this method. The results were satisfactory in both.

#### TYPE II.—MIXED CARTILAGINOUS AND BONY SPURS.

*Case 6.*—Mr. L. C. C. This excrescence is of the kind which commences anteriorly and runs upward and backward, following the sutural line of the vomer and cartilaginous plate of the septum, gathering volume and thickness and terminating opposite the middle turbinal or pressing into the middle meatus, reaching quite across the nasal space. January 4 and January 11, electrolysis to the anterior and middle segments respectively by the bi-polar method, twenty to thirty milliamperes, for seven minutes each. January 18, mono-polar method applied to the last and most prominent segment, a single steel needle being used for greater penetrating power, this part of the ridge being largely of bone and rather thin to accommodate double needles. The needle would not penetrate into the

<sup>7</sup> THE JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION, Jan. 11, 1896.

depths of the ridge and consequently it was passed into its cartilaginous surface. This treatment was much more painful than the previous bi-polar applications, ten to fifteen milliamperes only being tolerated for ten minutes. The final result is satisfactory, the spur being much reduced in prominence, the reduction in volume being probably commensurate with the proportion of cartilage contained in it.

*Case 7*, Mr. M. J. H. and *Case 8*, Mr. W. G. H., had spurs similar in location and composition to the last described; in both of them the opportunity has been accorded to inspect the parts a year after the cessation of treatment and in both the degree of reduction of the spur and the amount of nasal space gained thereby was found to be greater than was anticipated. Evidently shrinkage continues until cicatrization is complete, for a period of several weeks at least.

*Case 9*.—Master G. P., a youth with a similar spur, received three treatments, bi-polar method. It would seem that young persons should be especially amenable to electrolysis on account of the softer state of the bone.

*Case 10*.—Mr. W. G. B. had had a spur removed by the surgical method some years ago; between the bulge which had redeveloped and the opposite inferior turbinal an adhesion had formed. This was divided and space gained by making a gutter-like excavation through the bulge by electrolysis.

*Case 11*.—Miss E. P. is a bleeder, at least I was once compelled to pack the naso-pharynx to check hemorrhage after a trifling operation for adenoids. Her spur of mixed cartilage and bone has been reduced, not wholly removed by electrolysis.

*Case 12*.—Master D. P., was a failure, because the patient fainted and was slightly convulsed. I purpose using the surgical method in his case.

*Case 13*.—D. C.: presented no noteworthy features beyond a fairly satisfactory result; and in one other (*Case 14*) of this type the treatment is not yet completed, but the indications point toward a partial reduction only.

#### TYPE III.—BONY SPURS.

*Cases 15 and 16* have previously been reported in detail. They were large bony spurs of ivory-like hardness, into which needles could not be made to penetrate and upon which electrolysis made but slight impression. In all such I have since recommended the surgical method.

**Conclusions.**—There is little occasion to modify the opinion expressed in conclusion a year ago, that while effective in many instances, its scope of application should be limited in accordance with the following principles:

1. Strictly cartilaginous spurs can be thoroughly removed by electrolysis; one, two, or even three operative sittings being required. It is more tedious and less brilliant than the surgical method, but it is not accompanied by liability to hemorrhage. It is not to be indorsed as a universal substitute for the surgical method in even this limited class, but it is a serviceable measure for exceptional individuals of both this type and Type II, *e. g.*: *a.* For quite small spurs and thickened areas. *b.* For patients of delicate physique and those of highly sensitive or uncontrollable nervous organization. *c.* For "bleeders." *d.* For those who decline the surgical method.

2. As demonstrated by the cases reported under Type II, it will not thoroughly remove spurs which belong to that large class of mixed cartilaginous and bony substance; but it will reduce them in size. The majority of such cases would therefore better be treated surgically, as being the more thorough method; but instances will arise as above indicated in which the surgical method being inexpedient, benefit may accrue from the use of electrolysis.

3. As demonstrated by the cases reported under Type III, large spurs composed mostly of hard bone can not be successfully treated by electrolysis. For the reason that needles can not be caused to penetrate properly, and further, it is doubtful if the process is adequate, even if the needles should penetrate, to the resolution of hard and dense bone *en masse*.

4. Spur or excrescence, and not deviation of the septum, is the subject of this paper. Electrolysis is powerless to correct deviated septa of any form.

34 Washington Street, Chicago.

#### DISCUSSION.

Dr. JOHN O. ROE, Rochester, N. Y.—The point that Dr. Myles has made in regard to the ill-advised attempts frequently made to enlarge the vestibule of the nose by cutting out the interior of the passage, is well taken. This procedure invariably results in decreasing the size of the opening instead of enlarging it, for the reason that when a portion of the constriction is cut away, the circumference of the uncut portion is correspondingly lessened, and when the cut edges become coaptated during the process of healing, the lumen of the passage is made smaller. The vestibule of the nose may become narrowed by a variety of causes. In those cases in which it is obstructed by an exostosis which we frequently find in the floor of the vestibule, this exostosis should be removed subcutaneously in order to leave the mucous membrane uninjured, thereby avoiding the contraction of the passage. This is best done by making an incision in front of the eminence down to the bone and raising the mucous membrane together with the periosteum over the entire elevated portion of the exostosis. By cutting through these tissues on the posterior side they can be raised out of the way and the bony growth removed either by drill or saw. When this is completed, the mucous membrane of the periosteum can be replaced, leaving the passage of the nostril unobstructed. The vestibule of the nose is often also very much narrowed by the collapse or dropping inward of the alæ of the nose from a weakening or partial paresis of the dilator naris muscles, thus allowing the alæ to be drawn inward against the septum during inspiration, thus increasing the obstruction to ingress of air. I have removed this difficulty by making one or two incisions through the cartilage of the alæ, and inserting a dressing into the nostril sufficiently large to distend the alæ quite widely until the cut made through the cartilage has become firmly healed and fixed in this position, thereby maintaining the nostril freely open and preventing the collapse of the alæ on inspiration. I was also much interested in Dr. Casselberry's paper on the reduction of spurs of the nasal septum by electrolysis, although I have never employed that method. I have not done so for the reason that I have always disposed of spurs and ridges of the nasal septum by what seems to me to be a very much easier and simpler method—by simply cutting the spur away. If the spur is located on the cartilaginous portion, I employ a suitable small cartilage knife for its removal, and if located on the osseous portion of the septum I remove it with a saw or the Curtis drill. I have not attempted the more complicated methods because my patients do not object to having these obstructions removed in this manner. In the case of removing a small enchondroma, it can be so easily and quickly done with the knife that if the parts are thoroughly anesthetized with cocaine the patient is neither alarmed nor incommoded by the operation, and sometimes scarcely realizes that anything unusual is taking place. In regard to the danger of denuding the parts of mucous membrane, I have never experienced any difficulty in this respect after a cutting operation, if but a limited portion of the membrane is removed. Even in some cases where quite an extended area of mucous membrane is removed, I have observed it from day to day spread over the parts when maintained thoroughly aseptic, so that in a short time the site of the operation, from the loss of the mucous membrane, could not be perceived. After the use of the cautery, however, I have observed extensive scars and areas in which the mucous membrane had been replaced by fibrous tissue, thereby causing much annoyance from the dryness of the nose and the formation of scabs and crusts over the parts

in which there were no mucous glands to lubricate the part.

DR. MAX THORNER, Cincinnati, Ohio—I would like to refer to Dr. Myles' paper. The obstruction of the nasal vestibule is by all means the worst thing that can happen after operations. In the operation advocated by Dr. Myles I think we have means to prevent such occurrence. One case I had was that of a young man who had been kicked on his nose by a mule, and there was entire occlusion of the right nostril. I made the incision and occlusion followed, and it was as bad as before, if not worse. Later on I made a flap from the upper lip, turned it upward into the nose and sewed it to the inner surface of the ala nasi, after having loosened it from its adhesions. Then I packed the nostril with iodoform gauze. The result was not an ideal one, but the improvement was great and permanent.

In regard to Dr. Casselberry's method, I have used it in about eight or nine cases and my results and experience were about the same as his. I use it only in cases where the patients are timid and nervous. The current in Cincinnati is stated to be about 110 volts, but it varies from 108 to 115. I cut it down to eight volts, and use from three to six milliamperes. The apparent difference in strength of current used by Dr. Casselberry and myself is that I use a different meter, one made by Hirschman of Berlin, which is extremely delicate and accurate. His whole apparatus is very reliable, no shocks of any kind are experienced by the patient, as the increase or decrease of strength of current is very gradual. A water rheostat is used. My experience as to results corresponds closely to that of Dr. Casselberry. Bony spurs are not at all affected by it; the best results are seen in soft cartilaginous excrescences. No pain is felt by the patients, although in one case, that of a very nervous woman, peculiar, dizzy sensations were complained of. Only the bi-polar method should be used.

DR. HANAU W. LOEB, St. Louis, Mo.—I was impressed with the statement of Dr. Myles in regard to maintaining an opening. I remember one case in which there was complete stenosis as a result of smallpox; there was complete adhesion of both edges to the septum. To maintain the opening I used two rubber tubes, which were made after the fashion of Simrock's spectrum. These were worn without discomfort for six months, later being worn only at night, and at present there is a complete opening.

DR. W. E. CASSELBERRY, Chicago—I tried to make it plain in my paper that it was not my custom to attempt to reduce all spurs of the nasal septum or even all cartilaginous spurs by the process of electrolysis; that I selected the cases for this method of treatment in accordance with the size, location and composition of the spur and somewhat in accordance with the degree or timidity or nervousness of the patient, some cases objecting or being unsuited to the surgical method. I was led to test electrolysis for two reasons: First, on account of previous disagreeable experience from hemorrhage by the surgical method even in trivial cases, and second, by the remarkable results that seemed to have been obtained by Moure and others by electrolysis. I examined it to find out what was in it, and I regard it as a useful addition to my resources for the treatment of this class of cases, but by no means worthy of exclusive reliance. Regarding secondary hemorrhage, of course, it is possible, but I have not met with it. Electrolysis should not be confused with galvano-cautery; they have nothing to do with each other and I do not use them for the same purposes.

**To Check a Sneeze or a Cough.**—Dr. Brown-Sequard, in one of his lectures, said: "Sneezing can be stopped by pressing on the nerve of the lips near the nose. Pressing on the top of the mouth very hard is also a means of stopping coughing, and many say the will alone has immense power."—*Pop. Science News*, August.

## NEW MEXICO AS A HEALTH RESORT.

Read in the Section on State Medicine, at the Forty-seventh Annual Meeting of the American Medical Association at Atlanta, Ga., May 5-8, 1896.

GEO. M. KELLOGG, A.M., M.D.

CHICAGO, ILL.

The Rocky Mountain region, especially the mountains and the upland plains of New Mexico, is a land lifted up by nature into the pure serene for the general invigoration of the race. New Mexico belonging to the Rocky Mountain crest, its eastern slope and a larger portion of Arizona belonging to their western slope, has perhaps, the most equable climate known. There are no extremes of winter cold or of summer heat; while there is a notable absence of dampness in air and earth. Little moisture is left for this region after the hot winds of the Southern Pacific are wrung dry by the coast ranges. The elevation of this country from four to eight thousand feet is just sufficient to prevent that oppressiveness of summer heat which otherwise would be severely felt in these latitudes from 32 to 37 degrees north. The winter months throughout this region owing to the ever present sunshine, and the positive shelter of the mountains, afford the most satisfactory retreats for invalids.

The purity of the air is shown by the absence of atmospheric dust and disease germs. Its notable clearness over the plains has been remarked for many years. Objects are clearly seen at great distances which in ordinary atmospheres would be hidden by fog and dust. The sun is visible nearly every day of the year and often for months without a cloud-fleck to obscure its radiance. The sun's heat is really grateful instead of oppressive. The native when enfeebled by illness or age basks in the sun. It is the best medicine that he knows. It renews his youth by renewing life at its springs. The invalid or valedudinarian feels at once the mild stimulus. Simply to breathe the air seems a luxury and a delight.

A noted peculiarity of this upland country is the coolness of the nights, even in the extreme of summer. The earth heated by the sunshine freely radiates its surplus at night, there being no blanketing clouds to intercept or confine. Uninterrupted and balmy sleep is thus insured, bringing healing on its wings, while the absence of insects to torture is an additional security. It is certain, that change of climate as a curative measure, promising though it be, requires means in abundance to secure its best results. But, as though nature were willing to bestow her best resources, on the poor as well as the rich, the benefit of this climate is open to all at a minimum of cost. The least expensive structures afford ample security and shelter at all seasons. Nourishing food can be obtained on an average at its cost at our great population centers. Fuel too, cheap and abundant, is largely unnecessary where the sun's largess is so ever present and grateful. Not to mention the beautiful and abundant building stone, the Mexican adobe houses are delightfully cool in summer and warm in winter. These can be made with materials at hand, or by larger outlays, can be constructed as luxurious as could be wished. Along the leading routes of travel such might be conveniently located and nowhere be more than an hour from skilled physicians and needed supplies. While the elevations of New Mexico from four to eight thousand feet all possess the same general climatic features, each altitude has some especially desirable quality. The plains are more uniformly dry and

their winters are less vigorous than in or near the mountains. In all these sections the atmosphere has the same characteristic clearness save for occasional dust storms. The mountains catch the greater part of the rain and snow, and furnish the chief water courses and supplies for irrigation, etc. The summer rains from July 15 to September are chiefly seen in the mountains and are usually transient. In the plains they are much less frequent and there is an almost entire absence of dew. Nature as though to confound the wise, shows vegetable life in hundreds of native species flourishing in the plains with wonderful healthfulness, unvisited by mold fungus and vermin so inimical to plant life in damp regions. The cryptogamous plant world which elsewhere sends its spores and disease producing germs across the world is almost unrepresented in the mountains and plains. Fungi, mosses, ferns, lichens and liverworts, which thrive so signally in the damp and dark, find small encouragement in the sunshine State. The experiments of Tyndall to demonstrate the purity of the atmosphere in Alpine glaciers can be repeated most satisfactorily in the plains and foothills of the Rocky Mountains at an elevation of from four to six thousand feet. At such elevations in the plains putrescence is almost impossible. The ordinary ranchman knows he can, with impunity, hang his venison or beef under a tree or shed for weeks even in the summer. The manifold vermin of the infusorial and insect world are not tempted to climb or fly to this region from their eastern homes.

Most men believe that in the general upbuilding and economy of the earth "some steadfast purpose runs."

Have not these mountains been pushed up in accordance with a plan which involves the general good of the race. The genius of modern civilization may be maritime, but that of the most ancient periods certainly was not. The early home of the Caucasian race was in the uplands of Asia. The shepherds on the oriental mountains studied and named the stars ages before the first frail shallop was launched from the shore. The early Phœnician navigator had learned elsewhere to trust the stars before he ventured his fortunes upon the waves. The Aztec and Peruvian civilizations originated in the mountains and upland plains of the western continent. It may well be that those influences which led them to cultivate religion, art and science in the early periods still remain as a heritage to future mountain dwellers. History in certain broad senses repeats itself. It is at least certain that nature has upreared these mountains in order to diversify the conditions of mankind to vary their industries, their resources and character. The physical well-being of the race as well as its moral and intellectual nature, may here again find its highest expression. It is certainly possible for such as can not have the privilege in crowded and stifled cities to live clean and healthful lives in our mountains. Even in the most prolonged summer heats sunstroke is unknown in New Mexico. Diseases associated with malaria are excessively rare. Acute rheumatism, pleurisy and pneumonia seem only incident to special and unnecessary exposures to cold night air and subterranean damps peculiar to a miner's and cow-boy's life.

The diseases for which the mountain climate may be claimed as a prophylactic are first, those deadly diseases of infancy, summer complaint and cholera

infantum. Abdominal disorders are rare. Typhoid fevers are but feebly represented by the dreaded "mountain fever," which is neither so deadly or common as those dreaded diseases are in the East. There are some neuroses like chorea which seem to be aggravated in this country.

I have observed among native New Mexicans that heart disease, functional or organic, does not seem in any respect more common than in the Mississippi Valley and pursue much the same course. Pure neuralgias seem positively benefited by this climate. Tuberculous, bronchial consumption, and asthma are most uncommon among the native population. Invalids with lung disease seem often greatly relieved and cured by simple residence. But, where the lungs are riddled by disease and tied down by adhesions, the very rarity of air becomes a great disadvantage. Such cases are the great opprobrium of traveling patients who succumb to the inevitable "heart failure" of which so very many die before they reach a secure haven. The striking feature of the mountain country is the diathermancy of the air. Less heat is absorbed by the atmosphere than in lowlands. This obviates in great measure the oppressiveness of the air. Moreover, there is on this account an immediate and great difference between temperatures in the sunshine and in the shade. This difference has been calculated as equal to 1 degree F. for every 230 feet vertical ascent. This gives for elevations of 6,000 feet above 20 degrees F. difference. But the effect of sunshine in the absence of aqueous vapor in overcoming its direct depressing influence is something for which there is no accurate measure. Perhaps there is at the crest of the continent an electric or other earth aura which ameliorates the sunshine and causes it to quicken the pulses of life.

Statistics have proved that the West Indian islands and the Gulf States are unfavorable for most lung diseases and rheumatic fevers as well as abdominal disorders, generally, being hot beds of malaria. The same is true of the climate of India. The boasted climate of Nice and Mentone save for a short period of the year is found a signal failure. This is true of all the islands of the Mediterranean. Except the parched land of Egypt, no region has been admitted by English authorities as especially favorable for lung trouble. Egypt, however, is the home of the plague, cholera, of abdominal disease, and ophthalmia and a thousand discomforts. Great Britain in her ambition to possess the world has accomplished one important matter at least, though with great expense of life and treasure. She has tested many climates by means of her army. Her health and death rolls have established the extreme unhealthfulness of Gibraltar, the islands or shores of the Mediterranean, of the Black Sea, of India, China, the valley of the Nile, the West Indies and Central America and Demarara. Canada and Australia and her own foggy shores have given the best returns for salubrity as shown by England's army reports—a sad record at best. The Kerghees steppes near the Caspian, though below the sea level, owing to its dry air has been observed like the valley of the Nile favorable for tuberculous disease. In the elevated plain of Persia and Armenia, at elevations of about six thousand feet, phthisis is much benefited.

In the Alps at St. Moritz, on the river Inn in the valley of the upper Engadine are spas and winter cures where some happy results are experienced, despite harsh air and inclemency.

The elevated plains of Anahuac in Mexico have borne for several centuries a reputation for salubrity. The plain of Quito directly under the equator, at an elevation of nearly nine thousand feet, has a well established claim for general healthfulness, as also have Montana, Potosi and still greater elevations. New Mexico, with its clear dry air, affords a great contrast to many mountain regions, in particular to the Alps. These, placed between near and sharply contrasted seas—the superheated Mediterranean, the fierce, cold Baltic and the storm swept Atlantic have ever been the cradle of climatic excess. The mountain tops are eternally capped with snow and glaciers; their valleys are the hot beds of miasm and dampness, where consumption and cretinism prevail. The cold sides of the Alps are to-day, however, lined with hotels and *pensions* for invalids, who try to imagine themselves benefited by gazing on ice-clad peaks and mountain torrents. There is this to proclaim, and it is of higher importance than the story of matchless fertility, or of hills seamed through with the precious metals. In the Rocky mountains there is an area of 1,000 by 300 miles with a climate the most serene and invigorating of all that have been tested or in any proper manner demonstrated.

#### ALCOHOL OR NO ALCOHOL IN THE TREATMENT OF TYPHOID FEVER.

Read in the Section on State Medicine, at the Forty-seventh Annual Meeting of the American Medical Association, held at Atlanta, Ga., May 5-8, 1896.

BY J. B. GARBER, M.D.  
DUNKIRK, IND.

There is no disease in the entire catalogue of human ailments that is of more concern to both the physician and the patient than that of typhoid fever. It attacks the young, the old, the rich, the poor, the high, the low, the monarch and the slave, and while the disease has a special fondness for certain ages and conditions yet none are exempt even after having once had an attack.

It is found on the mountain top and in the valley, and an epidemic may begin on the mountain top and spend its force in the valley as was the case in the noted "Plymouth epidemic." It is both epidemic and endemic, and no physician who engages in the general practice of medicine will continue long ere he comes face to face with this dreaded destroyer of family ties and human comfort.

The diagnosis and symptoms of the disease have been studied and discussed since the dawning of the present century. Since the year 1813 it has been recognized as a distinct ailment, and in the year 1829 Louis gave it a name, but even then it was supposed, as its name indicates, to be a milder form of typhus; and not until nearly twenty years later was a differential diagnosis made; finally, in the year 1880 the bacillus typhosus was discovered and since that time we have been trying to obtain a remedy or plan of treatment that will destroy the germ without destroying the host. As to the medical treatment of the disease you will no doubt hear enough before this meeting closes to convince you that it is still unsettled and as to whether it can be aborted or not I leave for others to discuss, especially those who are engaged in this line of work. But there is another side of this question, and that is the sustaining of the vital forces while the disease is in progress.

It is the steering of the ship through the storm that

marks the successful mariner. The successful guide is he who avoids all dangerous routes. Likewise the practitioner is judged by the result of his work; his rate of mortality is what marks the successful physician and especially is this true in the treatment of typhoid fever. We believe sustaining the vitality of the patient is of as much importance as the medical treatment of the pathologic conditions present; also that any agent which contributes to this end is a great aid in the successful management of a case.

What influence does alcohol have in thus sustaining the vital forces of the patient through this trying ordeal? Let us first refer to some of our authors and notice briefly their teachings on this subject. Von Ziemssen, in an article which appeared in the *ASSOCIATION JOURNAL* of 1887, closes by saying, "It is better to give too much alcohol than too little." Another able writer in the *Medical Press and Circular* of 1887 says: "A very important point in the treatment of typhoid fever consists in the administration of alcohol. When we have a long continued febrile process it is requisite and necessary to give wine in all cases, without exceptions, from the first." The same author tells of the enormous amount that may be taken even by those who are not accustomed to its use. Another writer of the same year says, "In the treatment of typhoid in children, for food, give bouillon, barley water, lemonade and milk, and if there is much prostration alcohol and extract of bark."

These are only a few quotations showing the teachings of the last decade and we will hastily pass to the instruction given in our latest text-books.

Dr. Osler, in his first edition, 1892, says: "Alcohol is not necessary in all cases, but may be given when the weakness is marked, the fever high and the pulse failing." In his latest edition, 1895, the same language is used, showing no change in the author's opinion, or an oversight in revision.

Professor Whitaker, in his "Practice," tells us that "alcohol is the best whip for a flagging heart, in a mild case in the form of wine, in a severe case in the form of whisky and in the most protracted cases the alcohol should be given in the form of brandy." He also says: "A threatened collapse may be bridged over by a cup of black coffee with a teaspoonful of cognac," and closes the paragraph by informing us that nitroglycerin, 1-100 in doses of 3 drops in whisky is one of the most powerful agents we possess.

Bartholow, in the last edition of his "Materia Medica and Therapeutics," after discussing the subject of alcohol at some length, closes by saying: "The chief utility of alcohol in these diseases [referring to fevers and other depressing maladies] is not as a stimulant but as a food. It furnishes material, easily oxidizable, which can be applied as nervous, muscular and gland force," and then says, "it should be given with milk, eggs, broth and other suitable aliment." The same author says that the action of alcohol on the nervous system is that of a narcotic.

With such indefinite statements as to the action and use of so potent an agent as alcohol on the system is it any surprise that the mortality runs from 10 to 30 per cent? In reference to the medical properties of alcohol there is a difference of opinion. It may be germicidal, but this property can not be utilized in the treatment of typhoid fever. So we come at once to the question of greatest importance. Is alcohol a food and does it assist in tiding the patient over a crisis.

A food as defined by Dr. Chapman in his "Physiology," is any substance, inorganic or organic, solid or liquid, that will nourish the body and renew the material destroyed in producing the phenomena of life. The same author says that alcohol can be of no benefit to the system, for it is found as such in the organs untransformed or is excreted unchanged; hence, it can not supply any want by simply passing through the system and if it is burned up it must interfere with the oxidization of other substances, such as fat, etc. He further states that alcohol diminishes the amount of urea excreted and the action of the skin, interfering with natural combustion, thus preventing the whole nutrition of the body; and then closes by stating that as a medicine it is indispensable. This alcohol is a peculiar drug; it has been found in the brain unchanged, excreted likewise, yet as a medicine is indispensable. What medical property has it that can be made use of with benefit to the patient of typhoid fever?

Methinks I hear some one answer, "a food to nourish the patient;" another, "antipyretic to reduce the fever;" and still another, "a stimulant to tide over the crisis, to whip the lagging heart." Does it rest or strengthen a tired horse to whip him into a trot? Alcohol has a paralyzing influence and all the effects of its use, which seem to be the result of stimulation, can be shown to be those of paralysis. The first effect of alcohol on the brain is that of paralysis and affects the faculty of reason, and as Bunge says, "the emotional life is brought into free play unhampered by the guiding strings of reason." The same author states that another paralytic symptom which is erroneously regarded as one of stimulation is found in the deadening of the sense of fatigue.

Dr. Kellogg, in an excellent paper published in the December *Bulletin*, after reviewing the physiologic relations of alcohol as set forth by Professor Bunge, closes with the following language: "In view of such testimony as this how is it possible for anyone still to maintain the old error born of the ignorant and pernicious idea that alcohol is a food, a tonic, a stimulant, a rejuvenant and a conservator of energy. It would seem to be time that physicians were considering this question of the medical use of alcohol seriously and conforming their practice to the facts of science instead of the traditions of our medical forefathers and the formulas of obsolete text-books."

How is it to-day with the young doctor as he leaves his alma mater, his diploma under his arm? Among many other delusions and theories that fill his mind is one that alcohol is useful in all diseases and conditions, from the bite of the poisonous snake to puerperal hemorrhage. In one pocket he carries a dose book containing a list of poisons and their antidotes, and perchance a copy of the code of ethics. In the other his medicine case filled with tablets and triturates of all kinds, from nitroglycerin to sulphate of magnesia. I have wondered why some enterprising drug company did not make tablets of alcohol. How convenient they would be. Thus armed, the young disciple of Esculapius goes to the field of battle. It is not long till this young soldier comes in contact with a case of typhoid fever. The symptoms are not just like those described in the books or heard in the lecture room, but while he is waiting for something to happen the patient passes into the second week of the disease. By this time the symptoms are more marked and by exclusion a diagnosis is made and

time is hastening us into the third week, which is one of debility and depression, and the first thing thought of is alcohol, which is given freely. If it is well mixed or alternated with suitable nourishment the case may terminate favorably; if not the alcohol only hastens the end.

We believe the mortality from typhoid fever has been gradually lowering, and no doubt is due in a great measure to the non-use of alcohol in the treatment of the disease. There is hardly a week passes that some of our journals do not report a series of cases treated without the aid of alcohol in any form. I used alcohol in the treatment of the disease until two years ago, when I became alarmed at the mortality, so I changed my plan and in 1894 I treated thirty-seven well-marked cases of varying degrees of intensity. I had two fatal cases, and in both of them I had used alcohol. In 1895 I treated thirty cases of about the same type with no death. I only used alcohol in one of them and it caused me more trouble than any of the others. As this case was in the family of a saloon-keeper I could not control the matter, and they would give it during my absence. On my return I would find the face flushed, the temperature high, the pulse rapid and the patient nervous. By close inquiry I would find that some of the family had given just a little good whisky, which had been in the house for twenty years.

In closing, I wish to state I am well convinced that in the treatment of typhoid fever our patients will do better and stand a better chance of recovery if we abstain entirely from the use of alcohol in the treatment of the disease.

#### DISCUSSION.

DR. J. N. QUMBY—It can not be said that the author of this paper is at all prejudiced. He has tried the alcoholic treatment thoroughly. I have also tried the use of it. I grew up at a time when it was regarded as a panacea for all the ills that flesh was heir to. It was a food, a stimulant and a nerve supporter. It was just after the attention of the world was drawn to Liebig, who made the fatal mistake of thinking that because it had a certain amount of carbon it supplied what was needed in the body, when, in fact, it is no carbon. We started with the mistaken idea that alcohol was a stimulant and supported the body; that it would act as a powerful nutrient to the blood, but that it must not act as an anesthetic. It is impossible for anything to act as food when it acts as a narcotic. We have been using it because our forefathers recommended it. We did not take the trouble to analyze and see what it was. A valuable example is that of the soldier (Martin) wounded in the abdomen, the wound healed but the aperture remained open. Through this a physician was able to study the process of digestion. Whenever he used alcohol in any form it always interfered with digestion. There are the practical tests of Summerville, Richardson and thousands of others that have been made, and notwithstanding that fact, the majority of the medical profession continue to use alcohol as though it was food, stimulant and supporter of the basal nerves, when, in fact, those who have paid attention to the matter have concluded that it is neither one or the other, and yet, if you give a small dose it interferes with digestion, because it precipitates the pepsin of the gastric, and anything that does that is not a supporter. For the last twenty years I have not used a drop of alcohol. Give a certain amount of nourishment but do not destroy that with alcohol. In my cases there is generally a higher rate of cures than of those who use alcohol. I was once called in consultation over a very old gentleman, to whom the physician was giving alcohol,

a glass of champagne and one ounce of brandy. I decided that he had an uncertain pulse. It seemed to have a better volume, and I took into consideration that he was soothed with alcohol. You know 5 per cent. is a large portion. It is dangerous to introduce 10 per cent. Notwithstanding all the stimulants the patient died. I believe he died from alcoholism rather than typhoid fever. I give this as an example where we are making a grave mistake in using alcohol, because we know it is a narcotic, it paralyzes the mind and muscles. To administer it as a heart tonic will do more harm than good, because it is not a heart tonic but a narcotic.

DR. MCDANIEL of Alabama—I have some knowledge of this subject of alcohol, as we all have of every remedy we use. A man of my years has frequently heard these conflicting views and has witnessed the results as claimed of the different remedies. I do not wish to controvert nor yet to advocate what has been said here on the subject; my object is to enter a protest against extremism. I look upon alcohol as an anesthetic, and I believe is a fertilizer of the basal nerves. Illustration is one of the most powerful arguments brought into discussion. We are asked, what effect does alcohol have upon the vital actions and the functions of the body in health or disease? Suppose I take a small alcohol lamp and put a match to the wick. The first thing I know the alcohol is burned up. There has been some heat generated when the alcohol was burning and when the small wick was burning out. If we give alcohol to the patient it comes up to the capillaries of the lungs, which we call the wick of the human lamp. It keeps up the temperature of the failing, feeble patient. If he is disposed to get cold, if he verges beyond the stage which you describe, I think you have witnessed that this supplementary food was of some use. I don't believe we understand theories fundamentally enough to base an exclusive dogma on the action of experiments; but when I see the results on patients in typhoid fever I know something about the action of alcohol. I was once extremely prostrated with typhoid fever. A friend gave me sweetened water with cognac brandy and nutmeg grated over it. My nerves were all unstrung and I was tossing from side to side; but in fifteen minutes my nerves were quiet and easy. I have tried stimulants hundreds of times in that nervous condition of the system, and I know no other nerve tonic which can equal it. It will produce perspiration in a dry, raspy skin, and will produce sleep where there is insomnia. I know that alcohol does good sometimes. There are two sides to this question and we should not go to either extreme. Let us say it does have an important function. If you experiment upon yourself and are benefited by the use of alcohol, it is the alcohol which makes you feel so much better.

DR. QUMBY—I admit there is always apparently some benefit to be derived, but the point is, if alcohol has done so much good, which we admit to a certain extent, if it has saved one life, for that life it has saved I can cite over one hundred which it has destroyed. Therefore it can be treated on the practical point that there can not be found a case where alcohol will do for which other remedies may not be substituted that will do better. You hesitate about giving opium for fear of the danger that will result from the appetite created for it, and yet you prescribe alcohol. When you look over this broad land and see how many homes are beggared, how many graves filled from want, destruction and disease, and realize that this is done by the use of alcohol to a very large extent, I say if we possibly can avoid it, let us do so. There is much to be learned in reference to alcohol. It is not only injurious, but creates comment among the laity regarding the medical profession; then, too, there is the condition which the poisonous element of alcohol leaves one in. We have a double poison, that of alcohol and by urea. It prevents the destruction of tissue which ought to come out of the body. If not cleared of the poison that the system secretes daily, you are

sure to suffer from the effects of it. We have also much to learn in reference to the *modus operandi* of alcohol. It creates within the body an irregular form of appetite and habit. For these and countless other reasons we should make use of the many remedies which can accomplish all and more than the good resulting from the use of alcohol without its baleful effects.

DR. HIBBERD—It has been stated that a stimulant was one which was founded on nutrition. Is that true? Is not a stimulant something which renews strength in the tired organs and alcohol that which spurs them on to renewed activity? Depression comes simply because the active agents have been overtaxed; but there is that corresponding rest in depression until it shall recover the average strength. I think this definition of a stimulant is incorrect.

DR. KONER—It seems to me the Doctor's statement is somewhat misleading as to the effects of alcohol on the system. It is very difficult to understand that alcohol produces a paralyzing effect upon the heart muscle, when we all have seen the stimulating effects of a greater or less quantity of alcohol. The statement was made that it interferes very seriously with urea elimination. This may be the case in advanced stages of Bright's disease, but is certainly not the usual effect of alcohol. It has a stimulating effect on the kidneys. In regard to the particular effect of alcohol, the Doctor made a statement that whenever 10 per cent. of alcohol was taken in the blood it would prove destructive. That may be so, but I am inclined to think that he is confused in his ideas in regard to the operations that are going on in the stomach.

DR. COCHRAN—I am only going to express my gratification that alcohol has found some friends in this section of the AMERICAN MEDICAL ASSOCIATION. I think all of those books are unscientific and based upon indirect information. I recognize fully the value of alcohol. I can say it has been a blessing to the human race and so far as I am concerned, am sure that I would not be alive but for it. We should not allow personal prejudice too much latitude. As to killing people, I suppose it does; but how much time and alcohol does it require? As to destruction of property, it probably makes some people poor, but that is caused by abuse and not the use of alcohol. To combat that theory is the apparent benefit with which it is almost universally used. The most prominent, the wealthiest and most successful men use alcohol apparently with good results. When General Booth made the celebrated investigation into the causes of pauperism in East London, which cost many thousands of dollars and filled two or three volumes, he found that only 13 per cent. of the pauperism of East London was traceable to inebriety. There are many things connected with alcohol in the system that we do not know. I feel that the fact that it has always been used is a sufficient reason for its having some valuable qualities.

DR. GARBER—I do not wish the Society to understand that I am an extremist on this question, I simply wish to learn, and have been much benefited by the suggestions; there are a few things which have been said that I think should be referred to. In fact, some have drifted away from the subject and discussed the question from the moral standpoint. I did not refer to that in the paper. I believe that the trouble originates greatly from the teachings of the text-books. They teach that it is necessary in all of these cases. One brother has spoken of it saving his life in typhoid fever. I think under the same conditions hot water with some ordinary stimulant would have had the same result. The last gentleman on the floor has made the statement that most of the successful men have been in the habit of drinking. I would refer to Rockefeller, and Daniel of Ohio, as well as many others who are strictly temperate and yet have attained great success and achieved some prominence. He also spoke of the pauperism of East London. I have been connected with the Ohio Peniten-

tiary in an official capacity and the result of my observation is that 70 per cent. of 1,940 convicts come there directly or indirectly from the use of alcohol. I mention that as regarding the moral side of the question which I have heretofore avoided discussing. One gentleman used the burning of an alcohol lamp as an illustration; on the same principle why not use gasoline or make a decoction of coal products and other things we use outside of the body, for oxidization. I do not believe alcohol can be oxidized in the system. It can be burned outside. We would not think of inhaling natural gas because we use it for illuminating purposes. A few inhalations would satisfy us, I think. I have followed it with much interest, but I yet believe it is a bad thing to use alcohol in the treatment of typhoid fever.

### TRANSFUSION, INFUSION AND ANTO-TRANSFUSION; THEIR COMPARATIVE MERITS AND INDICATIONS.

Read before the Kentucky State Medical Society.

BY AUGUST SCHACHNER, M.D., PH.G.

DEMONSTRATOR OF ANATOMY LOUISVILLE MEDICAL COLLEGE; VISITING SURGEON LOUISVILLE CITY HOSPITAL, LOUISVILLE, KY.

Whenever a number of measures of a more or less varied and changeable character are advanced for the fulfillment of a long existing demand, it means an absence of unity in the selection of the proper measure and a general distrust in a satisfactory adjustment of the demand. This is clearly illustrated by the number of procedures that from time to time have been recommended to overcome the depressing and even fatal condition following enormous hemorrhages.

The fact that the operation of transfusion is but rarely performed at the present time, and that of infusion faring but little better, tempted me to refreshen the subject somewhat more than a month ago before one of our local societies. Since that time I have been impressed more than ever with the neglect to which these operations have been subjected and the importance of bringing them before the eyes of those engaged in operative work.

I may be pardoned for borrowing from my former paper the historic outlines in connection with the development of these minor operative procedures.

The first intimation of transfusion can be found in the 333d and 334th verses of the seventh book of Ovid's *Metamorphoses*, "Veteremque haurite cruorem Ut repleam vacuas juvenili sanguine venas." This carries us back to the time of Christ, and from then down to the present period; "a long but unbroken chain can be traced running through the Hebraic and Egyptian medical records." In 1492, or more than a hundred years before the circulation was understood, Pope Innocent VIII. was struggling with his last illness. He was attended by a Jewish physician who, it is supposed, was prompted by the idea noted in the verses of Ovid and performed transfusion with the blood taken from three Roman youths. In 1615 Andreas Libavious, of Halle, wrote an article upon a charlatan who is supposed to have performed transfusion. In 1628 another appeared under the authorship of Johann Colle; coupled with these came the discovery of the circulation by Harvey, which was directly responsible for the vigorous attention which the learned men at that time gave to the subject.

In 1652 an apparatus for arterio-venous transfusion was contrived by Folli, of Italy. In 1666, Richard Lower drained a good sized dog by tapping the jugu-

lar vein. When the animal was exhausted he filled the vessels with blood drawn from a cervical artery of a second dog until the animal had recovered; he then drained the same animal a second time and again filled his arterial system with blood from a third dog, thus completely changing the blood twice in the same animal without any unfavorable consequences. This represents the first well-authenticated experimental maneuver made in the direction of transfusion.

This aroused an interest in the Royal Philosophical Society, and it was then believed that a remedy had been discovered which was not only capable of curing disease but by means of which the aged could be transformed to the youthful and the immoral could be changed to the moral. So strong was the belief in the latter, that a trial was actually undertaken by Lower and King.

At that time a religious fanatic by the name of Arthur Boga, 30 years old, offered himself in consideration of a guinea as willing to undergo the experiment, which was conducted, in the presence of the Bishop of Salisbury and a large and brilliant audience, by Lower and King. Six to seven ounces were withdrawn and ten ounces of arterial blood from a sheep was injected. This operation was again successfully performed on the twelfth of December of the same year by the same operators.

It must be noted, however, that these experiments were preceded by others performed by Jean Dennis and Emmerez in Paris in the year of 1667, and to whom the honor of the first successful transfusion in a human subject is due. Dennis employed the blood of a lamb, and several times repeated the operation upon several different subjects with almost uniform success, so far as the transfusion was concerned. These operations aroused a vigorous and jealous opposition in Germany, France and Italy, and were partly terminated when Dennis narrowly escaped a trap that had been set for him, but notwithstanding his innocence, it had involved him in a criminal case.

From this time enthusiasm began to lag and matters continued with a varied interest until 1818, when James Blundell, the obstetrician, placed transfusion upon a scientific basis, at the same time giving a method for its correct performance. To Blundell is likewise due the honor of first employing human blood instead of that of lower animals for the transfusion. With this the history of transfusion can be dismissed. In parting we might add that there are but few procedures known to medicine whose histories are more replete with incidents that are as varied, interesting, pathetic and amusing as the history of transfusion.

Before entering upon the subject of transfusion, it is well to glance at the conditions which are produced by the loss of large quantities of blood.

In dangerous hemorrhages death may ensue from one of two causes, i. e., either from the absolute loss of blood itself or from a fatal reduction of the intravascular pressure. In the first instance, the amount of blood is insufficient to meet the demands necessary for the sustenance of life. This makes the case unmistakably clear, and the indications are more blood, or death must ensue. In these cases nothing short of transfusion will fulfill the requirement; fortunately, however, these constitute the minority. In the majority of cases the death following hemorrhage is not due to the direct loss of blood itself, but rather to a disturbance in the mechanism of the cir-

ulation. Let us glance at the physiology of the circulation.

Two factors must be considered: First and foremost, the force of the heart, and second, the elasticity and contractibility of the arteries. If the heart has an insufficient volume of blood, or perhaps more properly speaking, volume of fluid, for blood is not absolutely necessary for this feature, there is an irregularity in its contractions and a serious crippling in the proper working of its valves, and in consequence we have a condition at once produced which for the time being, can be compared to the worst variety of valve lesion, so that the heart not only fails in sending out the required amount for nutrition, but also for the closure of the valves. Aside from this, the amount of blood sent out is not sufficient to produce the necessary dilatation by means of which the elastic nature of the large arteries are enabled to propel the force of the heart to the more distant parts of the body.

When this state of affairs exists, the indication for an increase of the intravascular pressure is equally plain and the requirement then is more fluid; whether that be blood or salt solution is immaterial.

#### TRANSFUSION.

By transfusion we mean the injection of the blood of one individual into the vessels of another. Although this operation has been variously designated by different writers as both safe and unsafe, there can be no doubt that in the hands of a careful operator, all possible elements of danger can readily be eliminated.

*Indications.*—From the history of transfusion it is apparent that formerly its range of application was far more extensive than its merits justified, and in view of this state of affairs the disappointments naturally were quite frequent. This largely aided in relegating it to the disuse to which it was subjected. At present any factor may serve as an indication for transfusion, which reduces the quantity of the blood so that the remaining volume is unable either by reason of the reduction, or incapable by reason of any alteration to which it may have been subjected, to carry on the functions necessary for the sustenance of life. The principal conditions which such a statement would comprise, would be either an acute anemia, dependent upon an extensive hemorrhage, or a paralyzation of the oxygen carrying power of the red corpuscles, carbonic oxid, or other similarly toxic gases. We would still scarcely regard such conditions as morphin or atropin poisoning, leukemia, chlorosis and a host of other pathologic states as justifiable indications for the employment of transfusion.

*Modus operandi.*—There are a few practical features in connection with the operation of transfusion which deserves special attention. During the cholera epidemic of 1866, Von Graefe raised the question as to whether the centrifugal should be given the preference over the centripetal method? Whether it would be better to inject the blood into the arteries rather than into the veins? The advantage urged in support of the centrifugal method was that since the capillaries intervened between the arteries and veins, the blood in its passage through the capillaries was subjected, as it were, to the influence of a strainer which safely withheld any air or emboli which might be present in the transfused blood. The arteries which were employed were either the radial, tibial or

even perhaps the brachial. Although this method has the endorsement of Billroth, Landois, Heuter and others, it has likewise many very able opponents who have pointed to the force necessary for the centrifugal method which not infrequently resulted in a rupture of the capillaries with accompanying gangrenous conditions.

Another question to be decided is whether or not the blood should be defibrinated and whether we should select the venous or the arterial blood? Referring to the former of these two questions, we are safe to say that the verdict is almost unanimously in favor of the defibrinated blood. It has been said that the integrity of the corpuscle is considerably affected by the defibrination of the blood, but this is somewhat problematic. However, the dangers of a partial or an entire coagulation which attended the use of non-defibrinated blood, fully justifies the defibrination.

As to the second question, there are reasons why the venous blood is to be preferred to the arterial, namely, the veins are more accessible than the arteries. The tapping of a vein is simpler and is attended with less subsequent dangers than accompanies the opening of an artery, besides the blood, although venous in character, rapidly becomes arterialized during the act of defibrination. In addition to these we might ask, should the transfusion be direct or indirect, i. e., should the blood pass directly from the vessels of the donor into the vessels of the receiver without any exposure to air? To this we are inclined to say that we believe it to be far safer to employ the indirect method.

The extreme tendency on the part of the blood to coagulation, and the grave result which attends the introduction of even a minute embolus, not to speak of the chances of the introduction of air, even at the hands of a careful operator, makes us unhesitatingly declare in favor of the indirect method.

Should the transfusion be undertaken for the relief of a poisoned condition of the blood, such as results from the exposure to carbonic oxid gas, the individual should be subjected to venesection before the transfusion is undertaken. In the performance of the operation no elaborate outlay of instruments is necessary. Two or three bowls, a reversible aspirator, a glass rod and a scalpel, all of which being in a perfectly aseptic state, will fill the requirements. Everything in connection with the operation must not only be perfectly aseptic but must be heated to 105 or 110 degrees F. When all is in readiness, the blood is withdrawn from the arms of one or two donors into one of the aseptic bowls, the amount varying from five to fifteen ounces, according to the circumstances of the case. It is rapidly defibrinated by whipping it with a glass rod and then straining through a piece of sterile gauze into an aseptic bowl. This whipping may be carried out for a minute and a half before straining, but still better is to whip for a minute and strain whipping, whipping it a second time and again straining through a fresh piece of gauze. The actual operation must be performed within two or three minutes, and the greatest care must be exercised that all of the air has been forced out of the syringe and tube before the injection is commenced.

*Dangers of transfusion.*—The possible dangers that may attend the operation of transfusion are: Phlebitis, sepsis, embolus and the introduction of air into the veins; all of these can be readily eliminated if the operator exercises care in the transfusion.

## INFUSION.

By infusion we understand the introduction of non-sanguineous fluids into the circulation. Although the popularity of this measure is but of recent date its real history, however, can be traced as far back as the year 1677, when Johannes de Muralto of Zurich practiced the injection of milk into the vessels of one of the lower animals. The term infusion, however, as applied to-day carries with it the idea of a salt solution having the same strength as the serum of the blood. The advantages of this operation over that of transfusion are manifold, especially since death, in the majority of instances, is not due as much to the insufficiency of the remaining quantity of blood as it is to a disturbance of the mechanism of the circulation. By the use of the salt solution the dangers common to transfusion are all minimized and especially the dangers from emboli are entirely absent. This widens the field of its usefulness so that the indications for its use are not wholly confined to conditions following alarming hemorrhages, but include any pathologic state attended with a feeble pulse which is dependent upon a diminution of the intravascular pressure which makes it one of our most valuable measures for combating profound shock.

This property of restoring the tone of the circulation in a condition of shock is not entirely due to the increased intravascular pressure, but also due to the stimulating influence which the salt solution has upon the heart. This fact, however, has not received the recognition which it deserved, for it has been but a little more than a decade since it has practically received any attention.

In the year 1881, transfusion lost most of its esteem as a life saving measure in alarming hemorrhages. At this time E. Schwartz published his paper, "Ueber den Werth der Infusion Alkalischer Kochsalz Losung in das Gefass System bei Acutes Anemie." From this time the adherents to transfusion have been abandoning it in favor of infusion, not that the latter can ever completely replace the former in every case, but because it can successfully replace transfusion in most cases, and where such is possible it is always given the preference, owing to its greater safety and convenience. In view of these advantages, it is proper that we employ the saline infusion in all alarming hemorrhages.

This operation is uniformly followed by an improvement in the circulation. Should, however, the improvement in the circulation last but a brief interval, it is plain that the amount of blood remaining is incapable of carrying on the condition necessary for life and then it is evident that transfusion must be performed in addition to infusion.

In addition, it has been pointed out by other authors that the saline infusion protects the internal organs from a too rapid and extensive abstraction of their parenchymatous fluids, which nearly always occurs after an extensive hemorrhage.

By saline infusion we mean the injection of a solution of sodium chlorid having the same strength as the serum of the blood (0.6 per cent.) into the veins of the bloodless subject. Some add to this a trace of sodium hydrate or sodium carbonate, while others contend that this addition is unnecessary and that should either the carbonate or hydrate exist in proportion of more than a trace, their presence would become positively injurious. Again, others dissolve the salt

in a weak saccharin solution, or the infusion has been successfully carried out by Thomas and others with pure fresh milk.

As for the proper performance of infusion, there are several features to be observed. First of all, the solution should have a temperature of about 100 degrees F. The infusion must be made with a slow, steady and not too strong a stream. Ordinarily, sufficient force is obtained by raising the funnel or the vessel containing the solution to the height of an ordinary arm's length; should this convey the solution with too much force, the latter can easily be regulated by lowering the container to the desired level. The quantity to be employed must depend upon the nature of the case. It is not necessary in every instance to employ as much solution as the amount of blood lost; all that is required is to inject just enough of the solution to restore the tone of the circulation. Ordinarily twelve to fifteen ounces can be considered as the minimum quantity to be used for ordinary purposes, but from twenty to twenty-five ounces may be used in alarming hemorrhages.

The operation itself can be divided into three stages: First, the exposure of the vein, preferably at the bend of the elbow. In the second stage there is one feature that deserves emphasis, the transfusion tip should only be introduced into the vein while the fluid is running. The observance of this precaution not only washes apart the lips of the opening in the vein, but affords an absolute safeguard against the introduction of any air, which is one of the chief dangers associated either with transfusion or infusion. The third step consists in ligating the punctured vein and applying an aseptic compress.

The principal points in connection with the operation are: To have all steps performed in an aseptic manner, to be careful that the infusion is not made too rapidly nor with too much force, otherwise there will be danger of over distending and paralyzing the already much enfeebled heart. Care should also be exercised that too much fluid is not employed which might give rise to a two-fold danger. 1. By the unfavorable influence upon the corpuscles by the dilution of the blood. 2. By raising the intravascular pressure to such a degree as to occasion a rupture of one of the smaller vessels in some vital part of the economy. It is exceedingly important that great care should be exercised to have the salt solution absolutely free from any minute floating bodies, which if present might act as emboli producing death or perhaps a gangrene of one of the extremities.

Before dismissing the subject of transfusion and infusion we desire to recall the fact that owing to the extreme cerebral anemia which exists after dangerous hemorrhages, either of these operations can and should be performed without the use of an anesthetic. In this condition all manipulations are practically of a painless character and owing to the enfeebled heart an anesthetic would only be adding an additional danger.

## ANTO-TRANSFUSION.

By anto-transfusion we understand the forcing of the blood by means of elastic bandages from the extremities to the more vital centers. The indications for this can be summed up as follows: Shock or any condition attended with relaxation and diminished vascular pressure. Again, this is very useful in guarding against accidents in anemic subjects during chloroform narcosis.

## SUMMARY.

In conclusion I beg to submit the following:

1. In enormous hemorrhages the resulting danger are more frequently due to the reduced intravascular pressure than to the actual loss of blood.
2. In view of this the indications point more decidedly toward infusion than transfusion.
3. That transfusion has not received the attention which its merits justify.
4. In transfusion we possess a measure which in the severest hemorrhages is the only agent capable of restoring the vital functions.
5. The indication for transfusion includes any condition which reduces the total quantity of blood to a fatal degree or which alters the character of the blood to such an extent as to render it incapable of sustaining life.
6. When the transfusion is performed for the relief of a poisoned condition of the blood it should be preceded by venesection.
7. Centripetal is to be preferred to centrifugal transfusion.
8. In centripetal transfusion the injection should be made with a slow steady stream, carefully avoiding undue force.
9. In withdrawing the blood from the donor the veins afford an easier, safer and better source than the arteries.
10. Indirect transfusion with defibrinated blood is safer than direct transfusion with non-defibrinated blood.
11. In alarming hemorrhages infusion should be performed before transfusion; should however, the improvement be transient in its nature, the infusion must be supplemented with transfusion.
12. In addition to hemorrhages the indications for infusion include any pathologic state attended with a feeble pulse which is dependent upon a relaxed condition and a diminished intravascular blood pressure, namely, shock.
13. Restoring the tone of the circulation by infusion is not wholly dependent upon the increase of the intravascular pressure, but is in part due to the stimulating influence which the salt solution has upon the heart.
14. In performing transfusion or infusion after an enormous hemorrhage, the use of an anesthetic is not only unnecessary but absolutely dangerous.
15. In the auto-transfusion we have a valuable measure for combating shock and preventing accidents in anemic subjects during chloroform narcosis.

## OVARIAN TUMORS COMPLICATING PREGNANCY; WITH REPORT OF A CASE.

Read before the Chicago Medical Society, June 15, 1896.

BY C. S. BACON, M.D.

Professor of Obstetrics, Chicago Polyclinic.  
CHICAGO, ILL.

Within the last ten to fifteen years the management of this interesting and important, if somewhat uncommon, complication of pregnancy has become much more uniform, with a corresponding improvement in the prognosis. While formerly the let alone policy, the induction of premature labor and the puncture of the tumor were methods quite commonly employed, now the much better results obtained from ovariectomy are generally known and recognized, and this mode of treatment has been substituted for the

others. Two questions of much interest are still undecided. One is, Which is the better route to reach the tumor, the abdomen or the vagina? The other is, What is the best time to operate? The following case is presented because it may have some bearing on these mooted questions and because the casuistic contributions are not yet too great:

Mrs. C., aged 32 years, III-para. Family history good. Nothing abnormal in menstrual history. First pregnancy, four years ago, was without complications. Labor was slow and forceps were applied, probably unnecessarily. Laceration into the rectum with severe hemorrhage resulted. A few months later I was first called in and repaired the laceration. During the examination a small tumor was noticed on one side. The differential diagnosis was not made between a small cyst of the ovary, a parovarian cyst and a pedicled subserous myoma of the uterus.

Soon after the operation the patient again became pregnant. This pregnancy was also undisturbed. I attended her confinement, which was quite normal. After labor the adnexa tumor was again noticed as a rather hard mass, to the side of the uterus, about one inch in diameter.

May 4, 1896, the patient came to me, to arrange for her next confinement. She had removed from the city to a suburb. She had no suspicion of anything abnormal and complained only of feeling unusually weak with much distension of the abdomen. Her last menstrual period occurred Nov. 1 to 4, 1895. Fetal movements were first felt March 17, 1896, *i. e.*, in the twentieth week. She therefore would be in the beginning of the twenty-seventh week of pregnancy.

Examination disclosed the following condition: The uterus lay in the left side of the abdomen, the fundus being but a finger's breadth below the ribs. The child lay with the head presenting, freely movable above the pelvis and corresponding in size to the supposed age of the fetus. In the right side of the abdomen, extending about two inches above the navel, was a tumor which could be distinguished from the uterus by a groove which ran along between it and the uterus one to two inches to the right of the median line. Through the vagina the pelvis was found filled with a tumor apparently in connection with the tumor in the right side of the abdomen. The cervix was reached above the symphysis a little to the left of the middle line.

May 12, in the twenty-eighth week of pregnancy, I operated at the Polyclinic Hospital, with the valuable assistance of Professor Henrotin. On opening the abdomen the large veins of the pampiniform plexus, feeling like coils of intestine, were found lying in front of and to the left side of the tumor, which was not adherent. Its contents were evacuated through a trocar and an attempt made to follow the sac to its pedicle. Then it was found that the tumor arose from the left broad ligament, a fact that could have been suspected from the location of the pampiniform plexus on the left side of the tumor. With considerable difficulty the sac was pushed under the gravid uterus, its broad pedicle ligated and the sac removed. The abdominal wound was closed with deep sutures through the skin and muscular layers, and two rows of continued sutures through the peritoneum and the muscular fascia. A small accidental incision of the peritoneum covering the uterus had been closed with three sutures.

The tumor sac, which held nearly two quarts of brownish transparent fluid, was plainly of ovarian origin.

For thirty-six hours after the operation the patient had considerable pain, for which she received three or four hypodermic injections of one-fourth grain morphia. There was also considerable nausea for two days, but after free action of the bowels she became easy and made a good convalescence. Except for a temperature of 101.2 degrees the evening after the operation there was no fever. As a special precaution against premature labor she was kept in bed till the twenty-third day. She then got up and improved rapidly in strength, and on June 7 felt perfectly well and planned to leave the hospital the next day. During the night, however, labor pains came on, resulting in the delivery of a living child June 8, 9 A.M., not quite twenty-eight days after the operation. The labor was not unusually painful and the abdominal wound, which had perfectly healed, was not disturbed. The placenta was delivered shortly afterward by the Duncan mechanism. Its uterine surface contained several old hemorrhagic fibrinous patches and was quite friable. The child was 43.5 cm. long and weighed about three pounds. It was not very vigorous, and was kept in an improvised couveuse and fed every hour. In spite of this attempt to save it the child became cyanosed and died about eight hours after birth. The patient was

rather weak after labor and had a temperature between 100 and 101 for two days, which then became normal. She is now, one week later, perfectly well.

This case illustrates the rapidity of growth of ovarian tumors during pregnancy. Two years ago, at the last confinement, the tumor was not more than one inch in diameter. There were no symptoms indicating anything abnormal in the pelvis before the beginning of pregnancy; hence we may conclude that the growth of the cyst went on hand in hand with the development of the egg. It was, no doubt, at first located posterior to the uterus, and as it gradually grew to fill the pelvis the uterus was crowded up into the abdomen. Perhaps because the patient was in the habit of lying on her left side, the uterus came to occupy the left side of the abdomen, while the tumor, as it rose out of the pelvis, came to lie to the right of the spinal column.

Two views have prevailed concerning the influence of pregnancy in modifying the rate of growth of an ovarian tumor. Koeberli held that the growth of the tumor might be retarded by pregnancy on account of an increasing pressure and cessation of ovarian activity. A case of Spencer Wells is often cited in support of this view. A patient had a dermoid cyst for eighteen years which decreased in size during successive pregnancies and increased after labor. On the other hand, most cases, like the one reported, support the views of Spiegelberg, who held that ovarian tumors grow more rapidly during pregnancy on account of the increased supply of blood to the pelvic organs. This also accords with the fact that other pelvic tumors, especially fibromyomata of the uterus, increase rapidly in size during pregnancy. There are probably three chief factors which determine the rate of growth, namely, the supply of blood, the degree of pressure on the tumor and the nature of the tumor. In reference to the last element it is well known that dermoids do not grow as rapidly as ovarian or parovarian cysts with fluid or colloid contents. The effects of pressure are seen in cases of tumors which are confined to the pelvis. They may cause much pain and disturbance of the bladder or rectum, and become serious obstacles to labor, without growing to a large size.

In my case the diagnosis was made without difficulty, thus supporting the statement of Schroeder that, with a careful examination repeated if necessary, and making use of anesthesia, a diagnosis is always possible. Yet a mistake is often made. Quite frequently the pregnancy has been recognized and the complicating tumor overlooked. Generally, in these cases, the tumor is small and may cause no disturbance during confinement. If it be located in the pelvis and not spontaneously drawn up into the abdomen, it becomes an obstacle to labor which, undetected, leads to the most dangerous obstetric operations. Forceps are applied, great force is employed, the tumor is ruptured and hemorrhage or peritonitis with death results. Or the soft parts are severely torn, and bleeding with probable infection cause severe illness or death. If the unrecognized tumor be large and labor be not obstructed, it may be mistaken for a twin.

Again, the pregnancy may be overlooked in the presence of a tumor. This was true in eight out of 135 cases of ovariectomy during pregnancy collected by Dsirne. In several of these cases pregnancy was not discovered, even after opening the abdomen, until

the gravid uterus was punctured or incised for a supposed tumor sac. Should the uterine cavity be opened, either through mistake in diagnosis or accidentally, it should be emptied of its contents and its walls united as in a conservative Cæsarean section.

The symptoms which indicate pregnancy in the presence of an ovarian tumor are the cessation of menstruation and the usual symptoms of uncomplicated pregnancy. The symptoms of a tumor when the fact of pregnancy is established are sometimes prominent and often nearly lacking. If the tumor is in the pelvis, the bladder and rectal symptoms with bearing down pains and backache are present. If large, the distension of the abdomen with dyspnea and disturbance of the functions of the kidney and liver are to be expected. Yet it is remarkable how often nearly all symptoms may fail, as illustrated in my case, and then we must rely on physical signs, never omitting the vaginal examination.

If the diagnosis be made during pregnancy, the method of management must be determined by the urgency of the symptoms calling for immediate interference, and the probable result to be expected from leaving the case to nature or from active treatment. Pressure on the heart, lungs, stomach, liver or kidneys, due to a large tumor in the abdomen, resulting in dyspnea, edema, symptoms of intoxication, etc., may call for immediate relief. A tumor confined to the pelvis may also cause so much disturbance, both directly and reflexly, as to render its removal desirable. Another indication for interference may be the danger of abortion. Jetter found among 215 cases, 36 of abortion and premature labor, *i.e.*, about 17 per cent. Pregnancy may be interfered with in one of two ways. The disturbance of the uterus caused by pressure of the growing tumor may directly bring on uterine contractions, or the same pressure may limit the blood supply to the fetus and cause its death, thus secondarily producing labor pains. Twisting of the pedicle with resulting shock or hemorrhage into or rupture of the sac, may also call for immediate interference during pregnancy.

If no interference be instituted and pregnancy go on to term, it may end in various ways. The prognosis has been variously given in different statistic tables. Litzmann records twenty-four deaths in fifty-six labors, *i.e.*, 43 per cent. Jetter gives the death rate at about 30 per cent. Heiberg, as quoted by Müller, found among 271 cases that one-fourth of the mothers and three-fourths of the children died.

The most favorable termination is when the tumor opposes no obstacle to the expulsion of the child. Sometimes when the tumor at first lies in the pelvis there is spontaneous reposition, *i.e.*, it is spontaneously drawn up into the abdomen so that the child can be born. In still other cases it is possible to dislodge the tumor from the pelvis by manual interference. This is the treatment that should be tried first in all cases where the tumor is discovered after labor has already begun. One should always make use of anesthesia, and also place the patient in a favorable attitude, such as the knee-chest position. Care should be taken not to rupture the sac.

If the tumor can be gotten out of the way so as to allow the expulsion of the child, it often falls again into the pelvis and prevents the delivery of the placenta. Here a second reposition, not always very easy, must be made.

The dangers from the tumor are not yet over when

the uterine cavity is emptied. If the tumor again returns to the pelvis it may compress the cervical canal and cause a lochiometra. Post-partum hemorrhage may be caused by adhesions between the tumor and the uterus, preventing efficient uterine contractions. But the most dangerous of all complications are those due to rupture of the tumor or to its rotation and the twisting of the pedicle. Lawrence reports ten cases of this kind requiring laparotomy, and Condamin among others calls special attention to this danger. Suppuration of the tumor is also a frequent occurrence after labor. So common are these results, and so dangerous, that it has become the rule to remove the tumor very soon after labor. Schroeder recommended to wait six weeks, but more recent reports seem to justify a much earlier operation. In case any serious symptom arises denoting one of the complications just described, immediate laparotomy is at once to be done.

It is thus seen that considerable danger is to be anticipated even in the favorable cases where the tumor either causes no obstruction to labor or when it can be removed from compromising the parturient canal. Yet much more serious is the prognosis where the tumor can not be raised out of the pelvis. If it be a monolocular cyst with fluid contents it may be evacuated with a trocar from the vagina. If it be multilocular or if the contents be colloid, or if we have to do with a dermoid cyst it becomes necessary to make an incision into the posterior vaginal wall and break up the contents with the finger. If the tumor be solid it must be removed, through a vaginal incision if that be possible, if not by laparotomy. Should it be impossible to remove the tumor by either route a Cæsarean section must be made. In case the vagina be incised, either for the purpose of breaking up and evacuating the contents of a tumor, or to remove the tumor it is desirable to close the wound before the passage of the child in order to obviate infection or to prevent further tear. This is often difficult to accomplish because the head generally enters the pelvis as soon as the tumor is removed. An attempt may be made to prevent this undesirable rapid progress by elevating the pelvis and keeping the head in the abdomen.

The results of the obstetric operations, the application of forceps and version with manual extraction, are so bad that they should be done only in the most exceptional cases. Version should never be done in a head presentation and forceps, with a mortality of over 50 per cent., are rarely to be used. If the head be firmly wedged between a solid tumor and the side of the pelvis so that the removal of the tumor is impossible perforation and craniotomy is the safest procedure.

When labor is obstructed and no interference at all is instituted the outcome is generally fatal. The woman may die undelivered from exhaustion, or from rupture of the uterus or from infection. The cases are slightly more favorable when the cyst ruptures. If the contents are those of a dermoid the peritoneum will probably be infected and peritonitis result. Cases have occurred when the vagina has ruptured and the tumor extruded followed by the birth of the child.

Since the dangers during labor are great and even if these be overcome the dangers of the puerperium are considerable it becomes important to investigate the results of interference during pregnancy. Three methods have been advocated: induction of premature

labor or abortion, puncture of the sac and ovariectomy. The first method which was championed by Barnes is now entirely given up since the results of ovariectomy are so much improved. It sacrifices or greatly jeopardizes the life of the child and leaves the mother with the tumor and exposed to all the dangers that arise from its rupture, torsion or suppuration.

Puncture of the sac was warmly advocated. Twelve or fifteen years ago even by so eminent a laparotomist as Sir Spencer Wells. It is now generally given up during pregnancy for the following reasons:

1. It gives only temporary relief since the sac often refills very quickly. Atlee punctured a cyst sixteen times and then was obliged to perform laparotomy.

2. There is danger of injuring large blood vessels. Whoever has seen the large veins of the pampiniform plexus during pregnancy must have this danger clearly in mind. In my case I first mistook them for coils of small intestine. One never knows where they lie, on account of the rotation of the tumor, or, as in the case reported, the displacement of the tumor to the opposite side from which it originated.

3. The uterus may be punctured or injured. This has happened a number of times. Should the accident occur Cæsarean section should at once be made.

4. The peritoneum may become infected by the contents of the cyst escaping through the opening made by the trocar.

5. The formation of adhesions with their resulting consequences are an objection to puncture the same as in non-pregnant conditions.

These two palliative operations being discarded there remains to consider only ovariectomy. The results of this operation have been shown so satisfactory by recent statistics that now there is almost universal agreement in advising it. The most recent collection of cases was made by Dsirne in 1893, who has given synopses of the reports of 135 cases. Among these there were eight deaths, being a mortality of 5.9 per cent. The cases since reported would probably not increase the rate of mortality. This shows that the mortality rate for ovariectomy is not greater during than in the absence of pregnancy.

At this point I may consider the question. Which is the better route to reach the tumor, through the abdominal wall or through the vagina? Until quite recently the abdominal route has been selected because it was supposed to furnish a better oversight of the field of operation and enable one to meet the complications that may arise. Especially when the tumor lies more or less in the abdomen it may be difficult to remove it per vaginam. It may be multilocular or it may have colloid contents and there may be adhesions. The advantages of a vaginal operation are well recognized by those who have followed the recent progress of vaginal celiotomy. It leaves no scar in the abdomen to become a hernial opening, and it is a much slighter operation and thus less likely to disturb pregnancy. When we look back to the case reported we see that the vaginal operation would have been easier. The cyst could have been emptied and the sac pulled down and tied off without difficulty. There was considerable disturbance of the uterus in replacing the sac under it. Recent improvement in the technique of vaginal operations has led to the performance of many vaginal ovariectomies and I predict that in the future the operation will be employed much more commonly in these cases.

Another very important question concerning ovar-

iotomy during pregnancy is its influence in interrupting gestation. Olshausen found pregnancy interrupted in 20 per cent. of the cases collected by him numbering 82, while Dsirne in 114 cases found the percentage of interruption to be 22 per cent. Different explanations have been given of the way in which pregnancy is disturbed. Sometimes there is imminent danger of abortion before the operation. Martin reports such a case where abortion was prevented by the operation. The uterine contractions excited by the tumor cause placental hemorrhages of greater or less extent. These disturb the fetal circulation so that the death of the fetus and its subsequent expulsion may result perhaps some time after the operation. Or these hemorrhages occurring before operation may predispose to still more extensive hemorrhages when operative manifestations or vomiting excite still further uterine contractions. Any injury to the uterus as in the separation of adhesions or a wound of the serous coat would help to excite contractions.

Another cause of abortion is the disturbance in the blood supply of the uterus due to the ligation of the ovarian artery. This factor would probably be especially potent in case of a double ovariectomy.

It is quite interesting to study the table given by Dsirne, which shows the effect of the operation in disturbing pregnancy at different fetal ages.

At Mos.	No. Cases	Interruptions of Preg.	Percentage.
2	11	5	45.5
3	28	4	14.3
4	21	2	9.5
5	10	4	40.0
6	11	4	36.4
7	5	3	60.0
8	5	2	40.0
9	1	1	100.0

From this table it is seen that the most favorable time for operating, so far as the fetus is concerned, is during the third and fourth months when only 10 to 15 per cent. of the cases abort. Later 40 to 50 per cent. of interruptions of pregnancy may be expected.

These results are not very satisfactory and have led to considerable discussion concerning the advisability of postponing the operation, in the absence of urgent symptoms, until the child is viable. Fehling and Veit have contended for this rule. Nearly all authorities, however, agree with Schroeder and Olshausen in advocating operation as soon as the tumor is discovered, because of the danger of abortion, rotation of the tumor with constriction of the pedicle and peritonitis, rupture of the cyst, dyspnea, etc. It has not been proven that twisting of the pedicle occurs more commonly during than in the absence of pregnancy. Dsirne found it to occur in only 9.1 per cent. of his cases. This is not a much larger ratio than is found in all cases of ovarian tumors. It is in striking contrast to the frequent twisting found during labor and in the puerperium.

Another objection might be raised to postponing the operation to the last month of pregnancy where in at least half the cases labor will be brought on, namely, the danger of breaking open the abdominal wound. I am inclined to think that there is prevalent an exaggerated fear of the effect of labor pains on a laparotomy wound. The question can be settled only by an examination of the records. I have looked up accessible cases where labor occurred within some days or even weeks after the operation. In but few cases was there any reference to the effect of labor on

the abdominal wound. Generally the reports mention only an uninterrupted recovery. One of the most important cases is reported by Pippingsköld. He removed a large tumor from a patient in whom labor pains had already begun. Labor was completed in a few hours after the operation with no hemorrhage from the stump and no disturbance of the abdominal wound. The only case I have found where reference was made to an abdominal hernia was one of Schroeder's. The operation was made in the fourth month and was followed by abortion thirteen days later. The patient afterward had two children and during the second subsequent pregnancy it is noted that she was troubled with a large abdominal hernia. That this would be laid to the abortion is hardly reasonable in view of the not unfrequent occurrence of hernia after laparotomy in the absence of pregnancy. In my case labor did not cause the slightest disturbance of the abdominal wound.

The question of the time for the operation in its bearing on the prevention of abortion is one of the most important. Each case must be decided on its own merits. If the patient has no children greater effort should be made to save the child than if she has a number, especially does this rule hold when the tumor is double. If the tumor be discovered in the second month the operation should be delayed a month or two because the results in the second month are bad. After the fourth month if the symptoms of dyspnea, etc., including those of impending abortion, be not too urgent it may be desirable to wait until the thirty-fourth or thirty-sixth week provided the patient can be kept under observation. After operation the patient should not rise too early and the first symptoms of labor should receive prompt attention.

426 Center Street, Chicago.

## IN FUTURE BATTLES WHERE SHALL THE FIELD HOSPITALS BE PLACED?

BY EDMUND ANDREWS, M.D.

FORMER SURGEON OF ARTILLERY AND SURGEON IN CHIEF OF CAMP DOUGLAS, CHICAGO.

Behind every fighting line there is a danger space within which lie the wounded. The modern long range rifles, and the new far reaching artillery have greatly widened this zone, while the increased rapidity of fire may sweep the ground with such fierceness that within its range ambulances can not approach, litter bearers can not carry off the wounded, and surgeons can not work. In case the field is very level and devoid of shelter, the problem of where to place the field hospitals, and how to get the wounded back to them has become one which greatly perplexes military surgeons.

Take for instance the level plain on which Chicago stands. From Lake Michigan west to DesPlaines River, and from Evanston southward to Thornton extends a level plateau ten miles wide and thirty miles long, on which the natural contour of the ground affords not the slightest shelter from fire. If two modern armies should meet on such a plain, what could be done with the wounded?

The arrangements of the medical department in battle in a general way are as follows:

A portion of the medical officers accompany the fighting line to give what is called "first aid" to the injured, in which they are assisted by a certain number of fighting privates who have received special

training, and non-combattant "Geneva Cross men," who are still better educated. Whenever there is a lull in the firing these collect the wounded and make temporary first dressings.

The main surgical work is done at places called field hospitals, where are assembled all the surgeons not detailed to accompany the fighting line. In a level field, devoid of shelter, these must be located far enough to the rear so that the assembled patients shall not be cut to pieces by shot and shell nor the surgeons and their subordinates killed in such numbers as to stop the work. How far back must these hospitals go?

Surgeon Major Girard asserts that men may be wounded by the new rifle at 7,300 yards, which is over four miles. I think this is probably a misprint in the Major's article. At any rate no military officer will waste his ammunition at such ranges. Others advise to locate the field hospitals at 3,000 meters behind the fighting line. This is about two miles. Others say 2,000 yards, which is a little over one mile. After much study of the subject, aided by conference with the best military surgeons, and fighting officers, I have come to the following conclusions:

It is the artillery and not the small arms which will prevent the field hospitals in level ground from taking a position anywhere near the fighting line, because the shrapnel shells reach much farther than musketry.

Still the distance back to a fairly tenable hospital ground is exaggerated in many minds by the popular accounts of the great range of modern projectiles. The immense ranges of two, three, or four miles are only obtained by aiming up in the air at high angles and trying to drop the shells from the sky, as it were, among the enemy. This kind of fire is so very inaccurate, that it rarely hits anything, or endangers anybody. Now, artillery ammunition is costly, and very heavy to transport. It is therefore very precious and is reserved for nearer work. No commander will waste it by tossing it loosely all over the country. The artillery begins effective work at about 2,500 yards. It directs its shrapnel shells so as to explode them about fifty yards in front of the line aimed at, that the fragments and contents as they move onward may spread out in a cone and fly in the faces of the opposed troops. The fragments of shell and the enclosed bullets are thus dispersed in the air and soon lose their force. Hence a field hospital some little distance from the line is not in great danger. My observation is that a few badly aimed shells which have failed to burst at the proper point occasionally come into the vicinity, but they are not numerous enough to render the hospital untenable. Highly educated officers say that even on a level field surgeons can work without great risk 2,000 yards from the enemy, or a little over a mile. As their own lines will be nearer than those of the enemy, the field hospitals can usually be carried up to within 1,200 yards of where their own fighting line commences to meet many losses. But even this distance is too great to allow of getting the wounded back, if the enemy persists in sweeping the ground clear of all moving objects.

However, armies do not throw away much needed ammunition, by uselessly firing when there is no charge impending. Most of the firing comes in gusts, with lulls, and sometimes long intervals between. During the firing the injured should lie as flat on the ground as possible, getting behind any available shelter which may exist. When a lull comes, efforts can

be made to get them back. About 70 per cent. of the wounded are able to walk and can go back of themselves. The remaining 30 per cent. have to be carried. Just here is the weak point in surgical arrangements. Although there are four Geneva Cross bearers to each litter, the carrying back of injured men long distances is a most exhausting labor. Lieutenant v. Kries of the Austrian army has experimented on the ability to stand this work. He found that the bearers rapidly broke down with fatigue. Thirty-two bearers, carrying eight litters, brought back a distance of about 1,200 yards only 32 men in about three hours; that is, the bearers can bring that distance in three hours only one man to each bearer, and at the end of the three hours they were exhausted and could do no more.

Now, the bearers number 2 per cent. of the fighting force. In a division of 10,000 men there will be 200 bearers carrying fifty litters. In the 10,000 men engaged, if the loss is severe, there will be 2,000 hit. Of these about 600 will be killed and 1,400 wounded. Of these about 980 will be able to walk, and 420 will require litters. The 200 litter bearers will be able to carry back 200 men to a field hospital 1,200 yards distant in three hours, and the bearers will be so far exhausted as to be obliged to stop, leaving 220 wounded at the front. If the action is only half as severe it would be possible to carry in all the wounded.

At this rate as the ambulances can not work any nearer to the front than the surgeons, it will be impossible to clear the field except by slow degrees, and perhaps by working all night, and searching the field with lanterns.

Lieutenant Melville of the British army comes to similar conclusions. He says in a British brigade of 4,000 suppose 10 per cent., or 400, to be hit. About 30 per cent. of those struck will be killed, leaving 280 wounded. About 180 can walk and 100 will have to be carried, and it can be just barely done by completely exhausting the 80 bearers, if none of them are shot. If the action is more severe and 20 per cent. are hit, 100 will remain on the field after the bearers are exhausted. This looks discouraging; however it shows the great importance of lightening the work of the bearers by getting the field hospitals as close to the front as possible, even if the danger of the surgeons is increased.

The conclusion is this: If the field of battle is level and destitute of shelter, and the enemy insist on keeping the field swept of everything that moves, the wounded must lie where they are, with such first aid as the surgeons in front can give them, until the action is over, or the fighting lines move on elsewhere, and then the field hospitals must move up into their midst.

The opinion in army circles is that in the exigencies of battle, the fighting officers will not detail men from the ranks to aid the bearers, except when necessary to retreat before uncivilized hordes, who would murder the wounded if left behind.

The foregoing discussion is all based on the supposition of a level field such as surrounds Chicago. Fortunately such fields are few. In my own experience I never was in an action where there were not numerous hills and valleys, or at least considerable undulations of ground or standing timber. In these cases fighting lines stretch themselves along the crests, where the soldiers can lie just behind the summit ridge and fire over. The first aid stations can

then be close to the lines and the field hospitals need not be far off. I have sometimes located them less than 300 yards from the front, and even ambulances, conspicuous marks as they are, can sometimes be driven along the hollows, taking the wounded directly from the first aid stations.

Surgeon Fischer, of the Austrian army, thinks the number of wounded will be greatly increased. It seems to me that this popular idea is erroneous. Most of the fighting will be at greater distances than it was formerly, and the new guns are no more accurate than the old ones. Beside, experience shows that even well disciplined men can rarely be made to stick to their work after 30 per cent. of their number are hit. This old rule will be as true in the future as in the past, and no change in weapons will prevent men from shrinking from danger when it exceeds their fortitude.

Fischer also thinks the mortality of the wounds will be doubled, but Melville dissents from that conclusion.

The facts point in two directions. A few wounds will perhaps bleed more than the old ones, on account of swift shots cutting more like a knife than slow ones, but we must remember that the injuries will be inflicted at greater distances, when the bullets have largely lost their velocity.

Close shots will tear and shatter more in consequence of what is called the "explosive effect," but these only occur at near range. Most of the injuries will take place at greater distances, and the bullets being very small, the wounds will on the average be less fatal from shock, and less open to septic infection. Many will heal by first intention.

On the whole, I think that no more men will be hit than formerly, and that of those wounded more will recover.

Finally, all the utensils and everything about the field hospitals must be made as simple and portable as possible, so that they can be thrown into the wagon and rushed forward, at a moment's notice, to where the wounded lie, as soon as the fighting admits of the advance. In this way the men can be taken care of without waiting for the slow, interminable and exhausting work of litter bearers.

2520 Prairie Ave., Chicago.

**E. WERTHEIM'S NEW METHOD OF RESTORING RETRODEVIATIONS OF THE UTERUS THROUGH THE VAGINA.**

BY A. J. HOSMER, M.D.  
ASHLAND, WIS.

The operation consists in shortening the round ligament through the vagina. The technic of the operation in uncomplicated cases is as follows: After the necessary antiseptic precautions, the patient is placed in the exaggerated lithotomy position. (A curettement is performed, when indicated.) The limbs are supported, retractors used, and the cervix uteri is seized with bullet forceps and drawn down, as in vaginal hysterectomy. With a scalpel, a transverse incision about one and one-half inches long is made at the anterior utero-vaginal junction, down to the uterus. Now with the index finger or with blunt pointed scissors, the uterus is separated from the bladder. The vesico-uterine space (anterior cul-de-sac), or rather the peritoneum lining it, is reached

with ease. The peritoneum is seized with two anatomic forceps and opened between them with the scissors. The incision is then extended transversely about an inch each way. Now while still holding to the ante-

FIGURE 1.

rior peritoneal flap with one of the forceps, a needle, with medium sized silk, is passed through it and attaches it to the cut edge of the anterior vaginal wall.

FIGURE 2.

Two other stitches are used attaching peritoneal flap to the cut edge of the vagina, thus entirely covering the raw surface of the bladder. Easily now with the

FIGURE 3.

fingers one can reach the body of the uterus and ascertain its condition as well as the state of the Fallopian tubes and ovaries. When necessary, loosen adhesions, replace ovaries, remove small subserous myomas, etc.

Next, unfasten the bullet forceps from the cervix, allowing it to go back as you roll the body of the uterus forward into the vagina or at least into plain view. If there are no adhesions, the uterus comes forward without force. If there are adhesions they are easily reached with the fingers and separated.

The round ligament is the first cord in sight and can be seen, examined and differentiated from ligamentum proprium and Fallopian tube. The ligament is seized from one to two inches from the horn of the uterus, with bullet forceps and drawn out, thus necessarily *doubling it upon itself*. With medium sized silk, its approximating doubled surfaces are sewed together. By thus folding it upon itself by the use of three or four stitches, the round ligament can be shortened from six to nine centimeters.

The other round ligament is treated in like manner, and thus the uterus is *held up* and anteverted. The stitches holding the peritoneum to vagina are now cut and the two peritoneal surfaces re-united. The transverse incision at the utero-vaginal junction is then sewed vertically thus lengthening the anterior vaginal wall, and shoving the cervix back.

A little gauze is placed in the vagina and the operation is finished, in most cases without having tied a blood vessel, and unless the wound has been infected, without danger.

There is no danger of injuring the ureters, if the operation is done as described above, as they are shoved out of the way. In cases where there is a relaxed vagina and an anterior colporrhaphy is needed, instead of making the transverse incision, an elliptic piece can be removed from the anterior vaginal wall, and the bladder separated from the uterus directly under the eye. The round ligaments are treated as in the first case. In sewing up the vaginal wall you have, of course, done an anterior colporrhaphy.

This operation was first made by E. Wertheim of Vienna, in January, 1896, and his first publication of the same appeared in the *Centralblatt für Gynäkologie* in February, 1896, since which time it has been performed about twenty-five times and with perfect results.

Its advantages over the Alexander-Adams operation are: 1, it leaves no visible scar; 2, the operation is easier to perform, the ligaments being larger at this point and easy to find; 3, the transverse cut in the vagina, sewed vertically, assists in anteverting the uterus; 4, it allows perfect access to the pelvic viscera, thus permitting of minor repairing at the same sitting, when indicated; 5, the operation is less dangerous.

Its advantages over any method of anterior fixation which will prevent the free growing of a gravid uterus are very apparent. The bladder is left in its normal position. A subsequent pregnancy will not be hindered, as the shortened ligaments can stretch as in the normal state. That every antefixation which will prevent the free growing of a gravid uterus is likely to be the source of danger, is well illustrated in Milander's report (*Zeitschrift für Geburtshülfe und Gynäkologie*, Bd. xxxiii, Hft. 3). In fifty-four cases of full term labor after ventrofixation, eleven were operative, four forceps, two Cæsarean sections, four turning and one extraction.

The uterus is not only anteverted, but it is *held up*, as one can very easily prove by doing the operation upon the cadaver, and the organ is not antefixed, but held in its normal position by its normal attachments.

This operation I have witnessed frequently in Schauta's operating room, and the ease and rapidity with which it is done, beside its many advantages over other known methods, is my excuse for sending this report.

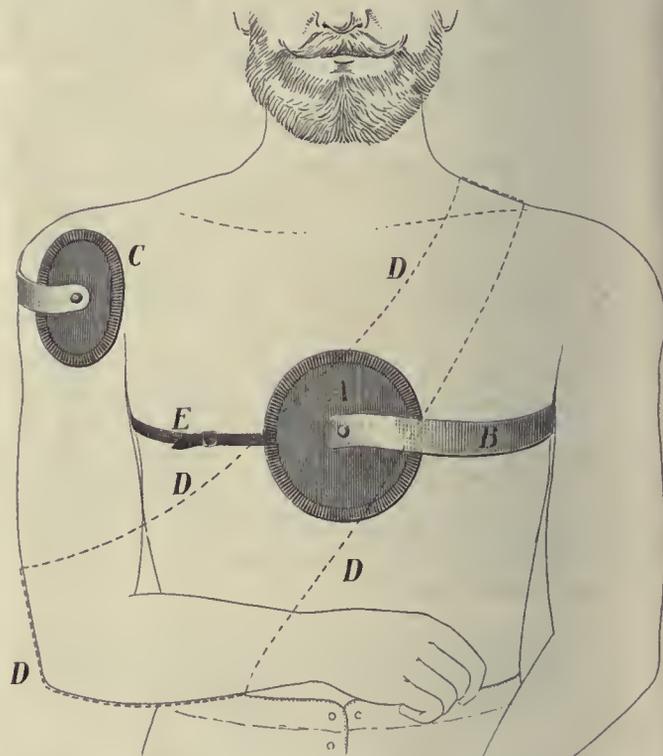

For the past year, I have not had access to any medical journal except the *JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION*, hence if this method of E. Wertheim's has been reported in an American medical journal, I am ignorant of the fact.

## A NEW APPARATUS FOR FRACTURE OF THE CLAVICLE.

BY EVAN O'NEILL KANE, M.D.

KANE, PENN.

The treatment for fracture of the clavicle is almost uniformly unsuccessful. Were it not that the resulting rounded shoulder, narrowed chest and bone deformity do not materially injure the patient, the best surgeons would be continually mulcted in malpractice suits.

Front. A, chest pad; B, spring on sound side; C, shoulder pad and spring on injured side; D, dotted lines indicating ordinary sling; E, elastic strap and buckle.

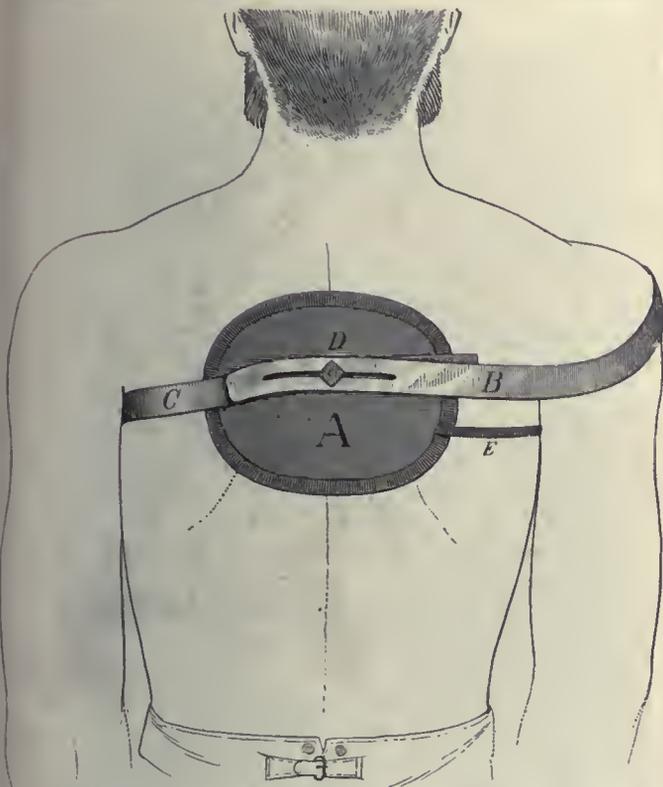

It is true that if the patient can be placed for three or four weeks upon his back; a narrow cushion below and a shot-bag above, a perfect result may be obtained; but few can bear with so irksome a treatment for so comparatively trivial an injury. No other methods of treatment produce perfect results; and all are painful or even prejudicial to the patient's health. Many of these apparatus are now discarded as cumbersome, complicated and unsatisfactory. the pad in the axilla sooner or later exerts so much pressure upon the nerves and vessels as to require its removal. Bandaging the arm across the chest, rarely attains more than fixation and the prevention of falling of the shoulder, while it so cramps the arm and constricts

the chest as to make it unbearable for sensitive patients.

The plaster of paris figure of eight and the adhesive plaster dressing are fairly satisfactory, if they can be endured, but they are, especially in warm weather, very difficult to be borne for more than a few days, and when removed the arm on the injured side is sometimes so paralyzed, swelled or cramped as to be nearly useless for a number of days, while, the results are not perfect in either case.

The displacement in fracture of the clavicle may generally be stated as occurring inward, forward and downward, while on account of the difficulty of overcoming the shortening incident upon muscular contraction considerable over-riding is present.

On account of the difficulty of obtaining a proper point d'appui but one of the deformities is ever completely obviated, *i. e.*, the downward displacement

Back. A, back pad; B, spring passing forward around injured shoulder to terminate in front in small shoulder pad; C, spring passing around chest on sound side to terminate in large pad on middle of chest; D, set screw and slot in spring; E, elastic strap.

usually rectified by some form of sling. I am omitting the treatment by dorsal decubitus.

By my spring-lever apparatus and a sling I believe I have obviated all the difficulties formerly met, securing to my patients fair motion of the thorax and comparative freedom to the hand and arm of the injured side; a perfect co-aptation of the fragments; freedom from shortening and practically no deformity with a minimum of discomfort. My device consists of a combination of springs and pads with an elastic strap. The springs, two in number, are fastened, one on each side, by a screw bolt to a large pad behind, each terminating in front in another.

One pad, large and circular, acts as a counter pressure upon the chest from in front; the other, a smaller one at the termination of the spring on the injured side, is arranged to press upon the anterior surface of

that shoulder. Thus the spring passing from the back pad around the sound side to the chest pad holds the whole apparatus in position, although, allowing full play to the respiratory muscles, while the spring passing from the same position behind, around forward and over the shoulder on the injured side, by its continued traction backward drags the shoulder with it, prevents over-riding or angular deformity of the bone and yet allows motion. The elastic strap though not necessary is an additional security against sliding of the apparatus. It is fastened to the back pad and passes around the thorax on the injured side to be attached to the chest pad in front, and with quiet patients can often be dispensed with.

The same result is attained and maintained *permanently* when the apparatus is in position as that *transiently* produced by the surgeon when he grasps the shoulder and draws it backward in setting the bone; and which he is unable to retain with his dressings when he relinquishes his grasp unless he places his patient in the dorsal decubitus.

In addition, an ordinary sling is required in order to keep the shoulder from falling, but this does not cause any discomfort. The apparatus, which can be taken off or put on as readily as the simplest rupture truss, may be removed every night when the patient retires. He must then, however, lie upon his back, preferably along a narrow cushion. This he is glad to do on account of the additional freedom and comfort afforded. It requires no skill on the part of the attendant to replace the apparatus when the patient arises in the morning.

This contrivance may readily be constructed with a combination of slots and set screws to enable it to serve for either right or left side and for various breadths of shoulders.

In my hands it has been productive of perfect results, as well as affording far less discomfort than any other method of treatment which I have adopted and, though more expensive than ordinary bandages and adhesive plaster, it pays both surgeon and patient amply for the slight extra expense in the comfort it affords, and the freedom from deformity which follows its use.

### SOME UNUSUAL CONGENITAL DEFORMITIES.

Read before the Tenth Annual Meeting of the American Orthopedic Association, at Buffalo, May 18-20, 1896.

BY JOHN RIDLON, M.D.

Professor of Orthopedic Surgery, Northwestern University Medical School; Senior Orthopedic Surgeon to St. Luke's and Michael Reese Hospitals, and Surgeon-in-charge of the Home for Crippled Children, Chicago.

Believing it to be the duty of a specialist to present a record of unusual cases to his associates, I beg to offer for your consideration a brief report of the following cases that have come under my observation during the past three years.

*Case 1. Congenital constriction bands, etc.*—H. D., male, 2½ years old, the first child of healthy parents. There is no physical defect or deformity in the family for at least three generations. The pregnancy and birth were uneventful and in all respects normal. The mother is unable to offer any suggestions as to a possible cause for the deformities.

Left hand: The index finger was joined (webbed) to the ring finger, and the ring finger to the little finger from the tips nearly to the junction of the proximal and middle phalanges; and the middle finger was amputated at the end of the proximal phalanx and was pointed (conical). Otherwise the hand was normal.

Right hand: The index finger was joined (webbed) to the ring finger as in the other hand, and the middle finger was amputated and conical (see Fig. 2); but the little finger instead of being webbed as in the other hand was incircled by a constriction band between the root of the nail and the distal joint (see Fig. 2). Otherwise the hand was normal. When first seen by me all the webbed fingers on both hands had been amputated at the end of the proximal phalanges as shown in Figs. 2, 3 and 4.

Left foot: A constriction band incircled the great toe. Otherwise the foot was normal.

Right foot and leg: The foot presented a moderate degree of talipes equino-varus. This had only been treated by occasional gentle hand stretching by the mother. Around the

FIGURE 1.—Case 1. Congenital constriction band and talipes equino-varus.

ankle was a constriction band (see Figs. 1 and 2) having the appearance of cicatricial tissue, about a quarter of an inch in width. This band creased the soft parts very deeply, about three-eighths of an inch at the front of the leg and about seven-eighths of an inch at the posterior and inner side. The mother reported that at birth there were no voluntary movements in this right foot, but that at the time the fingers were amputated this constriction band around the ankle was incised transversely in three places, and that since that time there have been some voluntary movements in this foot, and that these have increased under rubbing and manipulations. No other deformities or peculiarities were found.

FIGURE 2.—Case 1.

Treatment: Under the impression that there would be no difficulty in looking up the literature of the subject, I arranged to operate on the constriction band about the ankle, but I was not able to find a report of an operation upon such a case. I therefore made two circular incisions around the leg, one above and the other below the band and dissected it out. I found little or no subcutaneous fat beneath the band, which appeared to involve only the skin except at the

points of the three transverse incisions already referred to. At these points the cicatricial tissue extended deeply; it was dissected out. The skin and superficial fat and connective tissue were then dissected up for about half an inch entirely around the leg, both above and below; these edges, bridging over the crease, were brought together and sutured, and dressed without drainage. The result, a year later, is shown in Figs. 3 and 4.

The equino-varus was operated upon about four and a half months after the operation upon the constriction band, by subcutaneous division of the Achilles tendon, manual rupture of the posterior ligament of the ankle joint, and subcutaneous division of the anterior half of the deltoid ligament.

Case 2, was one of congenital constriction bands very much like Case 1, but only affecting the lower extremities. The parents of the patient refused operation; it has been lost sight of, and my notes of the case have also disappeared.

FIGURE 3.—Case 1. Showing result of operation on constriction band.

Case 3. *Congenital amputations.*—Male child, 3 months old when first seen. Born with both legs amputated at the knee joints, and left arm amputated at the elbow joint. No other congenital deformity or defect. This was the third child of healthy and well formed parents, and the mother knows of no congenital deformity in either her family or her husband's family. The child died in Cook County Hospital before photographs were obtained.

Case 4. *Congenital rickets.*—Congenital rickets is, in my experience, exceedingly rare. Indeed, this is the only case I have ever seen. For the photographs of this case and the history I am indebted to Dr. John L. Porter, late House Surgeon to St. Luke's Hospital, Chicago, and now assistant to the Chair of Orthopedic Surgery in the Northwestern University Medical School.

This child (Figs. 5 and 6) was born at St. Luke's Hospital, Chicago, on Feb. 3, 1896, in the service of Dr. J. C. Hoag. Weight at birth 7 pounds. The head presents a typical cranio-tabes, the entire vault from the frontal

prominences to the cerebellar fossæ of the occipital bone and between the two parietal bosses being soft and membranous and without ossification. There are small centers of ossification at each of the above named centers. At birth the parieto-occipital, parieto-frontal and parieto-temporal articulations overlapped. In the upper extremities there was marked enlargement at the distal epiphyses of the radii. In the lower extremities there was a marked exaggeration of the anterior and outward curves of the femora, but the most marked deformity was in the anterior and outward bowing of tibiae and fibulae, together with the enlargement of the distal epiphyses. The feet tended somewhat toward the equino-varus deformity. Tenderness to pressure and manipulation was noticed very early at the enlarged epiphyseal junctions and to some degree over all bony prominences.

FIGURE 4.—Case 1. Another view after operation.

The photographs, Figs. 5 and 6, were taken on the tenth day after birth. They do not show the bowed femora nor the anterior bowing of the shins to advantage.

The mother, 36 years old, has had ordinarily good health since childhood. She has by a former husband two other children aged 15 and 4 years, both in good health and free from deformity. No history of syphilis in the mother or in either husband can be obtained. During the last pregnancy the mother has been in extremely poor circumstances, and has been at work with poor hygienic surroundings and insufficient nourishment up to the date of confinement.

*Case 5. Congenital recurvated knees; knock-knees; talipes equino-varus; spina bifida, with incontinence of feces; and convergent squint.*—The child, a female, was 21 months old when first seen by me; at the time the photographs were made. According to the mother's statement the knees were recurvated about 20 degrees at birth, and very little passive motion at the

joints was possible. Under manipulation the motion has increased. They can now be extended (recurvated) to about the degree above mentioned, and can be flexed about 10 degrees beyond the straight as shown in Fig. 7. The patella can only be felt as minute hardish nodule in the tendon extending from the quadriceps femoris muscle to the tibia on either side.

The knock-knees and the talipes equino-varus, both of only moderate degree, are shown in Figs. 8 and 9.

The spina bifida was the size of a small orange and of firm consistency. The mother stated that it had been much larger prior to the operation by the family physician. The operation appears to have been simply suturing the tumor through and through. A crease, apparently the suture line, appears on each side; one of these is seen in Fig. 7.

The incontinence of feces apparently depends upon the spina bifida. The urine is passed with unusual frequency, but there can not be said to be real incontinence.

FIGURE 5.—Case of congenital rickets, showing anterior and outward curvature of tibia and enlarged epiphyses of tibiae and radii.

The convergent squint is seen in Fig. 8. It is not of marked degree and is seen sometimes in one eye and at other times in the other. The bridge of the nose is sunken and the frontal prominences are protuberant.

The child appears mentally deficient. The parents and the other children are healthy and well formed, and the mother can offer no plausible explanation for the defects in this child.

*Case 6. Congenital polio-myelitis anterior.*—C. S., female, 9 years old when first seen by me. The mother states that at the birth of the child the labor was very difficult and prolonged; and she believes it was dry labor. Dr. Charles Gilman Smith was the attending physician and Dr. W. W. Jaggard, the consultant. Both are now dead and no positive record of the condition at birth can be obtained. Dr. Smith, however, advised operation on the feet. Dr. Charles Adams advised against the operation and none was done. Later, the late Dr. Mathias Roth, of London, England, prescribed elaborate and minute forms of

massage, and the use of steam to induce muscular contraction. Under his direction day braces and night braces were worn. Mr. Bernard Roth has not been able to find any record of this case although the mother is positive that he saw the case with his father. Still later, Dr. Dobie, and his son, Dr. Henry Dobie, of Chester, England, advised an operation, but the advice was not taken and Dr. Roth's treatment was continued for some years.

FIGURE 6.—Case of congenital rickets and cranio-tabes, showing unossified portion of skull with exception of fontanelles.

The child did not walk until  $2\frac{1}{2}$  years old. The braces ordered by Dr. Roth and made by Ernst, of London, were copied by Sharp & Smith, of Chicago, and she continued to wear them until seen by me.

FIGURE 7.—Case 5. Showing spina bifida, and full degree to which flexion of knees was possible.

At that time, both feet were held in full extension (equinus) without lateral distortion. The anterior

part of the feet was broadened and the Achilles tendon attached to the inner side of the posterior border of the os calcis in each foot as it usually is in congenital talipes equino-varus; the leg muscles were shrunken, and the whole general appearance of the legs and feet, taken with the history of the case, led

FIGURE 8.—Case 5. Showing knock-knee and talipes varus.

FIGURE 9.—Case 7. Showing deformities of fingers and toes. me to look upon the case as an ordinary case of con-

genital equino-varus and to prognosticate a development of strength in the dorsal flexors of the foot when relieved of the strain of the extended position.

I divided the Achilles tendon subcutaneously, and had no difficulty in fully dorsal flexing the feet. Good union of the cut tendons took place at the end of two weeks. After this the patient was allowed to walk in braces that prevented the toes from dropping beyond a right angle with the legs, and massage was given daily. At the end of a year and a half the feet remain in good position, but there is no ability on the part of the patient to dorsal flex the feet. Had the case been one of ordinary congenital talipes equino-varus normal strength in the dorsal flexor muscles would ere this have developed; but from the results of treatment I can only conclude that the deformity was due to an intramutrine attack of poliomyelitis anterior.

*Case 7. Congenital constriction bands.*—I am indebted to Dr. Chas. E. Thompson, of Scranton, Pa., for permission to publish the following case:

J. L., male, 6 years old, robust and strong in every way (Fig. 9). Father, mother, three brothers and three sisters living, well and well formed. The mother attributes the deformity to the fact that during the third month of her pregnancy she tied a cord tightly around her own finger to stop the bleeding from a cut.

At the birth of the child the following deformities were noted:

Right hand: Constriction band around the middle finger, in front of the nail on the dorsum and somewhat farther back on the palmar surface. See Fig. 9. Otherwise the hand is normal.

Left hand: All of the middle finger beyond the distal end of the proximal phalanx was absent "except a mere thread" which the mother removed. The remaining stump is shown in Fig. 9. Otherwise the hand is normal.

Right foot: Distal phalanx of great toe amputated; and two distal phalanges of second toe amputated. Third toe has no nail. Otherwise the foot is normal.

Left foot: Great toe and second toe amputated as in the right foot. The third toe is considerably longer than its fellows. There is a constriction band surrounding the second phalanx; on the dorsum it approaches the third phalanx and on the palmar surface it approaches the first phalanx. The fourth toe is very much smaller than its fellow on either side. The fifth toe is normal as is the foot in every other respect.

## SELECTIONS.

**On Solid Preparations for Internal Use.**—The past decade has wrought great changes in the administration of medicine. Responding to the more esthetic demand of the age, medical practitioners have quite largely dispensed with the older forms of liquid mixtures, and adopted the solid and more elegant products of the pharmaceutical art. While dry medication has been increasing in favor for the past twenty years, history discloses some of the errors its votaries have been led into. First was the sugar coated pill period, which set in about 1870 and reigned supreme until about 1880, when it was superseded by the gelatin coated pill, despite the attempt to stampede its followers in 1875 by the compressed pill. For ten years the gelatin coated pill was the favorite form, until the general use of gelatin capsules relegated it to the insoluble and unsatisfactory sugar pills of the patent medicine men.

The introduction of the tablet triturate some ten years ago met with much favor for the administration of alkaloid salts, and represented a convenient form for the ready preparation of solutions for hypodermic and antiseptic use. But, as disclosed by the history of other forms of medication, the original purpose of the tablet triturates was perverted, and in the modified form of compressed tablets, the "idea" was extended to comprise nearly every combination of remedies, irrespective of therapeutic uses, and in utter defiance of well-known chemic and pharmaceutical laws and principles.

For the purposes of studying the administration of solid substances, they may be grouped, from a therapeutic point of view, as follows:

**Powders.**—The medicinal agent in a finely divided condition, either alone, associated with some other agents or triturated with some inert substance. The object to be attained is either quick solution, absorption or local effect, which is produced in the degree that the mixture is finely powdered. Following the law of solution, the greater extent of surface presented to the solvent action, the more the process of solution is facilitated. With most substances the effect is a question of absorption, which is again dependent upon solubility. The only exception to this are sugars and gums, which dissolve so readily, and the solution formed is so viscous, as to interfere with complete solution except under certain conditions.

**Troches, lozenges, tablets, pastils and similar forms** by whatever name, mixtures of medicinal substances intended for solution in the mouth.—The medicinal agent is incorporated either with a dry diluent, such as sugar, and the mixture made into forms by compression, or into a mass with an excipient and then divided into various forms, as in pills. The medicinal agent is mixed with the diluent or excipient, which, being sugar or gum, slowly dissolves by the heat and moisture of the mouth and serves as a vehicle for the gradual distribution and solution of the medicinal agent. A prolonged local effect is thus produced upon the surfaces of the throat and respiratory organs.

**Pills.**—Medicinal agents designed for slow solution and retarded absorption in the stomach and intestines. These are made into a mass with adhesive substances, gum, sugar, etc. (excipient), which, responding to the exception noted in relation to solution, permit the gradual solution of the mass, and consequently retard the effect of the medicinal agent. The complete solubility of a pill is of course essential in order to assure the desired action, and for this reason such excipient must be selected as will not react with the medicinal agent, so as to cause the mass eventually to become hard and insoluble. The essential property of a mass and therefore of a pill is a physical condition which will insure softening; then gradual disintegration and finally complete solution in digestive or intestinal fluids. A pill may be so hard as to be brittle (comp. cathartic pill) and yet be perfectly soluble, and again when so hard the pill may be almost insoluble in the liquids of the body. The salts are generally not adapted to the pill form unless mixed with extractive or saccharin matter as in the case of the compound cathartic pill, and compounds of mercury, antimony, etc. The salts of the alkaloid are largely administered in this pill form and may become quite insoluble in course of time. Even the substances mostly used as excipients, sugar and gum, while inert therapeutically, it must be remembered are not chemically inactive and may produce compounds more or less insoluble upon change and exposure. This is true in a greater degree when two or more chemic agents are combined in a pill. For example, bismuth subnitrate and calomel made into a mass with mucilage or glycerite of starch affords a pill which, upon standing, becomes as hard as cement and entirely insoluble. Reactions take place between chemic substances like these, no matter how carefully selected the excipient, which either impairs their solubility or renders them otherwise unfit for therapeutic uses.

The medicaments adapted to the pill form administration may be said to comprise the following:

Tonics, hematinics, stomachics, hepatics; purgatives, laxatives, cathartics, anthelmintics; ecbolics, emmenagogues, antispasmodics; antigonorrhoeal, aphrodisiacs, antiaphrodisiacs.

The medicinal agents adapted to the troche or tablet form of medication are confined to the following:

Astringents, antacids, aromatics; expectorants, pulmonary sedatives; demulcents, emollients, vermifuges.

Powders.—These comprise by far the greatest number of remedies, but the following are chiefly represented by this form of medication:

Emetics, diaphoretics, sialogogues; sedatives, narcotics, hypnotics; tonics, antiperiodics, antipyretics.

The objection to powders is the disagreeable taste of many remedies. Since this has been overcome by the use of cachets or konseals it leaves in this modified form powders as the most elegant form in which a very large class of remedies may be dispensed. It enables the physician to formulate his own prescriptions instead of prescribing ready-made combinations, and also affords the pharmacist the opportunity to practice his art for the preparation of medicines.—Read by C. S. N. Hallberg, Ph. G., at the Forty-fourth Annual Meeting of the American Pharmaceutical Association, Montreal, Aug. 15, 1896.

**Reduction and Fixation of Fracture of the Zygomatic Arch.**—Dr. Rudolph Matas describes his method in a case of fracture without laceration of the overlying tissues: As the injured area was extremely sensitive, a general anesthetic was administered. The usual antiseptic precautions were carefully observed. A long, full curve (semi-circular) Hagedorn needle, threaded with silk as a carrier, was made to penetrate the skin about one inch above the midpoint of the displaced fragment, and was carried well into the temporal fossa under the broken bone. Then the point of the needle was raised and made to emerge about half an inch below the lower border of the broken arch. As the needle was pulled out a strong silver wire about one foot long was attached to the silk carrier and dragged through the tract of the needle so as to form a metallic loop under the misplaced bone. By twisting the ends of the wire together, a loop was formed which permitted strong and easy traction to be made on the broken fragment. Traction was begun by pulling directly upward and outward. The displaced fragment yielded and instantly returned to its normal position with a snap. The contour of the arch was immediately restored and the displaced fragment showed no disposition to relapse into its abnormal position. Notwithstanding the apparent permanency of the reduction, it was not deemed prudent to trust the fracture without a more permanent support, and the following simple plan was adopted to secure permanent fixation: An ordinary glass slide of the kind used for mounting microscopic sections, after careful sterilization, was wrapped in a layer of iodoform gauze and placed over the seat of the fracture with its greatest length corresponding to the long axis of the zygoma. The slide was long enough to rest upon the malar prominence anteriorly and upon the temporal root of the zygoma posteriorly, thus resting upon two fixed points. After twisting the wire firmly over the splint, it was evident that the bone could not be displaced. The dressing was then completed by applying a layer of sterilized gauze and absorbent cotton over the slide as a dressing, the whole being held in place by a roller head bandage.

On the second day following the reduction, a thin shell of vulcanite or dental rubber, molded to the shape of the normal zygomatic prominence, was prepared by a dentist and substituted for the glass slide. The wire which held the fragment in position was not removed, but twisted over the vulcanite shield. The new splint was now covered with a layer of absorbent cotton soaked in flexible collodion and applied without any additional dressing. The patient was confined to his room only twenty-four hours. On the ninth day the wire, splint and all dressings were permanently removed. There has been ever since (about fifteen months), a total absence of scar, deformity or inconvenience.—*New Orleans Med. and Surg. Jour.*, September.

**Physiologic Study of the Uterus.**—Keiffer's thesis on the uterus is winning him honors at home and abroad. It is based on the most extensive and thorough research-work, with the myo-

graph and manometer on dogs and other animals. He states as the results of his experiences: 1. That the uterus in dogs contracts under the influence of central and peripheral excitation of the median, crural and sciatic nerves. Also of the parietal and visceral peritoneum, and of the pelvic organs. Also of the vagus, both central and peripheral. Also of the direct excitation of any point of the genital apparatus. 2. The crural nerve can suspend, by reflex action, the tonicity of the uterus. He has observed, in fact, remarkable relaxation of the uterus caused by exciting the central and terminal segment of this nerve. He explains this fact by the inhibiting influence exerted by the spinal cord on the uterus, and peripheral excitation of the crural nerve, sets this influence in play. 3. The pneumogastric nerve is not a direct excito-motor of the uterus. Frank has already established this in regard to the bladder. But Keiffer found that excitation of the central end of the pneumogastric produced a most active response. The action is therefore, reflex. There was no response to excitation of the central end of this nerve after section of the spinal cord at any point in the dorsal or lumbar region. Hence centripetal excitation of the pneumogastric must act through the mediation of the motor centers in the spinal cord. Every excitation of the peripheral end of the vagus invariably produced very decided curves. But if sufficient atropin is administered to the animal to inhibit the suspension action exerted on the heart by exciting the vagus, with the accompanying modifications in arterial pressure, or if sufficient chloroform is given to extinguish the reflex sensibility of the vagus, there is no motor reaction, not even when the strongest electric stimulus is applied. 4. Asphyxia causes tonic contractions of the uterus by the action of the asphyxiated blood on the lumbar genito-spinal centers. In all of Keiffer's experiments, arresting the respiration produced extreme constrictive muscular activity in the uterus. As soon as respiration became reëstablished, the muscular activity subsided to normal. This phenomenon does not appear after destruction of the lumbar portion of the spinal cord. 5. The cervix uteri is a true sphincter like the other muscular rings of the body, but resembles most the iris. There is no antagonism between the muscular activity of the body and that of the neck of the uterus, but both combine in a succession and combination of movements to produce the maximum effect in shortening the uterus and dilating its outlet. The cervix as it opens obeys the suspensive action of its circular sphincter, but also and principally, the constrictive action of its radiating fibers, and a longitudinal constriction of the vagina and of the body of the uterus. 6. The tonicity of the uterus is maintained by the reflex activity of the lumbar portion of the spinal cord. 7. The tonic center seems to be located in the dog, on a level with the principal part of the fifth lumbar vertebra. 8. In the coördination of the muscles of the body and of the neck of the uterus, opposite effects may be produced in one or the other of them, at the same time, and by the same excitation. 9. The pneumogastric is not an excito-motor nerve, nor a direct moderator of the uterine sphincter. 10. Asphyxia contracts the cervix; then relaxes it. 11. Acute anemia produces complete relaxation of the cervix uteri; transfusion produces constriction. The proof that the tonicity of the cervix is maintained by reflex activity proceeding from the spinal cord, lies in the following facts established by these experiments: 1. That the cervix can support a pressure indicated by a column of liquid that varies with the excitation, if the cord is intact. 2. That the height of this column, and consequently the amount of pressure supported, can be increased or diminished at will by exciting the lumbar portion of the cord (fifth lumbar vertebra). 3. That destruction of the spinal cord in the vicinity of the fifth lumbar vertebra paralyzes the cervix to a greater or less degree. 4. That destruction of the region of the spinal cord below the fifth lumbar vertebra completely abolishes the sphincter function. It even

relaxes the entire uterus. 5. It is probable that this point in the spinal cord corresponds in the dog, to Budge's genito-spinal center, which varies in different animals. In conclusion Keifer seeks to establish an absolute physiologic similitude between the uterus in mammals and the human uterus, basing his statements on the development of the embryo, and on a long array of clinical facts which confirm what he has learned in his experimental investigations.—*Annales de la Soc. Méd.-Chir. de Liège* for July.

**Success of Ichthylol in Tuberculosis.**—The efficacy of ichthylol in the treatment of whooping cough, ozena, urethritis, etc., has been announced in these columns, and the *Journal de Méd. de Paris* of August 9, now adds an enthusiastic recommendation of it as an effective weapon in our struggle with tuberculosis, the first article which has appeared in France, although Scarpa, Unna and Cohn have been advocating it for some time, with a record of 300 cases treated. The writer is Le Tanneur of the Belleville Consumption Hospital and Dispensary. He describes his experiments to determine the antiseptic power of ichthylol, and states that absolute sterility is secured with 5 per cent., although the shape of the Koch bacillus is altered and its development much retarded at 2 per cent. and even less. He administered it to his patients in capsules (Chiron's) 0.25 centigram each, from four to twenty-four a day. No effect was observed under six to eight capsules. He commenced with two and increased to twenty per day, taken three times a day, during the meals, but there is no necessity for so much caution now, as none of the fifty cases treated ever showed any inconvenience from its use, and several cases of complicating diarrhea and gastric disturbances were found to be cured by it. The cough was much improved owing to the liquefaction of the sputa produced by the ichthylol, which also cured the congestion of the bronchial tubes. The color of the expectorations changed from green to yellow, then to gray, and finally to the ordinary color of mucous secretions, a long stride toward recovery, even in the minor point that they ceased to cause gastric disturbances when swallowed. The dyspnea is relieved at once by the liquefaction of the sputa and the decreased congestion, which rests the heart and raises the general tone of the system. Pain in the intracostal region is also much relieved, probably for the same reason. The general health does not show improvement as soon as with hypodermic injections of guaiacol, but it arrives and progresses none the less surely, and the patients gain flesh much more than with guaiacol. Several gained seven to eight pounds in the first month, others four, and two-thirds of the cases showed marked increase in weight. The sweats also diminished, but apparently only as the general health improved, as this effect was not noticed as promptly as with creosote or guaiacol. The appetite was not unfavorably affected as frequently by guaiacol, but was improved and restored to normal in many cases. One of the ten observations he records was a man of 41. Primary tuberculosis, coughing and expectorating for four years, without relief from creosote or any remedy. Fever 102 degrees every day. Dullness at the upper part of both lungs. Gained six pounds in one month of ichthylol treatment. Coughs only in the morning and "feels strength and respiration returning." Another, 67. Bronchial catarrh for thirty years. After one month of ichthylol treatment cough entirely gone, and "feels better than ever." Another, 35. Advanced case of tuberculosis. Strength entirely gone. After one month, "Aspect of astonishing health." Coughs less than a quarter of what he did previously.

Le Tanneur concludes by stating that while ichthylol is by no means the long-sought specific for this terrible disease, yet great benefit is derived from its use as a substitute for creosote and guaiacol when, as so often happens, the system has become so habituated to them that they fail to affect it. It is

especially indicated in bronchial tuberculosis, which it most promptly relieves. Its disagreeable odor renders the use of the capsule imperative.

## PRACTICAL NOTES.

**Success of Serum Treatment of Oriental Plague.**—A telegram from Yersin announces that he has succeeded in curing twenty-five out of twenty-seven cases of the bubonic plague with his anti-plague serum from his laboratory established in Annam a year ago. The usual mortality is 95 per cent.—*Bulletin Méd.*, August 12.

**Thermotherapeutics of Gonorrhoea.**—Neisser has stated that the gonococcus loses its power of development at a temperature of 113 degrees. Callari has found that the normal male urethra will bear this temperature and the female two degrees higher. He has been treating gonorrhoea with injections at 113 degrees and reports a progressive disappearance of the gonococci in the majority of cases with this treatment. In order to avoid unnecessary congestion, he injects a 6 per cent. solution of cocain ten minutes before.—*Gaz. degli Osp. e delle Clinic.*, August.

**Successful Treatment of Ozena with Ichthylol.**—It is reported from Vienna that ichthylol will cure the fetid breath in ozena more rapidly and permanently than any other known remedy. After washing off the crusts with tepid water, two or three syringes of a 2 to 5 per cent. solution of ichthylol are injected into each nostril, the head held well forward and the mouth open to avoid swallowing the liquid. The rhino-pharyngeal mucous membrane is then swabbed with a cotton wad dipped into a 25 to 30 per cent. solution of ichthylol. It is also stated to be the best treatment for dry pharyngitis, with or without complicating ozena.—*Semaine Méd.*, August 12.

**Fragrant Antiseptics.**—In cases of foul smelling cancers, etc., the odors are completely disguised if the room and bed are well sprayed with a mixture of alcohol, 500 gr., essence of thyme and essence of lavender, 50 gr. each. This agreeable disinfectant also possesses powerful antiseptic properties. Huchard recommends a similar antiseptic spray for the apartments of tuberculous patients: guaiacol 50 grams, eucalyptol 40, phenic acid 30, menthol 20, thymol 10, essence of cloves 5 and alcohol at 90 degrees, q. s. to make one liter.—*Gaz. Méd. de Liège*, August 20.

**Hypodermic Alimentation with Saccharin Solutions.**—Some recent experiments at Munich with persons in normal health prove that artificial alimentation is possible in this way. Dextrose, levulose and maltose injected in a 10 per cent. solution were entirely assimilated by the organism, while cane or grape sugar were rejected and eliminated *in toto* by the kidneys. The slight pain that followed the injections was cured by massage. The best method of making the injections is to use a glass receptacle with a rubber tube and T-shaped canula. A needle is inserted into each branch of this canula, so that an injection can be made into each thigh at the same time, and a whole liter injected in fifteen or twenty minutes. The amount was increased progressively from 100 to 1000 c.c. Former experiments at Würzburg failed of success probably because the solutions were too strong.—*Semaine Méd.*, August 12.

**Treatment of Syphilis with Mercuric Iodid Hemol.**—As this is the only preparation that contains iron, its use is indicated whenever a tonic action is desired. It is effective and simple, although no internal medication takes the place of frictions and injections. Rille reports thirty-seven cases he has treated and eighteen from Neumann's practice. A few slight transient inconveniences followed its use occasionally, but they were less than with any other internal medication. He administered it as follows: 10 grams Kohert's mercuric iodid hemol; 0.8

decigrams opium powder, and q. s. licorice powder; made into fifty pills; taken two or three times a day, after meals. He recommends it for anemic and scrofulous cases of syphilis.—*Annales de Derm. et de Syph.*, July.

**What is Indicated by the Tongue.**—A white tongue, according to Dr. Ardhill, indicates febrile disturbance; a brown, moist tongue, indigestion; a brown, dry tongue, depression, blood poisoning, typhoid fever; a red, moist tongue, inflammatory fever; a red glazed tongue, general fever, loss of digestion; a tremulous, moist and flabby tongue, feebleness, nervousness; a glazed tongue with blue appearance, tertiary syphilis.—*Pop. Science News*, August.

**New Method of Preserving Specimens with the Original Coloring.**—Some preparations a year old were exhibited recently at the Académie de Médecine by Melnikoff-Rasvedenkoff of Moscow, which appeared as fresh and perfect in their coloring as if they were only a few hours old. According to this new method the fresh organ is placed in formalin, an aqueous solution of formaldehyde at 40 per cent., which toughens and discolors the tissues. At the end of twenty-four hours the piece is transferred to alcohol at 95 degrees, and left six to eight hours. In this bath the organs recover their previous coloring and the blood a tint as if the vessels had been freshly filled. The piece is then placed in an aqueous glycerin solution of potassium acetate. (Acetate 30, glycerin 60 and dist. water 100.) This sets the color permanently. After this it is removed to the final preserving fluid, made by boiling together 100 grams of gelatin and 600 grams of water, to which are added 350 cubic centimeters of solution of potassium acetate. After filtering this through a double filter, 700 cubic centimeters of glycerin are added, and the process is complete.—*Bulletin*, August 4.

**Actinomycosis of the Lower Jaw.**—Ducor of Paris reports a case of an enormous tumor on the lower jaw, with great emaciation and general distress. The patient belonged to the upper classes and submitted to treatment from twenty surgeons, during eight years before a correct diagnosis and relief were obtained. Ducor suspected and established the presence of the ray fungus, and secured great improvement with potassium iodid, 2.5 grams per day, painting the intra-buccal surface of the tumor with tincture of iodine, and injecting it into the parenchyma, mixed with equal parts of glycerin. Potassium iodid in this case again, showed itself the specific remedy for actinomycosis, although the lesions were of too long standing to expect complete recovery. There is no doubt that this disease is far more frequent than is generally supposed, but fails of recognition, so that the possibility of actinomycosis should be borne in mind in any tumor of the jaw. In this case it was found that the patient had the habit from her youth of chewing grains of wheat, etc., and picking her teeth with the stems. See this *JOURNAL*, July 11 and 25, pages 98 and 226.—*Bulletin de l'Académie de Méd.*, August 4.

**Treatment of Malarial Splenic Troubles with Oleate of Rue and Cyclamen.**—In a communication to the *Gaz. degli Osp. e delle Clin.*, August 9, Colasuonno remarks that physicians in Italy have especial opportunity to observe the effects of malaria, and that he has had a wide experience in treating splenic disorders, which are the most important manifestation of chronic malaria, as the spleen is not only the chief seat of the localization of the active agents of the disease (Maragliano), but owing to the frequent hypertrophy produced, it causes a series of ills, especially if the organ becomes displaced. He then proceeds to announce with confidence that he has established the efficacy of a combination of oleate of rue and cyclamen roots as a remedy for malarial splenomegalia, and has even secured complete recovery in a case of wandering spleen. This was a woman of 40 who came to the hospital at Naples to have an operation performed, as the enormously hypertrophied and

displaced spleen caused by chronic malaria was producing intense gastric disturbances. Instead of an operation the region was frictioned five to ten times a day with the oil of rue and cyclamen. At the end of a month of this treatment the spleen had been reduced to its normal size and position, and has remained normal during the seven years since. He used equal parts of crushed cyclamen roots and oleate of rue made from the leaves, which he has well rubbed into the region, with massage.

**Ununited Fracture—Use of Bone Ferrule.**—The patient sustained a severe fracture of the humerus some months ago as the result of a gun-shot wound. There was great loss of the shaft of the bone with paralysis of the musculo-spiral nerve. The case had been operated upon on the Pacific Coast, at which time several fragments were removed and the remaining ones wired together. Unfortunately there was no attempt at reunion. On April 2, we operated upon this case and found that there was great longitudinal diastasis of the fragments of the bone and also those of the nerve. The fragments of bone were freshened obliquely and a bone ferrule slipped over the point of their approximation. These ferrules are made from the femur of an ox and have been but partly decalcified. The distal end of the nerve was easily found in this case, while the proximal end was found with great difficulty. After succeeding in finding it, however, we sutured the ends and surrounded the point of union by muscular tissue, in this way preventing the implication of the line of union of the nerve with the cicatrix of the bone. At the point of the fracture we now find considerable definitive callus. The ferrule has taken the place of the provisional callus. We have every reason to believe that this case will soon recover. I know of no more effective way of uniting compound fractures, whether primary or secondary, than that by means of fixation with bone ferrules. The limb was dressed with a simple right angle splint, held in position by a plaster of paris dressing, which included the shoulder. The bone ferrule will be absorbed in from six to eight weeks.—Dr. Nicholas Senn in the *Clinical Review*, September.

**Veratrum Viride in Puerperal Eclampsia.**—Dr. C. D. Hurt says: Veratrum viride is a nervous sedative, a muscular relaxant, a glandular excitant. When taken into the system it lessens the susceptibility of the sensory nerves, and modifies the action of the spinal cord and vasomotor nerves. At the same time, if coma exists it has a property of removing it and restoring the mental functions. Other remedies for puerperal eclampsia have their places, and some of them are valuable; but no one meets all the indications as does veratrum viride. Taken internally chloroform acts as a sedative narcotic, operating chiefly through the nervous system, independent of vascular action or congestion or without any beneficial influence on the latter condition. Veratrum is a sedative, operating through the nervous system, relieving coma, and removing congestion, and eliminating certain effete matters by stimulating the secreting organs. Bromid of potash and chloral are too feeble, unreliable and slow in their action. Morphin stupifies, lessens pain, but is objectionable in locking up the secretions. Apomorphia produces greater distress with fewer good effects. Venesection is admissible in all robust patients or cases of plethora, by removing a certain amount of effete matter from the system and encouraging easier and more rapid dilatation of the os. Indeed, with venesection and the judicious use of veratrum there is no condition of the os not dependent upon actual stenosis which will not yield to parturient pains and avoid the necessity of incising—a surgical dexterity into which some obstetricians are easily tempted. Veratrum is suited to the treatment of eclampsia, whether ante-partum or post-partum, unless chronic disease or excessive anemia be present.—*Atlanta Clinic*, August.

THE  
Journal of the American Medical Association  
PUBLISHED WEEKLY.

SUBSCRIPTION PRICE, INCLUDING POSTAGE:

Per Annum, in Advance . . . . . \$5.00  
Single Copies . . . . . 10 Cents.

Subscriptions may begin at any time and be sent to

THE JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION,  
No. 61 Market Street (Occidental Buildings), Chicago, Illinois.

MEMBERSHIP IN THE AMERICAN MEDICAL ASSOCIATION.

This is obtainable, at any time, by a member of any State or local Medical Society which is entitled to send delegates to the Association. All that is necessary is for the applicant to write to the Treasurer of the Association, Dr. Henry P. Newman, Venetian Building, Chicago, Ill., sending him a certificate or statement that the applicant is in good standing in his own Society, signed by the President and Secretary of said Society. Attendance as a delegate at an annual meeting of the Association is not necessary to obtain membership.

On receipt of the subscription the weekly JOURNAL of the Association will be forwarded regularly.

Gentlemen already members of the Association should send their annual subscription to the Treasurer, or direct to the JOURNAL office.

All communications and manuscript of whatever character, intended for publication in the JOURNAL, should be addressed to the Editor, and all communications relative to the business of the JOURNAL, proof sheets returned, or in regard to subscriptions, should be addressed to THE JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION, 61 Market Street (Occidental Buildings), Chicago.

Original communications are only received with the understanding that they are exclusively contributed to this JOURNAL.

INFORMATION WANTED.

It would greatly facilitate the prompt delivery of the JOURNAL to those members of the ASSOCIATION living in large cities, if they would kindly furnish this office with their street address in those cases where it is omitted from the wrapper of their JOURNAL, as we have been notified by the postmasters of the larger cities that second-class mail matter not having street address, would be placed in the general delivery to await call.

SATURDAY, SEPTEMBER 12, 1896.

JANUS.

The name of the two-faced Latin deity has been given to a bi-monthly journal, the first issue of which, for July and August, 1896, has just reached this continent from its headquarters in Amsterdam, Holland. JANUS looked backward as well as forward that he might have ever in view the lessons of the past for his guidance in the uncertainties of the present, and he is thus made to symbolize the intentions of the Editorial Staff of this new undertaking in medical literature, the "Archives internationales pour l'Histoire de la Médecine et la Géographie médicale," or rather this attempt to resuscitate, under the conditions of the present day, an undertaking which failed under those of half a century ago; for although to many this *Janus* is a new thing, to those who are versed in the archives of medicine it is *Janus Redivivus*. This is shown in an enthusiastic introductory paper written by Professor STOKVIS of Amsterdam, at the request of M. le Directeur Dr. PEYPERS of the same city, who modestly characterizes himself as too little known out of his immediate circle to be the proper accoucheur for an international journal.

Fifty years ago, that is in 1846, an era of extraordinary progress dawned upon medical science. The heavy chains of the philosophy of the age, with which the natural sciences, together with the science of medicine in Germany had been riveted, were broken forever. The microscope and other new appliances for physical research, with newly discovered chemical methods, led to a return to experiment and careful

observation. Hypotheses and systems were rejected, while facts developed by the methods of natural science conduced to the recognition, one after another, of many hitherto unknown biologic phenomena of the greatest importance to the science of art and medicine. The cell was already appreciated as the primitive element of life. HENLE had already published his Anatomy, in which he continued the immortal work of BICHAT. The predecessors of PASTEUR in following the light of SCHWANN and HELMHOLTZ had already shown that fermentation is a vital process which ceases as soon as the conditions needful to the life and development of the microorganism are withdrawn; and the medical world was on the verge of the discovery that every special fermentation is determined by a specific microorganism, and that those of the alcoholic, acetic, lactic and butyric fermentations, are distinguished one from the other, not only by their function, but by their form. At this time medicine became permeated with new blood. The fruits of the genius of CORVISART, of LAENNEC and of CRUVEILHIER, had been planted, improved and propagated by SKODA and ROKITANSKY of the school of Vienna. HENLE was preparing his Rational Pathology. CLAUDE BERNARD, who unveiled so many of the mysteries of animal and vegetable life, was already close to his discovery of the glycogenic function of the liver. The brothers WEBER had just announced the first illustration of an inhibitory nerve. TRAUBE was beginning his beautiful series of researches in experimental pathology, and VIRCHOW, the grand master of our modern pathology, revealed in this year the pathogenesis of fibrin in the vessels, of embolism of the pulmonary artery and of leukemia.

In the midst of this era of progress the original *Janus* was started by HENCHEL of Breslau, aided by many foreign collaborators. It may be observed that a number of National Archives had been launched before this, and had foundered because one country alone was unable to sustain a historic review on the paying basis of a practical journal, just as at present it is claimed that one country alone, even though that country be the United States of America, can not maintain a minor metal on a parity with a major metallic element. Even HENCHEL's international effort failed. The medical world was too busy looking forward to have time to look behind in this formal way. *Janus* failed in 1848, but its editor, aided by HEUSINGER of Warbourg, and others, reestablished it in 1851. Despite, however, the enthusiasm of a few, it again failed, because the active members of the profession took but little interest "in the important papers on the history of medicine and medical geography which it contained."

Now, in the year of 1896, when, as in 1846, the medical world is on the qui vive for fresh developments, *Janus redivivus est*. Will it succeed? Have

we time to look back? Do we need to look back with full face? Few systematic articles in this JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION fail to bring their subjects up from ancient times to date. This testifies to the use made of our medical libraries. Is this enough, or do we require a new and special journal? All sorts and conditions of men make up the world, and all sorts and conditions of minds make up the medical world. The energetic, enthusiastic workers are in advance on the skirmish line; but should there not be cautious, conservative minds surveying the pathways which led to the present position, the better to indicate those which should be pursued for final triumph? We think so. We think that *Janus* has a mission; for when we find among many notable European names on the Editorial Staff those of PEPPER, OSLER and STERNBERG, and among the collaborators the names of N. S. DAVIS and NICHOLAS SENN, of JACOBI, of New York, and of HARE and GUITERAS, of Philadelphia, we must conclude that the International Archives will prove their value and meet that success under the conditions of the present age which was denied them half a century ago.

#### "THE NEW NURSE" AGAIN.

Being a woman, it follows that in the universal process of rejuvenation and modernizing to which everything is to be subjected the nurse must also be made over. It might seem that the professional nurse were herself such a modern product that any remaking after the manner of the new woman, would be a wholly superfluous proceeding. But in England, at least, protest has apparently become necessary, and we suspect it may be about time for Americans to reconsider the questions of over-education or mal-education, proper functions and delimitations of the nurse. Dr. MALCOLM MORRIS in *The Practitioner* for July, 1896, has some rather sarcastic remarks upon the subject. To us at least, and pondering the matter from our point of view, Dr. MORRIS seems to be somewhat too ironical. Perhaps the dreams and ambitions of our American girl are kept well *in petto* and are only awaiting power and greater storage to break into the expression which has piqued the transatlantic editorial pen. Doubtless American gallantry would have been slower to snip or snub the nursoreal ideal or tendency. We are proverbially more generous to our sisters than the nation which has labored so long and only at last half successfully to permit a deceased wife's sister to cast sheep's eyes at the widower of her defunct sister. We may be too impulsive but our generosity is equal to permitting the deceased wife's sister the freest privileges and ambitions.

But surely she is a better nurse than any man, and we are all happy to acknowledge that these modern doctoring days are much easier for us, and the prognosis in the patient's case is far better than it was

before we had the nurse's beautiful conscientiousness, and gentle patience to aid us. Dr. MORRIS even denies the fact which we thought so true and well-recognized as to be pure platitude, that the presence of the young women in the wards and private rooms of the hospital has been the principal and persistent cause of a decided improvement in hospital manners, student brutalities and vulgarities, and even in professional characteristics. "The type of Bob Sawyer was extinct long before the 'lady-nurse' came upon the scene," he says and otherwise dashes the poor girls with the quintessence of his irony, ending up with the wild lunge that the softening of manners is due more to "the fear of the examiner" than the subtle influence of the nurse. In all of which we fear the Englishman has let his prejudice get the better of his generosity and courtesy. We believe no American physician would for one moment deny that not only in the past but in the present time the whole atmosphere of the ward and clinic is purified of the former vulgarity and rowdyishness by the silent presence of "petticoats," the white-capped priestesses of dignity and purity hovering about, dextrous in service, and often as powerful in influence when they only "stand and wait."

The only fear we have as to the matter of "over-ambition" and "over-education" of nurses concerns their physical and neurologic ability to do their work, and receive and digest the scientific food they seem both willing and eager to have given them. If they could safely do so, we do not see why they should not have all the lectures and examinations on "surgical anatomy," or upon any other subject related to their calling, they are pleased to desire. But precisely this doubtful "if" gives us pause. We feel like finding a way out by lengthening the course of study or apprenticeship so that there shall be greater freedom, or at least some little relief from the frequently frightful and inhuman over-work and over-worry of their schools. This is certainly easy of accomplishment, because now there are so many girls wishing to enter the schools that, by reason of the greater numbers possible, the hours of work might be shortened and the drudgery lessened. In this way the standards of character and acquirement could be raised without endangering the health. We have no such fear as seems to glare at one from between the lines of our English contemporary, that any one, even a nurse, can be too highly educated for the most menial occupation. We have no tendency, thank heaven, to look upon the nurse as a menial or as a servant. It is rare indeed that one will hear an American physician speak to a nurse in a harsh or dictatorial manner, and as if she were a common maid-of-all-work.

There is one aspect of the nurse question to which we have seen no allusion in any of the controversies, and which may deserve a passing word.

Women are natural politicians, born partisans, good in execution and obeying, poor in leading and ordering. It is proverbial that the worst enemies of some women are other more fortunate or shrewder women, and that in stores or factories the harshest and most unkind "heads of departments" or "bosses" are those women who are put in authority over other women. From all this it results that instances have been known in which the chief nurse has been an inexhaustible fountain of trouble and injustice. In the first place, she is almost certain to have a favorite doctor or two, and to be as "hateful" and intriguing toward others she does not like, as she is more than kind and intriguing toward her favorites. Worse than this, her partisanship is almost certain to be hotly active in the matter of favoritisms and antipathies to the girls who must be as tools in her hands. She gives her favorite doctor her favorite nurses, and to the unfortunate whom she detests she allots the poor child who has justly or not incurred her ill-will. No one so keen as she to find symptoms of "nursitis" in the medical student or young resident physician, and to trace the infecting *materies morbi* to its source with a certainty and celerity any bacteriologist might envy. In the legal manner of speaking, justice is liable to fall with an all too heavy hand upon the weaker party. It has been also whispered that at times she allows herself a greater freedom in the matrimonial game than she gives her competitors, and that wily and subtle-minded physicians have made use of the favor of the chief nurse to further the getting of patients, the delivery of lectures, and other ways of self-seeking forbidden men of greater self-respect. However all this may be, it would seem well not to allow too much autocratic power and authority to her ladyship until it shall have been proved, by some fifty years of service, that she will not use it except justly among the poor voiceless creatures with whom she has such numerous and devious means of unjust subjugation or reward, or as relates to the hardly more important matters of professional life or therapeutics.

---

#### THE LOWERING DEATH RATE

There is certainly no more astonishing and gratifying fact in modern civilization than the enormous decline and still progressively decreasing death rate of the more progressive and best governed countries. We have in England a proof of the fact which, owing to the length of time over which they extend, and the accuracy of the statistics, brings the result clearly before the mind. Estimated by quinquennial periods the general English death rate per 1,000 from 1858 to 1895 was as follows: 22.22, 22.58, 22.42, 21.96, 20.79, 19.40, 18.90, and 19.04 respectively. In London alone, the largest civilized city in the world, the rate has been reduced to about 17, while certain dis-

tricts of the metropolis have reached as low a rate as 14, 13, and even 12.

In the United States, with less concentration of population in large cities, we must confess the shameful fact that human life is more recklessly and needlessly sacrificed to the brutality of politics and sanitary heedlessness than in older countries. It is nothing less than a disgrace that in our smaller cities, and with the injuries of bad hygiene less necessary, we yet are killing off our citizens at the rate of from 5 to 10 per 1,000 faster than in European cities. Think of what this means in a city the size of greater New York! If her death rate is 5 per 1,000 greater than it need be, one shudders to contemplate the many thousands of citizens needlessly murdered every year.

In some of our cities the condition makes this fact still more evident and startling. Accurate figures are not before us as we write, but we believe that in a number of moderately sized cities the death rate has been reduced to a remarkably low figure. It has lately come to our notice that in one of our cities, Buffalo, by the persistent and heroic labors of the energetic health officer, the rate has been reduced to 11.67. If we are not mistaken, this is the lowest ever made by any city of the world of equal size. If the saving of one life is worthy of medals and public honors, what kind of medals and honors should be awarded to Dr. WENDE for the thousands that are living in that city to-day, who under a less thoroughgoing sanitary management would have died? And, on the other hand, what rewards should be given other cities where the death rate is double that of Buffalo? Perhaps their problems have been harder and the difficulties more insuperable, but perhaps, also, they have not. Leastwise, they have not been so proportionately to the contrast in the death figures.

Buffalo's death rate in the year preceding Dr. WENDE's accession to the office of Health Commissioner (1891) was 23.48 per 1,000 population; prior to that it had averaged above 20 per 1,000. In 1892 the rate was reduced to 19.98, to 19.03 in 1893, to 16.76 in 1894 and to 13.95 in 1895. For the first six months of 1896 the rate is 11.67, with prospect that the year will see it not far from 12 per 1,000.

All physicians know the essential prerequisites of such a reduction of disease: A reorganization at once upon a thoroughly business-like and scientific basis of the health department and the stamping out of the causes of disease. In Buffalo the immediate reporting of cases of contagious disease by telephone was made mandatory; visitation and vaccination in the public schools instituted; the sealing up of an emergency inlet of sewage-polluted water supply followed. Weekly examinations of the water are continued to this day; a thorough and watchful reorganization (with prose-

cution of delinquents) of all the conditions surrounding the milk supply was made; food and drug inspection; tenement house inspection; a justly tyrannical oversight of all drainage, plumbing, etc.

It must not be forgotten, also, that the death rate alone does not represent the expense either in suffering or dollars to the community. Dr. FARR estimates that for every death there are on the average two years of illness in a given community. It is needless to emphasize the tremendous significance, to those with open eyes and humanitarian feelings, of the thousands of years of prevented illness and suffering, shown in the foregoing figures.

There are many lessons to be gleaned from these figures, but there are one or two that we can not omit to notice:

1. In a general way it can not be denied that this, the greatest good that has been brought to humanity, is in the main due to medical science, and to the virtue of medical men. Either in the long historic series of preparations for the realization of the endeavor, or in actually and practically working it out, or in both, the medical profession has undoubtedly been the chief instrument. Without undue self-satisfaction we may lay no little emphasis upon the fact and justly claim that although our work is with disease, and our wage drawn from the conflict with disease, yet there is not one lay citizen more glad, probably none so genuinely happy as we, that we are stamping out disease and death. Surely few or none are so unsatisfied with the result, grand as it is, and so resolutely determined to go on and make the blessing still greater. We have reduced the death rate in the last twenty-five or thirty years, of smallpox from 219 to 22 per 1,000; of typhoid fever from 373 to 135; of typhus fever from 81.4 per million to 2; of phthisis from 2,565 to 1,512, and so on. As to scurvy, leprosy, the plague, cholera, malaria, etc., they are fast becoming mere names in the history of medicine. But is the community grateful? Witness our half failures, and half successes, with more absolute failures, to wrench from the public even the simplest essential medical practice acts! The public loves its quacks far more than it does us.

2. And what is this precious public for whom we labor, not only not doing for the elevation and protection of the profession, but what is it doing for its own sake, more directly, in founding and supporting bacteriologic and hygienic institutes, boards of health, etc? If we had the money wasted on paper cutters, pocket books, and luscious luxuries by our legislators we could pay the expenses of a dozen such institutes and save the lives of a hundred thousand people in a few years. Suppose even we could have a few of the millions now given as bribes to fraudulent pensioners! This public can endow theologic schools and chairs to teach boys Hebrew, Latin and Greek, etc., but where is the endowment to be found to endow medical col-

leges or chairs where shall be taught the saving of life?

3. Not only may we complain of not being helped, but we have to fight against opposition. Take the crying abuse of turning a medical Health Officer out of office in obedience to the criminal demands of "practical politics." The place-hunter and spoilsman must have his turn regardless of the community's health and rights. The term of office of an Officer of Health should and must be made unlimited and solely dependent upon success and capacity. It is simply disgusting that just when the year or two of experience has begun to fit a man for the efficient discharge of his complex duties, he should then be turned out to make way for a novice.

#### EDUCATIONAL NUMBER.

For the convenience of students, and the information of the profession generally, we shall issue an educational number next week. It will be seen that in the last decade, gigantic strides have been taken in bringing up the average standing of the medical colleges. The increase in the facilities for laboratory instruction is one of the gratifying features of the new exhibit.

There are many alleged medical schools not accounted for in this exhibit, but as a rule they ought not to be considered. We have been informed that there are about fourteen medical schools in Chicago alone; only a few of these have any reason for existence, and if rigid requirements were insisted upon they would close their doors.

The struggle for existence is at the root of the evil; finding themselves unable to compete with the real college professor in obtaining practice from the public, these persons, with others of the same ilk, start a so-called medical college, and become "professors" themselves. There are few statutory requirements; an act of incorporation can be obtained for a silver dollar in any stage of depreciation, a building rented, and a flaring sign put across its front. Verily, the "professors" are as plenty as the leaves of Vallambrosa. If we look into the equipment of these raw institutions, we find the Laboratory woefully lacking in the most ordinary apparatus, and like Do-the-boys Hall, squalor and filth are the most prominent characteristics. The only wonder is, that such men, with such miserable equipment, can find students; but they flourish in some way. The cure for this evil will come when the real medical colleges have endowed chairs, and the professor no longer enters into bread-and-butter competition with the general profession. Then it will be possible by statutory enactment to prevent the establishment of improper and imperfectly equipped schools. It should be a simple thing for the legislature of any State to fix a minimum standard of equipment. If this were done the tone of the medical school would be much higher, and the profession generally better pleased with them.

## CORRESPONDENCE.

## Dislocation of Hip.

CLYDE, N. Y., Sept. 2, 1896.

*To the Editor:*—In looking up some of the literature relative to dislocations of the hip, I especially noticed the remarks made when reviewing the work of Dr. Allis relative to some difficulties attending the reduction of the same, and which I found in the *JOURNAL* of April 10 of this year.

My notice was especially attracted by them, as they reminded me of a case which came under my care in 1859, where the head of the femur was upon the dorsum, which I failed to reduce by every known means except that by Chapman (manipulation), afterward revived by Dr. Reid, which I did not try. Dr. Reid was then a resident of Rochester where, as now, was also the home of "our own" Moore.

When obliged to give it up, and having visions of a suit for malpractice (as the accident was in a poor family), I sought the aid of Prof. E. M. Moore to help me out of my trouble. He in his goodness of heart not only personally came to my rescue, but also brought Dr. Reid with him, saying: "This is Reid's hobby, and we will let him reduce it by manipulation." After arriving at the house, and when everything was in readiness, Dr. Reid began his manipulations. After vainly trying for a long time he did not succeed, and gave up the reduction of it by what was then called his method, and requested me to apply Jarvis' Adjuster, hoping that with it it might aid in another effort by manipulation.

By this time the mercury was as high as it could conveniently climb in the thermometer, and all hands stripped as for a pugilistic encounter. Dr. Reid again renewed his attack and succeeded in changing the locality of the head from the dorsum to the thyroid foramen, where it is at this day, and where I have, from that time to this, wished the head of the young man was also, as he and his friends for a long time were unceasing in their denunciations of me, and even went so far as to consult an attorney. The attorney's reply, I afterward learned, was, "You can not recover against the Doctor with such men as Moore and Reid at his back." That ended all thoughts of prosecution, but not the vehemence of the young man's and his friend's abuse.

There was to me a gratifying sequel to this case which was this: Five or six years after the circumstances above related, a messenger came for me in great haste to visit a young man who had been thrown from a horse, and whose leg was thought to be broken. I visited him, not suspecting whom I was to see. I found a fracture of the femur at its lower third. As I was about to make preparations, the young man said, "Doctor, you have had something to do with this leg before," whereupon making some inquiries, I learned that he was the young man who had denounced me so savagely some years before. I rose from my chair and said to him, "Then you are the individual who, some years ago, was unremitting in your denunciations of me for not having done what two distinguished surgeons also failed to do. I am glad you have enlightened me. I would have reduced your fracture and done for you to the best of my ability, but I shall not place myself in a position for history to repeat itself. You must secure the assistance of another surgeon."

It was pleasing to me to hear him beg and promise that whatever the result might be, if I would assume the care of his case, he would never murmur. Another surgeon was called and what the outcome was I am unable to say, as he lived in another town, and beside that I never made an inquiry.

This communication is intended more especially to refer to the cause of our inability to reduce the dislocation, which cause was the one given by Professor Moore at the time, the "untorn portion of the capsular ligament," and he went so far as to say to the mother of the young man (she was a widow),

"If you will let me take him to the hospital I will cure him by cutting down and liberating the head of the bone," but she declined.

This was thirty-seven years ago, years before antiseptics were thought of, and when, if I remember correctly, cutting into a joint was considered fatal so far as future use of it was concerned, if not fatal to the life of the patient. I well remember that on our way home Drs. Moore and Reid had a warm discussion relative to the propriety of the operation which Dr. Moore had urged upon the mother, the latter strenuously opposing it as it would be fatal. Dr. Moore would have made it, however, regardless of the amount of opposition which could have been arrayed against it, had he had the opportunity.

At this late day even, I don't forget how gratifying it was to me to know, poor as I was, that I was warmly sheltered under the wings of Drs. Moore and Reid, as suits for malpractice were much more frequent then than at the present day, for obvious reasons. D. COLVIN, M.D.

## Treatment of Phthisis Pulmonalis.

KNICKERBOCKER, TEXAS, Aug. 29, 1896.

*To the Editor:*—As a country doctor, debarred by semi-invalidism from leaving a dry and salubrious climate to drink fresh draughts of knowledge at the fountains of learning perpetually flowing in every modern medical center, I derive no little satisfaction and mental profit from noting the progress of medicine as recorded weekly in our *JOURNAL*.

Having found that while in my own person the progress of pulmonary phthisis is satisfactorily arrested by climatic and hygienic measures, these nevertheless fail for obvious reasons to act so favorably upon many other invalids who resort hither, I therefore naturally feel a profound interest in every new therapeutic claim which relates to the treatment of consumption. Although somewhat skeptical of the confident claims advanced in behalf of every new treatment of phthisis since Bergeon failed and Koch fell short of success, I yet cherish the hope that with the onward march of medical progress, a greater measure of success than ever before lies just ahead of us. And, so, when experienced and eminent bacteriologists, like Dr. Paquin and Professor Klebs, offer a serum or a definite product of the bacteriologic laboratory scientifically prepared by experts and favorably reported on by clinicians, I am disarmed of my natural prejudice sufficiently to accept the scientific basis on which their preparations are claimed to act, and in selected cases to give them a trial. But when "A New Treatment of Phthisis," as presented by Dr. Hubbard Winslow Mitchell in the *JOURNAL* of August 15, prescribes a formula of simple chemic agents, supported by extraordinary curative claims based on two years' observation and an extensive list of cases treated, my old skepticism returns rampant on noting the indefiniteness of the composition of the "fluid" recommended.

In view of the magnitude of the claims made for a "fluid" composed of so simple ingredients, I wish to protest against the inexactness of the published formula, to which, after giving the list of chemicals entering into its composition (designated for the most part by unofficial terms) is appended the direction: "Sodic carbonate, potassic carbonate, equal parts added in sufficient quantity to bring the solution to the proper (*sic*) degree of acidity." In the name of suffering humanity, what does this mean? Let us suppose in the absence of a working formula for the preparation of this "fluid" that an experienced pharmacist shall possess sufficient practical technical knowledge of chemistry to prepare a .5 per cent. aqueous solution of chlorin, being guided in his efforts by the quantitative tests of the .4 per cent. official solution of the pharmacopoeia, and then should fail to guess the exact quan-

tity of sodic carbonate and potassic carbonate required "to bring [Does he mean reduce?] the solution to the proper degree of acidity?" In the event of failure to secure the expected therapeutic results, would rural practitioners like myself, who live far from chemic laboratories, be expected to draw their supplies of this new "fluid" from an expert who prepares it under the immediate supervision of the author and inventor of the "fluid?" If not, why is a formula presented which would be compounded exactly alike by probably no two pharmacists out of a thousand, who might attempt to follow its directions?

It seems to me if the Doctor reports his discovery for the benefit of humanity and for the instruction of the medical profession, he should supply a plain working formula of the "fluid." But if it is to be made only by experts and under his own personal supervision, and is to be had on the market at so much a bottle, then the *JOURNAL* should send its bill to the laboratory for advertising, at regular rates.

BOYD CORNICK, M.D.

### The Polish Physicians of Chicago.

CHICAGO, Sept. 2, 1896.

*To the Editor:*—I have the honor to announce to you, that on Aug. 29, 1896, the Polish physicians of Chicago organized in a society, to be known by the name of "Towarzystwo Lekarzy Polskich" (Polish Physicians' Society), and filed the articles of incorporation. The articles were signed by the following physicians: Drs. Ed. Czerniewski, M. Dowiat, M. Orglert-Kaczorowska, J. P. Kaczarowski, M. P. Kossakowski, W. Kuflewski, J. Piszczak, W. J. Sieminowicz, W. Statkiewicz, B. P. Strzyzowski and J. Ziolkowski, and Dr. R. L. Lande from Milwaukee, Wis.

The directors elected for the first year are: President, J. Piszczak, M.D.; vice-president, M. Orglert-Kaczorowska, M.D.; secretary and treasurer, W. Statkiewicz, M.D.

The purposes of said society are purely scientific.

Meetings will take place alternately at each member's home. The first regular meeting will take place at Dr. W. Statkiewicz's, 3315 Laurel Street, Chicago, at 4 P.M. on the 12th inst.

Very respectfully, W. STATKIEWICZ, M.D.

### Pan-American Medical Congress.

*To the Editor:*—I expect to attend the Congress as delegate from the AMERICAN MEDICAL ASSOCIATION. Is it necessary to send my name and fee to the secretary general, City of Mexico?

G. B. G.

ANSWER:—Send your registration fee, \$5 (gold), to Prof. Dr. Van Francisco Bastillos, Calle de Tabuca, No. 7, City of Mexico, Republic of Mexico.

## BOOK NOTICES.

**Twentieth Century Practice.** AN INTERNATIONAL ENCYCLOPEDIA OF MODERN MEDICAL SCIENCE. By leading authorities of Europe and America. Edited by THOMAS L. STEDMAN, M.D., New York City. In twenty volumes. Volume VIII. "Diseases of the Digestive Organs." New York: William Wood & Co. 1896.

As was the case with Vol. VI, it has again been found necessary to issue the eighth volume out of the regular order. The publishers say Vol. VII will be the next to appear, upon the publication of which the series will be consecutive as far as Vol. VIII. The present volume has been prepared by eight different authors, four Americans and four Germans; is illustrated by 100 original engravings and includes diseases of the mouth, diseases of the esophagus, diseases of the stomach, pancreas, peritoneum, animal parasites, and diseases caused by them, and the treatment.

The contributors are B. Farquhar R. Curtis, New York; Max Einhorn, New York; Reginald H. Fitz, Boston; James M.

French, Cincinnati; J. C. H. Huber, Bavaria; Warner Kummel, Hans Leo, of Bonn, and Johann Mikulicz of Breslau.

The chapter on diseases of the mouth has been written by Mikulicz and Kummel, and with the usual thorough manner of the Germans, we have it beginning with the anatomy of the parts. Fitz has written a chapter in a very satisfactory manner on diseases of the esophagus; Max Einhorn on diseases of the stomach. Naturally, we expected to see a good deal on the subject of gastroscopy, as no one in this country has given more attention to it than Dr. Einhorn. A good deal of attention has been given to different apparatus for lavage, and this chapter is well illustrated. The chapter on diseases of the pancreas has been written by Professor Leo and although short is very concisely written. The chapter on diseases of the peritoneum by B. F. R. Curtis is an excellent one and under this head the author has included appendicitis. The chapter on animal parasites and the diseases caused by them, by J. C. H. Huber, is a very exhaustive résumé of the subject.

The volume is fully equal to its predecessors, which is paying a high tribute to the general merits of the work.

**Treatise on Surgery by American Authors FOR STUDENTS AND PRACTITIONERS IN SURGERY AND MEDICINE.** Edited by ROSWELL PARK, A.M., M.D. Vol. I. General Surgery, with 356 engravings, 21 full-page plates in colors, and monogravures. Philadelphia and New York: Lea Brothers & Co. 1896.

This work, which has been announced for some months, has been issued. The contributors to the volume are W. T. Belfield, Herbert L. Burrell, Duncan Eve, John A. Fordyce, Frederick H. Garrish, William A. Hardaway, H. A. Hare, James M. Holloway, Henry H. Mudd, Charles B. Nancrede, Roswell Park, John Parmenter, Joseph Ransohoff, Chauncey P. Smith and Edmond Souchon. Of the surgeons contributing to the volume all but two are members of the American Surgical Association. The editor states that the chapters on auto-intoxications and on the surgical sequelæ of acute non-surgical diseases are practically new. The first volume contains the more general subjects of surgical pathology, the general principles and theory of surgery, and surgery of the tissues. Of the chapters in the book, those on hyperemia, the blood, inflammation, ulcer and ulceration, gangrene, auto-infection, surgical fevers, surgical diseases common to man and animals, shock and collapse, scurvy and rickets, the sequelæ of other infections and diseases, poisoning by animals and plants, acute intoxications, cysts and tumors and surgical diseases of the osseous system (sixteen of the thirty-two) have been furnished by Dr. Park; that of syphilis by Dr. Fordyce; gonorrhœa and its sequelæ by Dr. Belfield; control of hemorrhages, burns, scalds, frost bites and minor surgery by Dr. Parmenter; anesthesia by Dr. Hare; surgical diagnosis by Dr. C. P. Smith; methodic report of a surgical case, an elaboration of which appeared in this *JOURNAL*, by Dr. Souchon; wounds, gunshot wounds, processes of repair and treatment of wounds by Dr. Nancrede; surgical diseases of the skin by Dr. Hardaway; diseases of the muscles, tendons, tendon sheaths and fasciæ by Dr. Burrell; lymphatic vessels by Dr. Garrish; surgical injuries and diseases of the veins by Dr. Holloway; injuries and diseases of the arteries, including aneurysm, by Dr. Duncan Eve; joint and joint structures and operations on joints by Dr. Joseph Ransohoff; fractures and dislocations by Henry H. Mudd.

The volume is well illustrated and well edited. As will be seen, the editor has himself been the author of one-half of the book.

**Deformities: A Treatise on Orthopedic Surgery, intended for Practitioners and Advanced Students.** By A. S. TUPPY, M.L., London, F.R.C.S., England. Illustrated with 15 plates, with 302 figures, of which 200 are original, and by notes of 100 cases. London and New York: McMillan & Co. 1896.

This volume is the outcome of several years' work by the author at the National Orthopedic Hospital, the Evelyn Hospital for Sick Children, and for some time in the Orthopedic

Department at the Westminster Hospital. The author, however, has not only made a record of his own work, but has given a fair account of the deformities as at present understood. It is pleasing to note that he has quoted freely from Bradford and Lovett of this country, and pays a graceful tribute to our Orthopedic Association by saying: "Above all, I can not omit to express my sense of indebtedness to the many admirable writers who have recorded their experiences in the transactions of the American Orthopedic Association."

There are nine chapters on deformities of the spine, constituting Section One; four chapters on deformities of the neck, chest and upper extremities, constituting Section Two; Section Three has only one chapter, that on rachitic deformities; Section Four, deformities of the lower extremities, has nine chapters; Section Five, ankylosis, congenital displacements, deformities resulting from cerebrospinal paralyzes and arthrodesis.

The illustrations are fair, and the type is large and clear. The book is timely, and, although conservative, is fully up to date. We quite agree with the author's estimate of the advantage of tarsectomy, in which he states: "Cases in which tarsectomy is necessary are very few and form a very small percentage." We commend the book as one being in every way satisfactory.

**Plomalis, Leucomains, Toxins and Antitoxins, or the Chemical Factors in the Causation of Disease.** By VICTOR C. VAUGHAN, Ph. D., M.D., and FREDERICK C. NOVY, Sc.D., M.D. Third edition, revised and enlarged. Lea Brothers & Co., Philadelphia and New York. 1896.

It has been apparent for some years that the study of bacteriology is fast returning to its ancient home in the chemical laboratory and that the products of bacteria are more important than the microbes themselves. We have heretofore expressed our opinion of the usefulness of this book, and have to state that that high opinion has been increased by glancing at the third edition. The work has been brought down to date and will be found entirely satisfactory as a book of reference on the subjects named, and as well for careful study. The arrangement and scope of the work remain the same as in former editions. The number of pages has been increased from 391 to 604. In these bacteriologic days, no medical man's library can be considered complete without a copy of this painstaking and exhaustive compilation. That the volume grows from edition to edition is evidence of the careful character of the work and the thoroughness with which the field of medical literature has been gleaned.

**Wharton's Minor Surgery and Bandaging.** By HENRY R. WHARTON, M.D., Demonstrator of Surgery in the University of Pennsylvania. New (third) edition. In one 12mo. volume of 594 pages, with 475 engravings, many being photographic. Cloth, \$3.00. Philadelphia: Lea Brothers & Co., 1896.

The issue of the third edition of Wharton's Minor Surgery and Bandaging affords pleasing evidence of the correctness of the favorable opinion which we expressed on the issue of the first edition. We are of the opinion, however, that many of the illustrations might be omitted as being no longer applicable to modern methods. For example, the scissors figured on page 218 for skin grafting are scarcely used, as Thiersch's method has effectually supplanted the others. The old spring scarificator, on page 191, has probably never been seen by a physician under 35 years of age. Petit's Tourniquet, on page 283, might also be consigned to an antiquarian resting place. We do not see in the notice of fixed dressings the paper pulp bandage which has of late come into use, nor do we find in the book a statement of elastic bandages, such as supporters, suspension bandages, abdominal bandages, and other items which we would suggest should be included in future editions. These suggestions, however, do not detract from the general merit of the book, which is very great, and we trust that when we have the pleasure of reviewing the fourth edi-

tion, which is in our judgment bound to come soon, the author will bring his revision quite up to date. The publishers have done their part of the work well.

**Transactions of the American Microscopical Society.** Edited by the Secretary. Eighteenth annual meeting held at Cornell University, Ithaca, N. Y. Volume xvii. Buffalo, 1896.

The papers of this flourishing society are usually carefully edited and well illustrated; those in this volume of transactions are no exception to the rule. A large portion of the papers are decidedly interesting to medical men, such, for instance as "The Action of Strong Currents of Electricity upon Nerve Cells," by P. A. Fish; "The Comparative Morphology of the Brain of Soft-shell Turtle and the English Sparrow," by S. B. Gage; "Formalin as a Hardening Agent for Nerve Tissues," by William C. Krauss, and the "Process of Life Revealed by the Microscope, a Plea for Physiologic Histology," by Simon Henry Gage.

**Eleventh Annual Report of the State Board of Health of the Commonwealth of Pennsylvania, 1896.**—This report consists of the secretary's report, the minutes, reports of committees, and reports of inspections of various towns, cities and counties throughout the State, appendices on quarantine, etc. It shows a vast amount of labor on behalf of the board and the great benefit conferred upon the State. The board is fortunate in having as its secretary, Dr. Benjamin Lee, whose long and faithful service entitles him to recognition beyond the usual meed of State health officers.

## PUBLIC HEALTH.

**Another Source of Infection.**—It is well known among oculists that the opera glasses which may be hired in most theaters frequently become the medium for spreading very serious eye diseases.—*Pop. Science News*, August.

**Inspectors of Mercantile Establishments in New York.**—The Board of Health September 1 appointed eleven inspectors, eight of whom were women. The law under which the factory inspectors are appointed directs that no child under 14 can be employed in a business establishment. Children between the ages of 14 and 16 must be provided with certificates from the board of health, showing that they are competent physically to do such work as would be required of them by their employers. The inspectors also look after the sanitary arrangement of all large business houses and workshops, with a view to the health interests of the employes.

**Health in Michigan August, 1896.**—Reports to the State Board of Health show that for the month of August, compared with the preceding month, typhoid fever, cholera infantum, dysentery, cholera morbus, erysipelas and remittent fever increased in area of prevalence. For the month of August, 1896, compared with the average for August in the ten years, 1886-1895, typhoid fever was much more than usually prevalent, and intermittent fever, consumption, remittent fever and inflammation of bowels were less than usually prevalent. Consumption was reported present in August, 1896, at 217 places, typhoid fever at 100, scarlet fever at 34, diphtheria at 34, whooping-cough at 27 and measles at 25.

**High Infant Mortality in Canada.**—The *Union Méd. de Canada* for August gives the statistics for 1895 in the Province of Quebec as follows: Population, 1,515,492; births, 58,653; deaths, 31,696, of which over eleven thousand were due to contagious diseases. Over ten thousand were children from a day to 1 year old, and 5,220 were children from 1 to 5 years; a total of 17,532 children, or more than half of the total number of deaths. It ascribes this high mortality to the lack of knowledge of preventive science in contagious diseases and to neglect. Where the parents are ignorant, it should be some one's

duty to instruct them in the necessity of isolation and disinfection and limit a contagious disease to the first one or two attacked. It also states that another cause may be the policies paid by certain life insurance companies, which speculate on the "little last-comer," so that the parents receive \$75 to \$80 if it dies. It protests against this practice as "immoral from every point of view." We note also that the deaths from intestinal diseases (4,068) were nearly twice as many as from tuberculosis (2,791).

**Report of Committee on the Contagiousness of Tuberculosis in Hospitals; Isolation Recommended.**—The committee appointed by the municipal authorities at Paris to investigate this subject, report the necessity of separate quarters for tuberculous patients, or at least the necessity of separating them from the rest in special wards appropriated to their exclusive use in the present hospitals, which they claim is feasible. Also the decentralization of tuberculous patients by removing them to special sanatoria in healthy localities. Letulle also suggests the establishment of curable tuberculosis colonies in Algiers and Corsica. They also demand that the patients and attendants should be carefully educated to understand the necessity of prophylactic measures, with penalties enforced for neglecting them. The attendants must also be selected with care, and all rejected that show any tendency to morbid conditions of the respiratory organs. They found that 1,296 of the total of 4,470 attendants connected with the hospitals of Paris were already diseased, 651 with bronchial affections and 526 with pulmonary tuberculosis. There have been 599 deaths among them during the past ten years, 217 due to tuberculosis and 154 to other diseases of the respiratory organs.

**Greater New York City Health Department.**—Chapter xix of the proposed charter, which relates to the Health Department, has been prepared by the Sub-committee on Charter of the Greater New York Commission for the consideration of the local sanitary officials. The chapter contains more than thirty thousand words, and has seven titles, as follows: 1, Powers and duties of the department and its officers; 2, marriages, births and deaths; 3, duties of physicians and others; 4, enforcements of orders and ordinances; 5, reimbursement for expenses; 6, abatement by suit; 7, tenement and lodging houses. In many respects the proposed chapter is a consolidation of the laws as they exist, and the title relating to tenement and lodging houses carries the intent of the Tenement House Commission. Of the head of the department the draft says: "There shall be a Department of Health, the head whereof shall be called the Health Commissioner. The Health Commissioner may be appointed and may be removed at will by the Mayor, and his term of office shall be coextensive with that of the Mayor appointing him, and until his successor shall have been appointed and qualified. The authority, duty and powers of the Health Commissioner shall extend over the waters of the bay, up to and within the quarantine limits, as established by law, but shall not be held to interfere with the powers and duties of the Commissioners of Quarantine or Health Officer of the Port. It shall be the duty of the Health Commissioner to make an annual report to the Mayor of the city of New York, of all the operations of his department for the previous year. The Mayor may at any time call for a more full report, or for a report upon any portion of the work of said Commissioner whenever he may deem it to be for the public good so to do." In regard to bureaus, the sub-committee provides for two, those of the Sanitary Superintendent and the Registrar of Records, as at present. Nuisances are to be treated as they have been heretofore, and the control or surveillance of noxious industries, trades or enterprises likely to be objectionable. The control of contagious diseases remains unchanged. These provisions apply to vaccination, disinfection and production of antitoxin by the Department of Health, and the sale of vaccin and anti-

toxin and disposition of proceeds of sale: "For the purpose of more effectually preventing the spread of smallpox by the thorough and systematic vaccination of all unvaccinated persons, and for the relief of persons suffering with diphtheria and other infectious diseases residing in said city, the Department of Health is hereby empowered to continue or organize a corps of vaccinators and of other physicians, within and subject to the control of the Bureau of Sanitary Inspectors, to appoint the necessary officers, keep suitable records, collect and preserve pure vaccin lymph or virus, and produce diphtheria antitoxin and other antitoxins, and add to the Sanitary Code such additions as will most effectually secure the end in view. Said Department of Health may take measures and supply agents, and offer inducements and facilities for general and gratuitous vaccination, disinfection, and for the use of diphtheria antitoxin and other antitoxins, and may afford relief to and among the poor of said city, as in its opinion the protection of the public health may require. Whenever the amount of vaccin lymph or virus collected by the said corps or of diphtheria antitoxin and other antitoxins produced shall exceed the amount required in the proper performance of its duties, the said Department of Health may authorize the sale of such surplus lymph or virus and diphtheria antitoxin and other antitoxins at reasonable rates, to be fixed by the Health Commissioner. The avails of such lymph or virus and diphtheria antitoxin and other antitoxins shall be accounted for and paid to the Chamberlain, and shall be set apart and constitute distinct funds, to be known respectively as 'the fund for gratuitous vaccination' and 'the antitoxin fund,' and they shall be subject to the requisition of the Health Commissioner for the purposes named in the preceding section. "In case of extreme measures being necessary to prevent the spread of disease, the Commissioner may cause any avenue, street, alley or other passage whatever to be fenced up or otherwise inclosed, adopt suitable measures for preventing all persons from going to any part of the city so inclosed, forbid all communication with the house or family infected with any contagious, infectious or pestilential disease except by means of physicians, nurses or messengers to carry the necessary advice, medicines and provisions to the afflicted, and adopt such means for preventing all communication between any part of the city infected with a disease of a pestilential, infectious or contagious character and all other parts of the city, as shall be prompt and effectual. There are other strenuous provisions against neglect that may cause the spread of disease. In regard to coroners, the draft provides for returns and reports and notices of calls for inquests, and the Sanitary Superintendent is given the power to order the burial of a body in certain circumstances. There is also a requirement that information in regard to diseases shall disseminate to local authorities elsewhere information that may be useful in regard to any disease. Quarantine officers and the department are to cooperate. The Sanitary Code of 1873, as amended, is declared to be binding except as it may be altered, amended or annulled by the Commissioner. The Health Commissioner is directed to establish offices in the Borough of Brooklyn and may appoint for this borough and that of Williamsburg a Deputy Commissioner and a Deputy Sanitary Superintendent and a Registrar of Records, with such clerical force as may be required. The Commissioner may also have a secretary and a chief clerk, and adopt a seal for the department and establish useful regulations. The draft provides for the appointment of fifty Sanitary Inspectors and may appoint eight men at the discretion of the Commissioner and there may be a sanitary engineer. Provisions in regard to the reporting and registration of births, marriages and deaths are the same as at present, and the duties of physicians and others are set forth as under the present regulations. The enforcement of laws and ordinances is set forth in a codification of existing laws.—*Standard Union.*

## NECROLOGY.

JAMES W. ANAWALT, M.D., at the Military Soldiers' Home at Dayton, Ohio, August 26. He practiced medicine in Greensburg for over twenty-five years. About ten years ago he sustained a stroke of paralysis, from the effects of which he never fully recovered. Dr. Anawalt had an excellent military record, having served in the late war. He went as a surgeon of the Eleventh Regiment, Pennsylvania Volunteers, and afterward was chief surgeon of the Eleventh and One Hundred and Thirty-second Regiments. He graduated from Jefferson Medical College in 1855. He was 68 years old.

J. A. BLOUSE, M.D. (Department of Medicine, University of Pennsylvania, Philadelphia, 1891) of York, Pa., August 27, aged 28 years.—Henry L. Harrington, M. D., (Rush Medical College, Chicago, Ill., 1875) at Chicago, Ill., of consumption, August 31, aged 50 years.

E. NICAISE, M.D., Paris, age 58. The distinguished surgeon and writer, one of the editors of the *Revue de Chirurgie* and contributor to many medical journals, former president Société de Chirurgie, and of the medical section of the French Association for the Advancement of Science, professor of anatomy and clinic surgery. His most recent works are on the early history of surgery in France, to which he devoted the strength remaining from his long struggle with pulmonary disease. Among his other works are classic articles on cutaneous transplantations, surgical treatment of the nerves and veins, treatment of tetanus with chloral, sub-periosteal amputations, arthrotomy of the knee, lesions of the intestines in strangulations, infective myositis, suture of the sphincter in anal fistulas, emphysema of the neck from rupture of the trachea during labor, and many others, the last mentioned having been read at the Académie de Médecine within a couple of months.

ARMAND DESPRÉS, M.D., age 62. A well known hospital surgeon and medical journalist of Paris, where his father had also been a hospital surgeon before him. He was noted for his ready wit and paradoxical views and conduct, "the intellectual type of the true gamin of the boulevard." He refused to recognize that surgery had made any progress since the sixties, and ridiculed the idea of asepsis and antiseptics, clinging to his prehistoric dressings and poultices to the last. The *Progrès Médical*, August 8, remarks that if he had lived in the United States, or even in Germany, his fantastic ideas on the subject of surgery might have brought him into serious trouble, adding, "Sometimes it is just as well to be living in France." But his pupils adored him. He served in the Chamber of Deputies with zeal and wisdom; was editor of the *France Médicale* for a while, and his numerous writings are valuable and interesting, although he repudiated the use of mercury. He was made Chevalier of the Legion of Honor for saving from captivity the wounded he was tending after a battle during the war. The Roman Catholic journals are lauding his memory for his indefatigable efforts to prevent the removal of the Sisters of Charity from the hospitals, to make way for trained lay nurses, while this is cited by other journals as a typical instance of the inconsistency of the professed freethinker and atheist.

DR. HENRY K. PUSEY died on the 2d inst., at Garnettville, Ky., at the home of one of his daughters. Dr. Pusey was nearly 70 years of age. His early education was received at Mount Auburn and he received his degree of M.D. from the Medical Department of the University of Louisville. He practiced his profession in Louisville for a number of years and during the governorship of Hon. Proctor Knott he was appointed as Superintendent of the Insane Asylum at Lakeland, near Louisville, serving during that term and again under Governor Brown after four years' retirement. When he took charge, the number of inmates was 300 and the buildings inadequate

and inconvenient; when he relinquished his office to make way for his successor appointed by Governor Bradley there were 1,200 inmates and the buildings modern in every respect and the methods of treatment the latest and best that has been devised. Dr. Pusey was a member of a number of societies devoted to the discussion of the insane, among them being the Medico-Psychological Association, the Medico-Legal Society of New York, the Southern Association of Superintendents of Insane Asylums and others. Dr. Pusey was a recognized authority upon hospital architecture and sanitation, and it was he who first suggested the advisability of building the houses for the insane no more than two stories high. The Board of Directors for the Asylum recognized the excellence of his ideas and the value of his accomplishments and they warmly approved all of his propositions for the improvement of the facilities of the institution. Knowing him thus the Directors gracefully testified their appreciation of him by naming the latest building addition to the institution "Pusey Hall," and put the name on a tablet of granite over the door. A year ago when the doctor gave up his work at the Asylum he was already a sick man and he told his close friends that he believed his life work was at an end. He accordingly began to set his affairs to rights and awaited the end with Christian fortitude. The board of directors passed suitable resolutions at a meeting held the Saturday after his death.

## SOCIETY NEWS.

**Reading (Penna.) Medical Association.**—This association has elected the following officers for the ensuing year: President, James W. Keiser; vice-president, Daniel Lengaker; secretary, S. T. Schmehl; treasurer, Walter Rigg; representative to the Board of Managers of the Reading Hospital, C. W. Bachman; censors, Henry Landis, J. L. Bower and C. M. Kurtz; curator, Henry Landis.

**Douglas County (Wis.) Medical Society.**—This society held its annual meeting at Superior, Wis., September 2. The officers elected for the ensuing year were: John Reeve, president; H. J. Orchard, vice-president; George Saunders, treasurer; C. S. Conkey, secretary; John Baird, L. B. Shehan and L. A. Potter, censors.

**Mississippi Valley Medical Association.**—At the twenty-second annual meeting at St. Paul, Minn., Sept. 15 to 18, 1896, the following papers will be read:

- President's Address, H. O. Walker, Detroit, Mich.
- Address on Medicine, Harold N. Meyer, Chicago, Ill.
- Address on Surgery, Horace H. Grant, Louisville, Ky.
- The Clinical Significance of the Child's Fontanelle, I. A. Abt, Chicago, Ill.
- Proprietary Prescriptions, W. W. Allison, Peoria, Ill.
- A New Operation for Cleft Palate, Truman W. Brophy, Chicago, Ill.
- Some Rarer Forms of Keratitis, Carl Barek, St. Louis, Mo.
- The Results of Operations *per se* in Cases of Tubercle and Cancer, A. C. Bernays, St. Louis, Mo.
- Mastoid Diseases; Their Medical and Surgical Treatment, S. S. Bishop, Chicago, Ill.
- Rupture of the Choroid Coat, J. H. Buckner, Cincinnati, Ohio.
- Operative Treatment of Pterygium, Eduard Boeckmann, St. Paul, Minn.
- Treatment of Some Inflammatory Diseases of the Gastro-Intestinal Tract, Gustavus Blech, Detroit, Mich.
- Kola, Gustavus Blech, Detroit, Mich.
- A Report of a Case Illustrating the Value of Secondary Physical Signs in the Diagnosis of Cardiac Diseases, R. H. Babcock, Chicago, Ill.
- Rhinoscopic Examinations in General Practice, B. M. Behrens, Minneapolis, Minn.
- Irregularities in Delivery Due to Short Umbilical Cord, Guide Bell, Indianapolis, Ind.
- Gastro-jejunostomy in Gastrectasis, A. H. Cordier, Kansas City, Mo.

Conventional Treatment of Heart Diseases versus Positive Treatment, Ephraim Cutter, New York, N. Y.

Tonsillotomy by Means of the Cautery Blade, J. Homer Coulter, Chicago, Ill.

The Newer Remedies in Otology and their Results, G. I. Cullen, Cincinnati, Ohio.

Infant Feeding; The Anti-dyscrasic Action of Cow's Milk, M. F. Cupp, Edinburg, Ind.

Ether and Chloroform; Their Comparative Merits as Agents for the Production of General Anesthesia, W. S. Caldwell, Freeport, Ill.

Appendicitis; To Operate or not to Operate, J. H. Dunn, Minneapolis, Minn.

Syphilis as an Etiologic Factor in the Production of Tabes Dorsalis, C. Travis Drennan, Hot Springs, Ark.

Preventive Medicine, J. O. DeCourcy, St. Libory, Ill.

Certain Misconceptions Regarding Cardiac Murmurs and their Significance, Arthur R. Edwards, Chicago, Ill.

A New Method of Fastening the Broad Ligament in Alexander's Operation, J. Frank, Chicago, Ill.

Cholelithotomy in America, with the Report of Four Cases, Alex. Hugh Ferguson, Chicago, Ill.

Pleuritic Effusions and their Treatment, G. Fütterer, Chicago, Ill.

Rational Operations for the Cure of Retroversions and Flexions, A. Goldspohn, Chicago, Ill.

A Demonstration of the Therapeutic Action of Antitoxins, E. M. Houghton, Detroit, Mich.

Stirpiculture, Florence W. Hayes, Terre Haute, Ind.

On the Importance of Physical Signs other than Murmur in the Diagnosis of Valvular Diseases of the Heart, Jas. B. Herrick, Chicago, Ill.

The Neural Factor in Clinical Medicine, C. H. Hughes, St. Louis, Mo., Honorary Fellow of the Chicago Academy of Medicine.

The Value of Medicinal Antipyretics in View of Newly Acquired Knowledge Respecting the Nature of Acute Infectious Diseases, Talbot Jones, St. Paul, Minn.

Treatment of Syphilis, J. H. Jelks, Hot Springs, Ark.

The Physiologic Treatment of Typhoid Fever, Elmer Lee, Chicago, Ill.

The Pathology and Treatment of Suppurative Salpingitis, F. F. Lawrence, Columbus, Ohio.

The Lumbar Enlargement of the Spinal Cord, L. Harrison Mettler, Chicago, Ill.

Indications for and Demonstrations of Removal of the Gasarian Ganglion, J. B. Murphy, Chicago, Ill.

The Surgical Treatment of Pyloric Obstruction, Wm. J. Mayo, Rochester, Minn.

Conditions which may Simulate Organic Obstruction of the Rectum, Thos. H. Manley, New York, N. Y.

Multiple Operations in Pelvic Disease, H. P. Newman, Chicago, Ill.

Nerve Sutures and other Operations for Injuries to the Nerves of the Upper Extremities, A. J. Ochsner, Chicago, Ill.

Submucous Linear Cauterization; A New Method for Reduction of Hypertrophies of the Conchæ, N. H. Pierce, Chicago, Ill.

The Treatment of Experimental Tuberculosis in Animals by the Use of Blood Serum, Paul Paquin, St. Louis, Mo.

The Pathology of Idiocy, Frederick Peterson, New York, N. Y.

Chorea, Curran Pope, Louisville, Ky.

Electro-diagnosis and Electro-therapeutics Simplified, Hugh T. Patrick, Chicago, Ill.

Trunk Anesthesia in Locomotor Ataxia, Hugh T. Patrick, Chicago, Ill.

The Use of Oxygen in Chloroform Narcosis, C. B. Parker, Cleveland, Ohio.

My Favorable Experience with Diphtheria Antitoxin, D. C. Ramsey, Mt. Vernon, Ind.

The Physiology of the Peritoneum from Experiments, Byron Robinson, Chicago, Ill.

Some Fads and Fallacies of Modern Rectal Surgery, Leon Straus, St. Louis, Mo.

Pregnancy Complicating Operations on the Uterus and its Appendages. Remarks with Cases, R. Stansbury Sutton, Pittsburg, Pa.

The Significance and Occurrence of Capillary Pulsation in Nervous Diseases, A. E. Sterne, Indianapolis, Ind.

Twenty-seven Cases of Croup, E. W. Sanders, St. Louis, Mo.

The Necessity of Vivisection, E. B. Smith, Detroit, Mich.

Gunshot Wound of the Liver; Report of Case Involving Diaphragm and Lung; Operation Successful but Fatal Termination Two Weeks Later from Pneumothorax, J. H. Taulbee, Mt. Sterling, Ky.

Further Report on the Treatment of 500 Cases of Gastritis (Demonstrations), Fenton B. Turck, Chicago, Ill.

The Rapid Cure of Gonorrhœa, Fred C. Valentine, New York, N. Y.

Some Unusual Cases of Appendicitis, Weller Van Hook, Chicago, Ill.

Mastoidectomy in Caries of the Temporal Bone, K. K. Wheelock, Ft. Wayne, Ind.

A Further Contribution on the Use of Dry Heat in the Treatment of Chronic Joint Affections, W. E. Wirt, Cleveland, Ohio.

A Further Contribution to the Ocular Treatment of Epilepsy, Casey A. Wood, Chicago, Ill.

The Decadence of the General Practitioner and the Reign of the Specialist, D. S. Maddox, Marion, Ohio.

Additional papers have been promised by the following:

Augustin H. Goslet, New York, N. Y.; Henry Hatch, Quincy, Ill.; R. C. Hefebower, Cincinnati, Ohio; Bransford Lewis, St. Louis, Mo.; I. N. Love, St. Louis, Mo.; A. H. Meisenbach, St. Louis, Mo.; H. O. Pantzer, Indianapolis, Ind.

## MISCELLANY.

**P.-A. M. C. Delegate.**—Dr. H. B. Lowry, of Omaha, has been appointed delegate from Nebraska to the Pan-American Medical Congress.

**Jefferson Appointment.**—Dr. Roy Harris, who has been practicing medicine in Atlanta, Ga., for the past five years, and teaching chemistry in the Southern Medical college, has accepted a professorship in the Jefferson Medical college of Philadelphia. He will teach pathology in that institution. He graduated from Jefferson College.

**Dr. Carlos F. McDonald,** president of the New York State commission in lunacy, has resigned, the resignation to take effect September 30, and Gov. Morton has appointed Dr. Peter M. Wise as Dr. McDonald's successor, the appointment to take effect October 1. Dr. McDonald's term would expire by limitation in May, 1901, but he retires to resume private practice.

**Husband Can Recover Expense for Medical Attendance.**—In Minnesota, the supreme court of that State holds, in *McDevitt v. City of St. Paul*, decided July 24, 1896, a husband may maintain an action against a municipal corporation for the recovery, among other things, of moneys expended by him for medical attendance on his wife on account of personal injuries received by her by reason of a defective sidewalk.

**A Question for the Jury.**—It is a question for the jury to determine, the supreme court of Minnesota holds, in the case of *Hale v. Life Indemnity and Investment Co.*, decided July 17, 1896, whether a man can be addicted to the drink and morphin habits, and grossly intemperate, and his family and his intimate business and social associates not discover it. It can not be assumed that he can thus conceal these habits, if he in fact has them.

**Marliesco's Pilgrimage.**—The *Semaine Médicale* has sent Marliesco on a scientific pilgrimage to the different centers of progress to interview the leading neurologists of the day. His letters from London, Edinburgh, Brussels and Liège, as they have been published the last few weeks, form an interesting *résumé* of the present status of neurology, and contain some things that have not yet been officially announced in the way of biologic investigation.

**Preventive Treatment of Hydrophobia.**—Dr. A. Lagorio informs us that 532 patients have been treated at the Chicago Pasteur Institute since its inauguration July 2, 1890. The patients treated have been divided into three classes: 1. Those bitten by animals recognized and ascertained to be rabid by the control experiment made in the laboratory, or by the deaths of other persons or animals bitten by the same animal (183). 2. Those bitten by animals recognized to be rabid by the symptoms of rabies shown during life (237). 3. Those bitten by animals strongly suspected to be rabid (112). Only two deaths

have been reported, giving a mortality of 0.37 per cent. There were 483 persons bitten by dogs, 24 by cats, 13 by horses, 5 by skunks, 2 by wolves, 1 by a mule, 1 by a pig, and 2 by hydrophobic human beings.

**Illinois' New Hospital for the Insane.**—The corner stone of the new Northwestern Hospital for the Insane was laid at the village of Watertown, eight miles east of Rock Island, by Governor Altgeld, Sept. 5. The Thirty-eighth General Assembly made an appropriation of \$100,000 for an institution to be located north and west of the Illinois river. The site comprises 400 acres on the bluffs overlooking the Mississippi river, which was purchased and presented to the State by Rock Island County and city and the town of Moline. The plans contemplate a system of eight groups of buildings, to be arranged in radiating lines from the main building, connected by hallways.

**Must Give Notice of Trial for Insanity.**—An inquiry and trial in the probate court in Kansas, had upon an information charging one with being a person of unsound mind and incapable of managing his own affairs, the court of appeals of that State holds, *In re Wellman*, decided June 12, 1896, should only be had after notice to the person alleged to be insane, and after opportunity has been given such person to be present at the trial, in person or by counsel. An adjudication of insanity that is had without such notice and opportunity to be heard, it holds is a nullity, and void, and a commitment thereunder to the insane asylum is illegal.

**Physicians Can Testify as to Stains.**—After both an examination thereof, under a microscope and a chemical analysis, the supreme court of South Carolina holds, in the homicide case of *State v. Martin*, decided July 11, 1896, that physicians are clearly entitled as experts to give their opinion as to the character of stains found on a piece of floor. That the latter was not taken from the house in which the defendant lived at the time of the alleged homicide until a few days before the trial, after the defendant had moved from it, and while it was occupied by another person, it is further held did not render it inadmissible in evidence, though the force of the evidence was perhaps weakened by these circumstances.

**Gleanings.**—Confirmation of favorable effect of lecithin on the quality of the blood, general growth and psychic development (dogs). Milk from typhoid patient produces characteristic agglutinations the same as serum. (See this JOURNAL, page 382.) (*Semaine Méd.*, August 5.)—Editorial urges immediate intervention in all wounds of the abdomen caused by firearms. Many lives would be saved if the internal perforations were sutured at once as a matter of course, no matter how trifling they may appear. (*Union Méd.*, August 8.)—First decade of the Paris Pasteur Institute, 17,337 patients treated, 83 deaths. (*Gaz. Méd. de Liège*, August 13.)—7,857 of the 29,747 students in the universities of Germany are studying medicine. (*Wien. Klin. Rundsch.*, August 9.)—Mackenrodt asserts that the only way to avoid infection in hysterectomy for carcinoma is to perform it entirely by thermo-cauterization. (*Gaz. Méd. de Paris*, August 15.)—Ten per cent. formal compresses found very effective in relieving and improving inoperable ocular tumors. (*Semaine Méd.*, August 12.)—London has 600,000 houses, with an average of 7 inmates to each; New York has 115,000 with 18 inmates each, and Paris only 90,000 with 25 inmates each. (*Journal d'Hygiène*, August 6.)

**The Phonendoscope.**—The newly invented phonendoscope is designed to be used by physicians and surgeons for detecting the presence of disease by sound. The instrument consists of a circular flat metal box or tympanum, having on its one surface two apertures for the attachment of the rubber ear tubes, while the other surface is formed by a thin disk which is readily thrown into vibration. The best results are obtained by sim-

ply applying this disk to the surface to be examined. By an ingenious contrivance a second disk can be superposed upon this one and a vulcanite rod attached to the former, so that the area of auscultation may be extremely circumscribed. The conduction of the sounds is only slightly diminished by the use of this rod, which thus combines the principle of the solid stethoscope with that of the tympanum. The rod furnished with the instrument is about two inches in length, but it is stated that there are other rods of various lengths, to enable the "phonendoscopist" to receive sound vibrations of the natural cavities which communicate with the exterior of the body. It is useful as an aid to auscultation, and yet not likely to entirely supersede the use of the stethoscope. It may also be found useful in class demonstration, since it would be easy by means of branched tubes to enable several persons to listen at the same time. The instrument will be particularly useful for the following purposes: In auscultation of the sound of the respiratory organs, in the circulation of the blood, and of the digestive organs in the healthy body as well as in the sick; the sounds made by the muscles, joints and bones; the sound of the capillary circulation; the slightest sounds produced in any diseased condition of the body; hence it is possible to draw on the body dimensions, the position or any alteration in the position of the various organs and of the fluids which have gathered in the most important cavities in the body.—*Pop. Science News*, August.

**Coffin Carrying.**—It is observed with some curiosity that our distinguished guest, His Excellency, Li Hung Chang, with certain other members of his suite, carry coffins with them as part of their baggage. It is said that this custom arises from distinction in classes whereby as it is highly probable that the remains of the illustrious dead might be defiled by touching or mixing with the common or unclean carcasses not belonging to the celestial or one of the same class. It has been said that one of the best means of longevity is the frequent contemplation of death and the tomb and it would seem that the oriental custom has its advantages, as in case of accident it would be unfortunate to be compelled to depend upon an American undertaker, who might prove a veritable iconoclast in handling the remains of a distinguished Chinaman.

**Compensation Must be Allowed.**—A servant employed in the Merchant's Hotel in the city of Detroit, Mich., was taken ill June 1, 1894. Her disease was pronounced measles by a physician. As she failed to improve, the proprietor of the hotel telephoned the board of health that he feared the case was smallpox. In reply, the contagious disease clerk at the health office said it was all right, only a case of measles, and it would be best to carry out the orders of the physician referred to. June 6 the girl died. An investigation was made by the health board and the case pronounced smallpox. The officers of the board of health immediately took possession of the hotel and placed it in quarantine, confining therein thirteen persons, several of whom were subsequently stricken with smallpox and detained in the hotel and there treated by the board of health. The quarantine continued until June 29, after which the board of health disinfected the premises and destroyed a considerable portion of the furniture which had become infected. They contended that what was thus done by them was necessary in the interest of the public welfare, and that the loss must be borne by the proprietor of the hotel. But the supreme court of Michigan takes a different view of it. *Safford v. Board of Health of City of Detroit*, decided July 8, 1896. It says that it thinks it is within the contemplation of the law that, when property is used or destroyed or services rendered under such circumstances as in this case, compensation should follow. It also holds that it is the duty of the board of health to pass upon the question of the amount of compensation, and where they refuse utterly to award compensation, that a writ of mandamus may be invoked to compel them to do so.

**Can Answer Hypothetic Questions.**—If a physician, who has professionally attended upon and prescribed for a person, and has also observed such patient while not thus in attendance, can give an opinion as to his condition, based upon facts he observed while not acting professionally, and excluding from his mind what he observed while in attendance, the appellate division of the supreme court of New York says that it can see no reason to doubt that he may also give an opinion upon a hypothetic state of facts stated in a question which excludes all knowledge of the condition of the patient which he derived while in professional attendance. The only objection, it further states, in the case of Meyer v. Standard Life & Accident Insurance Co., decided July 7, 1896, that can be urged to a doctor, who has been in medical attendance upon a person, giving an opinion in answer to a hypothetic question as to the condition of his patient, is that the knowledge he derived while in attendance might affect his answer. But the same objection exists to the physician's giving an opinion founded upon observation of his patient while not in actual professional attendance. Mr. Justice Landon, in a concurring opinion, says that the trial judge in the court below decided, in effect, that the attending physician could not answer the hypothetic question solely upon its hypothetic basis, but would to some extent base his answer upon his professionally acquired knowledge of the patient's actual condition. His reviewer, on the other hand, thinks that, as this is a question of fact, it should be decided upon evidence. It can not be assumed, as a matter of law, that the physician could not answer the question as a hypothetic one, wholly uninfluenced by his personal knowledge of the patient's condition. He therefore suggests that the proper practice would be to examine the attending physician preliminarily as to his ability in this respect.

**The Richard Formogen Disinfecting Lamp.**—This little apparatus resembles a lamp in its appearance and is as easy to manage, while it generates formic aldehyde in sufficient quantity and strength to disinfect perfectly any apartment, allowing 36 grams of methyl alcohol to the cubic meter. The vapors of the methyl alcohol pass through a wire screen into a reacting chamber enclosed in platinum, with twenty holes through which the heated air enters, producing brilliant incandescence of the platinum and transforming the vapors of the alcohol into formic aldehyde, according to the familiar formula:  $\text{CH}_3\text{O} + \text{O} = \text{CH}_2\text{O} + \text{H}_2\text{O}$ . Infected gauze is perfectly sterilized in six hours, and the vapors have such penetrating power that infected threads rolled in 250 grams of cotton are found absolutely sterile.—*Gaz. Méd. de Liège*, August 20, from the Brussels *Clinique*.

### Louisville.

**Feeble Minded Institute.**—There seems to be a disagreement between the governor and the commissioners of this institution as to the advisability of rebuilding the institution which was burned not long ago. The governor is not in favor of its being rebuilt and in this he is opposed by the commissioners. There seems to be some trouble in regard to the collection of the insurance money as it is claimed that there was negligence on the part of the officials in not keeping enough water in the tank for use in case of fire. The children are all comfortably housed in the out houses which have been used for shops and which were used for a similar purpose after the fire in 1889. It is understood that a majority of the commission favor rebuilding and that will likely be done as soon as arrangements can be made as to the insurance money.

## THE PUBLIC SERVICES.

**Army Changes.** Official List of changes in the stations and duties of officers serving in the Medical Department, U. S. Army, from Aug. 30 to Sept. 4, 1896.

Lieut. Col. Alfred A. Woodhull, Deputy Surgeon General, granted leave of absence for one month and ten days, to take effect about Sept. 15, 1896.

Major Henry S. Turrill, Surgeon, upon being relieved from duty at Ft. Riley, Kan., is ordered to Willets Point, N. Y., relieving Major Egon A. Koerber, Surgeon. Major Koerber, upon being thus relieved, is ordered to Ft. Crook, Neb., for duty.

First Lieut. Frederick P. Reynolds, Asst. Surgeon, is relieved from duty at Ft. Clark, Texas, and ordered to Ft. McIntosh, Texas, for duty, relieving First Lieut. Robert S. Woodson, Asst. Surgeon. Lieut.

Woodson, on being thus relieved, is ordered to Jackson Bks. La., for duty at that station, relieving Capt. Junius Powell, Asst. Surgeon. Capt. Powell, on being thus relieved, will report to the president of the examining board, appointed to meet at the office of the Surgeon-General of the Army, for examination for promotion, and upon conclusion of examination is ordered to Ft. Riley, Kan., for duty, relieving Major Henry S. Turrill, Surgeon.

**Navy Changes.** Changes in the Medical Corps of the U. S. Navy for the week ending Sept. 5, 1896.

P. A. Surgeon E. R. Stitt, to duty in the Bureau of Medicine and Surgery. P. A. Surgeon C. H. T. Lowndes, detached from the naval hospital, Philadelphia, and ordered to the Washington Navy yard.

Asst. Surgeon L. Morris, ordered to the naval hospital, Philadelphia.

Asst. Surgeon G. D. Costigan, ordered to the naval laboratory for instruction.

**Marine-Hospital Changes.** Official list of changes of station, and duties of Medical Officers of the U. S. Marine-Hospital Service, for the sixteen days ended Aug. 31, 1896.

Surgeon P. H. Ballhache, detailed to represent Service at meeting of American Public Health Association, Aug. 24, 1896.

Surgeon George Purviance, relieved from duty at Philadelphia, Pa., and directed to proceed to St. Louis, Mo., and assume command of Service, Aug. 25, 1896.

Surgeon J. B. Hamilton, when relieved from duty at Chicago, Ill., to proceed to San Francisco, Cal., and assume command of Service, Aug. 25, 1896.

Surgeon J. M. Gassaway, granted leave of absence for thirty days from Oct. 1, 1896, Aug. 24, 1896.

Surgeon John Godfrey, when relieved from duty at San Francisco, Cal., to proceed to Chicago, Ill., and assume command of Service, Aug. 25, 1896.

Surgeon W. A. Wheeler, when relieved from duty at Ellis Island, N. Y., to proceed to Cincinnati, Ohio, and assume command of Service, Aug. 25, 1896.

Surgeon C. E. Banks, to proceed from Washington, D. C., to Boston, Mass., for temporary duty, Aug. 21, 1896.

P. A. Surgeon D. A. Carmichael, granted leave of absence for thirty days from Sept. 5, 1896, Aug. 17, 1896.

P. A. Surgeon Eugene Wasson, granted leave of absence for five days, Aug. 25, 1896.

P. A. Surgeon S. D. Brooks, directed to rejoin station, St. Louis, Mo., and when relieved from duty at that place to proceed to Port Townsend, Washington, and assume command of Service, Aug. 25, 1896.

P. A. Surgeon J. H. White, relieved from special duty at Key West, Fla., and directed to rejoin station at New York, N. Y., Aug. 24, 1896. Detailed for duty in connection with immigration service at Ellis Island, N. Y., Aug. 25, 1896.

P. A. Surgeon P. M. Carrington, to proceed to Chicago, Ill., and assume temporary command of Service, Aug. 25, 1896.

P. A. Surgeon J. J. Kinyoun, detailed to represent Service at meeting of American Public Health Association, Aug. 24, 1896.

P. A. Surgeon T. B. Perry, detailed to represent Service at meeting of American Public Health Association, Aug. 24, 1896.

P. A. Surgeon G. T. Vaughan, detailed for duty in connection with immigration service at Philadelphia, Pa., Aug. 25, 1896.

P. A. Surgeon J. O. Cobb, when relieved from duty at Cincinnati, Ohio, to proceed to New York, N. Y., for duty, Aug. 25, 1896.

P. A. Surgeon W. G. Stimpson, relieved from command of Service at Port Townsend, Washington, on arrival of P. A. Surgeon S. D. Brooks, Aug. 25, 1896.

Asst. Surgeon E. K. Sprague, when relieved from duty at New York, N. Y., to rejoin his station at Boston, Mass., Aug. 27, 1896.

Asst. Surgeon H. S. Cumming, when relieved from duty at Norfolk, Va., to proceed to Evansville, Ind., for temporary duty, Aug. 25, 1896.

Asst. Surgeon J. B. Greene, to proceed from Baltimore, Md., to Cleveland, Ohio, for temporary duty; upon completion of which to rejoin station, Aug. 25, 1896.

### Change of Address.

Clarkes, Wm. E., from Chicago to 435 Park Av., River Forest, Ill.

Fest, F. T. B., from Plank Road, Mich., to Amoy, China.

Isbeter, R. T., from 1923 Indiana Av. to 218 Wabash Av., Chicago, Ill.

Mackee, L. V. G., from Brant Rock to Attleboro, Mass.

Narr, W. L., from 5451 Lake Av., Chicago, to 7404 Madison Av., Grand Crossing, Ill.

Mullen, T. R., from Marcus to Akron, Iowa.

Wimberly, J. S., from Sanford to Sunlight, Ga.

CHICAGO, ILL., SEPTEMBER 19, 1896.

No. 12.

## ADDRESS.

### INTRODUCTORY ADDRESS.

Read in the Section on Neurology and Medical Jurisprudence, at the Forty-seventh Annual Meeting of the American Medical Association, held at Atlanta, Ga., May 5-8, 1896.

BY T. D. CROTHERS, M.D., CHAIRMAN.  
HARTFORD, CONN.

This Section of Neurology and Medical Jurisprudence has reached a position in the department of medicine of intense practical interest.

Every practitioner is confronted with questions of neurology, and the legal relations and possibilities which are constantly springing out of the present conditions. Nerve strains and drains, and vast complex states of neurosis are increasing yearly. Half a dozen text-books and a score or more of pamphlets, and monographs have been published in English during the past year, exclusively on nerve diseases.

This is only a small part of the literature which is appearing in journals devoted to this specialty, and in society reports and general journals of medicine.

The topic of medical jurisprudence has been enriched with at least four encyclopedic volumes, and over a dozen separate works and almost innumerable papers, lectures, essays, reports of cases, and the renewed activity in the many societies devoted to this special study. Literally a new field of medicine is coming into prominence.

To the average practitioner there is something appalling in the significance of these topics. That is their magnitude and intricate relations to the every day practice, create a feeling of despair in being able to understand and apply the facts which are becoming so numerous.

In neurology the impression has been fostered, that only specialists with laboratory experience and facilities for accurate measurement and tests of the nervous system are able to judge wisely of these cases. This is wrong. Neurology is a general topic, to be studied by both the specialist and general practitioner.

The specialist with his means and appliances for exact scrutiny of the phenomena of nerve disorders, approaches it from one side; the practitioner with his observation of symptoms, and comparative study and grouping, from the other. Both may reach conclusions in harmony or differing widely, or both be in error.

Not unfrequently the specialists will make a diagnosis based on the readings of instruments of precision, and mechanical studies of phenomena of nerve action, that is not confirmed by the subsequent history. The general practitioner, will study the symptoms of the same case, and make a correct diagnosis from a comparison and study of appearances. This indicates that laboratory training and researches are not the absolute essentials for skill in diagnosis of nerve diseases.

I think the great demand in medical training to-day

is to teach how to observe accurately, and how to estimate and compare the results of observation. In nervous diseases more than in other branches the symptoms point to some local or general lesion and it is the meaning of these "distress signals" that will enable us to understand the disorder present. The mapping of certain symptoms and the reasoning of their meaning is simple enough, but their verification from repeated studies and confirmation by time and events is the final test. I think neurology and jurisprudence require more accurate observation of symptoms, and a higher degree of analytic skill and judgment than in any other problems of disease. Instruments of precision and laboratory researches are limited, but the approach from the clinical side, tracing back objective and subjective symptoms to their first causes, requires the highest type of pure reasoning and judgment. Neurology carries us beyond the boundaries of gross material life.

The defects of nerve and nerve fibers and their relation to each other, are practically a very small part of the subject. The realm of the psychical is still an unknown continent, and yet its laws and forces appear in every case that calls for treatment. Preventive medicine, the germ theories, the mysteries of chemic physiology, and all the vast range of "new lands" which are opening up before the student, are insignificant compared with the unknown power of mind, brain force and what is called nerve energy. No one can plead incapacity to work in this field. Its facts are everywhere open to observation.

Every person carries in his individual mental life mysteries, the solution of which is of the highest importance to the race. The mental and nervous element in disease, in injury, in surgical operations, the changes of mind and its influence over the body, the meaning of the phenomena of hysteria, and the terms neurasthenia and the constantly increasing names of symptoms of brain failures, are all "polar regions of mystery." We are confronted with the fact, that the present treatment of crime, insanity and drug manias by legal methods has not kept pace with the march of science. That the densest superstition prevails in the practice of the courts, and medical men are called on to harmonize the errors of the past with the teachings of the present. Who will wonder that expert testimony of this character will fail, and fall into disrepute. The jurisprudence of to-day can not be a modern edition of past medical theories and teachings of science. It must be founded on new facts of mind and matter, new discoveries of the relations to environment and human life, and the new physiology and psychology of the brain. Every year our relations become more and more complex. The demands for new adjustments of life and living call for new energies and create new sources of exhaustion. The brain and nervous system falters and retrogrades and the legal relations change. Out of harmony with the environment

clashing with existing conditions requires a new jurisprudence and new conceptions of responsibility and duty. Neurology is no longer the field of the specialist; it belongs to general medicine, to the country and village physician, to the city practitioner, and comes into the realm of every student of medicine.

Jurisprudence is equally broad in its requirements and application to every day life. If you will study the program of the several Sections you will notice how intimately neurology has become associated with the ever varying topics of medicine. If you will turn to your individual experiences and present conditions, and inquire of the mental phenomena, which is ever pressing for solution, some conception of the subject will dawn upon you. The study of the mental phenomena of neurology promises more startling discoveries than in any other field. The time has come for every student of medicine to assist in clearing up this realm of mystery and superstition. The quackery, humbug and delusions which infest these unknown phenomena of mind and matter will pass away. When neurology comes into general science, when jurisprudence become an exact study founded on certain definite facts, then the injustice and odium of the present will pass away. Our individual duty is to note and examine the phenomena of mentality and the various states of brain and nerve action and seek to discover laws which control them, and the causes and conditions which govern their origin and progress. The one central fact should never be forgotten, viz.: All nerve phenomena, and brain activities are the operation and manifestation of fixed and definite laws, whose movements are as exact and uniform as the stars above us.

In this confusing whirl of brain and nerve force, there is no accident or chance. All normal and abnormal manifestations spring from definite causes which may be known and anticipated. It would be reckless to deny the possibility of stamping out nerve and brain diseases in the future with the same certainty that the germ diseases are prevented. It is simply a question of knowledge of the facts which is the highest province of science to point out.

## ORIGINAL ARTICLES.

### THE BEST METHOD OF TEACHING GYNECOLOGY.

BY DENSLAW LEWIS, M.D.

PROFESSOR OF GYNECOLOGY IN THE CHICAGO POLICLINIC; ATTENDING GYNECOLOGIST AND OBSTETRICIAN TO THE COOK COUNTY HOSPITAL, CHICAGO.

At the last meeting of the AMERICAN MEDICAL ASSOCIATION there was some discussion relative to the best method of teaching the different branches of medical science. If this subject received attention, as far as gynecology is concerned, I have yet to see a report of what was said. I believe, however, that the usual method of teaching this comparatively new and certainly very important department of medicine fails of its purpose in many instances.

The primary object of a medical education is to train the faculties of observation and then to teach the application of peculiar knowledge for the alleviation of distressing symptoms and the relief of the responsible pathologic conditions. The task is most complicated, and it is not surprising that in many instances the student, who, perhaps, has passed a bril-

liant examination, fails ignominiously when confronted with the exigencies of actual practice.

Perhaps the fault is not exclusively his. Perhaps the medical education he has received, while teaching him many facts, has not taught him how to apply them. Perhaps, in the attempt to teach all that is known, too little effort has been taken to teach how to make use of knowledge. Too often it is forgotten that the science of medicine finds expression only in the application of the art.

Gynecology has been defined by Sænger as the surgery of the female genitalia. It is, however, much more than this. It includes a knowledge of venereal diseases; it must take into consideration diseases of the bladder, ureter, kidneys and rectum; as a matter of fact it often comprises all operations within the pelvic and abdominal cavities, and for its proper understanding the principles of obstetrics must have been mastered.

Before commencing the study of this extensive and important department of medical science it is obvious much preliminary work must be done. Anatomy, physiology, bacteriology, pathology, uranalysis, venereal diseases, obstetrics and general surgery must first be studied in detail. To minds thus fortified by a definite knowledge of medical facts, trained to processes of analysis and capable of logical reasoning so that sensible deductions may be made from true premises, the teacher of gynecology must endeavor to appeal so that the student having eyes may see, having knowledge may understand, and having common sense may appreciate at its true value what he sees and understands. He should not only be taught what to do but why he does it. The teacher, being necessarily a man of experience (otherwise he should not presume to teach) will have favorite methods which he will advocate. He should not, however, fail to remember that his individual methods are only of value if the reasons which induce him to resort to them are sufficiently apparent to demonstrate their superiority. His duty to the student is to explain *all* well recognized methods of procedure and to compare their value not alone in connection with the case under consideration, but in reference to other similar cases as well.

Text-books at best can give but a general idea of gynecology. I do not condemn their use. On the contrary I believe the systematic study of some manual to be advantageous. It teaches what to expect and, in the hands of an expert quiz-master, such a book unquestionably aids in the acquisition of indispensable facts. The peculiar tasks of the teacher of clinical gynecology can not be supplanted by any book or by any system of recitation. The Frœbel method of instruction is particularly necessary in imparting a knowledge of gynecology. Manual training is here indispensable. During his student days the medical man must be taught to see what there is to be seen and to perfect his sense of touch. Otherwise his teaching is superficial, his knowledge imperfect, and as a rule the result of his practice most deplorable.

To explain what I consider to be the best method of teaching gynecology it is perhaps preferable to refer to hypothetical cases. The women who serve me as subjects for clinical instruction are either ambulatory patients, able to be up and about, often able to work, or bed-ridden patients, incapacitated in consequence of some acute or chronic indisposition, often of a serious character.

Let us suppose that a patient presents herself at the dispensary. My second assistant writes out her history in full in accordance with specially prepared blanks which are designed to show a complete statement of important facts in the fewest possible words. The nurse then places the patient upon the operating table in the dorsal position with a sheet covering the legs and genitals. A curtain suspended from the ceiling falls about the patient's waist as she lies upon the table and separates her from the students so that her face is not seen. I first refer to the history of the case. The patient, for example, may have had three children, the youngest being now 2 years old. Her last labor may have been protracted, necessitating the application of forceps. The birth of this child was followed, we will suppose, by an illness that kept the patient in bed for six weeks and was accompanied by fever. Since that time the patient has never been well. She has suffered from pelvic pains varying in degree but usually more severe during menstruation. She has become anemic and weak. She is constipated and notices a constant leucorrhœa. Such a history, variously modified by individual circumstances, is a common record of many dispensary cases.

I introduce the right index finger and notice a laceration of perineum and cervix. With the fingers of the left hand placed on the abdomen over the symphysis the uterus is recognized as somewhat larger than normal, freely movable and not specially sensitive to touch. As the bivalve speculum is introduced the existence of a leucorrhœal discharge is observed.

Now what shall the teacher do under these circumstances? He has an opportunity of doing and saying a number of things, all eminently proper and all of value. Having recited the history of the case and having made a cursory examination of the patient, he may now deliver a didactic lecture on one or more features that suggest themselves to him, and in that manner occupy all the time at his disposal. It must be acknowledged that such a procedure is useful; and that the presence of the patient, even if no one touches her, serves to forcibly direct attention to her condition. I confess I often show in the amphitheater women who have recovered from placenta previa, postpartum hemorrhage or eclampsia, and I am confident their presence lends interest to any remarks that are made concerning the case. In a case like the one we are supposed to have before us such a procedure is, in my judgment, not the best method of teaching. In place, therefore, of delivering a lecture on traumatism of parturition, subinvolution, puerperal infection, endometritis or any other subject which might very aptly be discussed in this connection, the teacher will realize that his chief object is to point out what there is actually to see, and to instruct the student in the proper method of determining what is to be done. His efforts will be directed toward conveying definite knowledge, but he will chiefly endeavor, by emphasizing important facts, by referring to points of similarity and difference due to anatomic conditions and etiologic factors, to train the student to view the matter under consideration in all its relationships, more especially in reference to actual diagnosis and treatment. The teacher must, moreover, understand that he fails in his efforts if he tries to teach too much. In considering ordinary cases he must necessarily repeat much that he has already said. This is desirable rather than objectionable, but he should be able to present the same facts, from different standpoints, so that

his remarks are always of sufficient interest to command the attention of the student.

In the case under consideration the teacher will point out the bi-lateral laceration of the cervix. By means of tenacula he will demonstrate how the cervix should be after trachelorrhaphy. He will explain where incisions should be made, and speak of the "plug of cicatricial tissue," which is often a bug-bear to many students, and he will show where sutures should be passed after proper denudation of the laceration. Each student in turn sees the pathologic condition present. Each student sees the appearance of the laceration as it exists, and also as it should appear when repaired. Several of them take the tenacula in hand and demonstrate the necessary operative procedures.

While the students are thus engaged the teacher may refer to the hypertrophic changes that occur in consequence of cervical laceration. He may speak of the increased danger of infection at the time of labor in consequence of traumatism, and may mention how infection may extend by continuity of mucous surface through uterus and tubes, or through the placental site. He may show how a laceration can extend beyond the cervix even into the peritoneal cavity, and may call attention to the possibility of serious hemorrhage arising from such a laceration during labor and being mistaken for postpartum hemorrhage due to imperfect uterine contraction; he may explain the necessity of immediate operation in such an event.

He may also explain Dührssen's method of cervical incision in cases requiring immediate delivery, and he can point out how dangerous rupture into the peritoneal cavity is prevented by multiple incisions which obliterate the portio vaginalis. Incidentally he refers to more extensive lacerations of the cervix—the stellate lacerations—which may be practically inoperable and may necessitate an amputation of the cervix, and with the tenacula he demonstrates the operation of Schröder and others.

The patient is now placed in the left lateral position and a Sims' speculum is introduced. The wonderful perspicacity of our first master in gynecology is referred to and the advantages of his position and his speculum are pointed out. Emmet's discovery and operation are spoken of and the steps of the trachelorrhaphy are again demonstrated by other students taking the tenacula in hand. In connection with this demonstration the teacher may consistently speak of the dangers of undue traction in operative efforts on the uterus, or in the course of the examination. Howard Kelly's "third hand" may be mentioned and the possibility of separating adhesions, rupturing a peritoneal abscess or forcing pus from a pyosalpinx upon the peritoneum may be explained.

The speculum is now withdrawn, the patient is again placed in the dorsal decubitus and we proceed to the digital and bi-manual examination. While doing this it may be well to explain the inadvisability of using the uterine sound in most cases. The possibilities of exact diagnosis by other methods, the danger of infection and traumatism, and above all the relatively insignificant character of the knowledge that will be gained in ordinary cases by intra-uterine exploration will deter us from resorting to the use of the sound without preliminary disinfection and dilatation in special cases where intra-uterine exploration is clearly indicated, that is, when the benefits to be derived from this method of examination are plainly evident.

As the vulva is now examined by separating the labia a slight perineal laceration will be observed. Attention is called to the fact that the closure of this laceration has resulted in cicatricial tissue, very different in appearance from the vaginal mucous membrane. The ordinary appearance of the virgin vulva and the vulva in the nullipara is demonstrated by bringing the parts together with the fingers or tenacula. The gaping of the vulva with perhaps slight cystocele or rectocele is pointed out and the possibility of extreme degrees of these conditions is demonstrated by inserting a male sound into the bladder and the finger into the rectum. The remains of the hymen are shown and various matters of medico-legal importance are discussed.

As the examining finger is now introduced reference is made to the difference in sensation as observed in virgins, nulliparæ and in women who have borne children. The absence of a perineum pressing against the anterior vaginal wall is commented on. The sensation of a lacerated cervix, somewhat hypertrophied is mentioned. With the examining finger still in the vagina, the fingers of the other hand are placed over the symphysis and the uterus and its adnexa are palpated. Attention is called to the fact that the fundus uteri is usually felt just over the symphysis, and not over the region of the umbilicus. The student is also impressed with the fact that the finger in the vagina is intended simply to steady the uterus, and that extreme pressure upward is painful as well as useless.

Matters of interest in relation to the uterus are mentioned. The mobility, size, position and degree of tenderness are referred to. The student is taught first to recognize the fundus uteri, and after carefully but gently palpating the uterus he is instructed to pass the examining finger in the vagina to one side of the cervix, while the fingers of the other hand upon the fundus are carried outward so that abnormalities of tube or ovary may be appreciated. Each student in turn now examines the patient under the immediate personal supervision of the teacher. It is surprising how varied are the difficulties experienced by different students, and how quickly a little individual assistance will enable the student to successfully palpate the pelvic organs.

It must be remembered that many practitioners of great experience have never attempted a gynecologic diagnosis. They have vague ideas of the use of the uterine probe and sound, they consider the adjustment of suitable pessaries a matter of special skill, and they attach undue importance to the variations in the positions of the uterus. The possibility of mapping out the pelvic organs by bi-manual palpation is not seriously considered. The importance of recognizing the changes due to inflammation and the relative value of different pathologic conditions due primarily to infection is not fully appreciated.

While the student is being taught to palpate the pelvic organs he is shown normal and abnormal specimens of the female genitalia. He observes, for instance, the size of the tube in a normal specimen, and also in a case of salpingitis or pyosalpinx. As he looks at these specimens he realizes the condition of the tubes in the woman he is examining, and I believe his impressions of the condition of the patient are rendered more vivid and more exact by observing the specimens at this time.

The remarks of the teacher while a number of the

students are in turn examining the patient, will necessarily be varied, as many patients with almost identical histories will constantly present themselves. It will be found advantageous for the teacher to endeavor to impress certain facts in connection with each case, not attempting to exhaust any portion of the subject, but rather to help the student to make accurate observations, to arrive at sensible conclusions, and above all to appreciate the limitations of his examination.

He may, for instance, explain how infection may proceed through the uterus and tube and on to the ovary and peritoneum. He may demonstrate results by showing specimens of abscesses of the ovary or pyosalpinx. He may speak of ovarian and parovarian cysts, and of tumors of the uterus, ovary, tube and broad ligament. He may advantageously discuss inflammatory conditions of the cellular tissue, and may also refer to extravasations of blood and the development of pelvic abscesses, discussing their localization and usual course in consequence of the anatomic conformation of the parts.

In a word, the instructor is now teaching first of all diagnosis, which depends upon facts. He must speak of facts, that is, of the various possibilities compatible with the history, and he must teach the student to arrive at a conclusion by showing him what he may expect to find, and then what he actually does find. He must not only explain, for instance, that a mass felt between the fingers is a pyosalpinx; he must show, as well, why it can not be anything else. Finally, he must determine the proper course of treatment, and must show clearly and distinctly not only why the treatment recommended in this particular case is the best treatment, but also why other methods of procedure, while sometimes of value, are inferior in merit to the plan proposed. Thus alone can be perfected a differential diagnosis worthy of the name.

The course of procedure described is applicable to all dispensary cases. Each student should see everything there is to be seen and thoroughly understand what he sees. He should personally examine every case, make his own diagnosis and determine the best method of treatment. All vague and erroneous ideas should be exploded by demonstrating facts, and all vagaries of treatment should be exposed by a thorough explanation of the reasons that dictate the plan of treatment proposed.

In teaching how to operate, the ideal method would be for each student to operate under the supervision of the teacher. Such a method is manifestly impracticable in the great majority of instances, and for this reason the best method of teaching the student how to operate is for him to observe how his teacher does, watching every step of the operation and understanding how and why every incision is made and every suture passed. It is evident such a method is incompatible with the performance on the part of the teacher of brilliant and theatrical exhibitions of his skill. It must be remembered that he is not demonstrating his ability as an operator; he is doing the best he can to show each student how the different steps of the operation are to be undertaken, and he explains why each step is necessary or expedient. The teacher instructs the student so that he may operate. There is no endeavor—at least there should be none—to impress the student with his teacher's wonderful dexterity and exceptional ability.

I have elsewhere described my "phantom perineum"

which has been<sup>1</sup> used in my clinics for many years. I have within the past two years perfected a "phantom cervix" and quite recently have been able to manufacture a "phantom" of the uterus, tubes and ovaries for the purpose of demonstrating various gynecologic operations. These "phantoms" are of different colored cloth made into bags to represent different organs and layers of tissue.

In the case of the perineum they show the necessity of a true restoration by actually restoring the parts to the position they occupied prior to the injury. The operations of Hegar, Emmet, Martin, Tait and others can be exemplified, and it can be clearly demonstrated how the fundamental principle is subserved regardless of the differences in detail of operative technique.

In the case of the cervix, Emmet's operation, Dührssen's incisions, the closure of an extensive laceration at the time of labor, and the different procedures for amputation of the cervix, can all be clearly demonstrated.

It is my practice to show the different steps of the operation on the "phantom" while one of my assistants operates on the patient. In a perineorrhaphy or cervix operation the students walk around to see the denudation after it is made. They then see the sutures as soon as they are passed, and finally see the result when the sutures are tied. At the same time they see each detail of the operation as it is demonstrated on the "phantom." They may not be impressed with the cleverness of the operator, but I honestly believe they learn how to operate, each for himself.

In abdominal operations I first invariably insist upon the necessity of absolute asepsis, and I explain the methods adopted for securing surgical purity on the part of the patient and the operator. The abdominal incision is made rather long so that the structure of the abdominal wall may be demonstrated. For half an inch perhaps the skin alone is incised. For another half inch the incision extends through the superficial fascia. Then the aponeurosis is incised and the separation of the muscular fibers is shown down to the aponeurosis beneath. Finally the subperitoneal fat is incised and an opening is made through the peritoneum.

As the students now walk around the patient each one sees the different layers of the abdominal wall which are demonstrated by means of dissecting forceps. While this is being done comment is made upon the relative thickness of the different structures, the variations of the blood supply and the necessity for controlling it, the advisability of avoiding the linea alba so as to secure stronger union.

By means of scissors the abdominal incision is now made to include all tissues and the omentum is shown. Incidentally the appearance of the peritoneum is demonstrated and the possibility of adhesions of tumors, intestine, etc., is alluded to. The patient is now placed in the Trendelenburg position. The intestines are allowed to fall forward or are pushed out of the way, and a laparotomy sponge of gauze is introduced. Again the students walk around so that each sees the fundus uteri, the tubes, the ovarian cyst, the subperitoneal fibroid, or whatever pathologic condition may be present.

Supposing the case to be a pyosalpinx, the teacher

now introduces two fingers and feels for the fundus uteri, explaining what he is doing. He then passes his fingers behind the uterus and breaks up adhesions so that the mass may be dislodged. He brings it out of the abdominal incision and transfixes it in the usual manner. The students again inspect the tumor and observe how the ligature is passed and tied. They observe the stump after the mass has been cut away and notice the space it occupied prior to its removal.

While the teacher is at work in this manner he explains his reasons for each step of the operation and he refers briefly to modifications of the method that might be necessitated by certain complications. He explains the Staffordshire knot and his assistant demonstrates it on a towel. In the same manner other methods of ligating are shown and reasons are given for preferring the method adopted. The treatment of adhesions to intestine or different pelvic viscera is mentioned, and the advisability of vaginal incision in certain cases pointed out.

The indications for drainage are spoken of and the different methods discussed. The question of the "toilet of the peritoneum" and flushing out the peritoneal cavity are raised and definite directions are given. Finally, in closing the abdominal wound, the substance used and different methods adopted are explained and their relative value discussed. The students see the sutures in place and they notice how they are tied. They then see the application of the dressings and perhaps the hot bricks that are placed around the patient when she is put back to bed.

It is probable that I have indicated by what has already been said just what I mean by the best method of teaching gynecology. It is, I think, unnecessary to particularize further. To do so were to present a syllabus of my lectures on the different topics of gynecology.

It is evident the best method of teaching is not the best method of showing the phenomenal ability of the teacher. It is questionable if the latter method is of much benefit to the student. It must be remembered that he comes to learn. He will soon be thrown on his own resources. The fact that his teacher is a great man will help him but little in his extremity.

The student comes to us to learn and it is but proper he should be taught. He wants to see no operative pyrotechnics or only incidentally. The province of teachers is to teach. Their first duty is to help the student to help himself, and the method adopted should have that end constantly and pre-eminently in view.

217 Fifty-third Street.

## THE VALUE TO THE MEDICAL STUDENT OF PHYSIOLOGIC STUDY.

BY JOHN A. BENSON, M.D., COLUMB.

PROFESSOR OF PHYSIOLOGY COLLEGE OF PHYSICIANS AND SURGEONS CHICAGO; PROFESSOR JURISPRUDENCE OF MENTAL DISEASES, CHICAGO SCHOOL OF LAW.

In a superstructure like that of the art and science of medicine wherein we find the various subdivisions, so imbricated and intimately related to and connected with each other that injury to or removal of any one would endanger the integrity of the whole, it is manifestly improper, and in fact impossible to attempt to place a greater value on any one part than can be ascribed to any and every other. For in such a whole no particular fractional part excels any other as far as specific value is concerned, and the value

<sup>1</sup> Annals of Gynecology, Vol. viii p. 670, Chicago Clinical Review, May, 1895.

and dignity of the whole equal the sum total of the individual parts. And indeed were we to attempt to remove or neglect any part, no matter what, we would not merely be subtracting a fractional value or dignity and thereby lessening the total by just so much as would be subtracted, but we would be seriously attacking the safety of the whole building and peradventure would find its walls toppling over and falling about our ears with a fearful clatter. But if we find that any one part can be discovered as having borne parental relations to any other, we can of a certainty recognize such importance; for the son, even though acquiring equal or superior dignity to his father, must ever respect that father, and the progeny must defer to the procreator. By reasoning on this line I purpose to demonstrate the nobility of physiology among its confrères and to give reasons why special and careful attention should be given thereto, and why our college authorities should appreciate the great benefits to the student of thorough and correct physiologic teaching. What is physiology? The answer to this question opens up a field far wider than is usually imagined. Physiology has been defined as being the study of the phenomena of life, teaching us the direct causes of these phenomena, the varying conditions under which they appear, their coincident chemic and mechanical accompaniments, their modes of operation and their results. From the department of physiology we learn all that can be known concerning the active functioning organism with its various subdivisions each working in its own particular manner, each function modified, accelerated, retarded or inhibited to meet the requirements of the economy at large, and the whole structure endowed with personality and imbued with vitality. So far we find physiologic lore to be of interest to the natural scientist outside of specific medical application, but to the practical physician I will now endeavor to show that physiology is an absolute *sine qua non*, and he must pay strict attention to this branch before he can hope to become a diagnostician, a pathologist or a therapist. I imagine that it is hardly necessary for me to remark that a physician devoid of diagnostic ability, of pathologic knowledge or therapeutic skill is totally unfit to attempt to practice the profession of medicine; and I desire here to record myself in the most positive manner as being of the opinion that such ability, knowledge and skill are in direct ratio to thoroughness and completeness of physiologic study, and that when any individual has without such thorough and complete study, attained even considerable success in medical practice, he remains an empiricist and can never be considered a scientific physician. A man, a work of art, or a piece of machinery we describe as being perfect, as being good, or indifferent or even bad. We use these terms relatively, comparing the object under examination with a known and accepted "standard" which may be abstract or concrete; and a principal duty of our wise men, of our physicians, our teachers, our artists and our scientists is to establish a "standard" in each of their several lines. There is nothing "new" in disease. It is a modification or an alteration of the normal; a perversion of, or a departure from the "standard" and it is the duty and the prerogative of the physiologist to give the practicing physician the "standard" he has to use. This "standard" is the living human body in a condition of healthy physiologic equilibrium, with all

its various subdivisions working harmoniously together and constituting a perfect whole. After the student has become familiar with the normal action of this magnificent piece of mechanism, then and only then can he study the deviations therefrom which we term "disease." For example; of what use would it be for the tyro to place his ear to the chest of a patient suffering from cardiac disease? How would he know but that this tumultuous heaving, these varied sounds were the usual condition of affairs? First let him note all the characteristics of the heart's action, its rhythm, the accompanying sounds, the events taking place during the cycle, and the results and bearings of these events on far and near portions of the animal economy; then the slightest deviation from the known standard will mean something, and its specific value can be appreciated. A man practicing the profession of medicine without any "standard" to guide him, would resemble the unfortunate who was

"Condemned in labor or the arts to drudge  
Without a second and without a judge."

Groping in the darkness of the impenetrable shade of ignorance, such a man could never advance, and would have to be placed in one of two categories, to-wit: knowing and appreciating the deficiencies and weaknesses of his position he would endeavor to ameliorate them, he would seek a way out of the darkness, and his voice would ring out for truth and light, as a

"Child crying in the night  
A child crying for a light  
And nothing in its language but a cry."

For such a man there is hope. Or else blind and self-satisfied, he would recklessly stride along through the valley and the shadow firing blank shots into space and noting his own splendid marksmanship. Such a man is scientifically dead; for him there is no hope, no resurrection. Whose is the fault fundamentally in either case? The fault is at the door of the guides, of the teachers, of the leaders, of those who permitted or allowed such a lamentable condition to become possible.

This subject is one near and dear to my heart and peradventure were I not to call a halt and exert a reflex inhibitory influence on my pen, it might, by exercise, develop such strength and amplification as to emancipate itself from my autocratic grasp and gallop along indefinitely. Worse and more pitiable then would be the fate of the distinguished Editor of the JOURNAL, than even that of the guests of Helio-gabalus. For whereas the latter were smothered in roses, the former would of a certainty be drowned in "copy."

I imagine though that I have given in outline good and sufficient reasons for devoting time and attention to physiologic work; the next question that faces us is how should physiology be taught? To this I would answer that the work must be done in two ways: first, by direct observation; and second, by didactic explanation. In the first place I would familiarize the student with the well-developed, healthy, living human body as a whole, and his preliminary study in this regard I would have similar to that pursued by art students in painting and sculpture; that is the study of the nude, as conducted by director French of the Chicago Art Institute. Such a course of gross physiologic anatomy, modified somewhat perhaps to meet the requirements of the medical student, I hold to be of vast value. Then I would insist on a full

and complete laboratory course, not such a course as is but too often given (on paper in an annual announcement) but a thorough and painstaking course supervised by the professor of physiology himself, who would thus come into direct personal contact with each and every member of the class. Such work would be of the greatest value not only in inculcating physiologic data, but also in teaching the student how to think, how to draw and comprehend deductions from personally recognized conditions, how to explain to himself and reason out for himself the relations of abstract and concrete causes and appreciated results, and the bearings thereof. The master words for success in the attainment of actual knowledge are "direct observation," and only by this means can positive results be reached. Analogical deductions and inferences are unreliable and dangerous, no matter how cunningly traced, and the only data which can stand criticism are those born of experimental investigation. Structure and function are most intimately connected, and yet we find that we can not with a certainty depend on the structure of an organ as indicating its function. The two can only be correlated when direct examination demonstrates the fact of their association.

The lower we descend in the scale of life, the simpler do we find structure; in the lowest planes, the simplest. In these latter we note the existence of individual unicellular organisms without specific subdivisions, each part performing equally all the various vital functions. Thus the unicellular organism is uniform, simple and general, possessing the fundamental property of irritability and likewise the capability of initiating movement. This cell is therefore automatic and contractile, and at one and the same time is excretory, reproductive, and generally metabolic and motile, all these functions being exhibited equally by the same mass of protoplasm. As we mount higher we find various portions of the organism becoming more skillful in performing a few functions, and this for each part soon is narrowed down to one special function. At the same time, to a greater or lesser extent, the part becoming so specially educated withdraws from the performance of general functions. Each part becoming special renders the whole more complex, and we have anatomic changes taking place coincident with the educational amplifications. The accompanying conditions are; with relation to function, "specialization;" with relation to structure, "differentiation."

In order that we should acquire as distinct and clear an understanding as is possible of these complex, specialized and differentiated structures, we must begin our study at the lowest plane of life and note carefully the physiologic, histo-chemic and anatomic attributes of the simplest forms there to be found; continuing our observations on the same lines and mounting gradually higher and higher, we ultimately reach the most complex combinations. And further, in arriving at explanations of the structural, chemic and functional phenomena that confront us in the higher planes, we must go back to the period when these highly complex forms were themselves of simple degree. In this way embryology enters into our field of research, and in comparing the amplification and development of animal life generally with that of an individual member of some particular species, as for instance a human being, we find that we can aptly characterize the one as being a simulacrum of the

other, the only marked difference being the element of time which however may safely be left out of consideration.

At the highest point in the scale of life we discover the exact opposite of what we studied in the lowest, and we find the organism now to be multiform, complex and special. Each one of the various parts of such an organism, has to be studied separately, in order that we should determine as far as possible its individual characteristics, and this study should be begun in the particular tissue after isolation from the economy as a whole. Then entire organs or apparatus of associated organs have to be considered and this can only be done by experimental observation upon the living structures.

Last of all the functioning entity must be observed, all the parts, all the organs, all the associated apparatus of organs brought into relation with each other and working in harmonious or alternating action. This must all be done on the living body, aided by dissections, schema, working models, charts, diagrams and so forth.

In pursuing such work the teacher will be required to devote a certain amount of time to both structural and chemic analyses of the tissues, so physiology and histo-chemistry are indissolubly united. These observations, examinations and experiments require laboratory work. Here under the direct guidance of the physiologic professor, each student works as an individual alone and to a great extent apart from his collaborators, but at stated and frequent periods the entire class should meet the professor in the lecture amphitheater for didactic instruction. Here the laboratory work is fully explained and amplified, deductions are made, theories are advanced, causes and effects are considered, opinions are reduced, and work on similar lines in other portions of the world is reviewed; while the laboratory illustrations are supplemented by working models, sketches, charts, schemes, etc. Again, frequent convocations should be held at which the professor should question each student on the previous work, and this should be looked upon as being as valuable as the other modes of instruction, as the student's ideas on the subject matter can be elucidated and he can be materially assisted.

Speaking with an authority born of experience and study, I would say: 1. The physiologic course should be included in the curriculum for both the freshman and sophomore years. 2. Sufficient time should be given for at least five days in each week during the course, to laboratory work and explanatory or didactic instruction. 3. Once at least each week there should be a physiologic convocation in which the previous work should be carefully reviewed. 4. The chair of physiology should be a salaried position, as it is impossible for a practicing physician to properly administer its duties and bear its responsibilities. This chair is about the only one in a medical college which, to a practicing physician, has no commercial value, and the work of the incumbent each year is not by any means accomplished when the lecture course is finished. During vacation time original research, individual observation, review of the work of others, travel, visits to foreign and domestic universities and colleges and their laboratories, all are matters that will occupy time; in short as soon as one course is completed, preparations for the next should be initiated, for no scientific physiologist can depend on this year's notes for the next year's course; he can not

stand still, but must gain or lose, advance or retreat. 5. There must be a fully equipped laboratory in all that the words imply, with a complete zoologic addition. 6. In the freshman year there should be a preparatory course on physiologic artistic anatomy. There are many other details in this connection that time and space will not permit me now to dilate upon, but I would conclude by expressing the positive opinion that unless the fundamental elements of the positions above outlined by me are in force in a medical school, such school is not doing its duty either to the students or to the profession at large, and does not deserve to stand in the front rank. In a very large majority of our institutions of medical learning, physiology is slighted and ignored, and money and time are spent and much advertising indulged in concerning the so-called practical branches, the authorities forgetting that there is no branch so sternly practical to both the under-graduate and the post-graduate as is physiology.

**THE MEDICAL COLLEGES OF THE UNITED STATES.**

The Editor of the JOURNAL a few weeks ago addressed a circular to the Secretary or Dean of the various Medical Colleges, requesting them to state their plan of education, including the requirements for admission, the facilities they possessed for teaching, and the cost of attendance.

The general response to the circular has produced the very complete summary here presented.

It should be remembered that these statements are those prepared by the schools themselves and in no way changed in this office.

**ASSOCIATION OF AMERICAN MEDICAL COLLEGES.**

The Association of American Medical Colleges, requires for all members that candidates for matriculation will be allowed admission, subject to the conditions prescribed by Article III of the Constitution of the Association:

**ARTICLE III.**

SECTION 1.—Members of this Association shall require of all matriculants an English composition in the handwriting of the applicant of not less than two hundred words; an examination by a Committee of the Faculty, or other lawfully constituted Board of Examiners, in higher arithmetic, algebra, elementary physics, and Latin prose.

SEC. 2.—Graduates or matriculants of reputable colleges or high schools of the first grade, or normal schools established by State authority, or those who may have successfully passed the entrance examination provided by the statutes of the State of New York, shall be exempt from the requirements of Section 1.

SEC. 3.—Students conditioned in one or more of the branches enumerated as requirements for matriculation shall have time until the beginning of the second year to make up such deficiencies; provided, however, that students who fail in any of the required branches in this second examination shall not be admitted to the second course.

SEC. 4.—Colleges granting final examination on elementary subjects to junior students shall not issue certificates of such final examination, nor shall any member of this Association confer the degree of Doctor of Medicine upon any person who has not been first examined upon all the branches of the curriculum by the Faculty of the College granting the degree.

SEC. 5.—Candidates for the degree of Doctor of Medicine shall have attended three courses of graded instructions of not less than six months each in three separate years.

SEC. 6.—Students who have matriculated in any regular college prior to July 1, 1892, shall be exempted from these requirements.

**THE SOUTHERN MEDICAL COLLEGE ASSOCIATION.**

The Southern Medical College Association makes the following requirements, viz.:

Every student applying for matriculation must possess the following qualifications:

He must hold a certificate as the pupil of some known, reputable physician, showing his moral character and general fitness to enter upon the study of medicine.

He must possess a diploma of graduation from some literary or scientific institution of learning, or certificate from some legally constituted high school, General Superintendent of State Education, or Superintendent of some County Board of Public Education, attesting the fact that he is possessed of at least the educational attainments required of second-grade teachers of public schools; provided, however, that if a student, so applying, is unable to furnish the above and foregoing evidence of literary qualifications, he may be permitted to matriculate and receive medical instruction as other students, and qualify himself in the required literary departments, and stand his required examination, as above specified, prior to offering himself for a second course of lectures.

The foregoing certificate of educational qualifications, attested by the Dean of the medical college attended, together with a set of tickets showing that the holder has attended one full course of medical lectures shall be essential to attendance upon a second course of lectures in any college belonging to the Southern Medical College Association.

(1) . . . . ., 189—  
Dean of Medical Department of University of Tennessee—  
Nashville Medical College:

DEAR SIR—Mr. . . . . of . . . . . is a gentleman of good moral character. I recommend that he be allowed to enter upon his medical studies in your college. He has been my pupil . . . months.

Yours,  
[Sign here] . . . . .

(2) . . . . ., 189—  
Dean of Medical Department of University of Tennessee—  
Nashville Medical College:

DEAR SIR—I have examined Mr . . . . . of . . . . . and find his scholastic attainments equal to those requisite for a second-grade teacher's certificate in our public schools.

Yours,  
. . . . . Supt. of Pub. Instruction.

**BIRMINGHAM MEDICAL COLLEGE.**  
BIRMINGHAM, ALA.

This College requires an attendance of three terms of six months each before application for graduation, and a general average of 75 per cent. for a degree. The school has good hospital advantages and abundant clinics, and furnishes splendid facilities for the study of medicine. There is an excellent building well arranged for medical instruction, and well equipped laboratories. W. H. JOHNSTON, M.D., Dean.

**MEDICAL COLLEGE OF ALABAMA.**  
MOBILE, ALA.

The thirty-first annual session of this institution will begin Oct. 12, and continue six months. The Faculty offer a curriculum that has been carefully and systematically graded. The chemic, microscopic, surgic and pharmacutic laboratories are fitted in accordance with the most modern and advanced ideas, and afford ample and convenient facilities for the practical work exacted of each student in these departments. The dissecting rooms are large and well ventilated, and material for practical anatomy abundant. Medical and surgical clinics are held daily at the City Hospital and College Dispensary. Fees, including laboratory course \$100 for each session. Diploma fee, \$25. The requirements for matriculation and for obtaining the degrees are set forth in the annual announcement, which will be sent upon application. Geo. A. Ketchum, M.D., Dean.

**ARKANSAS INDUSTRIAL UNIVERSITY.**  
MEDICAL DEPARTMENT, LITTE ROCK, ARK.

Four years graded course. Twenty-three profes-

sors and teachers. Fees each course \$58; matriculation fee paid once, \$5. Graduation fee, \$25. Resources for clinic instruction, Pulaski County Hospital, Little Rock City Hospital, Little Rock Infirmary. Daily clinics.

Regular winter course begins Nov. 2, 1896, and continues six months. Preliminary course begins Oct. 5, 1896. J. A. Dibrell, M.D., President and Dean of Faculty.

E. R. Dibrell, Secretary.

#### COOPER MEDICAL COLLEGE.

SAN FRANCISCO, CAL.

Thanks to the generosity of its President, L.C. Lane, this school is amply provided with facilities for instruction. Its handsome buildings, its hospital and its endowments and funds represent half a million of dollars. An educational qualification or an examination is required before admission. Four courses of lectures are necessary to complete the curriculum, except for such as have through-college education or otherwise accomplished the work required for the first year. The regular or long term begins June 1 and continues six months. The short term begins February 1 and continues three months. The graduation exercises take place in December. The regular course is held in summer and autumn. The objections to the summer which obtain on the Atlantic border are entirely unknown here. The dryness of the atmosphere prevents decomposition; thus dissecting can be carried on with far more comfort and satisfaction than during the winter or summer months in other climates. Excellent clinical facilities are offered at the City and County Hospital and at the extensive College Dispensary. The Lane Hospital, adjoining the College, now just completed, will accommodate a hundred patients. A fee of \$130 is charged for each of three courses: Matriculation fee \$5; demonstrator's \$10; graduation \$40.

Henry Gibbons, Jr., M.D., Dean; William Fitch Cheney, M.D., Secretary.

#### UNIVERSITY OF CALIFORNIA; MEDICAL DEPARTMENT.

SAN FRANCISCO, CAL.

The sessions begin September 1, and continue eight months. During the term all the branches of medicine and surgery are taught, didactically and clinically. Regular clinics are held threedays in the week at the City and County Hospital (450 beds), where the professors of the practical chairs have charge of wards and possess every advantage for the instruction of students. There is also an active clinic conducted three times a week at the College Dispensary, where large numbers of patients are examined and treated before the classes. Didactic lectures are given daily by the professors, and evening recitations are held several times a week.

The dissecting room is open throughout the entire year. Material is abundant and costs but little.

The facilities for bedside study have been largely increased of late, and the student will find opportunities at his command which, for comprehensiveness, are nowhere surpassed.

The Medical Department of the State University was one of the first in the United States to adopt the four years' term of study. No student can present himself for final examination until he has attended four annual courses of medical lectures and clinics.

Graduates of accredited literary and scientific col-

leges, and such as have completed two years of the natural science department of a recognized university, are admitted to the second class without examination.

Fees: Matriculation (paid but once), \$5; demonstrator's ticket, \$10; fee for each course of lectures, \$100; graduating fee, \$25.

For the annual announcement and catalogue giving regulations and other information, address R. A. McLean, M.D., Dean.

#### DENVER MEDICAL COLLEGE.

MEDICAL DEPARTMENT OF THE UNIVERSITY OF DENVER, COLO.

(Incorporated in 1881.)

The next session of the school begins Sept. 8, 1896. The Faculty is composed of fifteen professors and ten assistant professors and lecturers. The school offers exceptional advantages to students who can not complete their college work in the rigorous eastern climate. Colorado is justly noted for its mild winters, and students coming to Denver can pursue their medical studies in the school surrounded by amply equipped laboratories, by large clinics and by an active, interested corps of teachers. The College is a member of the Association of American Medical Colleges and confirms to every requirement of that Association.

Fees: Matriculation (annually), \$5; tuition, \$75; graduation (not returnable), \$25; demonstrator's ticket (including material), \$10; chemic laboratory ticket, \$10; pathologic and physiologic laboratory, extra. No tuition fee is required from students who have paid for and attended three full courses of lectures in this College. Such students are admitted to the fourth course upon the payment of the matriculation fee only.

Samuel A. Fisk, M.D., Dean; E. R. Axtell, M.D., Secretary.

#### GROSS MEDICAL COLLEGE.

DENVER, COLO.

The College is legally chartered under the laws of the State of Colorado. It was established in 1887 and has made such rapid progress that at present it stands foremost among the medical colleges of this section. Being a member of the Association of American Medical Colleges, it complies with all the requirements of this Association and has adopted the four-year course of study.

This institution is well equipped for medical instruction, containing four large lecture rooms, abundant laboratory room and facilities. In close proximity to it is a large free dispensary, which furnishes abundant material for clinical instruction. It is situated within a few blocks of the County Hospital, at which regular clinics are held and bedside instruction given. The tuition fee is \$75 each for the first three years and \$30 for the fourth year. There is no graduation fee and no hospital fee.

Thomas Hayden Hawkins, A. M., M. D., Dean; Robert Levy, M.D., Secretary.

#### UNIVERSITY OF COLORADO; MEDICAL DEPARTMENT.

DENVER, COLO.

This school is a member of the Association of American Medical Colleges and gives a graded course of four years, the term extending from the first week of September to the third week of May.

The first year's course is given at the university in Boulder, where the facilities for instruction in the fundamental sciences are excellent. In order to

obtain superior clinical advantages the instruction of the second, third and fourth years is given in Denver. The dispensary of the school and hospitals of Denver furnish a large amount of clinical material.

The climatic advantages of Colorado enable students to pursue their studies here who could not do so elsewhere.

Tuition: For residents of the State, \$35 per year; for non-residents, \$45. Graduation fee \$10.

For further information apply to Clayton Park-hill, M.D., Dean; Howell T. Pershing, M.D., Secretary.

#### YALE UNIVERSITY, DEPARTMENT OF MEDICINE.

YALE MEDICAL SCHOOL, HARTFORD, CONN.

In the fall of 1810 a charter was granted to the President and Fellows of Yale College and the President and Fellows of the Connecticut Medical Society, authorizing them to unite according to the terms of certain "Articles of Union," before agreed upon, for the establishment of a medical seminary, to be styled the Medical Institution of Yale College. Two years later the school was organized, and in the fall of 1813 instruction was begun.

While the attention of the student is particularly directed to those branches which can be studied to advantage only in a well equipped medical school, the value of clinical instruction is fully appreciated and amply provided for. The curriculum consists chiefly of recitations of assigned readings in text-books, systematic laboratory work and personal instruction in clinics.

Terms of admission: Candidates for admission must be at least 18 years old, and must present satisfactory testimonials of moral character from former instructors or physicians in good standing. Each candidate must present proof that he has passed the matriculation examination of some scientific, literary or professional college in good standing, or present testimonials from the proper officer that he has pursued the course at some high school, academy or preparatory school approved by the faculty, or he must pass an examination in the following subjects:

#### REQUIREMENTS FOR A DEGREE.

1. He must be at least 21 years of age, and must sustain a good reputation for moral character.

2. He must have spent three years as a student in this school, or if but one or two years in this school, he must have pursued such studies in some other recognized institution, as are considered by the faculty to be the equivalent of the remainder of the full term of study. The last year must have been in this school.

3. He must have passed to the satisfaction of the faculty the prescribed examinations of the course; and he must have presented a satisfactory thesis on some subject relating to medicine. The thesis should be presented to the dean on the third Wednesday before Commencement.

Fees and expenses first year: Matriculation (paid but once), \$5; tuition, \$140; practical anatomy (including instruction and material), \$10. Second year: Tuition, \$140; practical anatomy (including instruction and material), \$5; practical pharmacy, \$5. Third year: Tuition, \$80; graduation, \$30.

Herbert E. Smith, M.D., Dean.

#### MEDICAL DEPARTMENT COLUMBIAN UNIVERSITY.

WASHINGTON, D. C.

The seventy-fifth session begins Sept. 30, 1896. The

numerous advantages afforded by the City of Washington for the study of medicine are well known. The clinic facilities of four large hospitals are open to students of the college. The new Congressional library, almost completed, will give the students additional advantages scarcely to be equaled in any other city.

The course extends over four years, and the annual fee for all expenses is \$106.

The bacteriologic and pathologic departments are under the direction of an accomplished teacher, who is also in charge of the Army Medical Museum of the city. Extensive experiments upon the antitoxins are being conducted by the biochemic laboratory of the Department of Agriculture, and by act of Congress the Government laboratories are available to students for clinical instruction.

D. K. Shute, M.D., Dean; E. A. De Schweinitz, Secretary.

#### MEDICAL DEPARTMENT, GEORGETOWN UNIVERSITY.

WASHINGTON, D. C.

The next session of this school will begin October 1, and continue until May 13, 1897. The four years' course is obligatory. Instruction is given by lectures, recitations and demonstrations in the lecture rooms, as well as by practical exercises in the dissecting room and the various laboratories, which are especially well arranged and equipped for this most important method of modern teaching. Ample and excellent facilities for clinical instruction are furnished by the hospitals and dispensaries. Positions as resident physicians in these are secured by competitive examination. Congress has opened the Government museums and libraries to students of medicine, greatly enhancing the facilities otherwise furnished. The fees are: Matriculation, payable but once, \$5; lectures and laboratories for each year, \$105. No other charges except a small one for anatomic material.

J. W. H. Lovejoy, M.D., President; G. L. Magruder, M.D. Dean.

#### HOWARD UNIVERSITY, MEDICAL DEPARTMENT.

WASHINGTON, D. C.

This school opens its twenty-seventh session, October 1. It has a graded course of four years. Each college year continues seven months. Students are required to complete the studies in each year before being promoted to the next succeeding year. A thorough training is given in histologic, biologic, pathologic and chemic laboratories. The Freedmen's Hospital is upon the grounds of the college and affords ample clinic facilities to the student to study surgery, obstetrics, gynecology and practice of medicine. The tuition fee is \$60 per term. Small laboratory fees are charged to meet the necessary expenses. The college is coëducational. Students are instructed and examined in the following branches: Physiology, anatomy, chemistry, toxicology, materia medica, therapeutics, obstetrics, gynecology, practice of medicine, surgery, minor surgery, neurology, histology, bacteriology, pathology, ophthalmology, otology, pediatrics, medical jurisprudence and psychiatry.

T. D. Hood, M.D., Dean; C. B. Purvis, Secretary.

#### ATLANTA MEDICAL COLLEGE.

ATLANTA, GA.

This college was established in 1854 and has been

in continuous operation since except during the war. The school requires three terms of six months each and regular courses in the chemie, bacteriologic and pathologic laboratories. Clinics are held daily both at the college and at the city hospital, to which the students have access. Written examinations are held at the end of each session, and students must show satisfactory progress before they are allowed to advance to the next course.

The college building is especially commodious, having three large lecture rooms, each with a seating capacity of 200 and in addition a modern amphitheater arranged to seat 300 students.

The fees are \$100 for each session, diploma \$30; these fees are adhered to and under no circumstances is any reduction given to students. W. S. Kendrick, M.D. Proctor.

#### MEDICAL COLLEGE OF GEORGIA.

MEDICAL DEPARTMENT UNIVERSITY OF GEORGIA.

AUGUSTA, GA.

Organized 1832. Three years graded course, six months in each year, October 1 to April 1. Faculty has under its exclusive control three large hospitals, the polyclinic, the city dispensary and the out-door obstetric service. From these sources abundant clinic material is always on hand for clinic instruction of students. Clinic teaching occupies a prominent place in instruction of students. Every member of the graduating class is accorded a two weeks residence in the hospitals. Preliminary educational qualifications required of students; proficiency in arithmetic, elementary English, geography, spelling, United States history, and English composition. Fees: Matriculation \$5; practical anatomy \$10; general course of instruction \$75; diploma or graduation fee \$30.

Eugene Foster, M.D., Dean; Thos. D. Coleman, A.B., M.D., Secretary.

#### COLLEGE OF PHYSICIANS AND SURGEONS.

CHICAGO, ILL.

The fifteenth annual course begins September 22, and continues for seven months. A spring course is also given, for which there is no additional charge to students in the college. The spring course of 1897 begins April 21 and ends June 30. The curriculum of the college is graded, and four years are required to complete the course. Instruction is didactic and clinic and by laboratory teaching. Instruction during the first two years is largely by laboratory work; in the last two years largely clinic.

The equipment of the college includes the college building proper, which contains the lecture rooms, clinic rooms; a six-story laboratory building; and a college hospital. All of these buildings are amply furnished for the purposes to which they are severally devoted. The college hospital has recently been acquired by the purchase of a modern hospital building formerly occupied by the Post-Graduate Medical School. This gives the college a hospital of 125 beds with three aseptic operating rooms and a clinic amphitheater. The clinic material at the disposal of the college is large enough to insure the hospital being kept full all the time. Hospital service is a part of the senior class work. In the course of a year each student gets practical bed-side experience of the most varied kinds.

The class is divided into sections for the purpose of pathologic work in the hospital; so that the students are given training in exact methods of tech-

nical examinations, and gain at the same time a correct appreciation of the relative importance of the pathologic and clinic elements of their cases.

Clinics are given daily in the County Hospital by members of the Faculty. There are also autopsies daily at the county morgue to which the students have access.

The college has abolished formal final examinations, in lieu thereof, the students are graded upon their daily work, upon their recitations and upon examinations held during the course of the year. One-fourth of the time of each teacher is given to quizzing. Nine scholarships of the value of \$100 each are awarded to the students who make the best records in the college. The annual fees are \$110. There are no extras.

William Allen Pusey, M.D., Secretary.

#### CHICAGO POLICLINIC AND HOSPITAL.

A clinic school for post-graduate instruction in medicine and surgery, Chicago, Ill. It is conveniently located in a populous district which furnishes an abundance of clinical material. The instruction is entirely clinic and offers unequalled facilities for the general practitioner to personally examine cases and follow out the latest approved means of diagnosis and methods of treatment.

Clinics covering all departments of medicine and surgery are in progress daily from 8 A.M. to 5 P.M.; a well equipped bacteriologic and chemie laboratory is a notable feature of the institution and affords the practitioner an opportunity to become acquainted with the most important modern branches. As all clinics are conducted throughout the year, students may enter at any time. The fees are moderate and vary according to the number of branches taken and the length of time one desires to remain.

Truman W. Miller, M.D., President.

Fernand Henrotin, M.D., Secretary.

#### NORTHWESTERN UNIVERSITY MEDICAL SCHOOL (CHICAGO MEDICAL COLLEGE).

CHICAGO, ILL.

This school was the first in this country: 1, to enforce a standard of preliminary education; 2, to adopt longer annual courses of instruction; 3, to grade the curriculum of studies.

The laboratory building contains laboratories of physiology, histology, anatomy, pathology, bacteriology, chemistry, pharmacology and pharmacognosy of the most modern form and with best equipments.

Davis Hall is a very perfect out-patient infirmary, where twenty-five thousand patients are treated annually.

A feature unique to this school is the grading of clinical instruction and the maintenance of small clinics by greatly multiplying them so that students may obtain individual instruction. Forty clinics are conducted weekly at Mercy and St. Luke's Hospitals and Davis Hall.

Instruction is given by lectures, recitations, conferences, laboratory and clinic methods. Numerous eclectic courses are offered to students who desire them, either that they may obtain "honors" or special knowledge. These courses are chiefly laboratory or combined laboratory and clinic.

The requirements for admission are a diploma from a recognized college, school of science, academy or high school, or an examination in English, arithmetic, algebra, physics, Latin and any one of the follow-

ing: chemistry, general biology, zoology, botany or German.

College opens Oct. 6, 1896; Commencement is June 17, 1897. The fees are, matriculation \$5; annual \$100; laboratory (for first and second years) \$10.

The Faculty consists of thirty-seven professors and forty-three instructors and demonstrators.

N. S. Davis, M.D., Dean.

#### NORTHWESTERN UNIVERSITY WOMAN'S MEDICAL SCHOOL.

CHICAGO, ILL.

This school was founded in 1880 as the "Woman's Hospital Medical College." In 1892 it was incorporated with the Northwestern University. It is conducted as a regular school of medicine for the education of women only.

Students graduating in 1899, and subsequently, are required to attend four graded courses of lectures, of not less than eight months each.

Instruction is given by didactic lectures, recitations, clinical lectures and practical work. Objective methods are given a prominent place.

Practical instruction is given in the laboratories of anatomy, chemistry, histology, physiology, pathology, bacteriology and pharmacy. Modern methods are pursued in all these laboratories.

The Cook County, the Mary Thompson Hospital for Women and Children, The Wesley, The Woman's Hospital of Chicago, and various other hospitals to which the students have access, afford excellent facilities for clinic instruction. Through these various hospitals and the college dispensary there are unusual opportunities for practical obstetric work. Each day of the week one or more clinics are held in the college building.

A matriculation fee of \$5.00 and an annual fee of \$75.00 are required. An extra charge is made for tickets for laboratory and hospital courses.

#### POST-GRADUATE MEDICAL SCHOOL AND HOSPITAL.

CHICAGO, ILL.

It has just completed a magnificent building, thoroughly equipped for modern scientific post-graduate instruction; convenient surgical amphitheatres, fine, well-lighted laboratories and clinic rooms, comfortable reading and smoking rooms, automatic ventilation, electric lifts and elevator.

The college is located at 2404 Dearborn Street, in the medical center of Chicago, and with unequaled hospital advantages, an abundance of clinic material, comprehensive and advanced curriculum; large working faculty and a continuous course throughout the year.

Students may matriculate with equal advantage at any time and receive a post-graduate course that is unsurpassed.

For particulars address Franklin H. Martin, M.D., Secretary.

#### RUSH MEDICAL COLLEGE.

CHICAGO, ILL.

The fifty-fourth course of lectures of this institution begins Sept. 29, and continues eight months.

The new laboratory building, in which are located the anatomic departments and all the laboratories, presents an unexcelled series of working rooms for the undergraduate. No more extensive and thoroughly equipped dissecting room is to be found in any medical college. Every student is required to take special courses in laboratory instruction in his-

tology, pathology, bacteriology and materia medica as well as in chemistry. The laboratories for these different special courses are extensively and thoroughly equipped.

A special feature of the instruction in this institution is the large number of men attending exclusively to teaching by recitations in the different classes divided into sections.

The clinics of this College are an especial feature of its instruction. Nearly all of them are held in the afternoon. In some of them the students are required to make their examinations and to defend their diagnoses before the class. The adjoining Presbyterian Hospital affords facilities for clinical instructions unsurpassed anywhere. A vast amount of surgical operations of all kinds is housed in this hospital and students of this college enjoy the advantage of such operations in the clinics to an extent equaled by no college in this country.

The Central Free Dispensary connected with the College affords about one thousand patients monthly. They are extensively utilized for clinical purposes throughout the year.

Fees: The general ticket \$125, and the matriculation fee \$5.

Edward L. Holmes, M.D., President.

James H. Etheredge, M.D., Secretary.

#### CENTRAL COLLEGE OF PHYSICIANS AND SURGEONS.

INDIANAPOLIS, IND.

The Faculty have remodeled the college building at an expenditure of \$4,000; this also includes the superb equipment in the several laboratories. The advantages for clinical teaching are greatly enhanced by the college dispensary, which is in charge of two physicians appointed by the faculty. The staff physicians that have been selected from the faculty also hold clinics at the Indianapolis City Hospital, St. Vincent Hospital, Deaconess Protestant Hospital and the Indianapolis City Dispensary.

The college is a charter member of the Association of American Medical Colleges and has adopted the four-years' graded course of lectures. The instruction consists of didactic lectures, practical demonstrations and personal laboratory investigations. The eighteenth regular session will open Sept. 23, 1896, and close March 24, 1897. The fees of the regular course are as follows: Matriculation, \$5; laboratory ticket (anatomy, chemistry, bacteriology, pathology or histology), \$5; general ticket, \$40; demonstrator's ticket (anatomy, chemistry, bacteriology, pathology or histology), \$10; hospital ticket (includes all hospital fees), \$6; graduation fees, \$25.

Joseph Eastman, M.D., LL.D., President; T. B. Eastman, A.M., M.D., Secretary and Dean.

#### FORT WAYNE COLLEGE OF MEDICINE.

FORT WAYNE, IND.

The college was organized in 1879. The length of term is six months with a four years' graded course. The expense for fees in all the departments will be about \$75 per year.

Clinics are held in the St. Joseph and Hope Hospitals, where there is an abundance of clinic material, both surgical and medical. The special advantages are, that in these hospitals many capital operations are made in the presence of the students, the seniors being assistants.

The college has fifteen professors and five lecturers. C. B. Stemen, M.D., Dean.

## MEDICAL COLLEGE OF INDIANA.

INDIANAPOLIS, IND.

Twenty-sixth annual term begins October 2 and ends April 2. Matriculation, \$5; laboratory ticket, \$5; professors' tickets, \$40; demonstrator's ticket, \$10; graduation fee, \$25; hospital tickets, \$6. Clinics are given at the city hospital, St. Vincent's Hospital, Bobb's Free Dispensary, city dispensary and college dispensary. Daily clinic instruction throughout the course. The clinic, histologic, pathologic and bacteriologic laboratories, dissecting rooms and museum are thoroughly appointed and complete, and no extra charges for same. The munificent gift of Dr. William Lomax of Marion, Ind., added to the former resources and equipment of the college enables the trustees to construct and equip an ideal modern medical college, which shall meet the most exacting demands for advanced, thorough medical education. Jos. W. Marsee, M.D., Dean.

IOWA COLLEGE OF PHYSICIANS AND SURGEONS,  
MEDICAL DEPARTMENT OF DRAKE UNIVERSITY.

DES MOINES, IOWA.

The fifteenth annual session will begin Sept. 16, 1896, and continue twenty-four weeks.

The fees are: Matriculation, \$5; general lecture ticket, \$45; final examination, \$5; hospital, \$5; practical anatomy, \$10; chemist laboratory, \$10; bacteriologic, \$10. The college has new quarters, with ample laboratory facilities. A large number of new microscopes have been recently purchased, and the course in chemistry, bacteriology and histology is the same as in other first-class schools. Clinics will be held one-third of the time at the Cottage and Mercy Hospitals. The county and city patients are treated at Cottage Hospital and afford an abundance of clinical material. The Mercy Hospital is a large new building, with a capacity of seventy-five beds. This affords good clinic advantages; in fact, better than any other hospital in the State.

The faculty consists of fourteen professors and nine lecturers. All have had from two to twenty years' experience as teachers. The course is four years' attendance upon lectures. The requirements of admission are those of the Iowa and Illinois State Boards.

Lewis Schooler, M.D., Dean.

STATE UNIVERSITY OF IOWA, MEDICAL  
DEPARTMENT.

IOWA CITY, IOWA.

The twenty-seventh annual session begins Sept. 16, 1896, and continues six months, closing in March, 1897.

The requirements for graduation are those of the Association of American Medical Colleges and the State Board of Medical Examiners. Fully equipped laboratories in pathology, histology, chemistry and pharmacy, and full clinics in all branches. Special advantages to advanced students in assisting at clinics and observing treatment of cases at Mercy Hospital. Positions as internes in all State hospitals open for limited terms of service to graduates passing meritorious examinations.

Fees: Freshman year, \$63; sophomore, \$48; junior, \$33, and senior, \$38. No charge for dissecting material.

For catalogue, address W. D. Middleton, A.M., M.D., Dean, or E. W. Rockwood, M.D., Secretary.

## KEOKUK MEDICAL COLLEGE.

KEOKUK, IOWA.

The regular fall and winter session opens in September and continues for six months.

The faculty is composed of experienced medical teachers. Clinics regularly at St. Joseph's Hospital.

A ten weeks' reading and recitation course following the regular winter session is provided.

Fees for regular session: Matriculation, \$5; lecture fees, including hospital ticket, \$28; graduation fee, \$30. Material at cost.

J. A. Scroggs, M.D., Secretary.

## HOSPITAL COLLEGE OF MEDICINE.

MEDICAL DEPARTMENT CENTRAL UNIVERSITY OF KENTUCKY,  
LOUISVILLE, KY.

The regular session of this college begins in January and end in June. The course of instruction is conducted by ten professors and fifteen tutors, demonstrators, and assistant instructors.

Freshmen are required to present evidences of good moral character, and satisfactory preliminary education, in documentary form. The course of study is graded and divided into three annual terms of six months each.

Candidates for the degree of Doctor of Medicine must be 21 years old, of good moral character, must have studied medicine four years, including preliminary reading with a preceptor, and have attended three complete courses of lectures, no two of which shall have been taken within a period of twelve months, and the last of which shall have been in this institution. He must have dissected during at least two sessions, and have attended two courses of clinic and hospital instruction.

The course of study at this college, in addition to the usual didactic lectures and quizzes, embraces two clinics every day in the college building; not less than four clinic lectures every week at the City Hospital, beside bedside instruction in the wards of the City Hospital and College Infirmary.

Fees: Professors', \$75; practical anatomy, including material, \$12; bacteriology and histology, laboratory fees, first year, \$10; chemical laboratory, second year, \$10; surgical laboratory, \$10; fee for final examination (not returnable), \$30; hospital fee required by the city, \$5. No fee is charged for intermediate examinations.

P. Richard Taylor, M.D., Dean.

## KENTUCKY SCHOOL OF MEDICINE.

LOUISVILLE, KY.

It is midway between the North and the South, and holding its session from January to June inclusive, is the pioneer spring and summer graduating school of this country.

It began in 1817 as the Medical Department of Transylvania University, but separated and took its present name in 1850. Since that time its success has been remarkable, having as many as 550 students at a time. It has given medical education to more than five thousand physicians. With an efficient and experienced faculty of thirty teachers, ample and thoroughly equipped laboratories and a large modern hospital of its own, recently erected, adjoining the college, this school is offering facilities for practical and thorough instruction unsurpassed in this country. It is a strictly one-priced college, each student without exception paying the same. For catalogue write to Samuel E. Woody, M.D., Dean.

NEW ORLEANS UNIVERSITY, MEDICAL DEPARTMENT.

NEW ORLEANS, LA.

This institution has a four years' course of study of five months each. The tuition fee is \$30 per session, while good board and room, with fuel, light and washing, can be obtained in private families for from \$12 to \$15 per month. The total expense of the session need not exceed \$125. The building is situated on an open, airy space and is a large three story brick, well lighted and ventilated. Street cars lines from all parts of the city make it easily accessible. The second story is used exclusively for a hospital and nurse training department, where students have the advantages of experience in the sick room every day. The city with its 250,000 inhabitants and large transient population affords excellent clinic advantages. The next session opens September 15.

C. F. Dight, M.D., Dean.

MEDICAL DEPARTMENT TULANE UNIVERSITY OF LOUISIANA.

NEW ORLEANS, LA.

Since 1893 this college has occupied a new and extensive building, with five large and fully equipped laboratories. Students are admitted without payment of any hospital fees to the great Charity Hospital, which has more than 30,000 patients annually and thus provides unsurpassed practical advantages (clinic, anatomic, etc.) for the study of medicine. A gymnasium for the use of students is attached to the college. The most recent improvements consist of numerous and important additions to the laboratory of the professor of chemistry, and the reorganization of the college library, rendering it more useful and accessible to students and the medical profession.

For catalogue and information address S. E. Chaillé, M.D., Dean.

BALTIMORE MEDICAL COLLEGE.

BALTIMORE, MD.

This college was organized in 1881. Within the past five years it has expended \$200,000 in the erection and equipment of a college and hospital which contains every modern facility and appliance required. Its laboratories are equal to those of the best institutions of this country. Its Faculty contains twelve professors and over forty associate professors, lecturers, demonstrators and assistants.

Its hospital and out-door department furnish abundance of material for clinic instruction. It has a special lying-in hospital of over thirty beds in addition to its out-door obstetric clinic. This college is a member of the Association of American Medical Colleges and has adopted the four-year graded course according to the regulations of this Association. During the past session its classes numbered over 514 students.

Clinics are conducted by the professors and their associates during the entire year.

The dental department of the college has one of the best equipped buildings in this country.

A preliminary course of lectures will begin September 1 and continue until October 1.

Tuition fees and laboratory fees included range according to classes from \$100 to \$125. Board and lodging near the college from \$3 to \$8 per week.

For catalogue apply to David Streett, A.M., M.D., Dean.

BALTIMORE UNIVERSITY SCHOOL OF MEDICINE.

BALTIMORE, MD.

The preliminary course begins September 1. The regular winter course begins October 1.

The curriculum is graded. Attendance upon three winter courses of lectures is required for graduation. In addition to didactic lectures, two hours daily are devoted to clinic instruction. Clinic material abundant. Large hospital and dispensary. Lying-in Department for teaching clinic obstetrics.

Send for catalogue, and address Z. K. Wiley, M.D., Dean.

COLLEGE OF PHYSICIANS AND SURGEONS.

BALTIMORE, MD.

This college is a member of the National Association of Medical Colleges. It requires four sessions of six months each to graduate. The fee is \$100, which includes all laboratory and matriculation fees. The clinic work is a special feature in the method of instruction. Small ward classes are formed so that each student can receive personal instruction in the diagnosis and treatment of diseases. The obstetric department affords excellent facilities for every student to learn practically the management of labor cases and all conservative operations. The chemic, histologic, anatomic, pathologic and bacteriologic laboratories are modern and well equipped. The free dispensary in the heart of the city affords an abundance of cases for clinic lectures.

Thomas Opie, M.D., Dean.

JOHNS HOPKINS UNIVERSITY, MEDICAL DEPARTMENT.

BALTIMORE, MD.

The medical department was opened for the instruction of students October, 1893. It has in addition to resources of the Johns Hopkins University and the Johns Hopkins Hospital available for its use a special endowment fund of \$500,000. It forms an integral part of the University and is in close affiliation with the Johns Hopkins Hospital.

The requirements for matriculation are higher than those of any other medical school in this country. Those who are admitted as candidates for the degree of doctor of medicine must possess a degree in arts or in science from an approved college or scientific school, and in addition must be able to read French and German and must have had a year's collegiate training with laboratory work in physics, chemistry and biology; or they must furnish evidence by examination that they possess the general education implied by a degree in arts or in science and the knowledge of French, German, physics, chemistry and biology indicated. Men and women are admitted upon the same terms.

The required course of instruction continues through four years, the academic year beginning the first of October and closing the middle of June. The first two years are devoted mainly to anatomy, physiology, physiologic chemistry, pathology, bacteriology and pharmacology, and the last two years to practical medicine and surgery.

Abundant clinic material is afforded by the Johns Hopkins Hospital and Dispensary, this Hospital being unsurpassed by any in the world in the perfection of its arrangements. The clinic amphitheatres and laboratories are in the hospital buildings. Physiology is taught in the biologic laboratory of the University, which is one of the largest and best equipped in this

country. The pathologic laboratory is a four story building on the grounds of the hospital. This building contains the autopsy theaters, the pathologic museum, the bacteriologic laboratory, the physiologic chemic laboratory and rooms for instruction and special work in all departments of pathology.

The charge for tuition is \$200 per annum. There are no extra charges for instruction in any department or for laboratory courses.

In addition to the regular course of instruction for undergraduates in medicine, special courses of instruction have been given to physicians in pathology and the clinic subjects since the opening of the Johns Hopkins Hospital in 1889. These are to continue. A fee of \$100 covers all of these special courses for physicians. The separate courses can be taken by payment of a fee of \$25 or \$50 according to the subject chosen.

William H. Welch, M.D., Dean.

#### UNIVERSITY OF MARYLAND.

BALTIMORE, MD.

The School of Medicine is one of the oldest institutions of medical education in America, ranking fifth in point of age among the medical colleges of the United States. Beginning with the modest number of five graduates, comprising the first graduating class in 1810, the list of graduates in medicine of the University of Maryland now numbers 4,574 names, among which are to be found some of the most noted names connected with the history of medicine in our country. While the policy of the faculty of physic has been one of wise conservatism, it has at the same time never been behindhand in the march of educational progress, and has often been the first and always among the first, in the adoption of measures tending to improvement in methods of medical teaching and to true elevation of the standard of medical education. One of the advantages of the University over other schools of that day was gained in 1823 by the erection of its own hospital, separated from the college by the width of the street and known as the University Hospital. Beside important additions and improvements to the University Hospital, the faculty has in the last few years expended and is now expending large amounts in the establishment and equipment of its lying-in hospital, its laboratories of chemistry, histology, pathology and bacteriology, and is therefore in a position to offer to students of medicine and graduates, a course of combined didactic, clinic and laboratory instruction which will compare favorably with that offered by any medical school in the United States. The course of study embraces three annual graded courses of not less than six months each.

Fees for the three years' graded course: Matriculation (paid each year) \$5; practical anatomy (paid two years) \$10; full course of lectures (first year) \$100; full course of lectures (second year) \$100; full course of lectures (third year) \$100; graduation fee, \$30.

R. D. Cole, M.D., Dean.

#### WOMAN'S MEDICAL COLLEGE.

BALTIMORE, MD.

The college was incorporated Feb. 14, 1882, being the fourth institution of the kind founded in the United States, and the first in the South. It is managed by twelve trustees, and has thirty-six professors, lecturers and assistants. It requires for graduation attendance upon four annual sessions, lasting each

eight months. With reference to entrance requirements it follows the regulations of the American Medical College Association, of which it was one of the founders. It occupies a group of buildings on the corner of Hoffman and McCulloh Streets, two of which it owns. It has laboratories of chemistry, histology, pathology, embryology and bacteriology. One-fourth of the time of lectures is devoted to quizzing. It has a general and also a lying-in hospital of its own. Clinics are also given at the Presbyterian Eye, Ear and Throat, Bayview, and the Hospital for Crippled and Deformed Children, by members of its faculty. It has a large out-door obstetric clinic. Pharmacy is taught and examined upon. There is a course of lectures on psychiatry by a well-known specialist. There is a library and a flourishing medical society of 127 members. The fees are \$100 annually; \$75 for missionaries; \$30 additional for graduation; \$5 deposit for breakage. There have been fifty-nine graduates.

I. R. Trimble, M.D., Dean; Eugene F. Cordell, M.D., Secretary.

#### CLARK UNIVERSITY.

WORCESTER, MASS.

Graduate courses in psychology, physiology, neurology, etc. Special attention given to the study of the brain and central nervous system, with laboratory work and clinics. Exceptional opportunities offered in the sciences underlying the study of medicine.

G. Stanley Hall, M.D., President.

#### COLLEGE OF PHYSICIANS AND SURGEONS.

BOSTON, MASS.

This college is now entering upon its seventeenth annual course of lectures.

The course is graded and comprises four years of study with four annual courses of lectures. Each course extends from the third Tuesday in September to the third Wednesday in June.

Rules and requirements are those of the Association of American Medical Colleges, of which this college is a member.

A good knowledge of English, Latin, algebra and physics are necessary for matriculates.

Extensive clinic advantages are under its control. The school is now prepared to furnish facilities for chemic, histologic, bacteriologic and other laboratory work. Located near Boston City Hospital, in a part of the city where good board and rooms may be obtained convenient to the college. Women are received and admitted to the same rights and privileges as are accorded to men. Extra advantages for observing clinic and dispensary work.

Matriculation, \$5 yearly; lecture fee, \$125 per year, or cash in advance for four years, \$400; laboratory courses, \$5 each; dissecting and operative surgery material at cost.

For catalogue and further particulars apply to the registrar.

Augustus P. Clarke, A.M., M.D. Dean; George F. Shurtleff, M.D., Registrar.

#### TUFTS COLLEGE MEDICAL SCHOOL.

BOSTON, MASS.

This is the only regular medical school open to both sexes in New England that is recognized by the Massachusetts State Medical Society.

Entrance examination is required, and to students who matriculate for the first time in 1896 four years of attendance.

The course is graded and all the branches of med-

ical science are taught. Abundance of clinic facilities. Fees \$115. The regular course of lectures for the session of 1896-97 will commence September 30 and continue for eight months.

For further particulars and catalogues address C. P. Thayer, M.D., Secretary, 74 Boylston St., Boston, Mass.

Albert Nott, M.D., Dean.

UNIVERSITY OF MICHIGAN.  
DEPARTMENT OF MEDICINE AND SURGERY.  
ANN ARBOR, MICH.

This school requires for admission a diploma from a first class high school or its equivalent. The course extends through four years with nine months in each session. The first two years are devoted to scientific work, a large part of which is done in the laboratories. The last two years are given to clinic work.

The fees are as follows: Matriculation fee for Michigan students is \$10; for all others \$25. This fee is paid only once. Annual fee for Michigan students \$35; for all others \$45. Diploma fee, all alike, \$10. The laboratory fees amount to about \$50 a year. The total amount of fees paid to the university during the whole four years' course is for Michigan students about \$300, and for others about \$340.

Victor C. Vaughan, M.D., Dean.

MICHIGAN COLLEGE OF MEDICINE AND SURGERY.  
DETROIT, MICH.

The regular term of the college will commence September 23 and will continue six months. The spring term will open April 7 and close June 19.

An addition to the college has been made this term, in the form of a building fifty by sixty feet, to be entirely devoted to the use of the Emergency Hospital Free Dispensary.

The special advantages pertaining to the college are that all lectures and demonstrations are given at the one location, the college building and the Emergency Hospital Free Dispensary, the lying-in clinic, and in fact all the clinics being under one roof.

Send for catalogue to L. E. Maire, M.D., Secretary.

HAMLIN UNIVERSITY.

MEDICAL DEPARTMENT MINNEAPOLIS COLLEGE PHYSICIANS AND SURGEONS.

MINNEAPOLIS, MINN.

This school was organized in 1883 as the Minneapolis College of Physicians and Surgeons, and in 1895 became the Medical Department of Hamline University. The course consists of four years of eight months each and fulfils the requirements of all State boards. The faculty consists of twenty-three professors and eight lecturers, not including demonstrators and assistants. The college building is within five minutes' walk of three leading hospitals and four dispensaries, so that the clinic advantages are excellent. The approaching term begins October 5. The fees are: Matriculation, \$5 (payable only once); general ticket, including lectures, demonstrations, etc., \$65.

J. W. Macdonald, M.D., Dean.

UNIVERSITY OF MINNESOTA.  
COLLEGE OF MEDICINE AND SURGERY.  
MINNEAPOLIS, MINN.

The ninth annual course of lectures begins October 1, and continues until the first week in June. Four courses of lectures in different years is required of all applicants for the degree of M.D. All pupils

entering this department of the university after 1898 will be required to furnish credentials equal to an "in course" matriculation of the academic department of a recognized college of literature, science or the arts. The State has invested \$150,000 in buildings and equipment in the last three years. They are located upon the campus of the general University in Minneapolis. There were 243 matriculants in attendance the last season, 47 receiving the degree of M.D. The department is directly connected with the general University, being amply supported by the State.

Perry H. Millard, M.D., Dean.

BARNES MEDICAL COLLEGE.

ST. LOUIS, MO.

Six months terms; three separate years' graded course. Begins September 21. Matriculation, \$5; lecture ticket, \$40, and anatomic ticket, \$10. Usual laboratory charges. Half rate concessions to physicians' and clergymen's sons and graduates in pharmacy and dentistry. A few \$10 scholarships to well attested worthy sons of indigent physicians, widows and others granted on proper presentation of suitable cases.

First course students are required as a precedent for admission to show a good English education by certificate of graduation from a literary college, academy, normal or high school, or of examination approved by the State superintendent of public schools, in English grammar and composition, arithmetic, algebra as far as quadratics, elementary physics, United States history, geography and Latin (equivalent to one year in high school); 80 per cent. grade required in these branches. Previous matriculates at other medical, dental or pharmaceutical colleges and graduates in medicine are exempt from this rule.

Clinical facilities embrace city general hospital, insane hospital, Woman's Hospital and other corporate hospitals, to which members of the faculty have access, and new and enlarged college and dispensary clinics. Thus, while its fees are moderate and concessions to the worthy are liberal, its curriculum and preliminary requirements secure educated classes.

C. H. Hughes, M.D., Dean; Pinckney French, M.D., Secretary.

BEAUMONT HOSPITAL MEDICAL COLLEGE.

ST. LOUIS, MO.

The college will begin the fall session September 22. It gives the three sessions graded course of instruction; maintains a high standard of requirements and has a well-earned reputation for thorough and practical teaching. Its building is well located and arranged and its laboratories are completely equipped with all things necessary for advanced investigation and demonstration. It offers special advantages in clinic teaching, having exclusive control of three large hospitals and two dispensaries, which furnish clinic material in abundance and in great variety. The destruction of the St. Louis City Hospital by the recent cyclone has not materially affected the clinic supply at this institution.

W. B. Outten, M.D., Dean; John T. Larew, M.D., Secretary.

ENSWORTH MEDICAL COLLEGE AND HOSPITAL.

ST. JOSEPH, MO.

The college is an endowed institution, with a full corps of experienced teachers and is properly equipped in its several departments. Its requirements prece-

dent to matriculation are those prescribed by the Association of American Medical Colleges and the State of Missouri. It affords the special advantage of an abundant outdoor clinic during the sessions at the hospital, as well as those afforded by the city hospital and State lunatic asylum. The tuition fee is \$50 for each session. In honor of Mr. Ensworth, the school grants a scholarship to each Congressional district of the State. The Ensworth has under its direct control the largest hospital in the Central West.

Thomas H. Doyle, M.D., Dean.

#### KANSAS CITY MEDICAL COLLEGE.

KANSAS CITY, MO.

This is one of the oldest schools in the West; was established in 1869. The twenty-eighth annual session begins September 15 and continues twenty-six weeks. The course of study is graded and extends over three years. The college building has been enlarged, new laboratories and lecture rooms having been added.

The clinic facilities of the school are large, and practical bedside instruction is a prominent feature. Clinic material is supplied by St. Joseph's, German, Municipal and St. Margaret's Hospitals, supplemented by a large dispensary service, medical, surgical and obstetric.

The annual announcement has been issued and will be forwarded upon request.

J. D. Griffith, M.D., Dean; Franklin E. Murphy, M.D., Secretary.

#### MARION-SIMS COLLEGE OF MEDICINE.

ST. LOUIS, MO.

The Marion-Sims College of Medicine, which was organized in 1890, has met with much success. This has been due to the untiring energy of the faculty, and to the disposition of its teachers to equip and maintain a medical institution fitted in line with the most advanced methods of medical instruction. A hospital was built by the faculty immediately adjoining the college, which has been a most valuable aid to the instruction in the institution. This hospital, known as the Rebekah Hospital, has afforded a great supply of clinic material. The school is well equipped with appliances of all kinds necessary for instruction in medicine. Its chemic, microscopic and physiologic laboratories are modern and complete. The college dispensary is large. A dental department has been added which bids fair to meet with the same success that the medical department has received. The length of the course is six months.

The fees are as follows: Matriculation (paid but once), \$5; entire lecture (each year), \$50; final examination (not returnable), \$25; dissecting ticket, \$10; single professor's ticket (where the entire course is not taken), \$20; general ticket for sons and brothers of physicians and sons of clergymen, \$25; lecture fee for three years, including matriculation, dissection and examination ticket, if paid in advance, \$150; hospital and clinic tickets free.

H. W. Loeb, M.D., Secretary.

#### WASHINGTON UNIVERSITY.

MEDICAL DEPARTMENT, ST. LOUIS MEDICAL COLLEGE.

ST. LOUIS, MO.

This institution has had for more than half a century successful annual sessions. It was one of the first among the medical institutions to enforce a graded course and to insist on a three years curricu-

lum (since 1880). Long experience in the advanced methods of teaching enables it to present to the student a well considered and consistent course of study.

Histology, comparative and practical anatomy are demonstrated in a well supplied laboratory and perfect dissecting rooms.

The apparatus and the facilities for experimental and original research in physiology are in charge of a professional physiologist. Biology and pathology have each well supplied laboratories in which practical work is assigned to the individual student. Clinic facilities are abundant and well utilized. For information apply to H. H. Mudd, M.D., Dean, or E. M. Senseney, M.D., Secretary.

#### MISSOURI MEDICAL COLLEGE.

ST. LOUIS, MO.

The oldest seat of medical learning west of the Mississippi, will enter upon its fifty-sixth year of instruction Sept. 22, 1896. Three graded courses of lectures of six months are necessary for graduation. A high preliminary education, including Latin, is necessary for admission. The fees are \$100 a year. Number of students in attendance 240. The number of cases treated during the past year in the two dispensaries conducted by the faculty, and from which clinic material is largely drawn, was 16,389; operations performed 1,084. The St. Johns, the Polyclinic and the Bethesda Hospitals are under the exclusive control of the faculty, besides clinics are given in the city and other hospitals attended by the professors. The museum is very large and rich, and the laboratory equipments rarely excelled. P. G. Robinson, M.D., Dean; H. M. Whelpley, M.D., Secretary.

#### ST. LOUIS COLLEGE OF PHYSICIANS AND SURGEONS.

ST. LOUIS, MO.

It is one of the three oldest medical colleges in St. Louis. The Preliminary Session begins Tuesday, September 1. Regular Session, Tuesday September 8, closing Wednesday March 17. The faculty numbers eighteen professors ably assisted by a corps of competent lecturers and demonstrators.

In the new building the laboratory and clinic equipment is complete. The surgical amphitheater is supplied with all the latest improved appurtenances to that line to work and nowhere in this section of the country can better surgical opportunities be found; material being drawn from the Merchants and Mechanics Hospital, St. Louis Baptist Hospital, City and Female Hospitals, City Insane Asylum and Poor House.

Fees are extremely moderate for the high grade of instruction offered; matriculation \$5, general lecture ticket, \$50. To sons and brothers of physicians and sons of the clergy \$25. Special terms to graduates in pharmacy and dentistry. Write for catalogue to Dr. Waldo Briggs, Dean.

#### UNIVERSITY MEDICAL COLLEGE.

KANSAS CITY, MO.

It requires of the student, before entering the college that he be either a graduate of a reputable literary college or, upon examination, show that he has a good English education and sufficient knowledge of Latin to translate and define medical terms; that he read one year under a preceptor, to the extent of having read the text-books of medicine; that he shall attend 80 per cent. of the lectures and clinics of a

three years' graded course of six months each before applying for graduation.

The college building is large and has seating capacity for 500 students. It has ample room for its chemic, bacteriologic, histologic and pathologic laboratories, which are all abundantly supplied with all the appurtenances for thorough teaching. It has a large corps of didactic and clinic instructors.

Its resources for clinic material are excellent. All Saints Hospital in the same block is under its control, where a school for trained nurses is taught. At its free dispensary in 1895 there were forty thousand patients treated distributed among the different departments. This dispensary runs all the year to which students have free access, and three or four hours daily (except Sunday) is devoted to clinic teaching by the professors. In its obstetric clinic there were 324 cases of obstetrics furnished during the sessions of 1895 and 1896. It has access where clinics are held at All Saints Hospital and the seven other hospitals in Kansas City. Matriculation fee \$5.00. Lecture tickets first and second years \$60 each, third year \$50. Examination for graduation \$20.

James P. Jackson, M.D., Dean.

UNIVERSITY OF THE STATE OF MISSOURI,  
COLLEGE OF MEDICINE.  
COLUMBIA, MO.

Organized in 1872.

Students must pass in the work of each class and year before admission to the next class or year.

Instruction is given by lectures, recitations, clinic teaching and laboratory work.

The length of the session, nine months, renders it practicable to distribute the different branches among the teachers in the most satisfactory manner, and in their natural order and succession. The student is thoroughly drilled each day by examinations upon the lectures of the previous day, and by recitations from text books.

The students are taught the use of the microscope, in relation to both pathologic and physiologic studies. The methods of bacteriologic investigation are taught by practical work in the laboratory.

Among the advantages offered by this school is the privilege granted, without further cost, to all students who enter the medical department, of pursuing such studies as they may desire in the academic course. Academic students may take anatomy and physiology in the first year of the medical course, preparatory to entering on the full medical course after graduating in arts or science. Such students are admitted to the second year's medical class.

Conditions of admission: Candidates for admission to the medical department must possess a good common school education. This is the minimum requirement, and evidence that the candidate possesses the requisite knowledge must be attested by certificates of former instructors or must be shown by examinations conducted by the Faculty.

Fees: First year matriculation, \$20; second year matriculation, \$50; third year matriculation, \$50.

A preliminary course of nine months will be given in chemistry, biology, physics and Latin.

A. W. McAlester, Dean. Woodson Moss, Secretary.

JOHN A. CREIGHTON MEDICAL COLLEGE.

OMAHA, NEB.

The curriculum of this school is graded, and attendance upon four annual terms, of seven months each,

is required. Instruction is carried on by means of lectures, recitations, laboratory work and clinics. The laboratories for chemistry, physiology, histology, pathology and bacteriology are very large, well lighted and well equipped for the teaching of these branches in a thorough and modern manner. The dispensary and hospital clinics furnish ample material for clinic instruction in all branches. The St. Joseph's Hospital, a magnificent structure, of three hundred beds, is under the exclusive control of the faculty of this college. The new college building, nearly completed, is one of the very best in the West.

D. C. Bryant, M. D., Secretary.

OMAHA MEDICAL COLLEGE, MEDICAL DEPARTMENT  
UNIVERSITY OF OMAHA.

OMAHA, NEB.

The curriculum is graded and divided into four annual courses of seven months each.

Preliminary examination is required of all applicants for entrance not in possession of literary credentials outlined by the Association of American Medical Colleges.

The college building is new and contains an outdoor dispensary, two large lecture halls, museum and laboratories of anatomy, physiology, pathology, histology and chemistry. The laboratory equipment is sufficient for a class of two hundred students.

Instruction is given by means of recitations, class room work, demonstration, lectures and clinics.

Clinics in all branches are furnished by a large outdoor dispensary, the Omaha, Presbyterian, Douglas County, Immanuel and Clarkson Hospitals.

Graduation requirements in compliance with the rules of the American Medical College Association. Fees for each session \$70.

W. O. Bridges, M. D., Secretary.

DARTMOUTH MEDICAL COLLEGE.

HANOVER, N. H.

The plan of teaching in this college includes a term of lectures with quizzes, from the middle of July to last of November, and a term of recitations and laboratory work from January 1 to June 20 each year. The Hitchcock Hospital affords excellent facilities for clinic instruction. The fee for the lecture course is \$82; for recitation term, \$40.

Entrance examinations in English, Latin, elementary physics and chemistry are required unless candidates have already properly performed the work.

Ten months' attendance in this school each year for three years, or three full courses of lectures and four years of study under a preceptor are required for graduation. They must pass written examinations in anatomy, chemistry, physiology, surgery, practice, obstetrics, gynecology and therapeutics.

O. P. Frost, M. D., Dean.

ALBANY MEDICAL COLLEGE, MEDICAL DEPARTMENT OF UNION UNIVERSITY.

ALBANY, N. Y.

Three years graded course which will be increased to four with session of 1897-98. Hospital and clinic advantages excellent, clinics being held in Albany, St. Peters, Child's and County Hospitals and Eye and Ear Infirmary. With the coming session the new Bender Hygienic Laboratory, for the study of pathology and microscopic work, will be opened to students. Fees: Matriculation, each year, \$5; each lecture course, \$100; dissection, chemic, histologic and pathologic laboratories, each \$10.

For catalogue and further information, address, Willis G. Tucker, M.D., Registrar.

#### BELLEVUE HOSPITAL MEDICAL COLLEGE.

NEW YORK.

The Collegiate year embraces a winter session and a spring session. The winter session for 1896-97 will begin Sept. 21, 1896, and continue for twenty-six weeks.

The recitations, lectures and clinics for the spring session will begin March 22, 1897, and continue for twelve weeks. Attendance on the winter session only is required for graduation.

New matriculates for the session of 1897-98 and thereafter will be required to present tickets showing attendance on four regular courses of lectures and certificates of four years' study of medicine as conditions for graduation.

Students who attend the regular session of 1896-97 or have attended one or more regular sessions at the Bellevue Hospital Medical College before 1896-97 may complete their courses in accordance with the present requirement of three years.

#### RESOURCES FOR CLINIC INSTRUCTION.

Bellevue Hospital receives annually between five and six thousand patients. Medical and surgical cases of all kinds are admitted except cases of contagious diseases.

The City Hospital on Blackwell's Island receives annually between eight and ten thousand patients. A considerable number of the patients admitted into this hospital are affected with venereal diseases.

The Bureau of Medical and Surgical Relief for outdoor poor is in the college building and furnishes most of the cases for the clinics held in the college lecture room. The number of new patients treated in this department in 1895 was 47,479.

#### FEES AND REGULATIONS FOR THE THREE YEARS' COURSE.

The matriculation fee, to be paid before any other tickets are issued, is \$5 for each year. The fee for each one of the three courses required and for each additional course is \$150. The fee for dissections, to be taken during the first and second years, is \$10 for each year. The fee for the regular laboratory courses, to be taken during the third year is \$20. The fee for specimens mounted in connection with the Carnegie Laboratory course is \$2. The fee for the examinations at the end of the second year is \$15. The fee for the final examinations is \$15. The fee for final examinations for those who have taken their first two courses at other colleges is \$30.

Communications relating to the business of the college should be addressed to Prof. Austin Flint, Secretary.

#### LONG ISLAND COLLEGE HOSPITAL.

BROOKLYN, N. Y.

The regular term of 1896-97 will begin Sept. 28, 1896, and continue until March 31, 1897. The reading term will begin April 1, 1897, and continue until June 18.

Beginning with the regular term of 1897-98, the course of instruction will be more thoroughly graded and will consist of four collegiate years of eight months each. The reading and recitation term will be abolished as separate terms after 1897 and merged into the regular term.

Through the munificence of Mrs. C. H. Polhemus of Brooklyn, a magnificent building is now being

erected as a memorial to her husband. This building will be occupied by the dispensary and college, and will cover an area of 67 x 92 feet, and be 115 feet in height. The instructions of the donor to the architect are to make it the most perfect building of its kind that money and skill can construct. It will be completed in June, 1897, and ready for the opening of the collegiate year 1897-98.

The success of the plan of the Long Island College Hospital depends mainly on two important facts:

1. The hospital and dispensary, in which 21,485 patients were treated in 1895, are under the immediate control of the Regents, and are therefore, available at all times for practical instruction.

2. The courses of instruction are given in the hospital buildings, so that the student, without loss of time, is brought in direct contact with patients, not only in the amphitheater, but also in the wards of the hospital.

The city of Brooklyn contains more than 1,000,000 inhabitants, being the fourth city in the United States in point of population.

The fee for the regular term is \$125. Board can be obtained at \$5 a week.

J. H. Raymond, M.D., Secretary.

#### NEW YORK POLYCLINIC MEDICAL SCHOOL AND HOSPITAL.

NEW YORK CITY.

The winter session of the Polyclinic opens Sept. 15, 1896, and will continue to June 15, 1897. The sessions of the school, however, are continued throughout the year, the summer session being from June 15 to September 15.

It is a school of clinic medicine and surgery for practitioners only. No didactic lectures are given. The clinics are held in the lecture rooms of the school and in the operating rooms of its hospital.

The operations done here embrace every variety of surgical work not only in general surgery but also operative treatment in the special branches of the eye, ear, throat, gynecology, etc. An immense amount of clinic material is supplied from the dispensary which is submitted to the members of the class at specified hours for personal examination and study under the guidance of the various teachers.

Operative courses upon the cadaver in the different departments are also given.

A general ticket admitting the holder to *all the lectures and operations* is issued: Twelve months, \$350; six months, \$250; three months, \$150; six weeks, \$100.

For further information address J. Riddle Goffe, M.D., Secretary.

#### NEW YORK POST-GRADUATE MEDICAL SCHOOL AND HOSPITAL.

NEW YORK CITY.

The New York Post-Graduate Medical School and Hospital has just entered upon its fifteenth winter session. Five hundred and forty-two physicians from all over this continent have attended the courses at the institution during the past year. More than one thousand operations were performed in the hospital, which is one of the largest in the city, containing special wards for babies and children, while nearly twenty thousand patients were treated in the out-door department. Recent discoveries have revolutionized medical and surgical methods and a man whose medical education ended fifteen years ago is not a phy-

sician or surgeon within the present meaning of the term. Post-graduate medical instruction is for the purpose of furnishing to these graduates in medicine a means of refreshing their knowledge. It supplies them with the opportunity of coming in direct contact with disease by means of the special courses we give in all departments of medicine.

D. B. St. John Roosa, M.D., LL.D., President.

**NIAGARA UNIVERSITY.**

MEDICAL DEPARTMENT.

BUFFALO, N. Y.

The medical department was organized in 1883, with the motto "Higher Medical Education."

Requirements for matriculation are an equivalent knowledge of Latin as found in Arnold's "First Latin Book," in addition to the State Board of Regents' certificate, which can be obtained by all graduates of any registered high school in the country, or the equivalent obtained in foreign countries.

Duration of course is from October 1, 1896, four years. Matriculants prior to this time are allowed to graduate in three years under certain conditions.

Free scholarship is obtained by competitive examination in higher mathematics and Latin.

Fees: General course of instruction, annually, \$75; registration fee each year, \$5; perpetual ticket, \$200; laboratory fees reasonable.

The clinic resources embrace: Buffalo Hospital of the Sisters of Charity (bedside instruction), Emergency Hospital, Buffalo Woman's Hospital, Buffalo State Hospital, Providence Retreat, St. Francis Hospital, Edward Street Lying-in Asylum (150 confinements yearly average), Edward Street Infant Asylum, The Erie County Hospital, Charity Eye, Ear and Throat Hospital, Buffalo German Orphan Asylum, The College Dispensary, Nose and Throat Department of the Buffalo Eye and Ear Infirmary.

Lectures begin Oct. 1, 1896; examinations close May 6, 1897; commencement exercises May 12, 1897.

President, John Cronyn, B.A., M.D., Ph.D., LL.D. Secretary, Harry A. Wood, M.D.

**UNIVERSITY OF BUFFALO MEDICAL DEPARTMENT.**

BUFFALO, N. Y.

The fifty-first regular session opens September 24, and continues thirty weeks. The lectures will be held in the large, new, three-story building, containing three amphitheaters and rooms for dispensary patients, chemic, pathologic, histologic, and pharmaceutical laboratories, thoroughly equipped with modern conveniences. Instruction by lectures, recitations, laboratory work, and clinics. Clinic advantages unexcelled.

Fees: Matriculation, \$5; regular term, \$100; perpetual ticket, \$200; laboratory, \$40; dissection, \$20, (\$10 each year); examination fee, \$30 (\$10 each year). For further particulars address,

John Parmenter, M.D., Secretary.

**COLLEGE OF MEDICINE, SYRACUSE UNIVERSITY.**

SYRACUSE, N. Y.

This college will hereafter occupy its new four-story building, which contains nine commodious, thoroughly equipped laboratories and lecture rooms. For clinic teaching it has the use of two hospitals, a dispensary and a State Asylum.

The college year begins the first Tuesday in October, and ends the second Tuesday in June. Entrance examinations, which must be passed unconditionally, will be held at the college, October 6, at 2 o'clock, P. M.

Fees and expenses, including lectures, laboratory

work, clinics, use of library, microscopes and other apparatus, examinations and graduation, \$125, annually, payable in advance. Rooms and board can be obtained on very reasonable terms.

It may be remembered that for twenty years, commencing sixteen years before State legislation compulsion secured uniformity in the length of courses, this college has maintained a three years' graded course. It was the first in the State, and the third in the United States to adopt this system of higher medical education, and it has already adopted the four years' course.

Ninety-two per cent. of its graduates have passed successfully the State Regents' licensing examination.

For announcements and other information, address, H. D. Didama, Dean, or D. M. Totman, Registrar.

**UNIVERSITY OF THE CITY OF NEW YORK, MEDICAL DEPARTMENT.**

Fifty-sixth year. The session will begin in October. Attention is called to the fact that the curriculum has been entirely remodeled and greatly improved.

Special clinics: Ophthalmology, otology, laryngology, orthopedy, pediatrics, skin diseases, venereal diseases, nervous diseases.

Examinations are held at the close of each year. The marks received for proficiency in practical work in the laboratory, dissecting room, etc., are added to the final examination marks in each corresponding subject.

The college possesses a corps of sixty-four professors and instructors in its various departments; and in addition to well-equipped laboratories and a dispensary where 20,000 visits are annually paid, it offers to students exceptional facilities for practical instruction at the bedside in Bellevue Hospital, which is directly opposite the college buildings.

Fees: For course of lectures, \$150; matriculation, \$5; demonstrators' fee, including material for dissection, \$10; final examination fee, \$30.

For further particulars and circulars, address the Dean, Prof. Chas. Inslee Pardee.

**WOMAN'S MEDICAL COLLEGE OF THE NEW YORK INFIRMARY.**

NEW YORK CITY.

The college gives a graded course of four years. The building is new and convenient. It has excellent dissecting rooms, well equipped laboratories for practical instruction in chemistry, histology and pathologic anatomy, a reading room and library. The college adjoins the infirmary of sixty beds, and the dispensary in which over 7,000 patients are treated annually. These and a large out-practice are utilized fully for clinic instruction. Besides the daily college classes, the senior students receive daily clinic instruction in small groups. Special clinic courses are given for them in Bellevue Hospital, the Blackwell Island Hospital for the Insane, and the Willard Parker Hospital for Contagious Diseases. Every student attends ten cases of obstetrics under direction. Students can attend operations and clinics in several of the city hospitals.

Fees for course of four years, \$515. Dr. Emily Blackwell, Dean.

**LEONARD MEDICAL SCHOOL.**

(SHAW UNIVERSITY.)

RALEIGH, N. C.

Sixteenth annual announcement. Next session opens

November 2. Length of session twenty weeks; minimum expense for the year for board, room-rent, fees, books, etc., \$70.

We do not claim the Leonard Medical School is the best in the world, but we do claim, and justly, that young men who graduate from the four years' course of the Leonard Medical School are equipped as few institutions equip them, to successfully practice their profession, and that this is done at a phenomenally small outlay of money on the part of the students.

A hospital building has been erected and will be used during the term for affording the students the best possible clinic instruction.

For catalogue and full information write to Chas. F. Meserve, President.

#### NORTH CAROLINA MEDICAL COLLEGE.

DAVIDSON, N. C.

This college has a nominal connection with Davidson College and has the advantage of the scientific equipment of this old institution. The chemic and electric departments are unusually well furnished.

A new laboratory is to be equipped this Fall. In the department of pathology and bacteriology, there is, in process of erection, a new brick and granite building to be used for class work and hospital purposes.

Length of session eight months, three of such sessions constituting a complete course, leading to graduation.

Matriculation fee, \$5; tuition, \$75; board and lodging \$10 to \$15 per month.

J. P. Munroe, M.D., President.

#### CINCINNATI COLLEGE OF MEDICINE AND SURGERY.

CINCINNATI, OHIO.

The forty-sixth year of college instruction begins Oct. 1, 1896, and continues until April 14, 1897. It has a faculty of twelve professors, four demonstrators, and nineteen assistants. The course of study, requirements for admission, advanced standing, and graduation are those indicated by the American Medical College Association, of which organization this school is one of the original members.

Facilities for didactic instruction, clinic observation and laboratory work are in accord with the best medical schools of this country. The college is coeducational for the sexes, sitting and study rooms are conveniently arranged.

The hospital advantages afforded medical students in Cincinnati are unexcelled. Nearly every professor in the Cincinnati College of Medicine and Surgery holds a hospital staff position.

S. C. Ayers, A.M., M.D., Dean; W. E. Lewis, M.D., Secretary.

#### CLEVELAND COLLEGE OF PHYSICIANS AND SURGEONS.

MEDICAL DEPARTMENT OF THE OHIO WESLEYAN UNIVERSITY, CLEVELAND, OHIO.

Formerly Medical Department of the University of Wooster.

The course of instruction is four years with terms of eight months each. The fees are \$100 for each separate year for general and hospital ticket. Matriculation and examination fee \$10 annually extra. In addition thereto a laboratory deposit of \$20 is charged to cover cost of material, a portion of which is returnable to the student in case material to that amount is not used.

The first two years of instruction in this school is

devoted entirely to the primary branches, much of which is taught by the laboratory method, requiring of the student individual work. The last two years are largely clinic, the student spending most of his time at the Cleveland General Hospital, the medical management and direction of which is exclusively under the faculty.

It will be observed from the foregoing statement that the first two years of student life are devoted to such work as will fit him for a clear comprehension of the advanced work, and that the last two years are eminently practical, fitting him especially for assuming the duties of active professional life.

H. W. Rogers, M.D., Secretary.

#### LAURA MEMORIAL WOMAN'S MEDICAL COLLEGE. CINCINNATI OHIO.

With the session of 1895-96, the college adopted the four-years' graded course.

The sessions are of seven months each, beginning the last Tuesday in September, and ending the last Thursday in April. The college with the hospital adjoining, is complete in all departments, the laboratories being newly and fully equipped. The clinic advantages include the large and varied clinics of the Cincinnati Hospital, the Presbyterian Hospital, the College dispensary, the eye clinics in Prof. Holmes' Ophthalmic Hospital, and the obstetrical cases of the Maternity Society, under Prof. Stewart.

The fees are: Matriculation \$5; general fee (paid annually) \$50; the practical anatomy and laboratory fees \$10 each; Cincinnati Hospital ticket (for third and fourth years' classes) \$5; graduation fee \$25.

J. M. Withrow, M.D., Deau.

S. E. Allen, M.D., Secretary.

#### MEDICAL COLLEGE OF OHIO.

CINCINNATI, OHIO.

The Medical College of Ohio, now the Medical Department of the University of Cincinnati, is the oldest medical school west of the Alleghenies, having been founded in 1819. Four courses of lectures are required. Fees \$100 per annum. With the beginning of the session of 1896-97 the college will be in its new location on McMicken Avenue, and in newly erected buildings. Its chemic, histologic, pathologic and bacteriologic laboratories are newly and thoroughly equipped. The large college dispensary with the Cincinnati Good Samaritan and Ohio Maternity Hospitals afford abundant clinic material.

Jas. G. Hyndman, M.D., Secretary; W. W. Seely, A.M., M.D., Dean.

#### MIAMI MEDICAL COLLEGE.

CINCINNATI, OHIO.

It requires the four-years' graded course. The session begins Oct. 1, and ends April 1. The fees are, matriculation \$5; tuition (annually) \$100. This includes all laboratory tickets and dissections. Graduation \$25; hospital ticket \$5.

In addition to the regular didactic and laboratory courses exceptional clinic advantages are possessed. The Ophthalmic Hospital building has been leased for the daily out-door college clinics, which have an average daily attendance of 200 cases, and ten members of the faculty give bedside instruction in the wards of the Cincinnati Hospital in medicine, surgery, obstetrics, gynecology, ophthalmology and otology in addition to the clinic lectures given in the amphitheater of that institution. This hospital admits 5,300 cases yearly, is within half a block of the college,

and the college hours accommodate themselves to the hospital clinics.

N. P. Dandridge, M.D., Dean.

#### OHIO MEDICAL UNIVERSITY.

COLUMBUS, OHIO.

The University comprises the departments of medicine, dentistry, pharmacy and midwifery; each department having its own faculty and separate apartments for general class work.

The main building is a fine structure, specially planned and erected for University purposes. A new four-story building is used solely for laboratory purposes. There are two amphitheatres, ten recitation rooms, twelve laboratories, dental operating rooms, library, museum, and free dispensary rooms.

The plan of instruction is by assigned topics and recitations and clinic lectures. Hospital facilities are provided by the Protestant and University Hospitals, which place all their clinic material at the disposal of the University staff for the purposes of clinic instruction, the Ohio Penitentiary, the Columbus State Hospital and free Dispensary.

The combined Faculty consists of fifty-four professors, instructors and adjuncts.

Length of term, seven months; fees \$50 in each department. Medical department, member of National Association of American Medical Colleges. Dental department has been recommended by the council of National Association of Dental Faculties for membership.

The University has adopted the *four-years' course*, giving separate instruction in each year.

G. M. Waters, A.M., M.D., Dean; J. U. Barnhill, A.M., M.D., Secretary.

#### STARLING MEDICAL COLLEGE.

COLUMBUS, OHIO.

The fiftieth annual session of Starling Medical College, Columbus, Ohio, opened on August 19, 1894. The college is one of the oldest in the State, and has a fine building, with all the modern equipments. Its hospital facilities are of the best, material being supplied from the two largest hospitals in the city, one being in the college building. Students are required to study cases at the bedside, and instructed in physical diagnosis.

Information as to terms can be had by addressing Thos. C. Hoover, M.D., Registrar.

#### TOLEDO MEDICAL COLLEGE.

TOLEDO, OHIO.

The sixteenth annual session will begin October 1, in its splendidly equipped new college building, and continue six months. The school requires four years' attendance for graduation. The clinic facilities are excellent. There is no other medical college in the city, and it has the active support of the profession, not only of the city, but of the northern part of the State. It has the entire material furnished by two large general and one lying-in hospital. The fees are as follows:

Matriculation, to be paid but once, \$5; professors' tickets, for each session, \$50; practical anatomy ticket, including material, each course, \$10; chemic laboratory, \$5; microscopy and bacteriologic laboratory, \$10; hospital tickets (obligatory), \$5; graduation fee, \$25.

For \$175 paid in advance, a perpetual ticket (not transferable) will be issued, which will entitle the

holder to attend four or more courses of regular lectures.

J. H. Pooley, M. D., Dean. Wm. J. Gillette, M.D., Secretary.

#### WESTERN RESERVE UNIVERSITY, MEDICAL DEPARTMENT.

CLEVELAND, OHIO.

Presents a three-years' graded course, each year a term of eight months. Instruction by recitations, lectures, clinics, quizzes and practical training. Ample laboratory, dispensary and hospital facilities and equipments are provided for all students. Tickets for year, \$100; tickets for whole course, \$250. Special courses as desired, and advanced students given standing according to assured acquirements. Year begins middle of September.

G. C. Ashmun, M. D., Registrar.

#### UNIVERSITY OF OREGON, MEDICAL DEPARTMENT.

PORTLAND, ORE.

The medical department of the University of Oregon is located at Portland, Oregon, a city of nearly 100,000 inhabitants, where the excellent facilities afforded by Good Samaritan, St. Vincent's and Multnomah County Hospitals offer advantages for clinic instruction equal to those of many cities of much larger size because of the very large extent of territory from which patients are drawn. This school is a member of the Association of American Medical Colleges, requires advanced matriculation examination, four courses of lectures of six months each, practical work in clinics, anatomy, chemistry, bacteriology, etc. Its courses are graded, examinations being held at end of each year for advanced grading. Fees are graded according to time of attendance: Matriculation, \$5; first year, \$130; second year, \$130; third year, \$100; fourth year, free; examination fee, \$30.

S. E. Josephi, M. D., Dean.

Curtis C. Strong, M. D., Secretary.

#### WILLAMETTE UNIVERSITY OF OREGON, MEDICAL DEPARTMENT.

SALEM, ORE.

This college is permanently located at the capital of the State, and is now entering upon its thirty-first year. The course of instruction continues through four years, in accordance with the highest and best standard of modern advancement.

The regular course of instruction will begin September 29, 1896, and continue six months. The school is conducted in entire harmony with the Association of American Medical Colleges, adhering strictly to the requirements of that association.

Fees: First year, matriculation, \$5; lectures, \$130; second year, lectures, \$130; third year, lectures, \$100; fourth year, lectures, \$20; examination fee, \$30. The medical faculty of the college have entire and exclusive control of the Salem Hospital, insuring to the students all clinic advantages that can reasonably be procured from such sources.

J. Reynolds, M. D., Dean.

W. H. Byrd, M. D., Secretary.

#### UNIVERSITY OF PENNSYLVANIA, DEPARTMENT OF MEDICINE.

PHILADELPHIA, PA.

Founded in 1765. The course of instruction extends over four years, with one session beginning October 1 and ending on the second Thursday of

June in each year. The tuition fee admitting the student to all the lectures and including all the laboratory work, dissection, etc., is \$200 per annum. The instruction is conducted in the Medical Hall, the Laboratory Building, the Hospital of the University, Maternity Pavilions, Wistar Institute of Anatomy and Biology, and the Laboratory of Hygiene. Practical work in the various laboratories is part of the curriculum and is required of every student. Attendance on the clinic instruction given in the amphitheater as well as bedside instruction in the wards of the University Hospital is a part of the daily duty of the students.

John Marshall, M. D., Dean.

#### JEFFERSON MEDICAL COLLEGE.

PHILADELPHIA, PA.

A graded four years' curriculum in college is required of those who take the medical degree.

The matriculation fee is paid but once; the annual ticket is \$150; no diploma fee.

Beside the medical hall and the old laboratory building, this fall there will be opened the new pathologic and bacteriologic laboratories equipped at heavy outlay. The college hospital provides a wealth of clinic material unequaled in America. It has 140 beds and in the out-patient departments over 300 cases are treated daily. In the maternity department there were 159 obstetric cases and 2,385 visits. Each student had bedside instruction in midwifery. With these facilities it is possible to train the student in all the branches of medicine.

J. W. Holland, M.D., Dean.

#### MEDICO-CHIRURGICAL COLLEGE.

PHILADELPHIA, PA.

The session at the college opens October 1, and continues until April 26, when examinations begin. It contains laboratories for physiology, chemistry, pathology, hygiene, experimental therapeutics, histology and pharmacy.

Free quizzing at this college is one of its characteristics. Quizzing is done by the professors and instructors.

Its course consists of three years and is of a very practical nature. During the coming session it will have a new clinic amphitheater with a seating capacity of 600. It equals if not surpasses any clinic amphitheater now in existence in its arrangement so as to meet the demands of modern efficient clinic teaching.

The new hospital contains 150 beds. The fees for the tickets are \$120 for each year.

All communications should be addressed to Isaac Ott, M.D., Dean, Medico-Chirurgical College, Philadelphia.

#### PHILADELPHIA POLYCLINIC AND COLLEGE FOR GRADUATES IN MEDICINE.

PHILADELPHIA, PA.

It was organized in 1882 to give practical instruction to graduates only. It has a Faculty of thirty-two professors, assisted by forty-four lecturers, adjunct professors and instructors.

The hospital is fully equipped for purposes of treatment and teaching. There are two dispensary floors, clinic amphitheater, operating and sterilizing suites. There is a five-story laboratory building connected with the hospital, containing necropsy and dissecting rooms, surgical, chemic, pathologic, bacteriologic and neurologic laboratories, all of which are fully

equipped with the latest improved apparatus and offer every facility for original research.

Courses may begin at any date. The situation of the hospital is almost equi-distant from the University of Pennsylvania, the Jefferson Medical College, and the Medico-Chirurgical College, and near to the Children's, Rush Consumption, Wills Eye and Orthopedic Hospitals

A general ticket entitling the student to attend all the clinic departments is issued for one week at \$20, six weeks for \$90, three months for \$150, and one year for \$350. In all cases an extra fee is charged for any laboratory course.

S. Solis-Cohen, M.D., President. Max J. Stern, M.D., Secretary.

#### WESTERN PENNSYLVANIA MEDICAL COLLEGE.

PITTSBURG, PA.

The regular session begins third Tuesday in September and continues six months. During this session, in addition to four didactic lectures, two or three hours are daily allotted to clinic instruction. Attendance upon four regular courses of lectures is requisite for graduation. A four years' graded course is provided. The spring session embraces recitations, clinic lectures and exercises, and didactic lectures on special subjects; this session begins the second Tuesday in April and continues ten weeks.

The laboratories are open during the collegiate year for instruction in chemistry, microscopy, practical demonstrations in medical and surgical pathology, and lessons in normal histology. Special importance attaches to "the superior clinic advantages possessed by this college."

For particulars address Prof. T. M. T. McKennan, Secretary.

#### WOMAN'S MEDICAL COLLEGE OF PENNSYLVANIA.

PHILADELPHIA, PA.

The course is four years with an entrance examination in English, physics, arithmetic and Latin. The following laboratories furnish thorough practical instruction: histologic and embryologic, chemic, physiologic, anatomic, bacteriologic, pathologic and pharmaceutic. The instruction in hygiene is supplemented by laboratory work and there is a department for attendance on cases of confinement. Bedside instruction to small sections of the class is given by the physician in charge of the Woman's Hospital and clinic professors and instructors in this and other hospitals. The total expenses including the graduation fee are \$516.

For further information address Dr. Ruth Webster Lathrop, Sub-Dean, Philadelphia, Pa.

#### MEDICAL COLLEGE OF SOUTH CAROLINA.

CHARLESTON, S. C.

Three years' graded course; good hospital advantages; well equipped chemic, pathologic and bacteriologic laboratories; modern dissecting room; excellent teaching facilities and ample clinic material. Every facility afforded for a thorough course of instruction by lectures, demonstrations, quizzes, laboratory work and frequent clinic. Lectures begin Oct. 6, 1896. Commencement exercises April 1, 1897.

Fees: First year matriculation \$5, lectures \$100, laboratory fee \$5; second year lectures \$100, laboratory fee \$5; third year lectures \$80, laboratory fee \$5. No further charge for dissecting and hospital ticket, or diploma fee.

College of Pharmacy two years' course, fees, first year \$45; second year \$80. Women admitted to medical and pharmaceutic courses. For catalogue and other information address Francis L. Parker, M.D., Dean.

#### CHATTANOOGA MEDICAL COLLEGE.

MEDICAL DEPARTMENT OF GRANT UNIVERSITY.

Splendid new college building, largest and most elaborate in the entire South, into which the school has just moved prior to opening its eighth annual session.

Six hospital laboratories, abundant material for dissection and excellent general equipment. Six months' term and three years' graded course. Requirements those of the Southern Medical College Association. Tuition fees average about \$93 per annum. Large faculty covering every separate branch of medical instruction. Practical teaching and personal drill are special features. Climate delightful, board cheap, scenery picturesque, city healthy—a resort for invalids from everywhere, and shows lowest mortality of any neighboring city.

E. A. Cobleigh, M.D., Dean; J. R. Rathmell, Secretary.

#### MEDICAL DEPARTMENT UNIVERSITY OF TENNESSEE.

NASHVILLE, TENN.

The Medical Department of the University of Tennessee was founded as the Nashville Medical College in 1876 and became in 1879 connected with the University of Tennessee. The curriculum of study extends over three courses of lectures with special laboratory courses. It has now connected with it thirteen professors, nine instructors and six demonstrators. Among its professors may be mentioned Prof. Paul F. Eve and W. K. Bowling. Its sessions occur from October through March of each year.

Paul F. Eve, M.D., Dean.

#### MEMPHIS HOSPITAL MEDICAL COLLEGE.

MEMPHIS, TENN.

It is a member of the Southern Medical College Association, three terms of six months each being required for graduation. The school enjoys excellent clinic advantages with material obtained from the city hospital, St. Joseph's Hospital and its own free dispensary, where several thousand applicants receive treatment yearly. The college is well equipped with laboratories for microscopic and chemic work under the charge of a corps of experienced instructors. The Faculty is composed of some of the ablest men in the South, all being men of large experience in the teaching of their general branches. The fees for instruction are \$75 per course; graduation fee \$25, returnable in case applicant fail or does not apply for examination.

W. B. Rogers, M.D., Dean.

#### SEWANEE MEDICAL COLLEGE, UNIVERSITY OF THE SOUTH.

SEWANEE, TENN.

The college is now in session, with a fair class. Its regular course opens about July 1, and continues six months.

The pride of the school consists in its thorough course in the principles of the various departments of medicine and its excellent laboratory facilities.

It is a member of and governed by the laws of the "Southern Medical College Association" except in

requirements for matriculation; its standard is with the highest.

It has been demonstrated that the summer and fall seasons in this elevated mountain retreat, offer rare facilities for the successful study of medicine.

The expenses of attending the school are quite moderate.

J. S. Cain, M.D., Dean.

#### TENNESSEE MEDICAL COLLEGE.

KNOXVILLE, TENN.

Was one of the first in the South to extend the regular course to six months, and to require attendance upon three courses of lectures as an essential for graduation; its great success is a source of special satisfaction to the friends of the school. Knoxville, with its suburbs, has about 50,000 inhabitants.

A hospital on the college grounds, costing \$30,000, was completed in 1895. Fees for each course \$65, or for the three courses a perpetual ticket is provided at a cost of \$150. This includes everything except graduation fee of \$25.

J. C. Cawood, M.D., Dean.

#### UNIVERSITY COLLEGE OF MEDICINE.

RICHMOND, VA.

The University College of Medicine was organized and chartered with the three independent departments of medicine, dentistry and pharmacy, Dr. Hunter McGuire President of the combined faculties.

The course of study comprises three sessions of seven months each. Tuition fees \$100 with no extras. The professors and instructors number forty-eight and constitute the medical and surgical staff of the Virginia Hospital and Richmond Eye, Ear and Throat Infirmary. Students also have the clinic advantages of the City Almshouse Hospital. The arrangements for obstetric service are ample, and every student receives personal instruction in all the clinics.

The college buildings are large and were erected for their special purposes, containing fifteen separate apartments designed to meet the requirements of didactic instruction with practical laboratory work so essential to a modern scientific training.

There were 239 matriculates during the last session Hunter McGuire, M.D., LL.D., President.

Paulus A. Irving, M.D., Secretary.

#### THE UNIVERSITY OF VIRGINIA, MEDICAL DEPARTMENT.

CHARLOTTESVILLE, VA.

The session begins the 15th of September and continues without intermission for nine months. The course is graded and extends over three years, chemistry, histology, bacteriology, and human anatomy being taken up for the first session; physiology, pathology, materia medica, and obstetrics for the second; and the remaining studies in the medical curriculum for the third. Optional courses are also offered in embryology, practical pharmacy, and toxicology.

The University fees including tuition, matriculation, laboratory and diploma fees are for the first year \$160, for the second year \$140, and for the third year \$100. These cover all charges for anatomic and laboratory materials.

The characteristic features of the school are the extreme thoroughness of the teaching, the ample practical courses in human anatomy, histology and bacteriology, and the carefully conducted clinics given at the free dispensary operated by the University. Each student not only hears the lectures but comes

under the individual instruction of the professor. This is especially important for the laboratory and clinic courses. In addition to the clinics at the dispensary, those at the Piedmont Hospital in Charlottesville are utilized.

Under the laws of the University, each professor charged with the duties of instruction is required to give his whole time to the collegiate work, and hence the courses are of unusual thoroughness.

Wm. M. Thornton, LL.D., Chairman of Faculty.

UNIVERSITY OF VERMONT, MEDICAL DEPARTMENT.

BURLINGTON, VT.

The thirty-fourth annual course of lectures will begin in January and continue six months, ending in July.

This extension of the term will increase the scope of the instruction, and prove of great advantage to the student. The preliminary term has been abolished. No private courses by any of the professors will be tolerated by the faculty.

Instruction will be given in the following branches: Anatomy, physiology, chemistry, materia medica and therapeutics, practice, obstetrics; surgery, diseases of children, medical jurisprudence, neurology, ophthalmology and otology, gynecology, dermatology, venereal diseases, pathology and bacteriology, hygiene, sanitary science and examinations for life insurance.

Laboratory courses at this college in urinary analysis, histology, pathology and bacteriology, and practical work in physical diagnosis, surgery and demonstrative obstetrics, are now compulsory.

The instruction is given by scholastic and clinic lectures, by recitations and by practical manipulations by the student.

The clinic advantages are in many respects unsurpassed.

For further information address A. P. Grinnell, M.D., Dean.

WISCONSIN COLLEGE OF PHYSICIANS AND SURGEONS.

MILWAUKEE, WIS.

The fourth annual course of lectures will begin September 22. The length of the course is twenty-seven weeks, exclusive of the holiday vacation, the term ending on April 5, 1897.

This institution adopted the four-year course in 1895, and all students matriculating this year and hereafter will be required to spend four years in college work, unless their previous studies have entitled them to apply for advanced standing.

The fees for the course, including laboratory and lecture fees, and anatomic material, are \$95.

Clinic cases are furnished by the Presbyterian Hospital, which is in the exclusive control of the faculty of the college, and by the College Free Dispensary.

W. H. Washburn, M. D., Secretary.

**Caroid.**—A vegetable digestive ferment, derived from the plant known as *carica papaya*, or "paw-paw" (not the indigenous plant but an exotic found growing wild in Polynesia and now cultivated in most tropical countries). Caroid is a concentrated extract of the juices of the plant, made by cold methods, thus preserving the ferment in all its strength and freshness. Its action, contrary to that of pepsin, on the one hand, which acts only in acid media, and of diastase, pancreatin, etc., on the other, which act only in alkaline media, is equally good in both acid and alkaline fluids. The dose is from 2½ to 5 grains.—*Nat. Druggist*, September.

## GONORRHEAL CONJUNCTIVITIS; ITS TREATMENT.

Read in the Section on Ophthalmology at the Forty-seventh Annual Meeting of the American Medical Association, at Atlanta, Ga., May 5-8, 1896.

BY LOUIS J. LAUTENBACH, A.M., M.D., PH.D.

Surgeon to the Pennsylvania Eye and Ear Infirmary; Nose and Throat Physician to the Odd Fellows' Home; late Chief of the Eye Clinic of the German Hospital, etc.

PHILADELPHIA, PA.

Conjunctival diseases are among the most frequent of eye affections, but each year as the general practitioner's special knowledge increases, he undertakes more and more the treatment of the inflammatory eye affections, especially of the appendices of the eye, and, in consequence, the specialist sees less and less of these troubles, except when present in an aggravated form. The study of conjunctival diseases is not only important in relation to their treatment but as they are very often symptomatic of other local or general conditions it is especially necessary to have a most intimate knowledge of their various aspects. Again their seriousness is not so much *per se* as in a weakening of the surrounding structures, thus giving rise to secondary inflammatory conditions.

Of these conjunctival inflammations there are several which are specific or general in their origin, bearing a marked resemblance to each other which can be traced not only in their origin but in their course and treatment as well. I refer especially to the diphtheritic, epidemic, gonorrheal, blennorrhic and trachomatous forms of conjunctivitis. All are occasioned by a specific germ and therefore all are contagious, all except the latter appear as localized epidemics, and formerly this was present often as an acute epidemic; all are of an acute type and rapid in their progress, all extend rapidly to various adjoining structures, especially to the cornea, tending only too often to the production of most serious lesions. In fact, blindness as a result of these specific inflammations is only too prevalent. This entire class of inflammations should be directly under the supervision of the State. A move in the right direction has been the passage of laws for the reporting and proper treatment of cases of ophthalmia of the newborn, which have now been passed by the legislative bodies of numerous States.

Blennorrhic conjunctivitis, the ophthalmia of the newborn and the gonorrheal conjunctivitis of the adult, are in many ways the most important and serious of eye inflammations, causing more than one-tenth of all the existing blindness, and in addition, occasioning partial loss of sight in twice as many. While the gonorrheal form is less common than ophthalmia neonatorum, it is not the less virulent and its results are often more serious. Some years ago I was assured by a member of the staff of a prominent general hospital that up to that time no case of gonorrheal conjunctivitis had left the institution without having lost the sight of one or both eyes. So serious were these cases looked upon in the immediate past that many institutions refused to receive them, basing their refusal both on its contagiousness and its origin; undoubtedly the bad results obtained had some weight in occasioning such a decision.

The ill results following a case of gonorrheal conjunctivitis can usually be attributed either to the usual indisposition of the patient to admit the cause of his trouble or his want of knowledge thereof, occasioning the consequent delay of treatment; second,

the rapid progress of the disease with the consequent swelling of all the tissues in and about the eye, occasioning destruction of important eye structures by pressure and interference with the circulation and nutrition of the parts; third, a want of thorough cleansing; fourth, a want of proper treatment.

The first of these is sufficiently familiar. How often do we see these cases progressing even to the pustular stage without application for treatment having been made, either because the patient did not recognize the ailment, or recognizing it, hoped to conceal it. In this way considerable mischief is often done before aid is sought. The seriousness of the disease is occasioned more by neglect of prompt treatment than aught else; a day lost may mean the loss of the sight. The public generally should understand that in eye diseases a stitch in time saves not only nine, but sometimes a whole lifetime of darkness.

The rapid progress of the disease, extending within two or three days through the infiltration stage with distended lids and chemotic conjunctiva into the pustular one with sometimes, almost simultaneously, ulceration and breaking down of the cornea, is unfortunately too frequent. To one unaccustomed to such cases or not having a true realization of their violence and virulence, the progress may be so rapid that serious results are produced without sufficient effort having been made to avoid them. In these cases the rapidity of the disease should be anticipated and guarded against by appropriate advice and treatment.

The need of thorough cleanliness is apparent, but the method of its accomplishment may not be so clear. Cleanliness in such cases means the effective removal of all discharges on the conjunctiva and in the folds thereof, and the decomposition and removal of all discharges and gonococci which may lie in the various minute fissures and crevices between the epithelial cells of the superficial layers. In these cases the cleanliness must be considered part of the treatment, and usually is the most important part. Many will recover without other treatment, whereas, local applications without cleanliness will often avail nothing; it is the one essential to be adhered to religiously.

To thoroughly cleanse an eye the seat of a gonorrhoeal inflammation is often no easy task. The swollen lids with the tenderness and photophobia make it peculiarly difficult, and when there is maceration or ulceration of the cornea it is yet more so, as there may be the added danger of bursting the ball by the necessary manipulations.

I will outline the method which in my work I follow as rigidly as circumstances will allow. I first wipe off the lids and any discharge which appears between them with a piece of absorbent cotton saturated with a 3 per cent. solution of peroxid of hydrogen. I invariably use the Oakland peroxid on account of its comparative purity and freedom from acidity. I then instill between the lids, with a pipette, about twenty or thirty drops of the same solution and continue this until there is little or no bubbling. I then evert the upper lid and instill into the opened palpebral folds more peroxid, and then wipe the parts with absorbent cotton wet with the solution. I then treat the lower lid in the same way, being sure to thoroughly cleanse the cul-de-sac. I replace the lids and gently rub the ball at all parts of the lids, with the finger tips. I then take a saturated solution of boric acid and repeat with it all the manipulations described

above, doing this very thoroughly and using the solution liberally.

The peroxid cleanses the surface and serves to destroy any diseased conjunctival epithelium and penetrates the crevices and interspaces where the pus and gonococci have collected and decomposes these masses, bringing the detritus to the surface. Allowing the peroxid to lie in contact with these diseased structures for a few minutes serves to so thoroughly decompose them that they are readily removed by the subsequent washing with the boric acid solution. This solution not only washes off the foreign matters but also relieves the burning sensation of the peroxid and while soothing the eye serves to produce a healing effect upon the ragged but healthy epithelial cells. In addition to this personal cleansing of the eye which I insist upon doing at least once or twice a day, the patient is to have his eye thoroughly cleansed by the nurse with a saturated solution of boric acid at least every hour and in some cases every half hour. If the swollen condition of the lids renders this cleansing difficult, the severity of the disease makes it only the more imperative.

It seems evident that no treatment can exercise its normal effect without the thorough cleansing above described. These cases are of such a nature that the neglect must be eliminated—the treatment must be most vigorous and thorough.

The local medicament of most value in these cases is undoubtedly the solution of nitrate of silver. In all the germ diseases of the conjunctiva its use is invaluable. I use it of a strength of from 10 to 60 grains to the ounce—the more severe and active the inflammation, the stronger the solution. It is to be applied thoroughly with a cotton wound probe (never with a brush) over the palpebral conjunctiva, carried into the cul-de-sac and then to the ocular conjunctiva, carefully avoiding the cornea. This application is to be made by the physician once or twice a day as necessary and is to be followed by the instillation of 4 or 5 drops of castor or olive oil which eases the pain and lessens the friction of the roughened and diseased conjunctival surfaces. In addition to this personal application, a one or two grains to the ounce solution of nitrate of silver is to be instilled into the eye by the nurse from two to four times a day, invariably after washing with the boric acid solution. If the cornea be ulcerated, the treatment is to be as thorough as is consistent with safety, avoiding the use of the strong nitrate solution on the cornea or its accidental access thereto.

If chemosis be present, I invariably incise the conjunctiva in numerous deep lines radiating from the cornea so that the subconjunctival infiltration may gradually find vent and thus afford sufficient room for the natural increase in the amount of the exudate, and at the same time by decreasing the tension, lessen the abnormal pressure on the corneal border.

In addition to the above, I use ice bags and iced cloths whenever the inflammation is peculiarly virulent, or there is very much swelling of the lid or chemosis, and use atropia or eserin locally whenever I have corneal involvement, the choice depending upon the tension of the ball as well as the location and extent of the ulceration and the general constitutional peculiarity of the patient; in those inclined to rheumatism, all other things being equal, I always prefer to use eserin. I have also found ice to be invaluable in the early stages of corneal involvement,

when the cornea first appears hazy. In fact in all corneal inflammations I have found the use of ice peculiarly beneficial in preventing the disorganization of this tissue.

A matter which I have not touched upon but which is of supreme importance, is the prevention of the disease attacking the sound eye. This is accomplished by thorough attention to the affected eye, which I hope I have fully explained, and preventing the discharge of the diseased eye from infecting the sound one. This is attempted by many by closing the healthy eye with a watch glass or adhesive plaster, carefully applied. I formerly built a dam of shoemaker's wax upon the bridge of the patient's nose, carrying it well down toward the tip and up on the forehead, directing the patient never to lie upon the unaffected side. While still occasionally using this method, I rely more on the bandaging of the sound eye and its regular daily cleansing by the physician before he treats the affected one. The cleansing is that outlined above, consisting first of the use of a 3 per cent. peroxid of hydrogen solution followed by thorough cleansing with a saturated solution of boric acid, then drying the eye and covering it thoroughly with a roller bandage, first dressing the eye with absorbent cotton covered with waxed paper.

By this method of bandaging, even though the discharges soak into the bandages, the waxed paper prevents their access to the eye, and should the germs surmount this barrier they will be absorbed by the cotton wad, which is an efficient sterilizer, and even though it were possible to penetrate through this they will meet a closed eye, which they can not enter. Another advantage of the bandaging is the rest given the healthy eye, thus preventing excessive motion in the diseased eye, and it will be found that corneal involvement will be more rare, and when it occurs it will be less severe.

In a few words the treatment can be summed up as rigid cleanliness carried to the extent of destroying and removing the gonococci and all the broken down cells, with sufficient stimulation afterward to increase the normal cellular activity, stimulating thus the reparative processes, meeting the complications as they arise, promptly and vigorously. The treatment of the unaffected eye to consist of rigid cleanliness with slight stimulation, careful bandaging and exclusion of the discharges from the diseased eye.

### THE USE OF CICATRICIAL SKIN FLAPS IN THE OPERATION FOR ECTROPION OF THE UPPER LID.

Read in the Section on Ophthalmology, at the Forty-seventh Annual Meeting of the American Medical Association at Atlanta, Georgia, May 5-8, 1896.

BY F. C. HOTZ, M.D.  
CHICAGO.

In my paper on skin grafting read last year at our meeting in Baltimore, I pointed out the superiority of Thiersch's skin grafts over the thick skin flaps usually employed in the operations for ectropion of the upper lid. I said, "occasionally, however, the skin flaps taken from the vicinity of the everted lid possess all the conditions necessary for a perfect cosmetic result." I had in mind the thin, glistening cicatricial skin which usually covers the vicinity of the everted upper lid. In several cases where the eyebrows had been destroyed to such an extent that a

large flap could be cut from this cicatricial skin above the lid, I used such skin flaps as a substitute for the lost lid skin, and found that, contrary to the general belief, these flaps could be transplanted as successfully as the flaps of normal skin, and that their use has

FIGURE 1.

several decided advantages over all other methods of transplantation.

FIGURE 2.

For these reasons I wish to report a case in which a cicatricial skin flap was used: In January, 1889, a boy 14 years old was admitted to the Illinois Charitable Eye and Ear Infirmary to be relieved of complete ectropion of the upper lid of the left eye and lower lids of both eyes, the result of extensive caries

of the orbital margins, when the boy was 4 years old

As the operations on the lower lids have no special interest, it is sufficient to state their reposition was accomplished by the well-known V-shaped incision combined with Arlt's operation for shortening the overstretched lid border.

The border of the everted upper lid of the left eye was drawn up and fixed to the temporal portion of the supraorbital margin, and above it a large stretch of cicatricial skin extended far into the frontal and temporal region (indicated by the dotted area of the pictures). The temporal half of the eyebrows had been destroyed, and their absence made the following operation feasible:

From a point (Fig. 3, *a*) near the inner canthus an incision was carried obliquely upward past the end of the eyebrows, well up into the cicatricial skin above

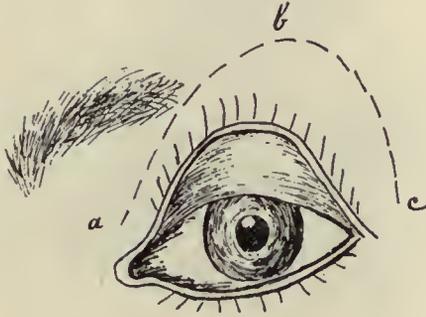

FIGURE 3.

the supraorbital margin, and then continued at a considerable distance from the lid border in a curved line downward to a point (*c*) about six millimeters from the external canthus. The large skin flap (*abc*) mapped out by this incision was carefully dissected from the underlying scar tissue down to the lid border, with which it was left connected. The lid, then, was released from all cicatricial adhesions and replaced in its normal position.

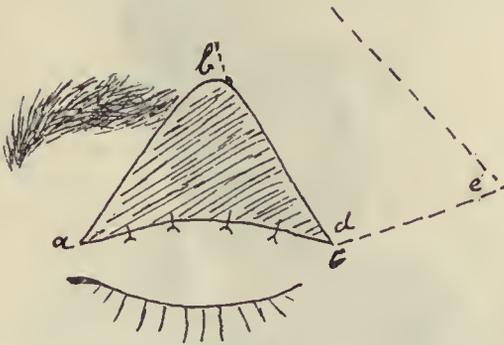

FIGURE 4.

The cicatricial skin flap (*abc*) shrank considerably as soon as it was detached from its basis; but in anticipation of this contraction, it had been cut so large that, after shrinking, it was still sufficient to cover the whole lid. It was spread out over this surface and its margin (*ac*) fixed to the upper border of the tarsal cartilage by four silk sutures.

The large wound (*abc*) above the lid was covered by sliding into it a skin flap (Fig. 4, *bde*) from the temporal region, its margin *bd* being united with *ab*, and *de* with the margin *ac* of the new lid skin. This flap also contained a great deal of scar tissue. The small wound remaining at the temporal side of the transplanted flap was left to heal by granulation.

The healing was uneventful, and the accompanying picture (Fig. 2), taken five months after the operation, shows the excellent result of this procedure.

This operation supplies the replaced lid with a thin and light skin which adapts itself nicely to the configuration of the lid and does not restrict its movements. In this respect it is fully equal to the Thiersch grafting, over which, however, it has the advantage that the lid need not be rendered immobile by sutures or ligatures for a number of days.

But the most important advantage of this operation lies in the fixation of the new lid skin to the tarsal

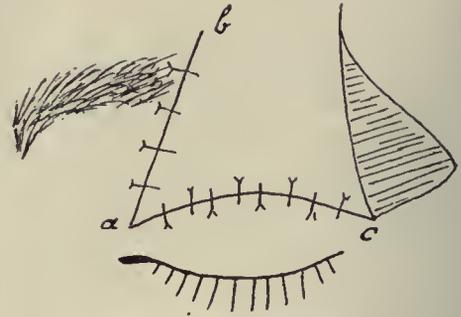

FIG. 5.—Operation completed.

cartilage. This fixation renders the lid skin independent of all tissue changes which may take place in the supratarsal region. No amount of shrinkage of the transplanted flap in this region can cause a reëversion of the lid, because the firm union of the lid skin with the upper border of the tarsal cartilage makes it absolutely impossible that the contraction of the supratarsal tissues could affect the lid skin and the lid border.

### MALIGNANT DISEASE OF THE NASAL CAVITY SHOWING THE VALUE OF EARLY DIAGNOSIS.

Read in the Section on Laryngology and Otology at the Forty-seventh Annual Meeting of the American Medical Association, held at Atlanta, Ga., May 5-8, 1896.

BY J. H. SHORTER, M.D.

MACON, GA.

I will mention briefly a case of what proved to be malignant tumor of the interior of the nose, to show what differences of opinion as to diagnosis, there may be among competent men.

It was the case of a gentleman, sent to me from Milledgeville, Ga., about a year ago. He complained of a lump on the side of his neck under the jaw, and a feeling of obstruction in the left nostril.

I found a large polypoid growth in the upper part of the left nasal cavity, which I presume sprang from the ethmoid, and which I thought presented the appearance of malignancy. I removed a large piece, examined it, and also had it examined by a competent microscopist, who pronounced it a carcinoma. I informed the patient's family physician of the confirmation of my opinion, and recommended an immediate operation, as the only hope of relief, though I did not think the growth could be radically removed without resection of the superior maxilla.

I did not see the patient again. The family became very much alarmed after my diagnosis, and sent him to a specialist well known throughout the South. This gentleman disagreed with my opinion, pronounced the trouble *syphilis*, and promised a speedy cure.

Notwithstanding vigorous medical treatment, he grew worse and began to lose flesh, and suffer great pain. I wrote and suggested that he go to some hospital, where he could have the best advantages. He then went to New York, consulted a well known surgeon, who had sections of the tumor made for microscopic examination. It was decided to be a fibroma and non-malignant. The surgeon removed the growth by section below the orbit, resecting the malar and part of the superior maxillary bones, promised the patient complete recovery and no recurrence of the disease.

On returning home, his physician wrote me as above. I replied that I sincerely hoped for favorable outcome, but much doubted it.

About three weeks later, the tumor reappeared, and the patient died at the expiration of three months with probable extension into the cranial cavity. There was headache, paralytic trouble, and great exophthalmus.

The diversity of opinion in this case appears to me as being unusual; one of the foremost men in the South pronounced it syphilis, another eminent surgeon of New York pronounced it non-malignant, both after careful examination, yet the patient succumbed promptly to what was evidently cancerous disease.

#### DISCUSSION.

Dr. D. BRADEN KYLE, Philadelphia—In regard to microscopic examinations as mentioned in Dr. Shorter's case, I find that it is not always possible to make a diagnosis from the tissue sent for examination, but if certain rules are followed the examination is of value. In a microscopic examination we must take into consideration the fibrous stroma, the blood vessel, and the cells, and their relations to each other. In the case reported I would like to know whether there was any ulceration of the tumor. In the mucous membranes, especially of the upper air passages in which there is very little connecting tissue element and where it lines a bony cavity, the small round cell (embryonic) of inflammation would resemble a sarcoma very much and if there was ulceration you would find the vessels beneath mere sluice-ways and lacking vessel walls, nothing more than an attempt at organization of the embryonic tissue, and not necessarily malignant, although resembling sarcoma. Such an eminent authority as J. Bland Sutton states that it is impossible to differentiate this condition from sarcoma. As carcinoma spreads by the lymphatics, has distinct and well outlined vessel walls, I do not understand how the mistake in diagnosis could be made.

### SOME OBSERVATIONS MADE DURING THE TREATMENT OF CHRONIC CATARRHAL DEAFNESS.

Read in the Section on Laryngology and Otology, at the Forty-seventh Annual Meeting of the American Medical Association, held at Atlanta, Ga., May 5-8, 1896.

BY THOS. H. SHASTID, A.B., M.D.

GALESBURG, ILL.

The treatment of chronic catarrhal deafness may be considered under three heads: Treatment of the ear directly, attention to the throat and nose, attention to conditions of the body in general.

As regards treatment of the ear directly, I wish to speak only of intra-tympanic operations. As a way out of the confusion that seems to exist regarding the propriety of the application of these procedures, I have divided them for the purposes of my own practice into two well-defined classes. Into the first of these I have placed such procedures as, while of

doubtful utility to the hearing, are of some, though slight, danger to life. These are the operations for the removal of one or more of the ossicles with or without part or all of the drum membrane, and mobilization of the stapes. These procedures, as much recorded (and perhaps much more unrecorded) experience goes to show, are often followed, even when performed under strict antiseptic precautions, by severe suppuration; and, as they do not very often produce a really valuable increase in the hearing power, I do not think that even total deafness can justify their employment. The second of the classes into which I divide intra-tympanic operations consists of single and multiple incision of the drum membrane, partial myringectomy, plicotomy, traction on the handle of the malleus, tenotomy of the tensor tympani. These operations are often productive of much good, seldom, if ever, of harm, and are moreover, when properly performed, entirely unattended with danger. Such procedures, even though by no means uniformly beneficial, are proper in cases in which they are not positively contraindicated and in which inflation and massage and treatment of the nose, throat and general system have not proved beneficial.

I report a case that possesses considerable interest from its bearing on the topic of intra-tympanic operations. A lady, aged 30, had been deaf from catarrh for several years. Inflation and massage and treatment of nose and throat conditions had produced no benefit. I, therefore, applied Lucaë's sound. The immediate result was gratifying. The hearing for both acoumeter and voice rose to nearly treble its former power. Within twenty-four hours, however, the patient returned as deaf as before. Again I applied the sound; again the result was brilliant; again the patient returned no better than before. Then I did a tenotomy of the tensor tympani, but without effect. At the end of twenty-four hours the patient returned and requested me to apply the sound again. This I did, with good result; but this time, and this is the point that is particularly worthy of note, the improvement was of comparatively long duration, lasting nearly three months. Encouraged by the measure of success in this case, I tenotomized the tensor in three other cases in which the pressure sound was productive of good but temporary results, but, so far as I could tell, without any effect whatever on the duration of the improvement. These four cases, taken together, impressed upon me the fact that the mechanical problem in cases of chronic catarrhal deafness, so far from being anything resembling a constant one, is of almost infinite variation, and that it is impossible to tell with certainty in advance whether a given operation will prove of benefit, but that in all cases of great severity and unamenable to other treatment, every intra-tympanic operation should be tried which offers a reasonable hope and which does not endanger either hearing or life.

While speaking of intra-tympanic operations, I desire to call attention to an improvement in the shaft and handle of instruments intended for such operations, which, though it was described in the "Archives of Otology" some three or four years ago, has not, I believe, received the general adoption it deserves. I refer to the shaft and handle of Dr. Barclay. In instruments mounted according to Dr. Barclay's idea the handle is joined to the operating shaft by a lateral shaft in such manner that the axis of the handle, prolonged forward, intersects the axis of the operating shaft

exactly at the operative extremity. I have had several instruments mounted in this manner, and find that it gives a precision and lightness of touch unattainable by any other means. I believe that Dr. Barclay's idea constitutes a real progress in otology.

Apropos of the effect upon the hearing of nasal and pharyngeal treatment, I urge the importance to the hearing, of vibration or massage of the nasal and pharyngeal mucous membranes when these structures are the seat of atrophy. The loss of hearing accompanying this throat and nose condition is not invariably slight, though it is usually asserted to be so, being in some cases great enough to interfere seriously with ordinary conversation. I believe that in these cases massage of the nose and throat mucous membrane, if persisted in for some time, will result in relieving a large proportion of them of a measure of their embarrassment. Such has been my experience, and I think that I have exercised reasonable care in the exclusion of other possible causes for the improvement. The only instrument that I have used has been Dr. Freudenthal's vibrator. I have seldom seen any improvement until the massage has been continued for a long time.

Under the head of attention to conditions of the body in general, I report a case in which the hearing was very powerfully affected by belladonna. A patient whom I was treating for chronic catarrhal deafness would, at irregular intervals, suffer a very considerable aggravation of his trouble. This would in a few days quite, or nearly, disappear, only to return in a few days more. The exacerbations were not accompanied by symptoms of cold, but by unusual dryness of the mucous membrane of the throat and nose. On inquiry I found that the patient was occasionally taking a purgative pill which contained, among other ingredients, a quarter of a grain of the extract of belladonna. Naturally associating the belladonna with the dryness, I directed the patient to observe whether or not his periods of increased deafness followed the use of the pill. He reported that they really followed its use. Then, in order to eliminate as possible sources of error the influence of suggestion and also of the various drugs which the pill contained other than the belladonna, I ordered a discontinuance of the pill and then each time the patient came to me I administered to him a tablet, sometimes a blank one, sometimes one containing a quarter of a grain of the extract of belladonna. Each time the tablet containing the belladonna was administered the patient suffered this aggravation, but at no time did he experience an increase in deafness after the administration of the blank tablet. It would seem that the deafening effect of the drug was exerted chiefly upon the middle ear; for the patient's ordinarily somewhat increased cranial perception was still further increased whenever he took the belladonna. I thought the increased difficulty in hearing arose from impairment of sound conduction due to inspissation of secretion among the tympanic folds and the ossicles.

**Roentgen Ray Locates Bullet Through the Skull.**—The last *Deutsche med. Woch.* (August 13) brings us actual photographs of the heads of a couple of Eulenburg's patients, in which the Roentgen ray discloses and locates a bullet inside the skull. The photograph was taken with the head of the patient resting on the plate holder, with the Crookes' tube about 24 c. above.

## SOME RELATIONS OF CRIME TO INSANITY AND STATES OF MENTAL ENFEEBLE- MENT.

Read in the Section on Neurology and Medical Jurisprudence at the Forty-seventh Annual Meeting of the American Medical Association, held at Atlanta, Ga., May 5-8, 1906.

BY H. E. ALLISON, M.D.

MEDICAL SUPERINTENDENT MATTEAWAN STATE HOSPITAL,  
FISHKILL LANDING, N. Y.

Any study of penology should consider not only crime and its punishment, but should also investigate the mental and physical state of the criminal, his capacity and his needs. There are conditions both of body and mind either congenital or acquired which render a person dangerous to himself and others, and attempts to repress criminal acts and to protect society from their consequences and their repetition can never be in any great degree successful until we look in part to the individual and examine him as to his status as a man. With this end in view and especially in the case of the young, who are first offenders, the courts should place criminals in secure custody where they should be confined upon indeterminate sentences and undergo careful observation and training at the hands of men capable of judging just what corrective or remedial measures are needed and for what length of time the convict should be deprived of his liberty.

The anthropologic study of the criminal has of late years interested scholars and especially medical men, and there has been much written and much active discussion as to the relations the criminal bears to himself and to society. As medical men we are interested in the criminal himself; and not so much in the nature and character of crime and its punishment, except as incidentally it involves the study of the man. A great deal of stress has been laid upon marks of degeneracy in the criminal and while we admit the existence of many physical anomalies and mental obliquities among the inmates of our penal institutions we can not point to any one feature or group of peculiarities that necessarily stamps the subject as certainly belonging to the criminal class. To a large degree, however, these factors are useful to enable us to judge something of the probabilities which attach to a person's pursuing a criminal career and aid us in adopting reformatory methods, educational, disciplinary and therapeutic, by which we may combat and change inherent or acquired conditions. We can realize that a child with an excellent heredity and a healthy body and mind is more insured against a criminal career than one presenting all the stigmata of degeneracy. Society has greater natural safeguards in the one than in the other.

The two great determining influences for good or evil are heredity and environment. The medical aspect of crime is more concerned with the former, although the latter can not be disassociated from the question. Environment being susceptible to educational influences and removable, either in a degree or entirely, is more related to the province of the sociologist. It is probable that to environment must be credited the greater number of criminal acts, as the early teaching and training of the child influences largely his subsequent career. Hereditary defects follow closely as a causative factor in the genesis of crime. Out of 6,151 admissions to the Elmira Reformatory, insanity and epilepsy in progenitors were clearly present in 11 per cent. of the number and to this should be added a proportion, uncertain in quantity, wherein ances-

tral history in this respect was untrustworthy or not ascertainable. Drunkenness in ancestry was clearly traced in 38 per cent. and was doubtful in 12 per cent. more. Insanity, epilepsy and intemperance, therefore, appear to exert their potent influence upon those who become the inmates of penal institutions. Necessarily such prenatal conditions must produce degenerative conditions which are stamped upon the offspring. The question arises as to the treatment of such cases. Is it wisdom to determine that it shall be altogether punitive and retributive? It should be the purpose of the law to afford every opportunity for the correction of defective organization by reformatory methods. The physical and mental status of the criminal should be improved by industrial and educational means, the earlier the better, and by efforts directed toward the full development of bodily health. The complex influences of heredity and environment should not be considered as a mitigation of the crime nor should the fact that the criminal is often a degenerate person be urged in condonement of it. His condition modifies but does not expiate his fault. He should be confined as an exemplary measure but the commitment should still further direct that he should not be released until it was reasonably assured that he was morally, mentally and physically fit to be at large.

Out of the same number of admissions to Elmira before mentioned the physical health was reported as "debilitated, diseased and impaired," in 11 per cent. and the quality of the inmates' physical condition was found to be "low and coarse" in 30 per cent. The mental capacity was tabulated as "deficient or only fair" in 19 per cent. Out of 596 cases admitted in 1893 to the Eastern State Penitentiary of Pennsylvania, 20 per cent. was classified mentally as "dull, simple, very weak or bad." In addition to this, the age at which convictions are found is such that opportunity is offered in youths to effect reformatory results. Out of 1275 inmates of Sing Sing Prison, 42 per cent. were sentenced before the age of 25 years, and out of 6151 inmates of Elmira to which institution young offenders are especially committed, 90 per cent. were admitted between the ages of from 16 to 25 years. There is therefore in criminal anthropology much to engage the attention of the medical profession in connection with the subject of reformatory methods in relation to heredity, intemperance and crime. A further interest attaches to the resulting conditions of degeneracy and to repressive and eradicated measures which should lead either to the reformation or permanent sequestration of the individual. Many abnormalities of the cranium and of the body and its appendages have been described as peculiar to the population of our penal institutions. Asymmetry of the skull and head, of the body, anomalies of the ears, the teeth, the jaws, the palate and of the sexual organs are all indicative of prenatal influences which affect the individual adversely and relegate him to a place among the defective classes. The moral sensibilities are stifled or altogether wanting and the impressionability of the criminal in this direction is slight or absent in the great majority of cases. They are devoted to excitement through alcoholism, sexual excesses or perversions of the sexual instinct and to every form of pleasurable stimulation of the appetites and passions. All these influences tend to mold the physiognomy, which in the popular mind and in a general way is often an index to character.

A great deal of careful study has been expended by

scientific men upon the physical characteristics of delinquent man. It appears to be established that among the great mass of criminals there does exist a defective physical and mental organization, an insensibility to moral influences and a predominance of degenerative and atavistic traits. Their instinctive faculties are often well developed and they have a large degree of cunning. Persons who are absolute idiots are not found among convicted criminals. The unfortunate condition of those who are thus affected prohibits them from being capable in the eyes of the law from the commission of crime, and they are not convicted. This condition, when pronounced, attracts attention in early life and invites care on the part of parents or guardians and such defective subjects are usually placed under proper restraint either at home or in custodial institutions. Their recognized place is in a school for feeble-minded children or in custodial asylums or homes. Neither are the insane as a rule found confined in prisons or in penal institutions; though insanity may be developed among those confined there. Many criminals, however, are on the borderlands of each condition. The higher the state of civilization the greater the differentiation between the grades of the defective classes and the more intelligent are the methods of care exercised in dealing with them. The aim in the education of the feeble-minded as well as of the deaf and dumb and blind is to render those so afflicted able to care for themselves in a measure and to relieve society in as large a degree as possible from the burden of their support. There are thus converted into productive units what otherwise, without training and care, would remain dangerous and troublesome factors. The care of the insane is based upon similar economic principles. In the treatment of criminals however measures are still adapted to punitive and retributive ends rather than to such as tend to promote the correction of inherited and acquired deficiencies by securing the reformation of the criminal. There are more reasons why the instinctive criminal who has failed of reformation and received several convictions should be for a long term, or permanently, deprived of his liberty than exists for the detention of the insane and other dependent classes. Out of 981 annual admissions to Sing Sing Prison in 1894, 66 per cent. had served one or more previous sentences and out of the total population of 1365 for that year 14 per cent. were known to have received from three to eight convictions. Numbers of recidivists in prisons are undoubtedly insane or possessed of a very unstable mental equilibrium which is disturbed by trivial causes.

In the State of New York convicted cases who exhibit mental derangement are transferred from all the penal institutions to the Matteawan State Hospital upon the certificate of the prison physician, approved by the agent and warden of the prison or other officer in charge.<sup>1</sup> This method of commitment is now modified. When a convict is so committed he is, upon recovery before the expiration of his sentence, returned to penal custody. If his sentence expires while he is still insane he is detained in the hospital until such time as he shall recover or be released under bond to the custody of his friends. This practice has led to the accumulation at the hospital of 137 cases with expired terms but who are still insane out of a total population of 325 convicted inmates. Many of these cases are defective naturally and confinement in prison has

<sup>1</sup> This law had passed and took effect July 1, 1896.

developed some degree of mental disturbance which often passes away, but even after their normal condition is restored it frequently is a question whether to retain them permanently as inmates of the asylum or to return them to prison. The fact that they have been determined sane by the courts at the time of their trial would seem to indicate that before the law they are considered responsible and therefore proper subjects for release. The great majority of these cases are addicted to vicious and immoral practices and to sexual indulgences. Their influence is corrupting and as a rule debasing. They display to a marked degree abnormalities of physical structure and certainly belong to a degenerate type of humanity. As a rule when at large they are intemperate in their habits and irregular in their ways of living. The form of insanity which affects them is not of an active or actually maniacal form, but is rather a quiet state of depression with delusions often of persecution. It does not reach an acutely maniacal type but rather seems to be an intensification of natural instability attended with morbid feelings of suspicion and of actual hallucinations of hearing and sight. There is not as a rule much display of intellectual power in their descriptions of their own subjective states. Their mental capacity is generally limited and their insanity consequently does not show much ideation of the higher and finer attributes of the mind, either of morals or intellect. As a rule, their moral sense is defective and their mental development below the average. Criminals who become insane are, in general, low-grade examples of the race. On the contrary, the inmate of an ordinary lunatic asylum, as a rule, is a patient possessed of good character, who has been self-supporting and is of a social, kindly and well-disposed nature. He is often possessed of a trade or calling in which he is more or less proficient, or he has been accustomed to labor regularly and honestly for his living. Upon his convalescence he becomes useful to the institution in those directions in which he is proficient and often in chronic conditions of mental disease he obtains intellectual diversions and physical exercise through occupation which benefits not only himself but others. The convicted insane, however, are a different class. They have engrafted upon a naturally defective mental and physical constitution, an early bent or training, the result in part of their environment which renders them dangerous factors in any community. Devoted to acts of housebreaking and inclined to thefts or robbery, upon convalescence or in chronic states, they turn their skill in such directions, toward escaping from custody. They are prone to associate together, to sustain and assist each other; they use their talents before employed in burglarizing and forcibly entering houses, to efforts now to get out of custody. The insane are said never to combine, but insane convicts will do so. The ordinary insane and the insane convict are not members of the same guild.

Occasionally a patient is committed to prison who is insane and whose crime is the result of such insanity. His mental condition may not have been recognized at the time of his trial and conviction; or the plea may have been put forward and failed as a defense. Such cases are quite different, both mentally and physically, from the ordinary inmates of the prison. They are properly classed among court cases, to whom we shall allude. The plea of insanity, however, while in many cases looked upon with disfavor by the public

yet often results in a duration of confinement which averages longer than a definite sentence imposed by the court.

In order to secure the proper certification of convicted cases from the penal institutions who may be regarded as insane, the State of New York in the revised insanity law presented to the Legislature this winter, proposed to adopt the following procedure, which is a modification of the present method: Whenever the physician in connection with any penal institution shall certify to the warden that any inmate therein is insane, the warden shall notify the judge of the district wherein the said prison is located who shall appoint two physicians to examine into the prisoner's mental condition and, if insane, the judge shall order his confinement at the Matteawan State Hospital, there to be detained during the term of his sentence unless sooner recovered, when he is to be remanded to prison. If he is still insane at the time his sentence expires, he shall remain in confinement until in the judgment of the medical superintendent he is fit to be at large. This procedure substitutes an examination by two physicians and a judicial order of commitment in the place of the simple certificate of the prison physician and order of transfer by the warden.

There is a second and very important medical aspect of crime. A certain class of the insane commit crimes as the result of their insanity, not for the sake of gain nor for the ordinary and sane motives which actuate most men, but by reason of delusions or mental derangement. A person whose mind is thus disturbed may offend the law by reason of some overpowering false belief. He may assault another in the frenzy of a semi-conscious state of epilepsy. He may act without adequate motives or from the weakest of motives as in the case of a pronouncedly demented person. These acts are not the result of any instinctive or acquired criminal habits or desires, but are the products of an actively diseased brain. The real animus which actuates the perpetrator may be a lofty one, it may be in the eyes of the patient an act of self-defense against imaginary enemies, the product of an insane delusion which controls the patient's mind, or it may simply be a purposeless unreasoning crime perpetrated without a motive in an automatic or semi-conscious state. These patients present a strong contrast physically, intellectually and morally to those committed from penal institutions. They are freer from those anomalies of physical development and growth which are so often found among those of the criminal type. There are among them more persons who have attained to a fuller stature and higher development, their cranial configuration and physiognomy and conditions of bodily growth betoken a better type of manhood.

Intellectually they show a greater natural endowment and a higher degree of education. Their delusions are more systematized and exhibit a wider range, spread over a larger field, embracing a much greater complexity of thought and arrangement. Their ideation is more vivid and relates to a greater variety of subjects in trades, business, law, medicine, religion, literature and the natural sciences, showing greater educational advantages and a higher cultivation and greater capacity of mind. Naturally they differ from the criminal class very decidedly. They have a higher ethical sense, a broader appreciation of the responsibilities imposed upon themselves and a greater

regard for the duties which they owe to others and to society. They are freer from vicious habits and intemperance and from unnatural sexual practices, and express an abhorrence of many things which the criminal regards with favor or indifference.

The nature of the crimes committed by unconvicted cases and those admitted to the asylum from prisons show an equal divergence. The former are acts largely directed against the person in the nature of assaults to do harm, while the latter consist of burglaries, thefts, robberies and crimes against property for gain. Among 1,733 patients admitted to the Matteawan State Hospital the ratio of crimes committed against the person by the cases from the courts compared with those from penal institutions has been as follows:

	Convicted		Unconvicted.
Assault to harm . . . . .	1	to	21 $\frac{1}{2}$
Murder, manslaughter, etc. . . . .	1	to	22 $\frac{3}{5}$

Crimes against property where the motive was simply gain, show an inverse ratio.

	Convicted.		Unconvicted.
Burglaries . . . . .	3	to	1
Larcenies . . . . .	21 $\frac{1}{2}$	to	1
Robbery . . . . .	7	to	1

Persons adjudged insane show a large preponderance of crimes against the person with intent to harm, while convicts who become insane while in prison are as a rule charged with offences against property. The degenerate individual who commits a crime for which he is arrested usually sins in the direction of appropriating something which for one reason or another he covets. He is disposed to acts of theft and robbery. He wishes to gratify in some way his appetite, and has very little regard for the property rights of others. He is incapable of resisting impulses to do wrong in these directions and constitutes a member of an unstable, weak and defective class of individuals. The cases from the courts, however, are not governed by these lower motives. Their acts are defensive acts, not as a rule aggressive, in the proper use of that term. They endeavor to avoid the necessity which they think exists to commit assaults to protect themselves. They may believe themselves poisoned, the victims of conspiracy, or in danger of their lives. They think and act as ordinary men would act but their premises are wrong and they are led by delusions which govern them. The commission of an assault with no good motive discoverable raises the presumption of insanity. The motive will often be found to be simply the promptings of disease. The insane know the difference between right and wrong in the abstract, and reason very clearly upon the subject, but in relation to their own particular act they can not form a rational judgment. This has led to a confusion as to the responsibility of a person charged with crime. He may know it is wrong to kill, but through his diseased brain imaginary voices prompt him; sights, sounds and all evidences of his senses mislead him and he is influenced to believe that what he apparently hears and sees is real. In relation to his particular act he does not know that he has done a wrong. He may know the nature of the act, whether it was homicidal or intended to be such, but he regards it as of the same quality as an act of self-defense and therefore as to this act he is unable to form a proper judgment. Many cases are improperly adjudged insane and committed to prisons for life, or executed, simply as a result of the misapplication of the legal test of responsibility. One-sixth of the life men committed to the prisons of New York are

inmates of the Matteawan State Hospital. Their insanity has been recognized after conviction and while serving terms of imprisonment.

Crime in one of its medical aspects may be regarded as in part the product of degeneracy caused by a bad heredity and intemperance in ancestry combined with a bad environment. An effort should be made to reclaim and reform the individual by efforts directed toward improving his mental condition and the development of his mind and body in early life by educational measures involving thorough mental and physical training and manual instruction in some self-supporting industry. Proper moral and religious training is essential, in which should enter the true spirit of Christianity as well as its forms, and which should permeate the life of the institution. The mind, the morals and the hands should be cultivated as far as possible. If the criminal be found incorrigible he should be placed for a long term of years in some penal institution or committed to the custody of a criminal lunatic asylum, there to remain. Aside from these conditions let his term of imprisonment be determined by his conduct within limits fixed by the court.

In the other medical aspect which relates to those features purely the outcome of disease, no personal responsibility can be attached to such offenders, but they should be placed in safe custody in an asylum, if possible in one devoted to the care of the dangerous insane. While they should not be imprisoned and punished as criminals, yet society should be most carefully guarded against their acts, and their release in the event of recovery should be a matter to be most conservatively considered. As a fact, the ratio of recoveries in such cases is not large. Hallucinations of the special senses are common, especially of hearing, and the disease is essentially chronic. Persons who commit murders or assaults upon life are not as a rule habitual criminals, and if their mental condition is questioned in court they should be carefully examined. The motive should be sought for, and if one is found, its origin should be determined, whether it had its inception subjectively in the diseased brain of the patient, or arose from external causes, such as affect men in general in their conduct. The absence of motive should also be given its weight. The unreasoning and semi-unconscious act of an epileptic, while it might relegate him to an asylum for life, should not place upon him the stigma of a felon. Serious crimes against the person are not usually committed by demented persons, yet they occasionally happen, and when they do, the well known and established character of the defendant is easily determined. The adoption of intelligent measures for the suppression and minimizing of crime is a subject that will always demand attention. It is a social question connected with government, and has many legal relations, but has as well a broad medical side to which the attention of the profession should be turned. Much may be done to awaken public interest in reformatory methods and to create a proper sentiment in relation to the custody and care of criminals, particularly such as are of the degenerate type or who suffer from the effects of an outbreak of actual insanity. The punishment of the criminal has more to do with the personality of the individual than with the crime itself. The subject is closely connected with questions relating to immigration and the importation of the degenerate, the

defective, the insane and the habitual criminal. It relates to the sequestration of all so affected, which custody not only confines the individual but limits for a time or permanently the exercise of his reproductive functions.

## SURGERY OF THE KIDNEY.

BEING A STUDY OF A SERIES OF CASES IN WHICH  
METHODS OF DIAGNOSIS AND TREATMENT  
ARE ILLUSTRATED.

BY BAYARD HOLMES, B.S., M.D.

PROFESSOR OF SURGERY IN THE COLLEGE OF PHYSICIANS AND  
SURGEONS OF CHICAGO.

### PERSISTENT RENAL HEMATURIA.

There are still many dark chapters in pathology and clinical medicine. To one of these belongs the subject of this paper. It can only be illuminated by calling the attention of the profession to the clinical features of these obscure cases and bringing to light the experience of the profession, which lies hidden in the literature and the note books. This paper tries to accomplish these two things and leaves for the fortunate pathologists the task of demonstrating the pathologic lesions of what seems to be a clinical entity.

Renal hematuria is to be distinguished from hemoglobinuria by the presence of blood corpuscles in the urine coming from the kidney in the place of urine stained with the coloring matters of blood.

The case here recorded and the collection of those relatively similar from recent medical literature seem to point to an unknown condition, or series of conditions, of which renal hematuria is the principal symptom. This condition has been met with in nearly all the hospitals of the world and it has been given, in the hospital reports, that clinical diagnosis, hematuria, which is so unsatisfactory to the pathologist. Thus, in the Berlin Charité, during five years ending 1893, there were 124,000 admissions, of which 22 received the diagnosis of hematuria. In the English reports this diagnosis is still more frequent.

Renal hematuria is common enough in injury of the kidney, in nephritis, in acute infectious diseases, in scurvy, in tuberculosis of the kidney and in calculus and new growths in the kidney. In the case before us the bladder showed no evidence of tubercular disease. The examination of the urine rejected nephritis and the examination of the blood excluded malaria. No detritus or formed elements, such as might reasonably be expected in cancer or other tumors could be found. No tubercular bacilli could be discovered in the sediment. The history had, to be sure, a distinct trend toward an acute local disease of the left kidney, but the condition of the urine from the two ureters pointed to a bilateral or to a constitutional disease.

This case, however, was carefully examined, the general conditions noted, the complete genito-urinary examination made and the contraindications to the removal of the left kidney, required by the clinical diagnosis, were made imperative.

The study of hematuria should always be prosecuted with the greatest care and exactness. The possibilities of tuberculosis, tumor, cancer and calculus are such grave possibilities that no means of diagnosis can safely be omitted. The urethra should be dilated, the bladder examined with the cystoscope and the catheters passed into each ureter, and even up to the pelvis of the kidney.

The danger of producing a ureteritis or a pyonephrosis, by the use of the ureteral catheters must not be forgotten. Nevertheless no case is recorded in which an unfavorable result has followed ureteral catheterization in the hands of experienced and careful operators. Casper<sup>1</sup> reported before the Medical Congress at Wiesbaden, that in 250 cases, of both men and women, in which the ureteral catheters had been used by him no case of infection had occurred. This procedure, like every other surgical operation, should, however, be employed only when adequate indications for it exist, and should, when such indications are present, never be neglected.

*Synopsis.* A multipara, 39 years old, with no history of hereditary or personal hemophilia; an acute painful attack in the left side accompanied with hematuria, which continued two years. This hematuria increased by exercise. A tender left kidney. Less than the normal amount of very bloody urine from the left ureter; more than the normal amount of less bloody urine from the right kidney; rest in bed and milk diet without improvement. Antisyphilitic treatment added; great improvement.

Mrs. C., 39 years old, was placed in my care in St. Luke's Hospital on April 14, 1896. She was a thin, anemic woman. She had never had malaria. Her husband has had an uncertain venereal history. Her mother is still living, but has some sort of skin disease of an unknown character. Her father died from an operation for hemorrhoids. No history of hemophilia in the family. One sister died of acute pulmonary tuberculosis. The other members of the family are in good health. Menstruation began when she was 13 years of age and was regular up to the time of the present illness. She was married at 18 years, had one child now 16 years old, and some years later had a miscarriage. Her present illness began two years ago with pain in the left side in the region of the kidney and with bloody urine. She was sick in bed at the time with chills and fever for several weeks. She does not know whether the pain or the bloody urine appeared first. During this sickness poultices were applied to the left side and back. The pain has been almost constant ever since. Bloody urine has been the most pronounced symptom of the disease. It is greatly increased on any exertion. The patient has lost twenty-five or thirty pounds and now weighs about 100. She is excessively anemic. The heart's action is violent on the slightest exertion. No evidence of disease could be found in the nose, throat, eyes, ears, or lungs. There was no heart murmur, no lymphatic enlargement, no enlargement of the spleen or thyroid. Since this disease began menstruation has been irregular, sometimes missing two or three months and the flow has been very scanty and watery. On admission she was put on a milk diet, her temperature was 99 degrees F., pulse 72, respiration 22. Twenty-eight ounces of dark bloody urine of an acid reaction and a specific gravity of 1.016 was passed in twenty-four hours. No pus, casts or formed matter, except blood corpuscles, could be found in the sediment, which was precipitated by the centrifugal machine. Examination of the kidneys demonstrated a body moving with each inspiration in the site of the right kidney; in the site of the left a similar body could be felt much less movable and very sensitive to a rolling pressure. The examination was easy on account of the spareness of the patient and the relaxed condition of the abdominal walls. The other abdominal organs seemed to be in normal position and of normal size. The spleen

<sup>1</sup> Berlin klin. Wochenschrift, Vol. 1, 1896.

was certainly not enlarged. The heart's apex was three inches from the median line, and while sitting, a little below the fifth interspace.

On April 14, the left ureter was catheterized and one cubic centimeter of urine, dark with blood, was collected in fifteen minutes. This urine after the removal of blood and albumin, contained 17 grams of urea to the liter. The right ureter was also catheterized. There were 10 cubic centimeters of bloody urine passed in fifteen minutes, containing 28 grams of urea to the liter. By vaginal examination the ureters could not be felt and they were certainly not thickened or enlarged. The interior of the bladder was pale as were all the other mucous membranes of her body. There were 3,500,000 red blood corpuscles per cubic millimeter in her blood. She had had several wounds, but never any symptoms of hemophilia.

It was evident from the examination that the discharge of blood in the urine was not a local disease and the anemia contraindicated the removal of the left kidney, which seemed to perform some little function. The patient was, therefore, put to bed on a milk diet and after a time of no improvement, antisyphilitic treatment was begun. During two months of this treatment the patient gained twenty pounds and the amount of blood in the urine was greatly diminished.

At a recent examination of her urine, about July 15, great improvement was noticed. The urine free from blood and albumin is high colored, 4 or 5 on Vogel's scale. There is about one-half the normal quantity in twenty-four hours, namely 500 cubic centimeters. The normal solids are also about one-half the normal average except uric acid which is relatively in excess and absolutely normal. The albumin is 0.2 per cent. by weight. The urea is 26 grams in twenty-four hours. There are no formed elements in the sediment except a few red blood corpuscles.

This is a very interesting case from the clear history of the disease of the left kidney, the large amount of blood in the urine and the almost absolute clinical indications of a unilateral disease, which might be helped by the removal of the left kidney. The examination of the urine from the two ureters, however, seemed to me a complete contraindication to the operation as it demonstrated the same disease on the other side. The anemia also was a contraindication to any operation, which did not promise to entirely arrest the hemorrhage. The value of catheterizing the ureters is not better shown than by this case. Before any operation is undertaken on the kidney both ureters should be catheterized and the results compared with the combined urine for twenty-four hours.

The pathology of this case is undemonstrated. It is evidently not a case of malaria, as the blood examination and the small spleen plainly showed. There were no parasites in the urine. Neither ureter was enlarged. Enlargement of the ureter might be expected in suppurative or tubercular disease of the corresponding kidney. The fact that some improvement was made under antisyphilitic treatment might be considered by many a positive diagnosis, but to me this fact does not warrant the conclusion. There are many cases in the literature which resemble this one in nearly all particulars.

In December, 1890, Senator<sup>2</sup> presented before the Berliner Medicinische Gesellschaft an interesting case of renal hematuria. The patient was a girl 19 years old, who gave a history of hereditary hemophilia. The cystoscope showed that the blood

came from the right ureter. Rest was tried without success. The kidney was exposed by lumbar incision and appeared normal. The hematuria was so great that extirpation of the kidney was considered necessary to save the life of the patient, which was threatened by the anemia. Sonnenburg, who was present, agreed in the conclusion of Senator to perform nephrectomy. When the kidney had been removed it still appeared normal. Microscopic examination discovered the fact that the hemorrhage occurred inside Bowman's capsule and that the urinary tubules contained blood. In the discussion Senator referred to three other cases of a similar nature, one reported by Sabatier.<sup>3</sup> The patient was a woman 30 years old. Pain in the region of the kidney came on suddenly, with dyspnea, vomiting, strangury and bloody urine. The hematuria continued seven years. The patient gave a tubercular family history and had a cough. Repeated examinations showed tenderness of the right kidney, but no tumor. The other abdominal organs were perfectly normal. There was no gravel and no pus in the urine. During the year her case was under observation various diagnoses were made, namely, 1, tubercular kidney and rheumatism; 2, tubercular peritonitis and uremia; 3, paroxysmal hemaglobinuria; 4, nervousness, simulation, and 5, calculous nephritis. Oct. 16, 1886, Sebatier extirpated the right kidney. No stone was found and the microscopic examination did not demonstrate anything abnormal except a slight sclerosis. Sabatier considered the kidney perfectly sound. After forty-eight hours of bloody urine the last trace of blood disappeared and the patient recovered perfectly. Shede<sup>4</sup> is also quoted by Senator as reporting the following case: A strong, well man, 50 years old, with no hereditary taint, had very bloody urine for years, coming on after taking a cold drink. The bladder was found normal. The urine contained red and white corpuscles in their normal ratio to each other, but no other formed elements. Through a suprapubic cystotomy opening the two ureters were catheterized. This procedure showed that the blood came from the left ureter alone. Five days later, July 1, 1889, the left kidney was explored through a lumbar incision. It did not appear abnormal and nothing was found in the pelvis. It was, however, removed, but the microscopic examination demonstrated no adequate cause of the hematuria. Lanphear<sup>5</sup> observed a case of hematuria in a man 55 years old, but he did not catheterize the ureters and made the diagnosis of renal hematuria by washing out the bladder with boric acid solution and finding the fresh injection clear.

Broca<sup>6</sup> recites a case which is interesting in this connection. The patient, well until the present illness, was confined two years before with a perfectly normal puerperium. She served nineteen months as a wet nurse. Menstruation began nine months after confinement. In July, 1890, one month after weaning the child, hematuria appeared with indistinct pain in the right side. This advanced little by little with increasing pain in the right lumbar region; in the left side there was only occasional tenderness. After thirteen months of hematuria, very great lassitude appeared. One physician diagnosed a downward dis-

<sup>6</sup> Broca, A.: Hémophilie rénale et hémorragies rénales sans lésion connue, Ann. malad. des org. genito-urin. December, 1894.

placement of the kidney, a truss was worn without improvement. Sixteen months after the beginning of the hematuria Broca first saw the patient and on strong pressure only could tenderness of the right kidney be demonstrated, but no enlargement or displacement. There was no colic. The urine was uniformly mixed with blood. There was frequent and painless micturition. The patient was in good condition and had a good appetite. A most careful examination of the urine gave no evidence of tuberculosis and no evidence of carcinoma. Rest in bed and a milk diet were tried without effect on the hematuria, which lessened a little during menstruation to increase again after it was over.

On Dec. 17, 1891, the kidney was laid bare through a lumbar incision, peeled out of its fat capsule and brought to view in the wound. Inspection and palpation failed to demonstrate anything abnormal. Exploratory nephrotomy revealed nothing more. This diagnosis was confirmed by Hartmann and Terrier, who stood by. The kidney and wound were closed, the latter without drainage, and recovery followed. The first urine passed after the operation was bloody, after that there was no more hematuria and no more tenderness in the right kidney. The patient was seen occasionally for three years and she remained perfectly well. It would have elucidated this case if the ureters had been catheterized. We do not know that the blood came from the right kidney alone.

Passet<sup>7</sup> describes an interesting and obscure case of renal hemorrhage in a woman who had four children. The first attack came on after menstruation and the next one six months later. It was considered a case of vesical hematuria and was treated by injections of nitrate of silver solution. Cystoscopy was impossible on account of the hemorrhage. Digital exploration discovered a small tumor (?). Suprapubic cystotomy was performed and the bladder found perfectly normal in appearance, the ureters were catheterized and the blood found to come from the right ureter alone. On account of the anemic condition of the patient it was not thought best to do nephrectomy at once. The bladder was sewed up and the patient recovered. The urine became clear and continued so for two years, when a transient attack of hematuria came on again. No similar attacks appeared during the following year during which she was under observation.

A somewhat similar case is reported by Stavely.<sup>8</sup> The patient was, a multipara, 39 years old, who noticed blood in the urine two months after the birth of her last child. It was intermittent, but at last it came on every other week. She was anemic, 3,172,000 red, 10,000 white corpuscles per cubic millimeter of blood. The urine was very bloody and contained 110,000 red blood corpuscles per cubic millimeter of urine. No tubercle bacilli could be found in the urine. The bladder was found clear, the left ureter was catheterized and 10 minims (.66 cubic centimeters) of reddish yellow urine containing blood corpuscles was passed in five minutes. This was repeated on the following day, but it was not possible to pass the sound into the right ureter in the ordinary manner. An incision was therefore made in the base of the bladder and the right ureteral orifice exposed and catheterized. The urine from the right kidney contained a

trace of blood, the wound in the bladder was closed with silk-worm sutures. The left kidney was then exposed and explored by a deep incision into the back of the kidney down to the pelvis. No disease could be found. The wound was closed. The patient recovered and the hematuria disappeared.

The second patient was probably 35 or 40 years old had borne children. A year ago she suddenly developed hematuria without any known cause, which hematuria had continued, with slight exacerbations ever since. The urine had a specific gravity of 1.020. It was slightly acid and contained quantities of blood but no casts. The ureters were catheterized simultaneously by touch. The bladder was full of methyl blue solution at the time. In fourteen minutes, 20 minims (1.3 cubic centimeters) of dark bloody urine was obtained from the left kidney and 10 minims (.66 cubic centimeters) of clear amber urine free from albumin from the other. The left kidney was exposed and incised along its back while the renal vessels were compressed between the thumb and finger, but no disease could be detected. The kidney was closed with gauze drainage. The wound was also closed. The amount of blood in the urine gradually disappeared until the fifteenth day after the operation, when it was all gone and never returned.

Denny<sup>9</sup> of St. Paul, Minn., reports a case of persistent hematuria and uses its ultimate recovery without operative procedure as an argument against early operation. It would be more logical from these data to insist upon an exact and absolute diagnosis. The history is very clear, but no positive diagnosis was made and as the man, who was 39 years old recovered promptly with vesical injections of nitrate of silver solutions, and has since remained well, it is possible that he suffered from hemorrhage of the bladder.

1. Renal hemorrhage can be demonstrated only by the catheterization of the ureters and kidneys, and these procedures should always be accomplished before nephrotomy or nephrectomy. The Pawlick or Kelley instruments may be used with females, but the Casper or Nitze instrument must be employed in males.

2. The patient should undergo a most careful observation in the hospital and a protracted rest in bed with a milk diet before an exploration of the kidney is made.

3. There is some unknown pathologic condition of which hematuria is a symptom, which has not yet been explained, and this condition seems to be relieved in some cases by nephrotomy and in others by palpation of the exposed kidney.

## LUXATION OF THE ENSIFORM PROCESS. BY LUCIEN LOFTON, M.D.

ASSISTANT TO THE CHAIR OF ANATOMY, AND ASSISTANT DEMONSTRATOR OF ANATOMY, SOUTHERN MEDICAL COLLEGE, ATLANTA, GA.

Dislocation of the xyphoid appendix is a rare occurrence, and only a few instances have been recorded. Owing to the rarity of this accident, I deem it important to give it publicity.

The patient, a German, aged 33 years, and of of a robust build, consulted me for what he termed "chronic indigestion" about one year ago. He gave the following history: About three years prior to coming to the city he was in Philadelphia on a visit. During his meanderings he inbibed too freely and mistaking a lamp post for the middle of the sidewalk ran against it with great force, receiving a terrific blow, as he explained, about the "pit" of the stomach. The blow felled him to the pavement where he lay unconscious for a few minutes. He was removed to his hotel where he rested fairly well the night of the accident. During the night he vomited freely several times, which seemed to give him relief. The next morning the patient left for his home before medical attention was summoned. After his return home the man was enabled to transact his usual farm duties after an elapse of two or three weeks. The patient has lived in this city for some time and has for the past several months been a sufferer from indigestion, which he says was invariably accompanied by vomiting. This is especially the case if he lies down directly after eating.

Upon examination I found a complete luxation of the ensiform cartilage from the gladiolus, which could be moved easily in all directions.

This manipulation gave the man some pain, and caused him to say several times he "felt sick at the stomach." I tried all manner of palliative measures which proved useless. I suggested an operation with a view to anchoring or extirpating the offending member, but this was not acceded to. The man has been, for the past half dozen months losing flesh steadily, and his weight is now, I learn, in the descendency.

Since consulting me a short while ago, I am informed, the man has moved to some point in Texas.

306 Equitable Building.

## SELECTIONS.

**Anti-Choleraic Inoculations.**—Dr. W. J. Simpson submits the results of the anti-choleraic inoculation work as carried on in Calcutta during the past two years.

The vaccins used for this work are prepared in the laboratory by a specially trained medical officer and the inoculations in the bustees and other parts of Calcutta are done by another medical officer.

The following records of the inoculations are kept in the Health Office:

1. A daily register filled up at the time of inoculation containing name, father's name, sex, age, caste, occupation, residence and place of inoculation; also any relative who may be inoculated.

2. An alphabetical register containing the names of the inoculated with the above details, so that ready reference can be

made as to whether a person attacked with cholera has been inoculated.

3. A ward register showing the residence of the inoculated people, so that when any particular locality is affected with cholera the inoculated in that locality may be easily found.

The number of people inoculated during the period under review was 7,690; of these 5,853 are Hindus, 1,476 Mahomedans, and 361 other classes. Considering that the system is a new one, that the inoculations are purely voluntary and everything connected with them has to be explained before the confidence of the people can be obtained, and considering how long new ideas are in taking root among the general population, and in this case it is not merely the acceptance of idea, but such faith in it as to consent to an operation, the number is certainly satisfactory for a beginning.

The present problem can be compared with the introduction of vaccination against smallpox in Calcutta. It took twenty-five years before the number of vaccinations reached an average of 2,000; whereas the inoculations against cholera have in two years nearly doubled that average. This is proof that in spite of the difficulties which every new movement naturally has to meet with, there are large numbers of people anxious to avail themselves of the protective effect of the inoculations.

There is a certain discomfort produced by the inoculations, such as an attack of fever lasting about twenty-four hours, pain at the seat of inoculation on moving, thus interfering with heavy physical work for about thirty-six hours. The discomfort is not, however, worse than that induced by vaccination when the vesicles have risen well, and it has the advantage of not lasting nearly so long. The method of inoculation has been recently simplified by dispensing with the first vaccin, the second now being used directly in smaller doses. This increases slightly the degree of discomfort, but does away with the necessity of undergoing two inoculations. As in vaccination, the symptoms after inoculation, *i.e.*, the degree and duration of the fever and local effect vary according to the idiosyncrasy or peculiarity of constitution of the inoculated person; but it is necessary to prominently bring to notice that although all sorts and conditions of individuals, weak and strong, sickly and healthy, young and old, well nourished and badly nourished, and often persons suffering from chronic diseases have been inoculated in every instance without exception, the inoculations have proved perfectly harmless. In several instances, like that lately in Serampore, reports have been spread that injuries have followed the inoculations; on investigation it has been proved by the official medical and civil authorities that these reports were absolutely untrue. Since the system is new and disquieting rumors are harmful it is important that the Commissioners should know the real state of things in order that they may be able to give assistance in dispelling any false notions on the subject.

When an epidemic, such as cholera, attacks a town there are always localities and classes of the population which are not reached by the infection, while on the other hand, even among those who are actually exposed to the infection there are a number who escape owing to their hereditary or gradually acquired powers of resistance. As a rule outbreaks occur in particular localities and houses. The investigations on the effect of the inoculations are made exclusively in those houses in which cholera has actually occurred, the object being to ascertain and compare the incidence of cholera on the inoculated and not inoculated in those houses in which inoculations have been previously carried out. For this purpose affected houses in which inoculations have not been performed and inoculated houses in which cholera has not appeared are excluded as they do not generally furnish a reliable basis for comparison.

In seventy-six houses there were eighty-nine deaths from cholera, seventy-seven being among the uninoculated and

twelve among the inoculated. The following is an analysis of the observations showing the relative resistance to cholera of the inoculated and not inoculated and the distribution of the occurrences in time.

As in six houses in which uninoculated people were attacked and the inoculated escaped, the number of inoculated present was under one-tenth of the total inmates, thus allowing very little chance of the inoculated being affected; these are not counted in the subjoined tables. As regards the rest the result is the following:

Among the uninoculated members after—		1, 2, 3, 4, 5, 6, 9,
Among the inoculated of the same households after 0,—		2, 3, 4, —
12, 13, 15, 17, 22, 24, 37, 44, 57, 62, 63, 71, 95, 99, 109, 114, 118, 119, 120, 129, 132, 139,	219,	—
143, 162, 189, 191, 203—	240, 251, 271, 281, 284, 300, 309, 318, 319, 334, 356, 359, 362,	—
370, 372, 378, 383, 384, 386, 391, 393, 394, 401, 404, 408, 416,	421,	433, 446, 448, 453
472, 493, 498—	675,—	720, 723, 724,—and 738 days.
512,—	688,—	785 and 788 days.

This statement shows that: 1, during the first 4 days after the inoculation cholera occurred among the inoculated and non-inoculated, though in a smaller degree among the inoculated; 2, after the first 4 days there was a period of over a year when there was almost absolute freedom among the inoculated, while among the non-inoculated in the same houses cases were occurring during the whole year; and 3, after this period cases began gradually to reappear among the inoculated as well as among the non-inoculated.

The grouping of the data according to these three periods gives the following results. In the houses where cholera occurred during the first 4 days, a period in which the protective influence of the vaccin is gradually asserting itself, there were 169 uninoculated individuals, who had 6 deaths (3.59 per cent.) and 3 attacks ending in recovery, and 259 inoculated persons who had 5 deaths (1.93 per cent.) and 1 attack with recovery.

In the houses where cholera occurred during the second period extending over a year, there lived 502 non-inoculated who had 42 deaths (8.37 per cent.) and 5 attacks ending in recovery, and 269 inoculated who had 1 death (0.37 per cent.).

In the houses where cholera has occurred during the third period, *i.e.*, more than a year after inoculation, there were 238 uninoculated who had 23 deaths (9.66 per cent.) and 3 attacks with recovery, and 96 inoculated who had 6 deaths (6.25 per cent.).

Thus a comparison of the proportion of deaths among the inoculated and non-inoculated in the three periods gives the following result: During the first period of 4 days the number of deaths among the inoculated was 1.86 times smaller than among the not inoculated. During the second period lasting over a year the number of deaths among the inoculated was 22.62 times smaller than among the non-inoculated; and during the third period, *i.e.*, more than a year after the inoculation, the number of deaths among the inoculated was only 1.54 times smaller than the non-inoculated.

Of the six inoculated belonging to the last group, who were attacked more than a year after inoculation, five had received only one inoculation with the first weak anti-cholera vaccin, and the sixth, inoculated on June 3, 1894, had two inoculations given in very weak doses, as was practiced before the observation made in July and August, 1894, in the East Lancashire Regiment in Lucknow. In this observation at Lucknow it was shown for the first time that the effect of weak doses with which the inoculations were begun in India, tends to disappear as time goes on and is confirmed by the Calcutta statistics. This fact brings the Calcutta statistics into conformity with those obtained in other parts of India and thus confirms the accuracy of the observations made. Since the latter part of 1894 the doses used in the treatment and the strength of the vaccins have been increased, with the object of producing a more lasting effect. But no figures are as yet available to demonstrate whether by such increased doses the object we aim at is actually obtainable.

Without excluding the occurrences of cholera in the inoculated during the four days necessary for treatment, and considering the results for the whole period of time, from the first day of the operation in Calcutta up to the end of last month, the results are as follows: 654 uninoculated individuals had 71 deaths (10.86 per cent.), while 402 inoculated in the same households had 12 deaths (2.99 per cent.). This shows that notwithstanding the incomplete protective effect of the first four days and the gradual disappearance of the resistance in those inoculated with weak doses of weak vaccins, which a large number of the inoculated people have received, the mortality amongst the inoculated, compared with that of the uninoculated, was in the proportion of 1 to 3.63, giving a reduction of mortality of 72.47 per cent., or in other words, in houses where inoculations were performed, and which were subsequently visited by cholera there occurred for eleven deaths amongst the uninoculated, three deaths amongst a similar number of inoculated.—*Ind. Med. Record*, August 1.

**The Dangers of the 'Cycle.**—The *Lancet* for July 11 has a well-considered special article on the above subject, which concludes as follows: "Two serious sources of danger are the use of the crowded roads by learners and the hiring of machines to novices. A busy road would seem to be the last place a sensible person would select for learning to ride a bicycle, yet three deaths have taken place from this cause within the past few weeks. The hiring out of bicycles to children and roughs bent on what they call a 'speer' should be checked by law. It should be quite possible to license those who let out cycles for hire, and such persons should be made responsible if an accident occurs through the letting out of a machine to an incompetent person. Our contemporaries who are devoted to the interests of 'wheeling' have, we know, already done good service in this respect, but we venture to assert that if they would impress even more strenuously upon the cycling public the importance of strictly attending to some such simple rules as the following much good would ensue. These rules are not intended to be exhaustive nor are they for the expert cyclist, although even the experienced rider should not ignore them. Thoroughly examine your machine before starting on a journey. Do not ride without a brake, which should be attached to the back wheel if possible. Beware of tram lines, especially when they are wet. Avoid turning sharply on a wet or 'greasy' road. Pass horses at a slow speed. Never take the feet off the pedals when riding down hills. Do not ride with the hands off the handles, especially in crowded thoroughfares. Ride carefully when passing side streets or the carriage entrance to houses. Before attempting to pass another vehicle ring the bell when at least twenty yards distant. This will give the rider time to see what the intentions of the driver of the vehicle in front are, and will enable the cyclist to take precautionary measures in time should such be necessary. When riding in parties vehicles should be passed in single file. Warning by the bell should be given in as gentle a manner as possible. The sudden ringing of a loud gong is apt to cause a pedestrian to lose his presence of mind and run into the very danger it was the intention of the cyclist he should avoid. When riding behind vehicles in a crowded thoroughfare be prepared to dismount at a moment's notice if necessary. Keep on the proper side of the road. Ladies should not attempt to ride in the public thoroughfare until they have absolute control over and confidence in their machine. They should keep as near as possible to the curb and ride slowly. Those who wear a skirt should see that it is not too long. It should be lined in front with some glazed material to prevent friction, and all loose drapery which is likely to be caught by the wind and perhaps caught in the machine should be avoided. In addition we would suggest that persons who let out cycles for hire should be under the control of the police. It should

be a punishable offense to let out machines not in proper order, and no child or other incompetent person should be allowed to hire a machine. It should be possible for the police to prevent novices learning in the public thoroughfares."

**On the Management of the Tuberculous at Hotels.**—The Pennsylvania Society for the Prevention of Tuberculosis, under the presidency of Dr. Lawrence F. Flick, has published circulars of information for gratuitous distribution. The third tract of the series treats of the duties of hotelkeepers in relation to their infected and non-infected guests. Among the points brought out are the following: The linen, etc., of consumptives should be washed separately and should always be well boiled before being washed. The persons to whom such articles are given to wash should be properly instructed as to what to do in order that they too may be protected. As far as practicable, consumptives in the advanced stage of the disease should be assigned to separated tables, in order that their tableware and linen can be kept apart from those of the other tables and washed separately. All such tableware should be boiled before washing. "All parts of a hotel or boarding house which are likely to be frequented by consumptive guests should be well supplied with cuspidors in which there should be at all times a germicidal fluid. This fluid should be changed once a day and the cuspidors should be thoroughly scalded with boiling water. In conspicuous places throughout the house and especially in the rooms assigned to consumptive guests, there should be notices requesting guests never to eject sputa into any place other than the cuspidor, and suggesting that a handkerchief should never under any circumstances be used for the reception of such sputa where a spittoon is at hand. When out upon the lawn, or in any place where a cuspidor is not of convenient access, the sputa should be ejected into paper handkerchiefs, these to be placed, upon returning to the room, in a receptacle furnished for that purpose; such handkerchiefs should not be thrown into the ash bin but burned by the chambermaid. After a room has been occupied by a consumptive, it should be carefully cleansed before another guest is assigned. Where the rules already laid down have been observed, wiping the walls, floor and furniture with a sponge dampened with a germicide solution, whisking the rugs with same solution, and sending the sheets, blankets and pillow cases and counterpanes to the laundry, will be all that is necessary. Where, however, no care has been observed and the consumptive has been careless about spitting on the floor, or into linen, silk and muslin handkerchiefs, or where the bed clothing has been visibly soiled with broken down tubercular tissue, it will be necessary to carefully rub the walls with fresh bread and then wash them with a strong germicide solution, to wash the floors and furniture with the same strong solution, to have all the bed linen and blankets thoroughly boiled and to have the rugs and other articles which can neither be subjected to strong germicide solution nor boiled, sent to a renovating place and steamed."—*Annals of Hygiene*, September.

## PRACTICAL NOTES.

**Silico-Fluorid of Mercury.**—This salt has been recommended as being twice as energetic as corrosive sublimate as an antiseptic. It is far less poisonous than the latter salt, hence it deserves attention. It is used in aqueous solution 1 to 1,000.—*Pharm. Era*, September 3.

**Acrocyanosis.**—Crocq described at the recent Neurologic Congress in France a disease he has observed in two hysteric young women, which he calls acrocyanosis. It resembles Raynaud's disease and also Charcot's blue edema, yet it is distinct from both. Raynaud's disease ebbs and flows, with severe pains, a tendency to the formation of gangrenes and

phlyctenæ, and a loss of sensibility in the skin. Acrocyanosis on the other hand, is a permanent condition, without severe pains or the other symptoms above. Charcot's blue edema is accompanied by paralysis, paresis or contractions, which are all absent in acrocyanosis. The three diseases all originate in disturbances of the nerve centers, but he considers the latter essentially a hysteric vasomotor phenomenon.

**Plastic Surgery.**—The *Jour. des Sciences Méd. de Lille* for August 15 describes a case where a cutaneous epithelioma on the ankle, 12 by 9 centimeters, was removed, a pear-shaped living flap from the thigh sutured in its place and the leg flexed against the thigh in a plaster cast. A small flap cut above was twisted around to cover the center of the open space, leaving only a couple of unimportant spaces at each end uncovered.

**Treatment of Measles.**—Dr. C. S. Merriman says that when the eruption does not appear or when it recedes we have complications. In such cases he employs the following treatment: Take a flannel blanket, wring it out of water as hot as the hand can bear and wrap patient up in this, with cold cloth on the head. Keep him in the pack about twelve or fifteen minutes; then transfer him to a dry blanket and allow him to cool gradually. This brings the eruption to the surface and relieves the mucous and serous membranes. If necessary give antipyretics for the fever and sedatives for the cough. He never has complications when this line of treatment is used. When there is bronchial cough he prescribes a combination of terpin hydrate and codeia sulphate made into an emulsion with syrup of acacia.—*K. C. Med. Ind.*, September.

**Further Experiments with Serum Treatment of Cancer.**—The *Revista Chilena de Higiene*, No. 6, describes at length the treatment of a number of cases of inoperable cancer with serum from asses and goats that had been inoculated with cancerous tissues. The results were not as favorable as those obtained by Richet and Hericourt, the only effect being the improvement of a few symptoms, the most notable, the relief from pain. The discharges also ceased to be fetid. The general health improved at first, but afterward grew worse, with increased emaciation and cachexia. The other symptoms were unaffected. He injected usually 2 c.c. every other day, or less frequently, never more than 5 c.c. on account of the tendency to produce fever. He adds, with the odd Spanish inverted interrogation point: ¿ will larger doses secure better results? And he remarks that our impotency in these malignant cases, fully justifies these hazardous experiments.

**Use of Forceps in France and Germany.**—An article in the *Revue Int. de M. et de C.*, August 10, compares the statistics of the use of the forceps in obstetric cases in France and Germany, greatly to the advantage of the French methods. The superiority of Tarnier's forceps which are used in France, to Nægele's which the Germans use, is one cause of the better results obtained. But the chief cause is the method of applying the forceps. In France the head of the fetus is seized symmetrically from ear to ear, the axis of the blades corresponding to the occipitomeatal diameter, except in superior strait cases. The practice in Germany is the reverse of this. The forceps are applied symmetrically to the axis of the pelvis, and the fetal head is seized as happens to be convenient. The statistics show the results in the frequent lacerations and elevated fetal mortality.

**Treatment of Phlyctenular Keratitis.**—Dr. M. F. Coomes commends a solution of eserine as the best remedy. It is a myotic, contracting the pupil closely, and by so doing excludes the excessive amount of light, and reduces intolerance to a minimum. In addition to the mechanical action upon the pupil, it also produces contraction of the capillary blood vessels, stimulating them, and bringing about a healthy condition of the ulcer, which can be accomplished by no other agent so readily.

The solution need not be strong, two grains to an ounce of water being quite sufficient for most cases. And its application should be made twice a day, and if there is great intolerance of light, three times a day. He advises no other local application.—*Louisville Med. Mo.*, September.

**Chronic Cystitis.**—Dr. S. B. Johnson used the following formula in a severe case of chronic cystitis:

R. Syr. yerbæ santæ . . . . .	32.0
Syr. simplex . . . . .	64.0
Eucalyptol . . . . .	16.0
Aquæ destil . . . . .	16.0

M. S. Shake well. Dose, a teaspoonful every two hours.

The patient was unable to pass his water without the aid of a catheter, and his urine was loaded with mucus. In the course of a week he began to pass his water without the aid of the catheter. In addition to the use of the eucalyptol he gave the following to keep the urine alkaline:

R. Comp. infusion buchu . . . . .	470.0
Bicarbonate soda . . . . .	4.0
Bromid of potassium . . . . .	7.5

M. S. Shake well. Dose, a wineglassful every four hours.

Under this treatment the patient recovered, and he attributes the rapid improvement to the action of the eucalyptol.—*Northwestern Lancet*, September.

**Absorption of Iron by the Organism.**—Gaule's interesting experiments to determine the method of absorption of iron in the organism are described in the *Deutsche Med. Woch.*, No. 19. They confirm Hall's statement that the absorption occurs in the duodenum alone, and not in the stomach or small intestine. Not only organic compounds of iron are absorbed, but also the inorganic, like ferric chlorid, but they have first to be transformed into an organic compound by combining with certain substances in the intestine. The iron is absorbed by the epithelium of the duodenum first, and then by the central lymphatic vessels of the villi. As early as two hours after the iron is administered, the quantity of iron in the pulp cells of the spleen is much larger than normal. The process of absorption of the iron is perfectly normal, and does not require any change in the usual processes.

**Treatment of Gout with Piperazin.**—Dr. Hager describes his victory over the gout in his own person, in the *Pharm. Post*, No. 30. After various experiments he found that he had conquered his old enemy with piperazin taken three or four weeks, in fractional doses, with soda water. After the swelling and pains had disappeared, he continued with diminished doses a while longer, 2.5 to 3.0 gr. per diem. The remedy seemed to lose its diuretic power in the course of two or three weeks, and he increased its efficacy at such times by supplementing it with a diuretic, using a decoction of bean pods for the purpose, taken in weak coffee, or with milk and the piperazin, or with the piperazin alone. There were no inconveniences at any time from its use, even at 3 grams a day continuously.—*Therap. Woch.*, August 23.

**Pain after Laparotomy.**—Dr. Byron Robinson has reoperated on a number of cases for annoying abdominal pains which massage, electricity, etc., did not relieve and concludes that the pain in peritoneal adhesions is due to the checking of the peristalsis in a viscus with a long pedicle and an active peristalsis of the sigmoid flexure, loops of small intestines, Fallopian tubes and bladder. The chief site of the adhesions is the cut ends of the Fallopian tubes or some point of the abdomen denuded of its peritoneal endothelia. Adhesions about fixed organs, as the liver, spleen, flexures, etc., do not induce pain, as their limited rhythm is not materially checked. In reoperating we should free all the highly peristaltic organs and cover up with peritoneum all exposed mucosæ or denuded endothelia.—*Memphis Med. Monthly*, September.

**Treatment of Tuberculosis with Baths of Rarefied Air.**—Vergara

Lope and Herrera of Mexico have constructed an apartment where they give baths of dry, equable and highly rarefied air to tuberculous patients. Although they consider it merely an attempt, its success fully justifies further experimentation on a larger scale. They conclude a modest report of what they have been able to accomplish in relieving congestions, strengthening the lungs, etc., with these words: The desideratum is to keep the patients night and day, and for a sufficient length of time to really accomplish a cure (not merely an occasional bath as with our present accommodations), in a highly rarefied, dry and even atmosphere, such as is not to be secured at any known natural point. (The variations in temperature in the mountains destroy much of the therapeutic effect otherwise obtainable there.) One chamber is not enough, but a whole series, fitted up with every comfort and hygienic appliance, and rendered attractive in every way to the patients in their voluntary confinement.—*Revista Quincenal*, July 15.

**Serum Therapeutics.**—Roger concluded his important address on this subject at the recent French Congress of Internal Medicine with these words: In spite of such numerous trials and investigations, serum therapeutics has only produced actually undeniable effects in the treatment of diphtheria. It has proved less efficacious in man than we were led to expect from our experiments on animals. Animals are easily inoculated with disease, while man succumbs only if there is some morbid predisposition or lack of tone in the organism. The serum only works, besides, after a certain period of incubation, and even if administered in time, we are not sure of obtaining a cure as the serum is impotent in regard to the concomitant auto-intoxication. This is the reason why it is impossible to deduce conclusions as to its effect on man from the effects obtained on animals. This is why the experiments in the laboratory are more successful than in the clinics, and why the old methods are not to be abandoned for the new. According to my opinion serum therapy is not destined to supplant the other methods; it should only be considered another weapon to use concurrently with the rest. This rule applies even to diphtheria. In a case of puerperal fever, no matter how great our confidence in serum treatment we should never trust to it alone, but employ all our known weapons to combat the phenomena produced by multiple causes, with means we know to be multiple in their effects. Although it is hazardous to forecast the future, we do not believe that serum therapeutics is destined to revolutionize the art of healing. Its indications must be defined and its use combined with other methods. This is the road for the clinicians to follow. At the same time the experimenters will be improving the antitoxins and eliminating the useless or harmful substances that accompany them. These are the tasks of the immediate future, and when completed new progress will have been accomplished in medical science and new benefits accrue to humanity.

**The Effect of Erysipelas Toxins upon Malignant Growths.**—Drs. L. A. Stimson, A. G. Gerster, and B. F. Curtis, at a recent meeting of the New York Surgical Society, submitted the following report upon the use of erysipelas toxins in the treatment of malignant disease: "We believe that in the instances of apparent cure or marked improvement the correctness of the diagnosis is open to doubt. We therefore submit: 1. That the danger to the patient from this treatment is great. 2. Moreover, that the alleged successes are so few and doubtful in character that the most that can be fairly alleged for the treatment by toxins is that it may offer a very slight chance of amelioration. 3. That valuable time has often been lost in operable cases by postponing operation for the sake of giving the method of treatment a trial. 4. Finally, and most important, that if the method is to be resorted to at all, it should be confined to the absolutely inoperable cases."—*University Med. Magazine*, September.

THE

Journal of the American Medical Association  
PUBLISHED WEEKLY.

SUBSCRIPTION PRICE, INCLUDING POSTAGE:

Per Annum, in Advance . . . . . \$5.00  
Single Copies . . . . . 10 Cents.

Subscriptions may begin at any time and be sent to

THE JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION,  
No. 61 Market Street (Occidental Buildings), Chicago, Illinois.

## MEMBERSHIP IN THE AMERICAN MEDICAL ASSOCIATION.

This is obtainable, at any time, by a member of any State or local Medical Society which is entitled to send delegates to the Association. All that is necessary is for the applicant to write to the Treasurer of the Association, Dr. Henry P. Newman, Venetian Building, Chicago, Ill., sending him a certificate or statement that the applicant is in good standing in his own Society, signed by the President and Secretary of said Society. Attendance as a delegate at an annual meeting of the Association is not necessary to obtain membership.

On receipt of the subscription the weekly JOURNAL of the Association will be forwarded regularly.

Gentlemen already members of the Association should send their annual subscription to the Treasurer, or direct to the JOURNAL office.

All communications and manuscript of whatever character, intended for publication in the JOURNAL, should be addressed to the Editor, and all communications relative to the business of the JOURNAL, proof sheets returned, or in regard to subscriptions, should be addressed to THE JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION, 61 Market Street (Occidental Buildings), Chicago.

Original communications are only received with the understanding that they are exclusively contributed to this JOURNAL.

## INFORMATION WANTED.

It would greatly facilitate the prompt delivery of the JOURNAL to those members of the Association living in large cities, if they would kindly furnish this office with their street address in those cases where it is omitted from the wrapper of their JOURNAL, as we have been notified by the postmasters of the larger cities that second-class mail matter not having street address, would be placed in the general delivery to await call.

SATURDAY, SEPTEMBER 19, 1896.

## THE EXAMINATION OF SCHOOL CHILDREN'S EYES.

An examination of the eyes of 8,125 London school children has just been completed by MR. CARTER, and sent to the Education Department; when we consider the methods of the examination we are surprised to learn that only 39.15 per cent. were possessed of "normal vision." We say in view of the methods of examination, because it is of this aspect we would suggest a qualifying word. It seems from the abstracts of the report at hand that to the teachers was allotted the task of separating the sheep from the goats, in other words they were to ascertain by prescribed methods the pupils that had "normal vision." Those thus diagnosed were apparently not further considered by the ophthalmologists. The fact will doubtless provoke a smile from American oculists, at least from every one worth considering. What public school teacher is capable of diagnosing the refractive condition of a pupil's eye? Having diagnosed "normal vision" how utterly meaningless is the fact! It is as devoid of significance as the findings of the divining rod. Because, no mydriatic being used, it is, as we all know, precisely the cases that have considerable refractive errors covered up by the accommodation, leaving "normal vision," that have the most decided reflex disturbances, headaches, denutrition, etc. The smile of the skilled refractionist becomes something very different from a smile when he thinks of the astigmatism uncorrected in that 39.15 per cent. of normal eyes! And then the remaining 60 per cent., if we had a mydriatic examination of

these, of what interest and value it would be to know accurately the precise refractive errors and muscle-balances! Astigmatism was, of course, found to be extremely rare, whilst with us the eye without astigmatism is almost a wonder. "Slight and moderate degrees of hypermetropia are the most common conditions, and the defect, *if it is to be called a defect*" (italics ours) "is scarcely sufficient to require the use of glasses, and would not be likely to lead to more than a sense of weariness in children who were underfed or taught in badly-lighted schools." This is not ludicrous; it is pitiable! Precisely when food is scarcest, and the lighting the worst, then is the greatest need of relieving the eye from strain. We are glad to learn that there is no evidence of an increase of myopia in the London children.

Another noteworthy finding is much amblyopia not to be accounted for by errors of refraction. (Again we must recall that the examinations were made by the ophthalmoscope and without a mydriatic.) This amblyopia is accounted for by the fact that city children are not exercised in seeing distant objects, but only such as are not farther than the street-width or room-dimensions! Our "ophthalmic surgeons" find other causes for amblyopia, but our English confrères smile at our testings of the ocular muscles and of astigmatism. It should be recognized as a fundamental principle that all examinations of school-children's eyes are utterly valueless to science, and the conclusions drawn from such testings are equally valueless or positively misleading, even concealing the truth, that are not carried out by means of a mydriatic, that do not include a precise estimate of the astigmatism, the anisometropia, and the muscular incoördinations or balances.

## MEDICAL EXAMINERS AND MEDICAL TEACHING.

During the past seven years the course of study in the majority of the Medical Schools of the United States has risen from two years of five months each, to four years of at least six months each. This advance has not been brought about by the action of any one force, but it has been accomplished by the coördinate action of the various State boards of health and by the coöperation of the better class of medical schools in the Association of American Medical Colleges. This increase in time has, in many schools, been accompanied by a greater advance in the methods of teaching and in the scope of the curriculum. The laboratory method of teaching for histology, pathology and various other subjects has been generally adopted. The amount of laboratory work and its quality has not, however, been just what could be desired. In some schools only a few hours a day for a very brief period is required, while in others a large amount of time is spent in the laboratory, but the pedagogic method of presenting the subjects to the

students has not always been carefully considered. The order of the laboratory has been frequently neglected and students have been allowed to form extravagant and slovenly habits and sometimes even have been instructed in erroneous methods of observation and faulty methods of reasoning. The shiftless habit which some teachers practice of preparing histologic specimens, mounting and distributing them to the class instead of requiring each student to catch, kill and prepare his specimens for himself, is all too prevalent. The method of requiring drawings of histologic specimens to be made is desirable and correct, but to permit the use of illustrated text books to define characteristics which poorly prepared specimens fail to discover, is pernicious. Many institutions with clinic advantages have neglected to pay that attention to the conduct of clinics which the real needs of the students demand. The students themselves look for tragic operations and crowd the laparotomy room while they neglect the tedious work of percussion, palpation and auscultation in the quiet of the dispensary. Lecture work still continues to occupy the most prominent place in the course and consume the largest amount of time. The medical library has not yet been utilized as an engine of medical education and most of our graduates still go out with little or no knowledge of the use of the storehouses of medical thought and experimental investigation.

It is probable that the length of the course of study has been sufficiently extended and that the work of the next ten years for medical education will be directed to improved methods of teaching. It is necessary now for the colleges to combine and demand of the State examining boards a rational, flexible and practical examination and one which will bring to the front those men who have most studied the healthy human body, the diseased body and the methods of preserving health and treating disease. Written examinations only will not do this. They encourage pedantry, cramming and a "cuckoo" style of recitation. Actual examinations at the bedside with all the paraphernalia of diagnosis and therapeutics must be substituted at once for the examination at the table. It is not enough to say that this would be expensive and would consume too much of the examiner's valuable time. The examinations are not designed for the comfort of the examiner, but rather for the improvement of the education of students. The great expenditure of money and labor required of the medical schools by the four years' course must be seconded by equal expenditure by State boards. When such examinations are instituted it will be easy to separate the wheat from the chaff and to designate those medical schools that give a real medical education. Until this is done any crowd of young quiz masters can outdo the best equipped college and the most experienced faculty.

#### THE TEACHING OF MATERIA MEDICA AND THERAPEUTICS.

Materia medica has been the *bête noire* of the medical student. The study of its dry and categorical details has been largely a matter of mental gymnastics. In its teaching, instructors have sought to make it more acceptable to the mental palate of the pupil by a liberal admixture—with the uninteresting story of drug origins, pharmaceutic preparations and dose tables—of therapeutic facts. Until recently the text books have adopted the confusing method of merging the treatment of these two, usually allied, but deservedly distinct topics. Their greater dissociation is desirable for the better development of each subject and for the adaptation to each of its own proper method of study.

Dr. HENRY M. BRACKEN, of the University of Minnesota, in an article printed recently in the *New York Medical Journal*, has been the first, publicly, to recognize the necessity for a departure from the customary mode of instruction in these branches. His recently published work, "The Outlines of Materia Medica," is in evidence to prove the possibility of their divorce without damage, at least, to the teaching of the primary subject. It does not meddle, by any serious intention, with the question of therapeutics. Its author holds that these branches, wisely associated under a single chair, have, nevertheless, their proper places in different parts of a medical course. His claim that a certain amount of knowledge of general chemistry and physiology should be pre-attained by the beginner in materia medica is in reason. He adopts, in the first instance, the chemic and biologic arrangement in the study of drugs, the only arrangement which fits the laboratory method of teaching. For materia medica must come into line with histology, anatomy, physiology, chemistry and pathology as laboratory studies. The day of the didactic lecture in the treatment of such a topic has gone by. Of no subject is the lecture a more awkward vehicle of instruction.

The student of materia medica should be, to an elementary degree, a pharmacist. He should see and handle crude drugs and their eligible preparations. He should understand the principles of compounding by practice in the art of preparing materials and putting up prescriptions. Then, and not until then, should he be taught the physiologic action of drugs. And here the laboratory idea again comes forward. The pupil should observe, by illustration, the methods of studying physiologic action in animals and, so far as possible, in men. He should learn the limits of comparison between physiologic action in the human and in other forms of life. All drugs should be recognized with caution—not to say suspicion—whose physiologic effects have not been ascertained or can not be scientifically determined. Such a principle

would tend to the eventual elimination from the materia medica of a large mass of remedies which have ceased to have any clinical importance and never possessed any real therapeutic value. It would go far toward checking the modern heresy of therapeutic nihilism if the materia medica were once and forever purged of these discarded and impotent agents.

Having accomplished this riddance, it would be equally effective, in the encouragement of therapeutic faith, in these days of commercial enterprise and pseudo-scientific ingenuity among the manufacturing chemists, if the laws should require the submission of all new remedial agents to a bureau of scientific investigation connected with a National or with State boards of health. It is remarkable that we should so long have persisted in taxing the student of medicine with the command of weapons, which, in his practical armamentarium, he will never use—which his teacher himself would never employ. Is it any wonder that the graduate, in his mental confusion of drug values, should fall back upon patent preparations or proprietary formulæ?

In a later year therapeutics has its place. It should be taught as an independent study, with its relations to the physiologic action of drugs well elaborated from the laboratory standpoint and its clinical side developed, less in the lecture room than at the hospital bedside and in the dispensary clinic.

By these methods materia medica and therapeutics may be effectively taught and will cease to be classed, as they are now, among the bugbears of the curriculum.

#### THE VITAL AND PSYCHIC COMPLICATIONS IN CASTRATION FOR PROSTATIC HYPERTROPHY.

In the current (September) issue of the *Annals of Surgery* there appears an interesting paper by Dr. A. T. CABOT on "The Question of Castration for Enlarged Prostate," in which the writer takes, on the whole, an unfavorable view of the operation as compared with the older one of prostatectomy. He finds from his analysis of the statistics that, in the matter of mortality, it (castration) has a less favorable showing than prostatectomy, and conjectures that with later statistics reflecting the latest improvements in technique this disadvantage would be still more in evidence. Prostatectomy has also the further advantage of allowing a thorough examination of the bladder and the consequent discovery and relief of other, perhaps unsuspected, morbid conditions. Its disadvantages are the longer confinement and the possibility of fistula. It is applicable, he claims, to more cases than is castration, which is apparently most efficacious in large, tense prostates compressing the urethra, and is of little use in myomatous and fibrous enlargement, while the older operation is, in the hands of a skilful operator, applicable to the relief of any and every

form of prostatic obstruction. It is, moreover, especially indicated whenever an inflamed condition of the bladder makes drainage desirable.

Dr. WHITE, the proposer of the operation and one of the editors of the *Annals*, takes up the question of Dr. CABOT's paper in what seems to be a very ably written editorial and warmly combats some of his conclusions. As regards the mortality of castration, which it would seem Dr. CABOT's statistics make unduly high, he seems clearly to have the advantage of the argument, especially as regards the deduction that the disparity would increase with improved technique in prostatectomy, for he shows by more recent statistics a decided reduction of the mortality, and he further shows from an analysis of Dr. CABOT's own list that certain fatal cases are included in which the final result certainly ought not to be attributed to the operation. The mortality of such an operation as castration certainly ought to be less, it would seem, than that of prostatectomy. As he says, Dr. CABOT's figures are, at any rate, rather small to base such positive statements upon.

As regards the utility of castration in myomatous and fibrous tumors, it would also seem that he had at least as good an argument in its favor as has Dr. CABOT against it, and he shows that the evidence as to the tendency to relapse is not adequate to confirm that author's conclusions. One point mentioned by Dr. CABOT, however, he neglects—that is the question as to the effects of castration on the general vitality, which CABOT claims is probably to some extent reduced by the removal of the organs. That these organs are absolutely without function at an advanced age is most certainly untrue for many individuals, even as regards their special reproductive utility alone. It would not seem improbable therefore that there might yet occur something at least of that general systemic reaction that is so marked in the younger individuals after castration, and that this might manifest itself in a more rapid failure of the vital energies and a quicker succumbing to the onset of senile changes. There is probably a germ at least of truth in the theory of BROWN-SÉQUARD as to the invigorating influence of the testicular secretion; certainly the experimenters in organo-therapy have not lost faith in it altogether. The organs do not atrophy completely, even after their special sexual function has apparently long been lost, and it is only reasonable to assume that they still have some utility in the organism.

The large proportion of cases mentioned by Dr. CABOT in which mental disturbance followed the operation is also noteworthy, even if it is not directly attributable to the character of the operation. We might perhaps expect some more emotional disturbance from an operation of this kind, associated as it is with the idea or recollection of the changes that follow it when performed in youth, and this psychic

element is not altogether a negligible matter. It may even have its share in causing the excessive (as it would appear) mortality that has followed so slight an operation.

While Dr. WHITE appears to have fairly replied to the other objections to the operation, this one is left unanswered, and it may not be an insignificant one. Time, of course, will be required to determine its full value and importance.

#### THE LABOR MOVEMENT AND MEDICINE.

The recent celebration of labor day throughout the country and the great extension and popularity of the so-called labor movement suggest certain questions that may become practical ones in the near future. Every one sympathizes with the desire of the working classes to improve their condition in all legitimate ways and the usefulness of labor organizations under judicious management need not be questioned. That their managers have not always been judicious is evident enough, but that is perhaps to be expected and it is to be hoped that more wisdom may guide their actions in the future than it has in the past. The question that concerns us most especially is that of their extension into certain lines of occupation that have hitherto been free from these complications. Medicine, being a liberal profession, is in no danger of falling into this line; the laws regulating practice are matters of public hygiene, not of private interest, though the medical defence associations that seem to be popular in Great Britain at the present time have some general resemblance to trades union or labor methods. There would, it may here be said incidentally, be no better object lesson of the evils of certain labor methods than a sympathetic strike of doctors, leaving their patients to go, in many cases literally as well as metaphorically, to the devil, according to orthodox beliefs. The nearest approach to this that is likely to occur is what happened, we believe, in England not long since, when the lay management of a certain hospital became so obnoxious that physicians refused to serve on its staff. Such an event would, however, be more the result of the individual expression of professional self-respect than of any combination analogous to trades organizations. There are, however, auxiliary to medicine certain occupations the followers of which can not be expected to be always governed by the high professional motives that are assumed to control regular physicians, and it is entirely possible to conceive of what we denominate labor troubles arising in their ranks. A general sympathetic strike in very many employments could easily have the most disastrous effects on the public health, a railroad strike involving the milk supply for only a few days in a great city would cause a terrible increase of infant mortality, and many other like instances and effects can be easily imagined. To

come down more closely, however, to strictly medical employments, a strike of hospital employes, especially if in connection and alliance with a general strike, would be most disastrous; yet it is a perfectly conceivable possibility. In certain hospitals this contingency is calculated upon and all employment is regulated by contracts requiring notice and other precautionary provisions.

It is not to be supposed that public opinion would support any long extended movement that would have gross inhumanity as its consequence, and it is to be hoped that no labor combination would really deliberately attempt to injure or prejudice the welfare of the helpless and the invalid. It must be remembered, however, that the greatest wrongs are committed not through deliberate malice, but by inconsideration and recklessness, and the inability to see beyond an immediate desired end.

## CORRESPONDENCE.

### Physicians' Cards.

ANDERSON, S. C., Sept. 5, 1896.

*To the Editor:*—Is it contrary to the Code of Medical Ethics or the by-laws of the AMERICAN MEDICAL ASSOCIATION to use on a business or visiting card the words "Diseases of Women and Children," or any other words indicating a special line of practice? If not those words, is the word "Gynecologist" admissible? For instance, "Dr. Leptandrin, Cormes, Florida, Diseases of Women and Children."

Awaiting your reply, am very truly yours, J. O. W.

*ANSWER:* The reading of the Code explicitly says: "It is derogatory to the dignity of the profession to resort to public advertisements, or *private cards*, or hand bills inviting the attention of individuals affected with particular diseases, etc."—Vide Code of Ethics, "Of the Duties of Physicians to Each Other and to the Profession at Large."—Art. 1, Sec. 4. Now this is the exact language of the Code, and is in all well regulated societies regarded as the safest plan to follow.

### The Bicycle.

IRONTON, OHIO, Aug. 30, 1896.

*To the Editor:*—I was greatly pleased to see so sensible an article in the last JOURNAL as that written by Dr. Brown of Birmingham. That the bicycle has come to stay is an assured fact. That more people are going to use them is another assured fact. That we, as physicians, should accept these as facts and devote more time to the "wheel and its effects" is also quite as much a fact. For the masses the wheel has come nearer annihilating space than anything that has so far been invented. Until we have a practical, low-priced flying machine people will continue the use of the wheel despite the fact that it produces pelvic troubles. I do not think, however, that it will produce as many of them as the same amount of horse-back riding. It is no more fair to call the hump-backed, ewe-necked, pop-eyed scorcher the typical bicycle rider than it is to compare the goggle-eyed thing that rides through Central Park to one of Buffalo Bill's riders in his Wild West Show. As long as we have in use the prevailing style of saddle we will have "the hump" because that is the easiest position. When we can have a seat that is flat, or nearly so, and receive its support from the center instead of the ends and has no prominent horn, then, and not until then, will we have what is to my mind, the

correct position. I have had one case of ruptured urethra and several cases of vesical irritation under my care, but have never failed to promptly give relief to the latter when the proper saddle was prescribed. When a fond mother asks me if I think her daughter can ride a wheel I say, "Yes, if the saddle is right." When a man asks me if he can ride a wheel I say, "If you get the right saddle and then use a little common sense." There are many good saddles now being manufactured and if we will use our influence in the right direction "the hump" and vesical irritation will soon be things that are not charged up to the bicycle. I have been a constant user of the wheel for three years, averaging about fifteen miles a day, the year round. Being compelled to investigate the saddle question, I went into the subject a little more seriously than if some one else were the patient, but since having the saddle right I feel as much freedom from pain and danger as if I were riding in a carriage. Prescribe the wheel for your patients, "but see that the saddle is right."

LESTER KELLER, M.D.

### Diagnosis of Knee Joint Affections.

MINNEAPOLIS, MINN., Sept. 12, 1896.

*To the Editor:*—While it is usually a comparatively easy matter to make a diagnosis in tuberculosis of the knee, it is possible to be mistaken, as illustrated by the following cases:

*Case 1.*—A young man 19 years of age came to the writer with a knee which had been pronounced tubercular by a number of physicians who had seen it. It had already been treated by iodoform and iodine injections. He gave a history of having sustained a slight injury about a year before the writer saw him, and some time afterward the joint began to swell and became painful.

When he came to me he had an enlarged white joint with enlarged veins. There was flexion, atrophy, muscular spasm and severe pain which was much worse at night. He was put in bed and extension made by means of weight and pulley. In about a month his pain was relieved, the deformity overcome and the swelling seemingly diminished. At this time there was no question in the writer's mind but that the knee was tubercular. A plaster cast was applied and the patient allowed to go out on crutches.

After a very few weeks the pain returned; the swelling increased and the patient returned to bed, where he remained until he died three months later from an osteo-sarcoma. At that time my belief was that the sarcoma was secondary to tuberculosis, but the probability is that it was sarcoma from the beginning.

*Case 2.*—A lady, 49 years of age, was brought to me, who had a knee which was decidedly enlarged and which had been pronounced tubercular by many of the eminent surgeons of three different cities. An independent diagnosis of tubercular synovitis was made and excision advised. There was local swelling and heat, and what seemed to be a tubercular abscess in the popliteal space. There was flexion and tenderness upon pressure, but comparatively little pain. The family physician, acting upon the advice of a consulting surgeon, had tapped the joint some time before, drawing off quite a quantity of serous fluid, after which he injected iodine. The patient accepted the advice of myself and all the other surgeons (except one who wanted to try iodoform injections) and requested me to excise the joint. The patient had a hemophilic joint, and died one week after the operation, from acute anemia.

These rare and unexpected cases may occur in any joint, but the above are the only cases occurring in the writer's practice.

JAMES E. MOORE, M.D.

**Work for the Association.**—Let every member get a new member before the close of the year! Try it now! Let us reach the ten thousand mark in the semi-centennial year.

## NECROLOGY.

ALEXANDER BUCHANAN, M.D., New York City, September 2, from complication of diseases from which he had been suffering for several years. He went to Sands Point early in the summer, but becoming worse he was taken to the Post-Graduate Hospital where he died. Dr. Buchanan was born in Glasgow sixty-five years ago. He came to New York in 1856, but returned to Scotland to study medicine and graduated from the University of Glasgow in 1860. In 1862 he graduated from the New York Medical College. He was a Fellow of the Royal College, of Physicians and Surgeons, Glasgow, a member of the New York State and County Medical Associations and a member of the New York County Medical Society.

ABRAHAM LIVEZEY, M.D., at Yardley, Pa., August 31. He was at one time professor of obstetrics at the Woman's Medical College of Philadelphia. He had been suffering for thirty years from lupus of the face. He was born in Solebury township, Pa., in 1821, and graduated from Princeton College in 1842, and from Jefferson Medical College in 1845.

ASBURY M. DAY, M.D. (Albany Medical College, Albany, N. Y., 1860), at Farmington, Del., September 4, aged 60 years. —William K. Conaway, M.D. (Jefferson Medical College, Philadelphia, Pa., 1890), of Ridgeley, Del., September 4.

CHARLES LOTIN HILDRETH, M.D., of Southampton, N. Y., who was gaining prominence among the younger poets and writers of this country, died at the residence of his wife's sister, Mrs. Mary Kyle Dallas, on August 12. He was 40 years old and leaves a widow who is an authoress. There are no children. Dr. Hildreth's death was due to nervous prostration brought on by the intense heat of the week previous.

MATT YOUNG, M.D., the oldest physician of Ashland, Ky., died August 26.

J. L. BENSON, M.D., aged 79, died at his home in Noblesville, Ind., September 8. He was a surgeon of volunteers during the war, and had practiced medicine for fifty years.

## NEW INSTRUMENTS.

### A NEW SELF-RETAINING NASAL SPECULUM.

BY J. R. STRAW, M.D., ASHLAND, WIS.

Late House Surgeon Baltimore Eye, Ear and Throat Charity Hospital, Baltimore, Md.

I have realized, as has I presume every other rhinologist, the need of an absolutely self-retaining nasal speculum. To obviate this, about two years ago I devised the instrument

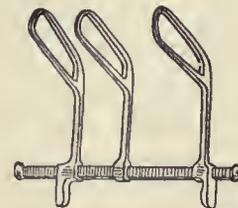

FIGURE 1.

illustrated in the accompanying cuts. As an inventor is always an enthusiast on his own devices, I have hesitated to recommend it to the profession, fearing it would prove, as many other instruments, useless for its designed purpose.

Knowing this fact, I have used it for the last two years, and am thoroughly satisfied as to its merits and practicability, especially for operations on the nose.

Cut No. 1 represents the instrument with fenestrated blades, consisting of three, on a straight, square bar, those on either end being movable, the central stationary. This latter or central blade is placed on one side of the septum, while the dilating blade on the opposite side of the nose to be dilated, is

brought firmly up against the septum and then, on the Lennox-Browne principle; locks itself. These two blades acting as a clamp on the septum, can not possibly slip; the other blade is then pressed out against the alæ of the side to be dilated, and also locks itself on the same principle.

Cut 2 represents the instrument in situ.

FIGURE 2.

The instrument is also made with solid blades, which protect the parts especially when the galvano-cautery is used. If desired the middle blade can be made adjustable, so that it can be extended back to protect the septum for some distance if necessary, although the cut does not show this.

I have recently had one made with solid blades, which I find more satisfactory than the one shown in the cuts. The original instruments have been made for me by Guinand Bros. of this city.

## SOCIETY NEWS.

**The Watertown (N. Y.) Medical Society** has reflected the following officers for the ensuing year: President, J. M. Crowe, Sr.; vice-president, Gilbert Cannon; secretary, C. N. Bibbins; treasurer, J. M. Crowe, Jr.

**The American Electro-Therapeutic Association** will hold its sixth annual meeting at Boston, Mass., September 29-30, and October 1.

Address of the President, Dr. Robert Newman, New York City. "The want of education in electro-therapeutics in medical colleges."

Reports of committees on scientific questions:

On induction coils and alternators. Mr. A. E. Kennelly, Philadelphia, Pa.

On meters. Dr. M. A. Cleaves, New York City.

On static machines and condensers. Dr. W. J. Morton, New York City.

On constant current generators and controllers. Dr. W. J. Herdman, Ann Arbor, Mich.

On electrodes. Dr. C. R. Dickson, Toronto, Canada.

On electric light apparatus for diagnosis and therapy. Dr. J. H. Kellogg, Battle Creek, Mich.

Papers:

What can be done by means of the use of electricity to avoid surgical operations? Dr. G. Betton Massey, Philadelphia, Pa.

Electricity in chronic non-suppurative affections of the uterine appendages. Dr. F. Shavoir, Stamford, Conn. Discussion by Dr. G. Betton Massey, Philadelphia, Pa.

Electricity in the treatment of diseases of the throat and nose. Dr. O. B. Douglass, New York City.

Accidents and risks in the use of street currents. How

far are they practicable and safe in the use of electro-therapeutics? Mr. J. J. Carty, E. E., New York City.

Electricity in the treatment of diseases of the larynx. Dr. W. C. Phillips, New York City.

Digest, showing the danger to patients and operators, the utter unreliability of fuse wires, resistance coils and incandescent lamps as a preventative of excess flow of current into patient. The liability of and danger due to the crossing of operator's wire, by wires carrying high tension current, both direct and alternating. Mr. John J. Cabot, E. E., Cincinnati, Ohio.

Experiments upon the effects of direct electrization of the stomach. Dr. Max Einhorn, New York City.

Electricity in diseases of the stomach. Dr. David D. Stewart, Philadelphia, Pa.

The static current of the post-apoplectic state. Dr. John Gerin, Auburn, N. Y.

The electric principles generally used in medical treatment. Prof. William L. Puffer, Boston, Mass.

The relations of physics to physiology. Prof. A. E. Dolbear, Tufts College, Mass.

Electro-therapy in the treatment of the nervous. Dr. W. S. Watson, Fishkill-on-Hudson, N. Y.

The role of electricity in the treatment of uric acid diathesis. Dr. J. G. Davis, New York City.

Some observations in electro-therapeutics. Dr. D. R. Brower, Chicago, Ill.

The physics of the production of the X rays. Mr. Edwin Houston, Philadelphia, Pa.; Mr. A. E. Kennelly, F.R.A.S., Philadelphia, Pa.

Treatment of strictures by electrolysis *versus* any other treatment. Dr. F. H. Wallace, Boston, Mass.

"The Newman method of urethral electrolysis." Its advantages and reasons why some operators fail. Dr. Francis B. Bishop, Washington, D. C.

Faradism in gynecology. Dr. R. J. Nunn, Savannah, Ga.

The motor dynamo—adapted to electro-therapeutic work. Dr. W. J. Herdman, Ann Arbor, Mich.

The application of electricity to surgery. Dr. J. W. Herdman, Ann Arbor, Mich.

A summary of the ultimate results in eighty-six fibroid tumors, treated by the Apostoli method. Dr. G. Betton Massey, Philadelphia, Pa.

Some experiences and experiments in the construction of high tension coils and electrodes. Dr. Frank W. Ross, A.M., Elmira, N. Y.

Electricity considered in its relation to surgical gynecology. Dr. O. S. Phelps, New York City.

A clinic report of case of rectal phlebitis treated with galvanism. Dr. D. B. D. Beaver, Reading, Pa.

On the electro-therapeutics of the constant current. Mr. A. E. Kennelly, F.R.A.S., Philadelphia, Pa.

**The New York State Medical Association** will hold its thirteenth annual meeting in New York City, October 13, 14 and 15.

Address by the President, Dr. Darwin Colvin. "Medical expert testimony."

The technique of intubation in children, some remarks on the time for operation and after treatment. Dr. Thomas J. Hillis, New York County.

Functionless organs, are there any? Possible use of the appendix vermiformis. Dr. Nelson L. North, Kings County.

The elongation of retracted muscles in club foot. Dr. T. M. Ludlow Chrystie, New York County.

Special report on Criminology. Dr. Austin Flint, New York County.

Brief comments on the materia medica, pharmacy and therapeutics of the year ending Oct. 1, 1896. Dr. E. H. Squibb, Kings County.

Discussion on Surgery: "Prostatic enlargement."

The discussion will be opened by Dr. J. W. S. Gouley, New York County.

The treatment of fecal fistula with reports of cases. Dr. Frederick Holme Wiggin, New York County.

Amputation of the lower third of the leg, with periosteal flap." Dr. Joseph D. Bryant, New York County.

Sutures of the liver for incised wounds. Dr. Stephen Smith, New York County.

Operation for rectal hemorrhoids and prolapse by submucous ligature. Dr. Benjamin M. Ricketts, Cincinnati, Ohio.

The practical uses of Roentgen's discovery as applied to surgery; with illustrations. Dr. Reginald H. Sayre, New York County.

The treatment of otorrhea and its importance. Dr. Edward B. Dench, New York County.

The relation of nose and throat affections to diseases of the ear. Dr. Frank S. Milbury, Kings County.

Temperature as an element in prognosis. Dr. John Shradly, New York County.

Diphtheria. Dr. Thomas G. Acker, Westchester County.

On the treatment of inebriety. Dr. T. D. Crothers, Hartford, Conn.

Further remarks on the domestic test for albumin in urine. Dr. John G. Truax, New York County.

A successful plaster-of-Paris bandage cutter. Dr. Sidney Yankauer, New York County.

The physiologic deductions regarding the usefulness of so-called animal extracts. Dr. H. A. Haubold, New York County.

Two interesting cases of surgery of the kidney. Dr. J. E. Jauvrin, New York County.

Recent investigations concerning eclampsia. William T. Lusk, New York County.

Puerperal eclampsia; studied with reference to pathogenesis and therapeutics. Dr. George T. Harrison, New York County.

The palliative treatment of cancer of the cervix and bladder in women. Dr. Nathan G. Bozeman, New York County.

Rare complications in two cases of hysterectomy. Dr. Ely Van de Warke, Onondaga County.

One point in the treatment of endometritis. Dr. William H. Robb, Montgomery County.

Address on surgery. Dr. Charles Phelps, New York County.

The vitality of cutaneous epithelium, with report of clinic observations in skin grafting. Dr. Zera J. Lusk, Wyoming County.

Acute amnesia. Dr. William D. Granger, Westchester County.

The duty of the public to the physician. Dr. William M. Bemus, Chautauqua County.

Supplementary notes upon tendon grafting and muscle transplantation for deformities following infantile paralysis. Dr. S. E. Milliken, New York County.

The medico-legal aspect of prison reform. Dr. Ernst H. Schmid, Westchester County.

Auscultatory percussion. Dr. Louis L. Seaman, New York County.

Druggist versus doctor. Dr. Henry B. Van Zandt, Schenectady County.

The peripheral neuralgias, traumatic and toxic. Dr. Thomas H. Manley, New York County.

The passing of venesection. Dr. H. D. Didama, Onondaga County.

A class of fatal cases, presumably due to intestinal ptomaines. Dr. E. D. Ferguson, Rensselaer County.

## PUBLIC HEALTH.

**Report of the Bureau of Health of Denver, Colo.**—Total number of deaths for August, 163; cases of phthisis contracted elsewhere, 24; death rate per 1,000 per annum, 13.04; death rate, excluding phthisis contracted elsewhere, 11.12; males, 86; females, 77.

**Typhoid in Marion County, W. Va.**—The typhoid epidemic in Marion County, W. Va., is spreading rapidly, the deaths multiplying daily. New England has 125 cases with an average daily death rate of 2. Every family in Riversville has one or more cases. Barnesville is in the same condition, five deaths occurring there on September 7. In consequence of the epidemic, the mining business is greatly disturbed and in some localities partially suspended.

**Diphtheria and Typhoid in Chicago.**—During the five days ending September 7 seventeen deaths from diphtheria were reported to the health department, a daily average of 3.4, or more than for any corresponding period since the epidemic of the winter of 1895-96. On September 4 seven people died from typhoid fever, breaking the record since 1892. The health department says the prevalence of the disease is due to

impurities in the drinking water. During August of this year typhoid claimed sixty-four victims, against fifty-nine for the corresponding period of 1895. About five hundred cases are reported at present in the city.

**The Old-time Enemies of Water.**—A writer in *Hospital* has made a partial collection of the sentiments of the ancient as opposed to the virtues and values of that blessing, water. In fact, he says, there are very few old writers who say a good word in its favor. The "Venerable Bede" (673-735) prescribed the following general directions: "In June of a morning a cup of cold water, fasting; for July the same, but in October for sweetening the blood, for the expulsion of stone, and for healing the lungs, instead of water one should take the milk of goats or sheep and should not wash very often; in February one should foment the limbs; in August he should not refresh in cold water, but in January he should plunge his body into warm water." One or two writers only are concerned to maintain that, "when begun in early life it [water] may be pretty freely drank with impunity," and they quote the curious instance given by Sir Thomas Elyot in his "Castel of Health," (1534) of the Cornish men, "many of the poorer sort, which never, or very seldom, drink any other drink, be notwithstanding strong of body and like, and live well until they be of great age." Thomas Cogan, the medical schoolmaster of Manchester fame, confessed in his "Haven of Health," 1589, designed for the use of students, that he knew some who drank cold water at night or fasting in the morning without hurt; and Dr. James Hart, writing about fifty years later, could even claim among his acquaintance "some honorable and worshipful ladies who drank little other drink and yet enjoyed more perfect health than most of them that drank of the strongest." The phenomenon was undeniable, but the natural inference was none the less to be resisted. Sir Thomas Elyot himself is very certain, in spite of the Cornish men, that "there be in water causes of divers diseases, as of swelling of the spleen and liver." He complains oddly also that "it flitteth and swimmeth," and concludes that "to young men and them that be of hot complexions it doeth less harm, and sometimes it profiteth, but to them that are feeble, old and melancholy it is not convenient." "Water is not wholesome drink by itself for an Englishman," was the verdict of Andrew Berde who was author of a *Breviarie of Health*, and who died in prison (1549), probably for debt, since it was his habit to make humorous speeches at fairs and who originated the sobriquet of "Merry Andrew." But the most formal indictment against water is that of Venner, who, in writing in 1622, ponderously pronounces "to dwellers in cold countries it doth very greatly deject their appetites, destroy the natural heat and overthrow the strength of the stomach, and consequently confounding the concoction, is the cause of crudities, fluctuations and windiness in the body." But be this as it may, allowance must be made for the numerous marshes and lazy streams of the day, which may have unconsciously pointed the moral of avoidance. Besides too there may have been rampant the usual excuses for intemperance, and the growing favor of boiled, or for the matter of that, malt drinks. For even at this late date the ingenuity of man is not so much wasted upon a pure water supply as upon the varied flavors of the shops, especially during a heated term. There are no fears especially if the compound is well sugared, and defies an analysis of its elements. Man yearns for the toothsome rather than for the salubrious.

**Safe Drinking Water for Travelers.**—Mr. Budgett Meakin, a globe trotter of renown, writes for a London newspaper some cautions about drinking water away from home. He says: "It is my opinion that it is a practicable undertaking to procure good drinking water abroad, derived not only from personal experience in France, Spain, Italy, Switzerland, Germany, Holland, Belgium, etc., on the continent of Europe, but also

on all three of the other continents. Not that the liquid supplied has always been of ideal purity, but that I have never suffered in any way from having remained throughout staunch to my pledge to abstain from all intoxicating liquors as beverages, though I must confess to the charge of a somewhat immoderate use of drinking water. In almost every large town on the continent I have been surprised at the quality of the supply, regarding which I have invariably made inquiry of local people other than hotel proprietors, who can hardly be considered disinterested persons. Wherever there has been the least doubt, I have felt safer in using aerated water as likely to be the best procurable on the spot, or when doubt was strong, apollinaris or Hunyadi, or other mineral water. Then these were, very rarely, not procurable or insufficient, I have had my drinking water boiled for at least ten minutes and, if need be, filtered. In such cases tea has always been my stand-by, a small box full of a decent quality being always ready in my handbag. For filter, let me warn tourists against all stone or charcoal block systems after they are once clogged and work slowly. The block must then be thrown away and replaced by a new one. For this reason the filters that can be recharged in a few moments with fresh charcoal, giving an absolutely new medium as soon as required are far preferable. All others soon become sources of danger instead of protection. The filtering when needed should precede the boiling, unless soup is required, though it is astonishing how often this natural order is thoughtlessly reversed. A pocket or small table filter can easily be carried in the lunch basket. It is well to inform the waiter on your arrival of your tectotal principles before he begins to recommend the cellar and to insist, on that account, on having the water bottles on the table and in the bed-room thoroughly well washed and refilled for your use. It is no use telling me that wine is purer, for I have seen how wine is made, and have trodden the wine press myself in Spain. When one is driven by thirst to doubtful water the best plan is to rinse the mouth well and gargle, or even to wet the face, neck and hands as well. Careful mouth-washing after rich food is an invariable ally to the total abstainer, and is invariably practiced by the Mohammedans, the abstemious races of India and many others. Before filtering muddy water, a little water will precipitate much of the suspended matter, and so will other substances less convenient in traveling. On country excursions there is no preparation like a bottle of cold, unsweetened tea, just bitter enough to prevent a mouthful being swallowed after the thirst is quenched. I have found an average of one pint a day sufficient for long rides in the sun in summer. Thus with a little care, the subtle excuse of bad water is disposed of, an excuse which does much more evil than we hear of in England. I am convinced that more travelers suffer from eating too much meat and that too fast, than from the water, and from inattention to the regular performance of digestion, which is an invaluable index. My own custom is to eat in every land the local food with such exceptions as pigs, carnivorous things, putrid (not rare) meat and shellfish; and I have been duly thankful in every clime for the best of health and good sleep."

**Health Report.**—The following reports of mortality from smallpox, yellow fever and cholera have been received in the office of the Supervising Surgeon-General U. S. Marine-Hospital Service:

**SMALLPOX—FOREIGN.**

Antofogasta, Chile: July 24 to 31, 1 case, 1 death.  
 Bombay, India: August 4 to 11, 4 deaths.  
 Callao, Peru: August 2 to 16, 24 deaths.  
 Gibraltar: August 16 to 23, 2 cases.  
 Licata, Italy: August 15 to 22, 3 deaths.  
 Madras, India: August 1 to 7, 1 death.  
 Madrid, Spain: August 18 to 25, 33 deaths.  
 Montevideo, Uruguay: July 18 to 25, 3 cases, 1 death (varioloid).  
 Moscow, Russia: August 8 to 15, 3 cases, 1 death.

Naples, Italy: August 15 to 22, 9 cases, 5 deaths.  
 Odessa, Russia: August 15 to 22, 4 cases, 3 deaths.  
 Pernambuco, Brazil: July 18 to 25, 50 deaths; July 25 to August 1, 51 deaths.  
 Rio de Janeiro, Brazil: August 1 to 15, 33 cases, 4 deaths.  
 St. Petersburg, Russia: August 15 to 22, 2 cases, 1 death.  
 Warsaw: August 15 to 22, 5 deaths.  
 Yokohama: July 17 to 31, 2 deaths.

**CHOLERA.**

Egypt: Cairo, August 4 to 10, 14 cases, 4 deaths; Alexandria, August 9 to 15, 22 cases, 21 deaths.

During the period from August 4 to August 15 there were 1,008 cases of cholera and 554 deaths from that disease reported from towns and districts in the interior of Egypt. From the beginning of the epidemic to August 14 the figures are: 17,453 cases, 14,498 deaths. In the Port of Alexandria to August 14 there have been 970 cases, 821 deaths.

India: Bombay, August 4 to 11, 21 deaths; Madras, August 1 to 7, 2 deaths; Calcutta, July 25 to August 1, 8 deaths.

**YELLOW FEVER.**

Brazil: Rio de Janeiro, Aug. 1 to 15, 7 deaths.  
 Cuba: Cienfuegos, Aug. 23 to 30, 6 deaths; Cardenas, Aug. 16 to 29, 65 cases, 22 deaths; Havana, Aug. 27 to Sept. 3, 100 cases (?), 60 deaths; Matanzas, Aug. 26 to Sept. 2, 31 deaths; Santiago, Aug. 22 to 29, 14 deaths; Sagua la Grande, Aug. 15 to 29, 145 cases, 24 deaths.

## BOOK NOTICES.

**Transactions of the Medical Society of the State of California.** Session of 1896. A. P. WOODARD, Chairman, W. W. KERR, A. H. TAYLOR, J. M. WILLIAMSON, M. H. WOOLSEY, Committee on Publication. W. A. Woodard & Co., San Francisco, Printers. 359 pp. Cloth.

W. G. Cochran delivered the address of welcome, which was responded to in a happy manner by R. Beverly Cole, M.D., Ex-President of the AMERICAN MEDICAL ASSOCIATION. President W. Le Moyne Wills, M.D., in his address, ably discusses the subject of medical progress, etc. He calls attention to the subject of transportation of tuberculous patients and says it is time the different States should give it attention, and if the railroad companies will not discriminate and protect healthy passengers, the States, through their medical officers and the profession, must protect themselves and those entrusted to their charge. The book contains, in addition to reports of committees, lists of members, etc., some thirty-eight interesting papers.

**A Manual of Clinical Diagnosis by Microscopical and Chemical Methods.** For Students, Hospital Physicians and Practitioners. By CHARLES E. SIMON, M.D., Late Assistant Resident Physician Johns Hopkins Hospital, Baltimore. In one very handsome octavo volume of 504 pages, with 132 engravings and 10 full-page colored plates. Cloth, \$3.50. Lea Brothers & Co., Philadelphia and New York. 1896.

The special feature of this work on diagnosis is indicated in its title, namely, the application of chemistry, and it is a fact, beyond controversy, that the great preëminence of certain European classes is due to the greater attention paid to chemistry, physiology, bacteriology and diagnosis. The author says: "It is curious to note that, notwithstanding the great importance of clinic chemistry and microscopy, but little attention is paid to these subjects, either by hospital physicians or by those engaged in general practice. This lack of interest is referable primarily to the fact that systematic study of these branches has heretofore been greatly neglected, not only in American medical schools, but also in those of Europe."

The laboratory method of diagnosis, when taken in connection with the well-known physical signs, makes the practice of medicine truly a science, and we can not have too many books of this character.

The directions for examination of the various fluids of the body and the excreta are so clear and explicit, that it does not require an expert to follow out the tests as laid down in the book. The work is well illustrated, and some of the illustrations, being in colors, are beautiful.

**A Manual of Venereal Diseases.** By JAMES R. HAYDEN, M.D., Chief of Venereal Clinic, College of Physicians and Surgeons, New York; Professor of Genito-urinary and Venereal Diseases in the Medical Department of the University of Vermont, etc. In one 12mo volume of 263 pages, with 47 engravings. Cloth, \$1.50. Lea Brothers & Co., Publishers, Philadelphia and New York. 1896.

In this little manual students and practitioners will find a practical dissertation on the three venereal diseases—gonorrhoea, soft chancre and syphilis, with their complications and sequelae. The general line of treatment and the formulæ given are those advocated by Prof. R. W. Taylor of New York, in his clinic. The discussion of the history and statistics of these diseases, which usually takes up a large portion of a volume, has been omitted from this manual. The illustrations are fair; the mechanical execution of the work is all that could be desired. We notice, however, that the Otis instrument figured on page 103 is an old pattern, and not the instrument having a tunneled extremity for the passage of the guide, which is that we believe most recently used and figured in the volume of Park previously noticed. For examination purposes, and those preparing for examination, the manual will be found very useful.

**Jackson's Ready-Reference Handbook of Skin Diseases.** The Ready-Reference Handbook of Diseases of the Skin. By GEORGE THOMAS JACKSON, M.D., Professor of Dermatology, Woman's Medical College of the New York Infirmary and in the University of Vermont, Chief of Clinic and Instructor in Dermatology, College of Physicians and Surgeons, New York. New (2d) edition. In one 12mo, volume of 589 pages, with 69 illustrations and a colored plate. Cloth, \$2.75. Philadelphia, Lea Brothers & Co., 1896.

In this the second edition of this work the author has added considerably both to the text and illustrations.

The greatest defect is that it gives too much space to the recipe, and too little to pathology and etiology. Practical physicians who form their opinions upon the analysis of the symptoms and history of a case rather than its disease label will regret this. The work however is a useful one and this edition will doubtless have a great sale.

## MISCELLANY.

**Dr. Charles A. L. Reed** has been elected gynecologist and abdominal surgeon on the staff of the Cincinnati Hospital, vice Dr. T. A. Reamy, resigned.

**Illinois Medical College Commencement.**—The second annual commencement exercises of the Illinois Medical College, Chicago, were held September 10. A class of ten, three of whom were women, received the degree of Doctor of Medicine. The Bishop prize for the highest grade in clinic surgery was won by William F. Sterman.

**A New Cycle Ambulance** has been invented by Dr. Honig of Berlin. It is not drawn by horses or men in the ordinary way, but is propelled by cyclists, and consists of a kind of litter resting on a frame with five wheels, three in front in the form of an ordinary tricycle, and two at the back.—*Albany Med. Annals*, September.

**Homage to Pasteur.**—An interesting feature of the recent International Congress of Applied Chemistry at Paris, was when the members repaired to the Cathedral of Notre Dame and defiled past the chapel where Pasteur's remains are lying, leaving there a magnificent wreath of cut flowers, with an appropriate inscription. They went from there to the Institut Pasteur, where they witnessed several antirabic injections, and closed the day by visiting the stables where the immunized horses are kept.

**Connection between Rachitis and Humidity.**—A study of rachitis or English disease, as it is called, is published in *Wratsch*, No. 17, which asserts that it is a physiologic condition in localities with a relative annual humidity of 80 per cent., while it

never appears where the annual humidity is 8 per cent., except under exceptionally favorable circumstance for its evolution, and is unknown in localities with less humidity than this.—*St. Petersb. Méd. Woch.*, No. 7.

**Post-Graduate Medical School of Chicago.**—The Post-Graduate Medical School of Chicago moved into its new building and new location at 2400 Dearborn Street, Sept. 1, 1896. The new building is an ornate structure, seven stories in height, constructed as a clinic school and a clinic hospital. The school is complete having the most modern lecture rooms and laboratories. The hospital has accommodations for 100 beds. One floor is artistically furnished for private patients. There are four operating rooms of the most modern construction, including an amphitheater operating room, which will accommodate 300 students. The building is lighted with electricity and is provided with elevators. The location is selected because of its superior clinic advantages. Within a distance of ten minutes' ride from the school proper are the St. Luke's, Charity, Michael Reese, Mercy, Woman's and Wesley Hospitals. Clinical instruction will begin in the new quarters at once.

**Criminallity of Hygienists.**—A witty article in the *Revue Médicale de Paris* laments the growing scarcity of the sick and the increasing numbers of physicians. It denounces Jenner, Pasteur, etc., as guilty of depriving their colleagues of their daily bread and wrecking the profession. Especially is this the case in the cities where prophylactic and hygienic measures are most strictly enforced and the sick number less in proportion. It adds a few figures in confirmation from the death records of Paris during the last ten years, stating that the figures to date for 1896 show even more marked reduction:

Deaths caused by	1885 to 1890.	1890 to 1895.
Smallpox . . . . .	1,271	656
Scarlet fever . . . . .	1,225	946
Measles . . . . .	6,671	5,192
Diphtheria . . . . .	8,383	7,588
Typhoid fever . . . . .	5,904	3,493

**Vaginal Hysterectomy.**—In cases where hysterectomy must be an operation of election there may be conditions that will require the vagino-abdominal or the suprapubic method. The following are some of the reasons why vaginal hysterectomy should be preferred to celiotomy: 1. There is less shock and more rapid and complete convalescence. 2. In pelvic suppuration there is less danger of septic infection from soiling the peritoneum. 3. Absence of suture or mural abscesses, and of sinuses following the use of drainage or an infected ligature. 4. Immunity from ventral hernia. 5. A lower mortality, fewer post-operative complications, and a more complete restoration to health in a relatively greater number of cases. The above are facts, as shown by the statistics of the most successful operators in celiotomy and vaginal hysterectomy; and in vaginal hysterectomy many of the cases were inoperable by any other method.—Dr. William H. Mathew, in *Am. Jour. Obst.*, September.

**Defective Breasts a Sign of Degeneracy.**—Hegar appeals to young men on behalf of posterity to select women with well developed breasts for their wives, and suggests that the young women can retaliate by refusing to marry a man unless he can produce a record of having been a "breast baby." He quotes statistics to prove that inability to nurse a child is a sign of degeneracy, and produces degeneracy. We note among the facts he cites that in a certain district which supplies large numbers of wet nurses to the city, the percentage of men physically incapable of military service amounts to 30 per cent., while in the neighboring districts where the mothers remain at home with their families, it is only 18 per cent. He also remarks upon the surprising numbers of deformed nipples encountered in the hospitals. Fehling mentions "hollow nipples" as occurring in 6.7 per cent. of his obstetric cases. Hegar warns mothers not to allow the clothing to constrict the growing breasts of their

daughters, and urges general hygiene as the best method to develop them.—*Deutsch. Med. Woch.*, August 20.

**Influence of Sugar on the Energy of the Muscles.**—Schumburg states that he has been experimenting with Mosso's ergograph to determine whether sugar increased the muscular power as some assert, or whether the increase in energy observed is due to psychic influences. He found that the sugar produced no perceptible effect on fresh, unfatigued muscles, but that muscles fatigued from previous severe exertion were strengthened to a noticeable degree. This effect was attained whether the muscles were strong or weak.—*Deutsch. Med. Woch.*, August 20.

**The Pan-American Congress.**—The committee in charge suggests to the home members climatology and a study of yellow fever and its disappearance as the altitude increases, as special subjects in which home talent might render great service to science. Also the study of leprosy and of the endemic "pinta." Typhoid fever and malarial disorders are also of universal interest, and the physician of Mexico has especial opportunity to observe them under varying conditions of climate, etc. Another subject for which he is especially qualified is the changes undergone by the organism in adapting itself to varying altitudes. The Mexican surgeon is also peculiarly an authority on the wounds produced by "cold steel." It also sensibly advises the home members not to expatiate on the deficiencies, but to reserve such facts for the national gatherings, and in the international congress, to dwell rather on what has been accomplished in their country.

**Treatment of Chlorosis with Ovarian Extracts.**—Spillman and Etienne have treated six cases of chlorosis with ovarian extracts with satisfactory results. They say of the ovary that it is a gland with an external secretion, the ovum; that it is also a gland which eliminates by means of the menstrual flow the excess of organic toxins, while at the same time it is a gland with an internal secretion, like the testicles, and this internal secretion plays an important part in the general nutrition. When the ovaries are diseased, these three functions of the gland are modified or abolished, and with the suppression of the menses appears that special intoxication, chlorosis. This general morbid condition prevents in turn the restoration of the ovaries to normal conditions. Administering ovarian tissue or extract favors the elimination of the toxins and introduces into the organism an antitoxic principle which seems to exert a beneficial effect on the general health, to increase the number of corpuscles and cause the reappearance of the menses. They administered fresh ovarian tissue from lambs, or the same desiccated, and also extracts prepared by the Brown-Séguard-d'Arsonval method. Mairst added to their communication to the French Medical Congress, that his experience confirms their statements and also the fact that the injection of blood and the products of other glands, notably of the testicles, improves the general nutrition. Teissier remarked in regard to the injection of renal extracts, that they attenuate accidents of renal origin by augmenting the elimination of poisons through the urine.—*Bul. Méd.*, August 26.

**Creation of Universities in France.**—There are no universities in France at present as we understand the term, but recent legislation to take effect in 1898 unites the separate "corps de facultés" which now have charge of higher learning into organized combined institutions similar to those in other countries. Fifteen cities have "corps de facultés," and half of them have all four departments, medicine, law, science and philosophy, but these departments have been heretofore separate entities, with no interests in common, their expenses paid by the government and the receipts from students paid to the government. The new law merges these separate faculties into universities, which are to retain a certain proportion of the fees from students, with other privileges depending upon

the number of students they attract. It is evidently an attempt to foster a spirit of emulation and catholicity of culture. A letter to the *Deutsch. med. Woch.* commenting on the new order of things, mentions the strictly obligatory nature of the French courses; three absences from a course without an excuse and one's name is dropped from the list and one loses the trimester. There is no such thing as academic option in France except in regard to the conventionalities and police regulations. It adds that there is more license allowed in Paris, at least, in these respects than anywhere else in the world probably.

**Pathologic Study of the Kidneys.**—Mircoli describes in the *Gaz. degli Osp. e delle Clin.* of August 23, a series of experiments on rabbits to investigate the beginnings and course of renal lesions, as such lesions usually come under observation in the clinics only in the latest stages. He found that one diseased kidney was apt to infect the other, also that lesions of the connective tissue and of the epithelium and albuminuria have a characteristic tendency to become aggravated and progressively chronic. The albuminuria in interstitial nephritis is the exponent of the various stages of the development of the morbid condition, rather than of the intensity or extension of the process; its disappearance may therefore coincide with the maximum of the lesions in the connective tissue. He also established the fact that a localized lesion tends to extend along the route of the connective tissue, and ultimately to affect all the viscera, with a diffuse alteration.

**Fat as a Factor in the Production of Hernia.**—Tillaux and Champouñère assert that the original cause of almost all hernias, congenital inguinal hernia excepted, is an exaggerated development of adipose tissue, or the other extreme, emaciation. The tendency to obesity should be combated on this account with gentle gymnastics, especially balancing, and the frequent use of mild purgatives to keep the intestines empty, with suitable diet, little meat, no alcohol in any form, and other means to keep the functions of the skin and kidneys active, hot dry or steam baths, mineral waters, &c. Elderly persons should seek gentle exercise, avoid effort in defecation and coughing, and also not lie too much in bed nor sleep too long. It is often best to precede an operation with antifat treatment of this kind. In certain cases of distressing hernia, surprising relief is sometimes obtained by reducing the obesity.—*Bulletin de l'Académie de M.*, August 25.

**Reinfection of Syphilis.**—The recent specialist Congress at London and also the French Congress of Internal Medicine, devoted considerable time and discussion to this question. Cases were described in each that seemed to prove conclusively the fact of recovery from the first attack and reinfection later. But the French and some others still cling to the theory that once a syphilitic, always a syphilitic, or as the English specialist remarked: "The soul of a syphilitic will rise syphilitic at the Judgment Day." Fourrier in France and Ogilvie at London cited convincing cases of reinoculation, but the latter protested against confounding the question of reinfection with the question of curability, as reinfection may occur in the midst of tertiary symptoms, as he has had occasion to observe, while on the other hand, he thinks that even if there is no such thing as reinfection, still this does not prove the incurability of syphilis, as immunity is not synonymous with disease.

**Applied Chemistry.**—The recent International Congress decided that the word "extractive" should be henceforth dropped as vague and unnecessary. The term "azoturic proportion" will also supersede the term "coefficient of azotic oxydations" in the analysis of urines, to express the proportion of azote in the urea to the total amount of azote in the urine. In determining the amount of uric acid, the Salkowski-Ludwig method is to be used where extreme accuracy is desirable, but the Denigès' method is sufficient for all practical

purposes. In testing physiologic and pathologic liquids, they are no longer to be measured by bulk, but by weight, with a standard quantity in a standard platinum capsule, for a standard length of time and under standard conditions of temperature. This system is already followed in analyzing sugars, wines and foods. The standard of acidity is to be the number of cubic centimeters in normal alkaline fluid. Gastric juice is to be the only exception to this. Its acidity will be estimated as hydrochloric acid, with phenolphthalin for the indicator. Further efforts were made to unify the Codex, and the congress officially resolved to appoint a committee in each country to establish the standard of purity for each medicine, and the quantities of the active principles contained in it, with a statement of the methods of dosage and the corresponding proportions in foreign pharmacopœias—this official analytic supplement to be included in each Codex.—From the *Bulletin de l'Acad. de M.*, August 11.

"Wisconsin Eclectic Medical College of Milwaukee," Wis.—We have received of Dr. C. R. Gay of Windsor, Vt., a letter which encloses various circulars of the Wisconsin Eclectic Medical College. It seems that the Medical and Surgical Directory wrote Dr. Gay, and receiving no reply, placed a star opposite his name: whereupon the diploma mill people write a letter to Dr. Gay, which runs about as follows:

"We notice your name in a Surgical Directory, but with a star appended, to which a foot note reads: 'No report received in answer to inquiry regarding graduation.' It by no means intends to convey the idea that the person so designated is not a graduate; yet naturally in such a case the presumption is fair that this is so. If, however, it should be that you are a graduate and have a regular diploma, then we can but tender our most sincere apologies for troubling you in the matter. But, on the other hand, if you are not a graduate and have no regular diploma, then the perusal of the enclosed prospectus can not fail to be of the most primary importance and interest to you. We would also desire to draw attention to the fact that to practicing physicians our fees are much reduced from the regular rate. To this class our fees are \$35 all inclusive. As proof of our legal standing and right to confer the degree of M.D. we can supply certified copies of our charter at 25 cents each, simply covering the cost of certifying officer's fee. Trusting soon to hear from you and standing ready to answer any or all questions you may wish to submit, we are  
"Yours very sincerely.

"WISCONSIN ECLECTIC MEDICAL COLLEGE."

They also inclosed in this letter a reduced cut of their diploma, the original of which, according to the veracious circular, is 18x23. This reduced cut bears the names of Fred Rutland, Ph.D., M.D.; Charles Podmore, M.D.; Rosa Dempster, M.D.; Jules Gordon, M.D., Prof. Anatomy; William Newton, M.D.; Horatio Myers, M.D. We also infer from certain insignia on the bottom of this valuable document that there are five ribbons attached thereto, of the colors respectively, black, red, white, blue and old gold. This seems to us most brazen effrontery. The papers in the case have been forwarded by us to the Attorney-General of the State of Wisconsin.

**Solidified Casein Casts and Improved Bandages.**—Soloviev states that fresh caseum mixed with one-eighth its weight of liquid ammonia, makes a gluey mass that is especially adapted for casts, on account of its lightness and cheapness, while it answers every purpose. It has to be made on a cast first taken of the part and removed with a longitudinal section. The caseum cast is then made on this with first a layer of felt, held in place with a piece of flannel, then the drilling soaked in the caseum glue is wound around it twice, with a layer of fine shavings between each layer. An outer layer of the caseum drilling completes the cast, which is then placed in the oven to dry until next day, when it is ready to be applied to the patient. A caseum corset retains its shape on a child for four months, but it is apt to crease on an adult in time unless it is strengthened by a few splints or bones. (*Semaine Méd.*, August 26.) Thilo of Riga, also writes to the *St. Petersburg Med. Woch.*

August 15, that he derives great advantage from a piece of white felt laid over the ankle or knee, in applying a compressing bandage for sprains, etc. It enables the bandage to be drawn much tighter than usual, without injury to the wounded joint. He slits the felt or makes an oval opening over the most sensitive part, and thus the pressure on top of this elastic protector can be indefinitely increased. The patient can even resume his ordinary occupations with a bandage of this kind, and the best results follow its use.

**Prevention of Suppuration in Acute Pelvic Inflammations.**—Wm. R. Pryor, M.D., says: The observation and experience of six years with conservative curettage have taught me to surely expect a complete recovery in cases of acute oviductitis with salpingitis and peritonitis when seen early in first attack. For two years, in all such cases, I have operated as follows: The uterus is thoroughly curetted and irrigated. All instruments being changed, in a few minutes the cul-de-sac is opened and a wide blunt dissection made in the vagina and cul-de-sac by separating two fingers. The fimbriated ends of the tubes are opened if found closed. All serous-fluid accumulations are evacuated, and the pelvis wiped dry. No irrigation is here used. I then pack from three to five yards of iodoform gauze into the pelvis, each strip being about three inches wide. The uterus is next tightly packed as is also the vagina. A self-retaining catheter is introduced. On the third day the vaginal gauze is removed together with that in the uterus. The vaginal gauze is renewed, but the uterine packing is not, unless the uterus be large. The gauze in the pelvis is removed in a week or ten days under chloroform and another large pelvic packing is made. The results of this operation are most gratifying. The lymph which is thrown about the antiseptic dressing disappears in a few months and the uterus becomes perfectly movable. Accidents have never happened and I have been uniformly successful in preventing suppuration. In several cases of relapsing salpingitis I have met with large hydrosalpinx and broad ligament cysts. These were merely incised and evacuated.—*Med. News*, September 5.

**Amendment of South Carolina Law as to Commitment of Insane.**—The South Carolina enactment approved Dec. 24, 1894, to further regulate and provide for the admission and discharge of patients to the lunatic asylum and promote the management of the same, was amended by an act approved in March, 1896, by adding the following proviso to the end of section 5 thereof: That the superintendent of the Lunatic Asylum, now known as the State Hospital for the Insane, shall receive into his custody and detain in said hospital for a period not exceeding five days, without an order from the judge of probate, any person as insane whose case is duly certified to be of violent and dangerous insanity and emergency by two reputable physicians, which certificates shall be separately signed and shall conform to all the requirements as now provided by law. In addition to such certificates, an application, signed by a trial justice, mayor or alderman, intendant or warden of the county, city or town in which such insane person resides or is found, shall be left with the superintendent of said state hospital for the insane, and said application shall contain the answers to the list of interrogatories now in use by the regents of said hospital; provided, further that when such insane person is committed and received in said hospital for the insane, the party committing such person shall give a bond in the sum of one hundred dollars to the treasurer of said institution, with condition that he or she will within five days procure an order for the commitment of said patient as now provided for by law, and failing therein said insane person shall be removed or discharged by the superintendent of said institution and suit brought by him (if he sees proper to do so) on said bond for the cost of maintenance of said person while confined. For the duties required of the judge of probate, under the provisions of this act, he is,

by further amendment, allowed the sum of five dollars. And the following fees and charges, it is further enacted, shall be paid for the conveying of insane persons to the hospital; to the officer or person conveying said insane party, \$2 per day and 12 cents per mile one way, and out of which said mileage herein allowed shall be paid all the costs and expenses of said insane person. If it shall be necessary to employ a guard to assist in conveying such insane person, such guard shall receive one dollar per day and his actual railroad fare. Said charges shall be paid out of the county treasury on order of the supervisor.

**Some Unrecorded Symptoms of Tetanus.**—De Brun writes from Syria to the Académie de Med. that tetanus is often encountered there, and is not infrequently produced by the use of cautery, which is quite a popular remedy. He has had seventeen cases under observation and records certain symptoms which are not noted by the authorities. One is the obstinate constipation, resisting purgatives and enemas, and returning after each laboriously secured evacuation. Another is the ravenous appetite in sub-acute or chronic cases. Thirst is torturing in all, and often the only service that can be rendered the sufferer is to keep the parched lips and mouth constantly moistened. Other symptoms are the tenacious and sometimes absolute insomnia, and the frequent and violent sweats, which persist at irregular intervals even after recovery in some cases, so severe that the patient has to return to bed. But they have no critical significance, and do not attenuate any of the symptoms. There is also an invariable and intense desire to keep changing the position. He mentions three cases in which the tetanus had shortened certain muscles, producing a strange inability to sit or lie down directly, to step on the heels, to open the mouth wide, etc. He describes at length one case of this kind, following cauterization of the shoulder for a contusion, the wound dressed afterward with chick-peas. It was three months and a half before the shortened muscles were brought to approximate normal length. His treatment was chloral, 10 to 14 grams a day, in fractional doses, 3 to 5 grams of antipyrin, and for one fortnight, 2 to 4 hypodermic injections of  $\frac{1}{2}$  milligram of sulphate of atropiu, with exercise of the muscles the last six weeks. Teissier refers in half a dozen words to this shortening of the muscles: "Occasionally certain contractions persist a long while."

**Expert Evidence as to Cause in Malpractice Case.**—The question: "Is it legally competent, in order to show malpractice, for a surgical expert, with the results of a surgical operation performed nearly two years prior before him, either through his own personal examination and investigation of that result, or through a hypothetical question placing the results before him, to give an opinion as to the cause or causes that produced the results?" was presented by the case of *Tullis v. Rankin*. The trial court held that it was not. But the supreme court of North Dakota reaches the opposite conclusion, as stated in the opinion handed down July 2, 1896, while admitting that the question is close, and that authorities can be found that give support to the ruling of the trial court. It is doubly important to note the facts, as it is said that each case heretofore involving the question seems to have been ruled to some extent by its own attendant circumstances. In this case, the plaintiff had his foot run over and crushed by the cars on May 5, 1893. On that same day his leg was amputated by the defendant, and he was sent to a hospital where he remained about two months. The wound never entirely healed, and the pain never left it, until after a second amputation was performed by three other surgeons, in March, 1895, when the limb healed, and all pain ceased. These gentlemen were severally sworn as expert witnesses for the plaintiff. They testified in detail as to the condition of the limb and the patient at the time of the second amputation. After having so testified, each was asked: "What, in your opinion, was the cause of the condition in which you

found the limb at the time you made the examination and amputation?" And to one of them, a hypothetical question was put incorporating the facts to which the plaintiff had testified as to his injury. Conceding that the ultimate object was to show that an improper or unskillful amputation was the cause of the condition, the supreme court still holds that the questions as asked should have been answered, and on that ground reverses a judgment which had been given the defendant, ordering a new trial. The opinions, if given as anticipated, it says would have concluded nothing. They would have gone to the jury for what they were worth. It was still open to the defendant to show that the original amputation was skillfully and properly performed; still open to him to show that other circumstances and events influenced or produced the results; still open to him to show by other expert testimony, if he could, that the opinions of the plaintiff's experts were unwarranted in scientific surgery. Courts as a rule, it is also said in this case, entertain an aversion to expert testimony, particularly medical and surgical expert testimony, and that experience no doubt warrants the aversion; but it is not to be excluded on account of the embarrassment its weight or lack of weight may cause a jury.

**New Light on the Pathologic Processes in Cholera.**—Federn makes the surprising announcement in the *Wien. Med. Presse*, No. 25 that he finds with the sphygmomanometer that the pressure of the blood is increased in cholera, instead of being lowered, as is stated by all the authorities from Griesinger to Leyden. This increased pressure can not be due to any stronger action of the heart, but rather to increased resistance in the vascular system, commencing in the splanchnicus region and probably spreading thence to the entire system. This throws a new light on the nature and course of the choleraic processes. Two factors must unite to produce this elevated pressure; the thickening of the blood from transudation, and increased resistance in the vascular system. When this resistance is great a slight transudation is enough to produce cardiac failure, and when both factors are acting powerfully the course is rapid. These facts show that the old methods of treating cholera were faulty in two respects: First, in considering the transudation in the intestines as of less importance than stimulating the action of the heart, at the beginning of the asphyctic stage, when the diarrhea grows less or ceases entirely, although the necropsies show that the transudation persists. This error can be remedied by tannin enterocleisis. The second error was in directing all the efforts toward stimulating the action of the heart, as it was never suspected that the pressure of the blood had been elevated by increased resistance in the vascular system. The results of Federn's observations will be that henceforth the effort will be to resist this tendency in the vascular system, and it may even be possible to prevent the asphyctic stage altogether. The problem of how to respond to these indications is still unsolved, as it has scarcely yet confronted practical medicine, except in the case of angina pectoris. But reasoning from analogy, Federn advocates the general use of calomel from the start, instead of beginning with astringents and opium, as, in most cases, increased blood pressure proceeding from the intestines is the result of irritation of the splanchnicus usually produced by constipation. Federn has also observed an elevated blood pressure reduced by natrium salicyl. in large doses, four to six grams, antipyrin, phenacetin, salipyrin in doses up to two grams, morphin, codein and chloral hydrate; but the most powerful effect is obtained by chloroform narcosis. Cramps of the capillaries are an important factor in the fatal termination of cholera, and thus the use of chloroform, our most powerful remedy for cramps of all kinds, is already indicated. He also suggests faradization of the intestines, which is sure to lower the pressure resulting from partial atony, but queries whether it is practicable in cholera, on account of the tendency to muscular cramps, even in the bowels.—*Therapeut. Woch.*, August 9.

**Cerebral Localization.**—President Pitre's address on this subject at the French Medical Congress last month, forms an interesting supplement to the editorial in this JOURNAL July 18, page 161. After a historic sketch and a description of the neuron, he referred to the two groups of cells which histologic investigation reveals in the cerebral cortex: the pyramidal cells, with their long axis cylinders, passing through the internal capsule into the subjacent bulbo-medullary centers, and the second group of cells, smaller and of various shapes, which are entirely contained in the gray cortical matter in a network of associated cells. Histologic anatomy reveals absolutely nothing in regard to the functions of the latter. But we have learned to know them by clinic observation, thanks to the arrangement of the elongated neuron processes in the internal capsule. Any injury to the internal capsule is liable to affect these elongated processes located in it, while not affecting at all the smaller associated cells which do not extend into it. He quoted various writers who have established from clinic experience that injury to the capsule and its cell processes produces motor and sensory disturbances, but never psychic. The intellect, the memory, the will, etc., are never affected by injury of the internal capsule alone. The psychic functions reside in the innumerable associated neurons, the second group of cells referred to above, whose branching terminals ramify all through the gray matter of the convolutions in every direction. These neurons not having any capsular process, and not being grouped in anatomically isolated islands, are not accessible to our methods of investigation. They even escape anatomic-clinic study, owing to that indeterminate extension and far-reaching influence of any lesion of the cortex, even the most limited. Everything tends to prove that the functions we attribute to them are not localizable. It is certainly a vain quest to seek for the seat of the memory, the intelligence, the will. These words represent entities in scholastic language, but in fact, they are only abstract terms, which mislead us into a false conception of the complex phenomena they represent. The intelligence is in physiology, something analogous to what we mean in economics by the State. This word State is also a substitute which represents by an abstract term, an infinitely complex reality, an organized power which acts through a multitude of agents, subordinate one to the other, and distributed throughout the entire territory in such a way that it would be necessary to suppress the entire army of officials of all kinds, in order to destroy at one blow the administrative, judicial, military, collegiate and religious mechanisms which combined, constitute the State. The mind is "fragmented" in the same way. Each cerebral cell contains a part of it. None is its exclusive organ. We have no grounds at present to suppose that there is anywhere, a conscience center, a judgment center, an intellect center, etc. According to the present status of our actual knowledge, we must consider the gray matter of the convolutions as the essential organ of psychic elaborations. They operate in the network formed by the terminal ramifications of the polymorphous cells of the cortex. This extremely complicated network in which, so far, we have been unable to establish any precise localizations, is connected with the periphery by the system of pyramidal cells with the long processes, whose functions are to receive, to record and to preserve the sensory images which form the first material for the mental operation, and the motor images which are the final product. Those which serve for the sensory impressions are distributed through the sphenoccipital lobes; those which serve for the motor impressions, through the frontoparietal lobes. This explains why lesions of the anterior lobes of the brain are not so important physiologically as lesions of the posterior lobes. The former produce disturbances in the sensory images perceived, but the latter prevent the formation of motor impressions and the transmission of will-impulses. This is the explanation, unless I am mistaken, of the structural identity of the convolutions shown by the histologists, and

of their functional diversity, which has been established again and again by thousands of exact, incontrovertible facts accumulated by investigators and clinicians of all schools and in all lands.

**Physician Commended Under Unusual Circumstances.**—The London *Lancet*, August 8, tells the following pitiful story of a woman's death and a physician's trying situation. It so happens that the good acts of the medical man were recognized—but what might not have been the jeopardy of his whole professional life, if some one or more had found it to his or their interest to lie about him. As the *Lancet* well says, the situation fairly "teems with difficulties," and dangers as well. The story is this: "An inquest was recently held at Chelsea touching the death of Miss F. T. Handford, who died aged 34 years after having miscarried. On June 25, 1896, she consulted Dr. C. J. Harrison, who prescribed for her for anemia. She then said, 'If I tell you a secret will you keep it?' and upon Dr. Harrison replying in the affirmative she mentioned that she was pregnant. July 8, she went again and suggested that Dr. Harrison should procure abortion for her. This he absolutely refused to do and dissuaded her as strongly as possible. On a subsequent occasion she repeated her request with the additional inducement of a blank check. Dr. Harrison again refused, and July 22 Miss Handford arrived at his house looking very ill and fainted in the consulting room. As she was obviously very ill and had profuse hemorrhage Dr. Harrison allowed her to remain in his own house and communicated with her friends. The cousin of the deceased arrived, and later in the evening the patient asked the nurse in attendance to write a statement for her, in which she said that Dr. Harrison had refused to bring on a miscarriage, so 'this morning feeling desperate I went to a doctor in — town, his name I refuse to mention, and he did something to me and told me that I should be all right, and as I walked toward home I turned faint and decided to go in and see Dr. Harrison before going home, and he allowed me to lie down; but I grew worse and fainted, and it was decided that I should stay here all night.' On the day following the deceased had a miscarriage, but went on well up to Friday, July 24, when the temperature went up. Dr. Herbert Spencer and Dr. Bradford saw her and considered her fit to be moved to Cheyne-walk, where she died upon July 27. Mr. A. J. Pepper, who made the postmortem examination, said that the deceased had nephritis. The uterus was healthy, but abortion had recently taken place. The cause of death was uremia from nephritis aggravated by the abortion. At the adjourned inquest on Wednesday, August 5, a verdict of 'Wilful murder against some person or persons unknown' was returned, and the jury adding: 'We wish to take some appreciative notice of the unselfish and Christian humanity of Dr. Harrison.' This is a very sad and very familiar story. We believe we are right in saying that the procuring of abortion otherwise than for reasons which can be medically justified is banned by the civil and ecclesiastical law of every civilized country, and as constructive murder it is right it should be so. But the whole question teems with difficulty. It certainly appears unjust, and very possibly is actually so, that a woman who, driven and harassed by shame and fear resorts to the questionable remedy of abortion should be liable to severe punishment, while the man who is equally responsible for the child goes free. Of course he is not responsible for the criminal act of the woman; but he is morally responsible in so far as he shared in bringing about the condition which made her resort to crime, and morally he is guilty although we fail to see how he can be made legally accountable."

#### Atlanta.

SOUTHERN MEDICAL COLLEGE.—Several changes have been made in the faculty of the Southern Medical College. Dr. Henry F. Harris, the former professor of chemistry and clinic

medicine, has resigned to accept the appointment of associate professor of bacteriology in the Jefferson Medical College of Philadelphia. Dr. Harris is one of the South's most able and energetic workers, and his researches in the field of amebic dysentery gives him prominence in this country. He has given much time to the study of this semi-tropical diarrhea, and will in a short time publish an interesting illustrated article on this subject. Dr. Ashby M. Purse of this city, has been appointed to succeed Dr. Harris as professor of chemistry in the Southern Medical College. He will fill the chair of chemistry with judgment and ability. Dr. G. G. Roy has been succeeded by Dr. C. D. Hurt of this city as professor of materia medica and therapeutics; Dr. Roy will remain with the college as an emeritus professor. Dr. Nicolson, the dean of this institution on the death of Dr. Powell, its founder, was made president by unanimous vote of the board of trustees. Dr. Nicolson's rank as a surgeon is well known. Dr. J. G. Bourns, late of Ann Arbor, has been elected professor of bacteriology, pathology and histology. Dr. Lucien Lofton of Atlanta, has been appointed assistant to the chair of anatomy, and assistant demonstrator of anatomy.

THE ATLANTA MEDICAL COLLEGE has made the following changes: Dr. H. P. Cooper will fill the chair of anatomy lately occupied by Dr. W. S. Armstrong, deceased. Dr. Hubbard of Atlanta, has been appointed assistant to the chair of materia medica.

INSOLATION.—A number of deaths have occurred in Atlanta and the immediate vicinity as result of heat stroke. Among the number, several children have succumbed. The immunity or resistance of a negro is noticeable. A fatal case of sun-stroke among the colored men hardly ever occurs here.

GOVERNOR ATKINSON recently appointed Dr. J. B. S. Holmes to succeed Dr. Olmstead on the regular board of medical examiners of Georgia.

WHY is it that the Georgia State Board does not look after the herd of wandering quacks that infest the city and the State?

DR. I. B. DIAMOND, recently of the Johns Hopkins University, was last month elected to the position of pathologist to the Grady Hospital.

### Cincinnati.

THE MORTALITY report for the week gives: Zymotic diseases 4; cancer 8; phthisis pulmonalis 11; other constitutional 3; local 40; developmental 12; violence 8; under 5 years 28; total 86; annual rate per 1,000, 12.77; corresponding week 1895, 124; 1894, 95.

THE ACADEMY of Medicine held its first meeting of the winter September 14. Dr. Albert Freiberg presented a paper on "Sub-phrenic Abscess following Appendicitis."

A MOVEMENT is on foot to organize a hospital for the care and treatment of the colored race in Cincinnati and vicinity. Dr. Frank W. Johnston is at the head of the movement.

DIPHTHERIA is spreading throughout the Mill Creek valley.

DR. JOSEPH EICHBERG, and Dr. S. E. Allen announce their removal to the "Lancaster" No. 22, W. 7th Street.

CHARLES COLLINS, a well known G. A. R. veteran has been appointed to succeed James Sherlock as supervisor of the Branch Hospital.

THE matter of the investigation of the Hygeia Medical College has at last been finally disposed of by the State Board of Medical Examiners, who have decided that the graduates from this institution will not be recognized as graduates and will have to pass the examination before the Board in order to be allowed to practice in the State.

THE ANNUAL REPORT of the Health officer, just issued, shows a balance on hand of \$4,835.93 out of an appropriation of \$44,393.23 set aside for the maintenance of the Health Depart-

ment. The milk inspector made 2,755 visits to dairies and prosecuted 25 cases for violation of the milk laws, of which 21 resulted in a conviction; 100,103 cows were inspected and stock valued at \$54,116 was condemned. The Health officer recommends the establishment of a central disinfection station for the thorough disinfection of all goods subjected to the influence of contagious diseases, public baths and the establishment of an isolation hospital.

THE CITY BOARD OF HEALTH of Mt. Sterling, Ohio, have ordered the public schools closed and all public gatherings stopped on account of the prevailing epidemic of diphtheria.

THE MEMBERS of the Hempstead Medical Association of Portsmouth have decided to prepare a black list of all persons who refuse or deliberately neglect to pay physicians' bills. The arrangement is to go into effect October 1, and medical treatment is to be refused to all persons whose names are on the list unless paid for in advance.

A CASE of fatal epistaxis occurred at Van Wert, Ohio, last week. The various methods for the checking of the hemorrhage were adopted but without avail.

Mississippi Valley Medical Association. The officers elect are: President, T. Hunt Stuckey, Louisville; Vice-President, Chas. A. Wheaton, St. Paul; Second Vice-President, Paul Paquin, St. Louis; Secretary, Henry E. Tuley, Louisville. Place of next meeting, Louisville, Ky.

## THE PUBLIC SERVICE.

**Army Changes.** Official List of changes in the stations and duties of officers serving in the Medical Department, U. S. Army, from Sept. 5 to Sept. 11, 1896.

The following named officers will report in person on Tuesday, Sept. 22, 1896, at 10 o'clock, A.M., to Colonel Charles H. Alden, Asst. Surg.-General, president of the examining board appointed to meet at the office of the Surgeon-General U. S. Army, for examination as to their fitness for promotion:

Captain William B. Davis, Assistant Surgeon.  
 Captain William W. Gray, Assistant Surgeon.  
 Captain Louis Brechemin, Assistant Surgeon.  
 Captain Louis A. La Garde, Assistant Surgeon.  
 Captain John M. Bantster, Assistant Surgeon.  
 Captain Aaron H. Appel, Assistant Surgeon.  
 Captain La Garde is relieved from duty as Attending Surgeon and Examiner of Recruits at Boston, Mass., to take effect upon the completion of his examination, and ordered to Fort Robinson, Nebraska, for duty.

### Change of Address.

Cobb, J. O., from Cincinnati, Ohio, to U. S. Marine Hospital, New York.  
 Dudley, Lewis W., from Chicago to Alma Sanitarium Co., Alma, Wis.  
 Eaton, Roy R., from Ithaca to Lowell, Mich.  
 Ferguson, R. V., from Guthrie to Hodensville, Ky.  
 Ferguson, J. W., from Canaan to West Salem, Ohio.  
 McMillen, R. M., from Kingwood to 1321 Chapline St., Wheeling, W. Va.  
 Maknen, G. Hudson, from Cresson to 1419 Walnut St., Philadelphia, Pa.  
 Ross, Geo. M., from 3628 State St. to 1216 Masonic Temple, Chicago.  
 Wadsworth, Chas. C., has removed his office and residence to 1104 Van Ness Av., San Francisco, Cal.

### LETTERS RECEIVED.

Alta Pharnal Co., St. Louis, Mo.; Ames, R. P. M., Springfield, Mass.  
 Bovee, J. Wesley, Washington, D. C.; Busey, S. C., Washington, D. C.; Bishop, S. S., Chicago.

## ORIGINAL ARTICLES.

### THE STATISTIC EVIDENCES OF THE VALUE OF VACCINATION TO THE HUMAN RACE, PAST, PRESENT AND FUTURE.

Read before the American Medical Association at the Jenner Centennial  
Celebration, held at Atlanta, Ga., May, 1896.

BY EUGENE FOSTER, M.D.

PROFESSOR OF PRINCIPLES AND PRACTICE OF MEDICINE AND STATE MEDICINE  
AND DEAN OF THE FACULTY OF THE MEDICAL DEPARTMENT  
UNIVERSITY OF GEORGIA, AUGUSTA, GA.

"Nothing however beneficent can escape the criticism of the times in which we live. The criticism of vaccination, often passionate and violent, related chiefly to points which, however interesting they may be, leave the main question unaffected. We may speculate about the possibility of the potency of vaccine being exhausted in the human family; we may be surprised to find that people with good vaccine scars sometimes have smallpox; we may dispute as much as we please about the average period when re-vaccination may be considered a prudent safeguard; but after all we find that we rest in a security against the horrid pestilence of smallpox unknown to former generations."—Dr. George Derby.

*Mr. President and Gentlemen:*—By invitation of your committee on the celebration of the anniversary of the discovery of vaccination, I appear before you this afternoon. Your greatly beloved and renowned Nestor, Dr. Davis, has most ably and charmingly made you acquainted with much of "The Work and Character of Jenner." The learned Surgeon-General of the United States Army, Dr. Sternberg, has delighted and edified you in his masterly presentation of the question, "The Scientific Basis of Vaccination." In my paper I am limited to "The Statistic Evidence of the Value of Vaccination to the Human Race, Past, Present and Future."

The great Jenner has long since gone to his reward; vaccination has reached a century old; millions of human lives, as I shall show, have been preserved by the fruits of Jenner's genius; yet to-day, no less than one hundred years ago, thousands upon thousands of men, some intelligent though designing, some intelligent though deluded, the great mass of them fanatical and ignorant, decried vaccination as not only being of no service to humanity, but positively a nuisance injurious to health and life, while millions of our fellow men are utterly ignorant of, or indifferent to the matter.

The study of statistics, gentlemen, is dry, uninviting, irksome to the vast majority of men. I therefore fear that I shall at least fail to interest, if indeed I do not weary you. I crave your attention for the reason that however dry and wearisome statistics may be, it is only by careful, critical study of statistics that we are enabled to rightly estimate the value and the magnitude of the immortal Jenner's discovery. In life, Jenner wisely and persistently insisted that the decision as to the value of his discovery should rest upon "that keenest of all arguments for or against the practice of vaccination, those which are engraved with the point of the lancet." I am here to present such an argument.

Standing as I do on this occasion to speak for the illustrious dead, I have attempted to so gather and marshal the statistic evidences of the value of his discovery that every intelligent, fair-minded man can know the truth about vaccination.

I propose to present you statistic data from almost every civilized country upon earth, indubitably proving that vaccination duly and efficiently performed is absolutely prophylactic against smallpox, and innocuous to human health and life. Be not frightened at the mass of manuscript before me, I shall read only a fractional part of it, and leave the balance to be studied at your leisure after it shall have been published. That I may present in an orderly arrangement the data bearing upon my subject I will lay down certain propositions and furnish the facts relative to each as it is reached.

Unless you are familiar with the history of smallpox in pre-vaccinal times, and know what it is at the present day independent of vaccination, you can not form a proper estimate of the beneficent results of Jenner's discovery. I shall, there-

fore, first show what smallpox was in pre-vaccinal times; and, second, what it is to-day in individuals and communities who neglect to avail themselves of its benefits.

#### PROPOSITION I.

Smallpox uncontrolled by vaccination was one of the most universally prevalent and destructive diseases of the human race. I shall first show this by historic records both professional and non-professional.

Prior to the introduction of vaccination, smallpox, except in remote or isolated populations, having infrequent and difficult intercourse with the business world, was a well nigh universal disease, existing continuously as an endemic in large communities, and breaking loose from its endemic haunts every few years<sup>1</sup> it assumed epidemic and not infrequently pandemic proportions. All classes, conditions and ages of people were attacked by smallpox. While most fatal and prevalent in the over-crowded homes of the poor, it spared not the dwellers in mansions nor the palaces of kings.<sup>2</sup> So universally prevalent was smallpox that it was quite exceptional in populous communities for anyone to reach adult age without having been attacked by the disease.<sup>3</sup> In 1518 smallpox concurred with fire and sword and famine to complete the depopulation of St. Domingo.<sup>4</sup> In the sixteenth century smallpox invaded Mexico,<sup>5</sup> destroying three million, five hundred thousand of her population. In 1563 smallpox invaded Brazil and exterminated whole races of men. In the Province of Quito (according to De la Condamine) it caused the death of 100,000 Indians. It decimated Siberia<sup>6</sup> and Kamschatka.<sup>7</sup> Several times this destructive disease has well nigh depopulated Greenland and Iceland.<sup>8</sup> Under the devastation of this cruel and relentless enemy communities literally dissolved themselves.<sup>9</sup> Remote and unprotected populations in North America have been most cruelly scourged by epidemics of smallpox.<sup>10</sup>

<sup>1</sup> Hillary on Smallpox, London, 1735.

<sup>2</sup> Burnett's history of Mary and William; Walpole's letters, 1750. Pepsy & Evelyn, St. Simon Besenval, Vohse, etc.

<sup>3</sup> Hillary, loc. cit., Haygarth, Smallpox, London, 1793.

<sup>4</sup> John Simon K.C.B., F.R.S. First Report Royal Commission Enquiry on Vaccination 1839.

<sup>5</sup> Prescott (Conquest of Mexico Vol. 6.) describes this epidemic as "sweeping over the land like fire over the prairies, smiting down prince and peasant . . . leaving its path strewn with the dead bodies of the natives, who perished in heaps like cattle stricken with the murrain. Dr. Stricker (Oppenheim's Zeitsche Vol. 84), referring to several subsequent epidemics of smallpox in Mexico says: In 1779 its ravages were dreadful. In the capital alone nearly 9,000 died out of 24,561 attacked. He then contrasts with the above periods the history of smallpox since vaccination. He says: In 1829-30 when smallpox was most severely epidemic, vaccination was almost always protective. In 1830-31 there died in New Leon 1,740 persons, without a single vaccinated person having contracted the disease.

<sup>6</sup> Pallas (Reisen, St. Petersburg, 1770) cites more than one epidemic of smallpox in Siberia, and in referring especially to the Ostjaks (vol. 3, p. 50) mentions this disease as the chief obstacle to an increase of their numbers.

<sup>7</sup> Capt. Cook (Voyages to Pacific Ocean 1785) refers to the first appearance of smallpox 1767 in Kamschatka as "marking its progress with ravages not less dreadful than the plague, and seeming to threaten their extinction."

<sup>8</sup> John Simon (loc. cit.), 1734, Greenland was first invaded by smallpox and lost by this one disease about two-thirds of her population. Iceland had been invaded by smallpox seventeen times prior to 1707. In this year 18,000, out of a total population of 50,000, died by this cruel disease. Crantz's History of Greenland, London, 1767, referring to the epidemic of 1707 says: "Empty depopulated houses and unburied corpses, some within and some without the houses, were commonly encountered. In one Island they found one girl with the smallpox on her and her three little brothers, the father having first buried all the people in the place, had laid himself and his smallest sick child in a grave raised with stone, and ordered the girl to cover him. Sir George MacKenzie (Travels in Iceland, Edin. 1811) speaking of smallpox in Iceland says: "Its ravages have been such as to render this disease important even in the political history of the Island."

<sup>9</sup> Ring, in his treatise on Cowpox, says, that after such a dispersion the capital of Thibet once remained for three years without inhabitants. He also, in referring to smallpox near the end of the 18th century speaks of a tribe of esquimaux on the Labrador coast having been put to flight by this disease and did not return for a space of three years: that their country had become a desert, without a living soul in it, but they found the skeletons of 500 persons who had fallen victims to that horrible disease. Dr. Mead's works describes the Hottentots on a particular occasion as drawing lines of defense against any communication with the sick, and shooting all who attempted to pass.

<sup>10</sup> Catlin (Letters and Notes on the Manners and Customs of the

So much for the epidemic prevalence of smallpox in those portions of the world having less constant and direct relations with more populous centers. In Europe, as might have been expected from constant intercourse of peoples of towns and nations, the disease was, in the run of years, as deadly as in the places above cited. "Its strength indeed was differently distributed. Not as in Greenland, twice or thrice in a century, but incessantly, that fatal sickle was in motion, and the harvest counted from day to day. Instead of coming after long absence on masses of population entirely unprotected against the infection, it recurred in each place so frequently that, for the most part, at any given moment, a more or less considerable majority of the inhabitants would have faced the danger before they would have obtained against its attacks that protective exemption which was generally the good fortune of survivors. But it is a moderate computation that for every five persons thus, at the price of much past suffering, almost secured against the disease, one at least must have died." John Simon.

Macauley,<sup>11</sup> the great English historian, speaking of the smallpox near the close of the seventeenth century: "That disease (smallpox) over which science has since achieved a succession of glorious and beneficent victories, was then the most terrible of all the ministers of death. The havoc of the plague had been far more rapid; but the plague had visited our shores only once or twice within living memory; and the smallpox was always present, filling the churchyards with corpses, tormenting with constant fears all whom it had not yet stricken, leaving on those whose lives it spared the hideous traces of its power, turning the babe into a changeling at which the mother shuddered, and making the eyes and cheek of the betrothed maiden objects of horror to the lover. Toward the end of the year 1694, this pestilence was more than usually severe."

Sir Gilbert Blaine<sup>12</sup> says: "It is greatly within the truth to assert that smallpox has destroyed a hundred for every one that has perished by plague."

Dr. Black, Lussmih, Frank and several other reputable writers, estimated that the average annual mortality from smallpox in Europe alone was in pre-vaccinal times 494,000. Within the London bills of mortality<sup>13</sup> smallpox, when not at its worst, averaged a fourteenth of the annual total deaths; a fourteenth too, at times when that total, as compared with the population, represented, perhaps, double our present death rate.

North American Indians, London, 1841 says: "Thirty millions of white men are now scuffling for the goods and luxuries of life over the bones and ashes of twelve millions of red men, six millions of whom have fallen victims to the smallpox." Again, I would venture the assertion, from books that I have searched and from other evidence, that of the numerous tribes which have already disappeared, and of those that have been traded with, quite to the Rocky Mountains, each one has had this exotic disease in their turn, and in a few months have lost one-half or more of their numbers. Loyd, Translator of Prince Maximilian's Travels in the Interior of North America, in the preface of the work wrote the following description of an epidemic of smallpox among the Indians, and says the general correctness of the details have been confirmed to him by several travelers who had subsequently visited those nations. "The disease first broke out about the 15th of June 1837, in the village of the Mandans, a few miles below the American Fort Leavenworth, from which it spread in all directions with unexampled fury. The character of the disease was as appalling as the rapidity of the propagation. Among the remotest tribes of the Assiniboins from 50 to 100 died daily. The patient, when first seized, complains of dreadful pains in the back and head, and in a few hours he is dead; the body immediately turns black, and swells to thrice its natural size. In vain were hospitals fitted up in Fort Union and the whole stock of medicines exhausted. For many weeks together our workmen did nothing but collect the dead bodies and bury them in large pits; but since the ground is frozen we are obliged to throw them into the river. The ravages of the disorder were the most frightful among the Mandans where it first broke out. That once powerful tribe which by accumulated disasters, had already been reduced to 1,500 souls, was exterminated, with the exception of 30 persons. Their neighbors, the Big-bellied Indians and the Ricarees, were out on a hunting excursion at the time of the breaking out of the disorder, so that it did not reach them until a month later; yet half the tribe was destroyed on the 1st of October and the disease continued to spread. Very few of those who were attacked recovered their health, but when they saw all their relations buried, and the pestilence still raging with unabated fury among the remainder of their countrymen, life became a burden to them, and they put an end to their wretched existence, either with their knives or muskets, or by precipitating themselves from the summit of the rock near their settlement. The prairie all around is a vast field of death, covered with unburied corpses, and spreading for miles pestilence and infection. The Big-bellied Indians and Ricarees, lately amounting to 4,000 souls, were reduced to less than the half. The Assiniboins, 9,000 in number, roaming over a hunting territory to the north of the Missouri as far as the trading posts of the Hudson's Bay Company, are, in the literal sense of the expression, nearly exterminated. They, as well as the Crows and Blackfeet, endeavored to fly in all directions, but the disease everywhere pursued them. At last every feeling of mutual compassion and tenderness seems to have disappeared. Every one avoided the others. Women and children wandered about the prairie seeking for a scanty subsistence. The accounts of the situation of the Blackfeet are awful. The inmates of over 1,000 of their tents are already swept away. They are the bravest and most crafty of all the Indians, dangerous and implacable to their enemies, but faithful and kind to their friends. But very lately we apprehended that a terrible war with them was at hand and that they would unite their whole remaining strength against the whites, but the smallpox cast them down, the brave as well as the fee-

M. De la Condamine<sup>14</sup> estimated that one tenth of the deaths in France were from smallpox. In 1805, Dr. M. Laborde, in an article entitled "An Account of the Introduction of the Vaccinal Disease into the Isles of France and Reunion," says: "I had been a witness of the variolous epidemic which had, in 1792, swept off one-fourth the population of the Isle of France."

Rosen claims that one-tenth of the deaths in Sweden were annually from smallpox.

Two<sup>15</sup> millions of the inhabitants of the Russian empire died of smallpox in a single year. In Russia previous to the discovery of vaccination it was estimated that a seventh part of the population perished by smallpox. See "Cross History of Variolous Epidemic in Norwich, England, 1820."

In Boston, Mass.,<sup>16</sup> in 1721, out of a population numbering 11,000 people there were 5,759 cases of smallpox, of which 844 were fatal. Thus it is shown that more than one-half of the inhabitants had the disease, and one thirteenth died of it. In 1730 there were 4,000 cases, with 200 deaths. In 1752 there were 5,000 cases of smallpox out of a population numbering 15,684, with 539 deaths. In 1764 there were 5,646 cases. In 1776, 5,292 cases. In 1792, 8,346 cases of smallpox.

Sir Gilbert Blaine says: "When there was no vaccination in our navy, one-fifth of all the men enlisted died of smallpox."

Bernouli,<sup>17</sup> writing in 1840, said:

"Great as were the ravages which the plague often caused in Europe, smallpox carried off more victims in the last century than the former disease did in any other. Certainly smallpox is not so deadly as either the plague or cholera. Formerly one-third of the cases among little children terminated fatally, but altogether only one-sixth to one-eighth of the total number of cases. On the other hand the disease (smallpox) had become an endemic contagion in Europe, which no where completely died out, to which nearly all individuals were susceptible, and from which but few escaped before even their tenth year. Of 100 adults only about four or five remained unattacked. It was calculated that two-thirds of all children born succumbed to it. In former times, too, there was greater probability of an individual dying from smallpox. According to the London list of 1708 to 1750 eight out of every one hundred deaths were caused by smallpox. In Berlin the smallpox mortality from 1783 to 1797 was one-twelfth of the total. Those who were carried off by that disease were naturally almost all children."

ble, and those who were once seized by this infection never recovered it is affirmed that several bands of warriors who were on their march to attack the fort, all perished by the way, so that not one survived to convey the intelligence to their tribe. Thus in the course of a few weeks, their strength and their courage were broken, and nothing was to be heard but the frightful wailings of death in their camp. Every thought of war was dispelled and the few that are left are as humble as famished dogs. No language can picture the scene of desolation which the country presents. In whatever way we go we see nothing but melancholy wrecks of human life. The tents are still standing on every hill, but no rising smoke announces the presence of human beings, and no sound but the croaking of ravens and the howling of the wolf interrupt the fearful silence. The above accounts do not complete the terrible intelligence we receive. There is scarcely a doubt that the pestilence will spread to the tribes in and beyond the Rocky Mountains, as well as to the Indians in the direction of Santa Fé and Mexico. It seems to be irrevocably written in the book of fate, that the race of red men shall be wholly extirpated in the land in which they ruled, the undisputed masters, till the rapacity of the whites brought to their shores the murderous firearms, the enervating ardent spirits, and the all-destructive pestilence of the smallpox. According to the most recent accounts, the number of Indians who have been swept away by the smallpox, on the western frontiers of the United States amounts to more than 60,000."

In Drake's Indians of North America (page 677-8, he says: "Scenes of wretchedness have been recorded in our early pages, occasioned by malignant diseases, among Indians of our own land. We are to relate the doings of death on a broader scale, in the regions of the upper Missouri. In October last (1837) the smallpox was still raging over that vast country. Up to the first of that month, the Mandans were reduced from 1,600 to 31 souls; the Minnetarees from 1,000 to 500, and they were still dying fast. The Ricarees, who had recently joined them, were hunting by themselves, when the disease was raging among their friends, and were not seized by the horrible malady until a month later. They numbered 3,000, and half of them were in a few days swept away, and hundreds of the survivors were killing themselves in despair, some with their own spears and other instruments of war, and some by casting themselves down high precipices along the Missouri. The Blackfeet had known no such foe before it reached the Rocky Mountains and swept away the people in a thousand lodges.

<sup>11</sup> Macauley's History of England.

PROPOSITION 2.

Smallpox in a population unprotected by vaccination is as generally prevalent and fatal disease at the present day as in the pre-vaccinal period.

In 1872-73, in a few months, in the town of Brunei,<sup>18</sup> in Borneo, 4,000 out of a total population of 35,000 died of smallpox.

On the Gold Coast,<sup>19</sup> in 1871, smallpox is described by Acting Administrator Salmon as decimating the population. He says: "Nothing but the active interference of the local government could have saved the people from annihilation."

At Ceara, in Brazil, smallpox killed 40,000 out of a total population of 70,000. These facts were reported by Mr. Ashbury, Member of Parliament for Brighton, who visited the spot about the close of the epidemic.

At Tamatave, Madagascar, according to the report of the United States Consul, smallpox in 1877 destroyed 800 citizens within two months. The disease attacked all who had not had smallpox or been vaccinated. The disease was confined almost exclusively to the natives, the foreign residents having been previously vaccinated.

Dr. Makena describes an epidemic of smallpox in the Argentine Confederation from 1846-48 as "sweeping with the wings of death over that enormous tract of country which extends from the seaboard of the Atlantic on the East to the Cordillera of the Andes on the West. Throughout this whole space it may be said that hardly a single house or ranch escaped its fearful visitation, wherever the current of human intercourse reached, and such was its fatality that I have known thirty children taken in one morning from the houses of one quadrangle of a street 150 yards long. Whole families were swept away, and, in short, the terrors of the plagues of former times were, if not surpassed, fully equaled by this horrible scourge. But that which struck me as most truly remarkable was that not one of those English people who had been vaccinated at home, and who had the large, deep, oval thimble-mark on one or both arms, ever took the disease."

In California, according to the reports of Doctors Logan,<sup>20</sup> Gibbons and Hatch,<sup>21</sup> who personally witnessed the disease, smallpox prevailed to a greater extent than was ever before known, and with a virulence and fatality which has not been surpassed. It was, if possible, more severe in private practice than in hospital. Dr. Hatch, in Sacramento, reports 1 death in 3.2 in hospitals and 1 in 2.9 in private practice, making the rates for deaths for both 1 in 3. This agrees with the observations of Dr. Logan, who reports 1 death to every 3 in Sacramento, and 1 to every 2.5 in San Francisco. When we bear in mind that the usual death rate for smallpox, before the introduction of vaccination, did not exceed 1 in 5 or 6, we will agree with Dr. Logan, "this fatality is almost unprecedented in the annals of this disease."

The reports of the Indians were brought by traders and do not furnish data upon which to make a statistic statement, nevertheless all agree in representing the manifestation and ravages of the disease as fearful. In many instances whole encampments were attacked and large numbers were swept off.

In Cincinnati, the epidemic, though not so virulent as in California, was the severest and most extended of any former visitation. During the months of November, December, January and February, 1868-69, the Cincinnati Board of Health had 2,674 cases of smallpox reported to it, and 511 deaths, making 1 death to every 5.24. This is deemed by many as a higher death rate than actually occurred, as it is claimed that some physicians did not report their cases of smallpox to the health officer. One thousand additional cases will certainly cover all unreported ones, and would make the death rate about 1 in 7.

How can we account for the extreme severity of the epidemic at these three points?

In California, Dr. Logan, physician to the Smallpox Hospital, Sacramento, says: "The primary and chief cause is inattention to vaccination. The large proportion of deaths that have occurred, especially in children, and in a certain class of the floating population of California, particularly the Mexicans, South American or Californian nativity, shows that the extensive prevalence of smallpox in our midst is not due to the failure of the anti-variolous power claimed for vaccination but to the neglect or absence of its protecting influence."

From far-off India<sup>22</sup> comes a most convincing argument, which I quote from a medical journal: "Although the epidemic of smallpox visited the northwestern provinces of India

in a fearful manner, causing 58,800 deaths in the single year of 1873 all attempts at introducing vaccination as a protective measure were resisted by the superstitious natives. They looked upon smallpox as a visitation from a deity, called by them Sitta, whose anger had to be appeased with special sacrifices and plagues. The faithful Hindoos considered it an act of impiety to still further incite the wrath of the deity by the administration of unholly medicines or vaccination. In spite of all this, however, vaccination, although under peculiar circumstances, was gradually introduced among the natives. The Thakers, a tribe that still practices infanticide to a horrible extent, first allowed their female children to be vaccinated, being convinced of its fatal termination, and hoping thereby to get rid of this superfluous progeny. All the sons, however, were carefully guarded against vaccination. Smallpox broke out in four of their villages a short time afterward, which carried off nearly all the boys while the girls escaped the disease. This unlooked for termination induced the natives to resort to the opposite practice, compelling the boys to be vaccinated while the girls were left unprotected. Beside this, a large number of cases were observed where children were concealed by their families from the vaccinators; in almost all instances these died, while those vaccinated escaped smallpox." Even one such remarkable and unanswerable illustration as this should convince every one of the utility of vaccination, but I have only commenced my arguments and will continue to give you more interesting ones.

Mr. Alexander Wheeler, Darlington, England, an ardent anti-vaccinationist, in a paper entitled "Vaccination in the Light of History," London, 1878, says: "In India smallpox carried off 101,397 people in 1875."

Hirsch, in his work, "Handbuch der Historisch-geographischen Pathologie," says that between 1866 and 1869 smallpox killed 140,000 natives in Bombay and Bengal. In the whole of India, 1873 and 1874, 500,000 inhabitants died of the disease. (See Second Report Royal Vaccination Commission of Great Britain, 1890, p. 10.)

To-day the terrors of smallpox are almost forgotten; only occasionally the disease attacks a population unprotected by vaccination. In 1884, in San Salvador<sup>23</sup> smallpox carried off nearly one-fiftieth part of the population.

PROPOSITION 3.

In every nation upon earth where vaccination of the populace has been generally resorted to a marked decrease in the smallpox death rate has invariably followed.

While statistic data are not available from all countries using vaccination as a weapon of defense against smallpox, the Great English sanitarian, John Simon, with the assistance of Mr. Hailie, has prepared a table which conclusively demon-

strates the great and positive benefits in controlling smallpox. This table shows two varieties of facts: "1, how many persons in each million of population died annually of smallpox before the use of vaccination; and, 2, how many persons in each

Approximate average annual death rate by smallpox per 1,000,000 of living population.

Terms of years respecting which particulars are given.	Territory.	Before introduction of vaccination.	After introduction of vaccination.
1777-1809 and 1807-1850.	Austria, Lower . . . . .	2,484	340

<sup>23</sup> U.S. Consul Murphy. Loc. cit. Berlin.

million of population have annually died of smallpox since, the use of vaccination." The author draws the conclusion, as the reader may also do, between the case of Sweden in the twenty-eight years before vaccination and the forty years afterward: "During the earlier period there used to die of smallpox, out of each million of the Swedish population, 2,050 victims annually; during the latter period, out of each million of population, the smallpox deaths have annually averaged 158." "Or, taking to metropolitan cities, you find that in Copenhagen, for the next half century, 1751-1800, the smallpox death rate was 3,128, but for the next half century only 286; and still better in Berlin, where for twenty-four years preceding the general use of vaccination, the smallpox death rate had been 3,422, for forty years subsequently it has been only 176. In other words, the fatality of smallpox in Copenhagen is but an eleventh of what it was; in Sweden, a little over a thirteenth; in Berlin and large parts of Austria but a twentieth." These statistics show that the adoption of vaccination has been followed by a reduction of the smallpox mortality to a tenth and a twentieth of its former magnitude.

Dr. William Ogle, superintendent of statistics in office of Registrar General, in first report of Royal Vaccination Commission, 1889, in comparing the mortality from smallpox in our day with that of the seventeenth and eighteenth centuries, said:

"I have taken as a basis for comparison the ten years from 1871 to 1880, which are the years which include the great outbreak in London in 1870-71, so that those years represent a time when smallpox was particularly abundant in London. Taking those ten years, I find that in round numbers, the smallpox deaths were 20 in 1,000, from all causes. I then go back 100 years to the corresponding decennium in the eighteenth century, 1771-1780, and I find that the smallpox deaths were then 97 in 1,000. Then going back another hundred years, 1671-80, I find that the proportion was 66 in 1,000; so that in the present century smallpox as measured by its proportion of deaths to deaths from all causes, has been from three to five times less common than it was in those previous times; and it is plain that if the death rate of the eighteenth century and the death rate of the seventeenth century was higher than it is now, smallpox must have been very much more prevalent, because a large proportion of a larger number of deaths occurred from it. Of course it is only an assumption that the death rate was higher in the seventeenth and eighteenth centuries than it is now."

Dr. Hopkirk presented the following table to the Royal Vaccination Commission:

TABLE A.\*--Table showing for the city of Berlin the number of inhabitants, deaths from all causes and the deaths from smallpox in the years 1758 to 1774 and 1782 to 1872, and in particular for each of the years of smallpox epidemics. (Zeitschrift des Königl. Preuss. Stat. Bureau. Jahrgang 12, 1872; Art. "Die Pocken-Epidemie in Berlin, 1870-72," by Dr. Guttstadt.)

John Simon presented the following table (see Royal Commission on Vaccination, first report, 1889, page 88).

General and Differential Annual Death Rates in London per 100,000 living, at seven different periods during the 226 years, 1629-1854.

Causes of Death.	Bill of Mortality.						Registration returns. (Dr. Guy.)
	1629-35	1660-79	1728-57	1771-80	1801-10	1831-35	
Smallpox . . . . .	180	417	426	502	204	83	40
Measles . . . . .	16	47	37	48	94	86	58
Consumption . . . . .	1,021	1,255	905	1,121	716	567	323
Scrofelia . . . . .	14	19	5	5	?	3	12
Dropsy . . . . .	146	349	218	225	131	133	59

What does the ratio of epidemics teach us? Read it. The report of the Epidemiological Society of London says: First, during ninety-one years, previous to inoculation, there were sixty-five distinct and well-marked epidemics, which is a ratio of 71.4 epidemics in one hundred years; second, during sixty-three years in which inoculation was practiced, and that to a great extent, there were fifty-three distinct and well marked epidemics, which is a ratio of eighty-four epidemics in one hundred years; third, during the last fifty years, in which vaccination has been practiced and inoculation declared illegal, there have been twelve epidemics of smallpox, which is a ratio of twenty-four epidemics in one hundred years.

To go back to Jenner's day we find the following testimony from his papers: "From 1762 to 1792 the number of persons that died of smallpox in the Danish dominions amounted to 9,728. About the year 1802 vaccination was first introduced, and the practice became general but not universal; however, fifty-eight persons died of smallpox in the year 1810. Vaccination, by order of the king, was now universally adopted and smallpox inoculation prohibited, and from the year 1810 to the year 1819 not a single case of smallpox has occurred. From Bombay, I learn the smallpox is there completely subdued, not a single case having occurred for the last two years."

Drs. Seaton and Buchanan, in 1863, examined more than fifty thousand children in the national schools and workhouses in England to attempt to determine what proportion of them were unvaccinated, what proportion had formerly been vaccinated, and the number among those vaccinated who had contracted smallpox since vaccination.

Classification of Children.	Number examined of each class.	Number in each class that had traces of smallpox.	Proportion having traces of smallpox per 1,000 children in each class respectively.
1. Without any mark of vaccination	2,837	1,010	360
2. With doubtful mark of vaccination.	508	30	59
3. With mark or marks of vaccination . . . . .	49,570	88	1.78

Lord Jeffrey, in 1807, at that time editor of the *Edinburgh Review*, a man most thoroughly skilled in the principles of searching and rigorous applications of the rules of evidence, highly endorses the value of vaccination, and says of Jenner's claim, "not until he had vaccinated some hundred children, and put them, at different intervals, to the test of inoculation for smallpox without effect, that he ventured to publish his discovery, in the year 1798, in a treatise, followed up the year after by a still longer list of such experiments and observations." In the same article he adds, "When the practice of vaccination was discussed and confidently recommended, in

1800, by all the eminent practitioners in London, this was done only after full consideration of its efficacy, as compared to inoculation for smallpox; that Dr. Woodville in particular, physician to the smallpox hospital, then stated that within the last six months he had vaccinated there 7,500 persons, the half of whom had been since inoculated with smallpox matter without the slightest effect being produced in any instance."

The report of the Faculty of Medicine at Prague to the Minister of the Interior, requesting information for the Government of Great Britain relative to the results of vaccination, offers one of the most interesting tables of any known to me. From this vast storehouse of facts the following summary is taken: From 1796 to 1802 inclusive, the average annual population observed was 3,039,722; total average number of deaths annually from all causes, 94,955; total deaths annually from smallpox, 7,673; showing one death from smallpox to every 396 of the population, and the deaths from smallpox to the total number of deaths was one in 12 $\frac{1}{2}$ . From 1832 to 1855 inclusive, during twenty-four years subsequent to introduction of vaccination, with an average population of 4,248,155, total deaths annually were on an average 131,412. The average number of deaths annually from smallpox was 287,724; showing deaths from smallpox to population to be 1 in 14,741; deaths from smallpox to total number of deaths, 1 in 457. Among an average annual population of 143,122 persons vaccinated and 4,291 unvaccinated, the cases of smallpox annually existing were 389 among the vaccinated, and 355 among the unvaccinated population, i.e., one case of smallpox occurred among 367 vaccinated; one case of smallpox occurred among 12 unvaccinated. These tables further show the following facts: One fatal case of smallpox occurs among 7,166 vaccinated; one fatal case of smallpox occurs among 40 unvaccinated. In the Grand Duchy of Baden similar fruits have followed vaccination. Reliable statistics show that for a long number of years of compulsory vaccination with an average annual population of 1,200,000, only 100 cases of smallpox occur each year, and only 13 of this vast population have died each year of smallpox.

In Great Britain from 1750 to 1800, of every 1,000 deaths, 96 were from smallpox. From 1800 to 1850, of every 1,000 deaths, 35 were from smallpox. During the latter period the population was quite generally, but by no means universally, vaccinated.

In the German States, where more attention was paid to vaccination, the following were the results obtained: Before vaccination of population, deaths from smallpox amounted to 66.5 per 1,000; subsequent to vaccination, 7.66 per 1,000.

Dr. Marson of England, from the records of his great hospital experience, shows the merits of vaccination: "The smallpox death risks of no vaccination are to the death risks of the very worst vaccination as three to one; to the death risks of the best vaccination as seventy to one."

From an experience of twenty-one years in Bohemia among four millions of population, the testimony of that country most strikingly illustrates the value of vaccination. Among the vaccinated population contracting smallpox the death rate was but 5.1 per cent; the death rate of the unvaccinated was 29.8 per cent.

The most reliable statistics, and at the same time the fairest, upon the value of vaccination, are to be found in the records of the army, for here alone is it possible to compel thorough vaccination of the entire population. Infringement of personal liberty, so dearly availed of as the shibboleth of the civilian, is treated with merited contempt in the army when it contravenes the rights of others. Vaccination having been decided an individual and collective benefit, the soldier has no choice in the matter; he is compelled to submit to it. In thus protecting himself he at the same time benefits his comrades. To the honor of the surgeons of the army and navy be it said they are able, fearless and conscientious sanitarians, and in no other department have the rich results of sanitary science shown forth so conspicuously. Sir Gilbert Blaine says prior to vaccination, "Smallpox was one of the greatest embarrassments to the operations of armies." Let us see how it was after vaccination.

By reference to the statistics of sickness and mortality in the army of Great Britain for the twenty years from 1817 to 1836 inclusive, the following data are to be found. (Every soldier is vaccinated upon entering the army.)

In the dragoon regiments and guards, with an aggregate of 44,611 men, with a total mortality of 637, but three deaths occurred from smallpox.

At Gibraltar, with an aggregate of 60,000 troops, with a total mortality of 1,291, only one death was caused from smallpox.

Among the British and white troops in the West Indies, with

an aggregate strength of 86,000, and a total mortality of 6,803; and among the black troops, numbering 40,000, with a mortality of 1,645, not one fatal case of smallpox occurred, although during this period several epidemics of smallpox decimated the islands.

Among the troops at Bermuda, Nova Scotia, Cape of Good Hope and Mauritius, for twenty years, there was not one death from smallpox.

In Western Africa, while smallpox was ravaging the inhabitants unvaccinated, not a case of smallpox occurred among the white soldiers who had been vaccinated.

From 1818 to 1836 inclusive, in an army of 40,000 aggregate, British troops at Malta, while smallpox was playing sad havoc among the unvaccinated inhabitants, in repeated epidemics, there were only two deaths from this disease in the vaccinated army.

During the same period in Ceylon, among the white soldiers, with a total mortality of 3,000, there were only four deaths, with eight cases, from smallpox, notwithstanding repeated epidemics of the disease among the natives.

In the British troops serving in the United Kingdom from 1859 to 1864 inclusive, the following were the results of vaccination: Total number troops, 473,483; cases of smallpox, 664; deaths from smallpox, 40; showing the ratio per 10,000 of strength to be: Cases of smallpox, .14; deaths from smallpox, 0.84.

In the British navy—home force—for the same period of time, 1859 to 1864 inclusive, the following data are furnished: Total mean strength, 127,660; cases of smallpox, 416; deaths, 29; ratio per 10,000 of strength: cases, 33; deaths, 2.3.

Since 1803 to 1863, among the thousands of vaccinated children admitted into the Royal Military Asylum of England, there has not been a case of fatal smallpox. This testimony is the more striking since the records show that during that time four deaths occurred among those who had previously had smallpox.

PROPOSITION 4.

As vaccination became more general smallpox decreased in extent and fatality.

Dr. Ogle reviews the statistics of smallpox in England and Wales from 1838 to 1887 inclusive, accurately kept in the office of the registrar general—the civil register having been commenced in 1837. The registrar general's returns show the smallpox death rate and the smallpox deaths in proportion to population for each year during the period 1838 to 1887, except the four years 1843-6, during which four years no returns were tabulated in the registrar general's office. Dr. Ogle then presented the table marked A hereto appended. This table shows that the smallpox deaths in 1838 reached 1,064 per 1,000,000, and that only one year in the forty-nine years (1871) did the smallpox deaths ever approach that of 1838. He then divides the deaths in these forty-six years into three periods. First, 1838 to 1858, inclusive, in which vaccination was nominally compulsory, but no effectual means of enforcing it, practically optional. In this period the smallpox death rate was 408 per 1,000,000 population. The second period, 1859 to 1871 inclusive, in which vaccination laws were more efficiently enforced (though not thoroughly carried out) the smallpox death rate was 223 per 1,000,000. The third period, 1872 to 1887, when compulsory vaccination was thoroughly enforced, the smallpox death rate per 1,000,000 population was 114; thus demonstrating a marked progressive decrease in the smallpox death rate corresponding in time with the changes in the vaccination laws. The decline from 1838 to 1887 was about 7.2 per cent.

ENGLAND AND WALES.

TABLE A.—Deaths from smallpox per 1,000,000 living, 1838-42 and 1847-87.

Year.	Deaths.	Year.	Deaths.	Year.	Deaths.	Year.	Deaths.
1838 . .	1,064	1851 . .	389	1864 . .	367	1877 . . .	178
1839 . .	589	1852 . .	401	1865 . .	303	1878 . . .	79
1840 . .	661	1853 . .	171	1866 . .	141	1879 . . .	25
1841 . .	400	1854 . .	151	1867 . .	116	1880 . . .	29
1842 . .	168	1855 . .	134	1868 . .	93	1881 . . .	124
1843 . . . . .	1856 . .	119	1869 . .	70	1882 . . .	54	
1844 . . . . .	1857 . .	204	1870 . .	116	1883 . . .	39	
1845 . . . . .	1858 . .	332	1871 . .	1,015	1884 . . .	87	
1846 . . . . .	1859 . .	195	1872 . .	824	1885 . . .	107	
1847 . . . . .	1860 . .	188	1873 . .	101	1886 . . .	13	
1848 . . . . .	1861 . .	66	1874 . .	91	1887 . . .	21	
1849 . . . . .	1862 . .	80	1875 . .	40	.....	.....	
1850 . . . . .	1863 . .	289	1876 . .	103	.....	.....	

N. B.—The above figures include deaths from chickenpox.

Dr. Ogle next considers the question of the possibility of this decreased smallpox death rate being attributable to improved sanitation rather than vaccination. He submitted the following table:

TABLE B.—Mean annual deaths from smallpox at successive life periods, per 1,000,000 living at each such life period, 1847-53, 1854-71 and 1872-87.

Period.	All ages.	0-5	5-10	10-15	15-25	25-45	45 and upward.
1. Vaccination optional, 1847-53 . . . . .	805	1,617	337	94	109	66	22
2. Vaccination obligatory, but not efficiently enforced, 1854-71 . . . . .	223	817	243	88	163	131	52
3. Vaccination obligatory, but more efficiently enforced by vaccination officers, 1872-87 . . . . .	114	242	120	69	122	107	47

In this table the period of optional vaccination begins with 1847, not with 1838, because the deaths were not abstracted in combination with ages until 1847.

He, Dr. Ogle, then points out the fact that if the decreased death rate from smallpox had been attributable to improved sanitary conditions under which the population lived that all ages would have shared in the benefits. But the table just referred to demonstrates that with the marked decline in the smallpox death rate (72 per cent.) that no such thing resulted. The table demonstrates: 1. That during the first five years of life the lessened smallpox mortality was 85 per cent. 2. In children between the ages of 10 and 15 years it declined 27 per cent. At every age period subsequent to 15 years the mortality actually increased. 3. From 15 to 25 years the smallpox death rate increased. 4. From 25 to 45 years of age the smallpox death rate increased.

Again to show that improved sanitation did not produce the result claimed for it by antivaccinists, the record shows that the decrease in the general death rate during the period in question was but 9 per cent, while the decreased smallpox death rate reached 72 per cent. The comparative decrease in zymotic diseases was as follows: Measles, 9 per cent.; whooping cough, 1 per cent.; smallpox, 72 per cent.

To further demonstrate Proposition 4, I cite the following tables. A glance at these tables conclusively demonstrates the vastly decreased smallpox death rate of those countries rigidly enforcing vaccination over those wherein vaccination is optional, or nominally compulsory.

Smallpox in Europe, 1870-1885.\*

Countries.	Period.	Population.	Deaths from smallpox.	Ratio per 10,000.
Italy (264 chief places) . . . . .	1881-84	7,149,256	4,673	1.63
England and Wales . . . . .	1880-84	26,418,861	8,823	0.67

Table showing, for the years 1871-74, the mortality from smallpox in Prussia per 100,000 inhabitants. (Lotz, "Pocken und Vaccination," p. 88, after Grotstadt.)

In the old Provinces without compulsory vaccination.	1871	1872	1873	1874
1. Prussia . . . . .	224	503	80	18
2. Brandenburg . . . . .	340	282	24	5
3. Pomerania . . . . .	237	249	15	3
4. Posen . . . . .	455	682	128	24
5. Silesia . . . . .	214	321	53	21
6. Saxony . . . . .	277	176	28	3
7. Westphalia . . . . .	255	209	14	2
8. Rhineland and Hohenzollern . . . . .	264	106	5	9
In the new Provinces with compulsory vaccination.	1871	1872	1873	1874
9. Schleswig-Holstein . . . . .	180	46	1	0.7
10. Hanover . . . . .	77	81	13	3
11. Hesse-Nassau . . . . .	93	45	9	4

I am indebted to Surgeon-General Sternberg, U. S. Army, for a translated copy of an article from the *Hanover Courier* relative to the effect of compulsory vaccination in Europe, furnished by the U. S. Consul General at Berlin, 1893, to the Secretary of State, U. S. From this article I make the following extracts:

The European States in regard to their position in connection with the question of vaccination may be divided into three categories:

1. Those—and these are the majority—which have only the facultative vaccination, but which warmly recommend and urge it: France, Austria, Russia, Belgium, Spain, etc.

2. States with obligatory vaccination, but without obligatory revaccination, as England, Sweden, Denmark.

3. In the third category stands Germany, which is the only state in which—since the imperial vaccination law of 1875 went into operation—vaccination and revaccination are obligatory.

Picking out a state from the second category we can clearly see the blessing of vaccination in the case of Sweden. There died there of smallpox annually from every 100,000 inhabitants:

a. Before the introduction of vaccination from 1774-1800, 165.82.

b. After the introduction of facultative vaccination from 1801-1815, 55.60.

c. After the introduction of obligatory vaccination from 1816-1883, 18.20.

The result in Prussia has been far more favorable since the introduction of the imperial vaccination law. In the decade 1875-85 there died of smallpox annually in Prussia from every 100,000 inhabitants 2.23, in England with obligatory vaccination three times as many, in Austria where there is no compulsion twenty-seven times as many, while before 1875 there were as many smallpox deaths in Prussia as in Austria.

In France with facultative vaccination there died in 1886 and 1887, in Paris alone, more persons from smallpox than in all Germany, namely, 1886, 218 in Paris, 193 in Germany; in 1887, 389 in Paris, 108 (less than one-third as many) in Germany.

The following figures speak for other years. From 100,000 inhabitants there died of smallpox in

	Germany.	England.	Belgium.	Austria.
1886 . . . . .	0.4	1.0	20.5	38.1
1887 . . . . .	0.35	1.8	10.2	41.2
1888 . . . . .	0.2	3.6	14.3	..

In Spain with 12,000,000 inhabitants, in 1888 there were 14,378 smallpox deaths or 120 to 100,000; in 1889, 8,472 smallpox deaths or 70 to 100,000.

The difference is shown still more clearly and conclusively by comparing districts bordering upon one another. In 1889, of smallpox deaths there were in Bohemia 3,329, or 60 to 100,000, in Moravia 1,100 or about 52 to 100,000; while in the adjacent parts of Germany the numbers were:

Prussian Silesia . . . . .	35 = 0.85	} per 100,000
Kingdom of Saxony . . . . .	7 = 0.29	
The Bavarian frontier districts. 22 = 0.79		

Independent of the imperial vaccination law are the vaccination regulations in the German army. In Prussia ever since 1834 recruit vaccination has been the general practice. The result is clearly to be seen. From 1825 to 1834, that is before the introduction of recruit vaccination, the average smallpox death rate was 364 to 100,000. It was greater than that of the civil population, which on the average was 268 to 100,000.

With the introduction of recruit vaccination the smallpox death rate at once decreased considerably and permanently; leaving out of consideration the war years, it has only once since reached the height of 65 to 100,000, being much lower than the death rate of the civil population, which up to the

time of the introduction of the imperial vaccination law remained unchanged, about 268 to 100,000.

The vaccination regulations worked admirably in the war of 1870-71; in spite of the very great danger of contagion, in an army averaging 600,000 men there were:

Smallpox cases . . . . .	2,746 = 465	} per 100,000
Smallpox deaths . . . . .	146 = 24.7	

For the entire German army this rate was more unfavorable owing to the fact that individual contingents had new and, therefore, not fully perfect vaccination regulations. In the entire army of 788,200 there were:

4,835 smallpox cases . . . . .	= 613.4	} per 100,000
278 smallpox deaths . . . . .	= 35.3	

On the other hand the losses in the French army from smallpox were much greater. It is impossible to fix exactly the number of deaths, but it is supposed that 23,469 is the correct number. The figures given for single corps do not contradict this estimate.

For the garrison of Paris (170,000 men) the number of cases from October 1870 to March 1871 was reported at 11,500, the deaths at 1,600. The small garrison of Langres (14,629 men) lost more from smallpox between September 1870 and March 1871 than the entire German army (788,213 men) in twelve months; namely 334 against 278.

Likewise in times of peace the advantage over the French and Austrian armies, due to protective vaccination, which is enjoyed by the Prussian army (inclusive of the Twelfth Royal Saxon and Thirteenth Royal Württemberg army corps) is apparent. In the fifteen years 1873-88 there were in the Prussian army only 300 cases of smallpox (including doubtful cases) and 3 deaths, while in the French army there were 7,807 cases and 698 deaths, and in the Austrian army 16,974 cases and 1,034 deaths. These two armies, therefore, had respectively two and three and one-half times as many smallpox deaths as there were cases of smallpox in the German army. In 1887 Austria introduced recruit vaccination and at once the number of smallpox cases and deaths became smaller than ever before.

(To be continued.)

## REMARKS UPON MEDICAL EXPERT TESTIMONY AND PROPOSED RELATIVE LEGISLATION.

Read in the Section on Neurology and Medical Jurisprudence at the Forty-seventh Annual Meeting of the American Medical Association held at Atlanta, Ga., May 5-8, 1896.

BY A. WALTER SUITER, A.M., M.D.

CHAIRMAN COMMITTEE ON LEGISLATION, MEDICAL SOCIETY OF THE STATE OF NEW YORK.  
HERKIMER, N. Y.

The amount of earnestly thoughtful consideration which has in recent years been given to the subject of medical expert testimony, both by the legal and medical professions, may be said to be enormous, and yet the great desideratum—its just and equitable regulation—is far from being accomplished.

The remarkable divergence of individual opinion as to the feasibility of the various plans proposed; the complexity of interests involved; the multiplicity of phases in which the subject in general may be made to appear in practical application, together with the necessary constant observance of certain sovereign and inalienable rights which are, under our governmental system, guaranteed to the meanest and the highest in like degree, all combine to make of this veritable *quaestio vexata* a problem so difficult of solution as almost to suggest an utter impossibility as to its final and satisfactory adjustment.

It seems indisputable that so long as testimony as to facts and what is commonly termed opinion testimony, differ so widely and yet merge so closely, and so long as the laws and the courts do not recognize the fact that doctors in general are not experts indiscriminately, and that no witness is qualified to express an authoritative opinion upon any subject who does not possess special knowledge derived from special study and experience, just so long will this great ques-

tion continue to be the *bête noire* of our profession.

It is universally conceded, and justly so from the medical standpoint, that the present method of taking testimony requiring expert opinion is defective in the extreme, and in many instances in practice absurd and ridiculous; attorneys, for example, taking advantage of the circumstances, frequently select and summon to the stand to pose in the attitude of medical experts upon the gravest and most momentous scientific questions, members of the profession whose only special qualification consists in having agreed with their employer to express a satisfactory reply to the hypothetic statement which supposedly covers the facts in the case at bar, or under consideration.

An instance in point in the writer's observation is amusing—the medical witness, when examined upon topics requiring expert knowledge of the important subject of antiseptics in the treatment of wounds, indignantly scouted the idea of making use of corrosive sublimate in his practice, but triumphantly declared that he did use the bichlorid of mercury instead!

And yet, with the existing confusion in the matter of differentiation between the expert and the non-expert, the courts would charge due consideration by the jury of the opinions and declarations of such a witness upon equal footing with those of the most accomplished specialist.

Herein lies the greatest fault in the prevailing system, namely, the absence of determining rules whereby the special qualification of the witness in a particular branch of medical science may be known and established beforehand; and the unlimited privilege which in the usage of courts is possessed by attorneys and counsel to select for themselves, regardless of qualification, the witnesses whom they are to present as experts in a given case, and who become *ipso facto* the honest partisans of their employer, especially when he fixes their compensating fee.

Another unjust phase of this matter relates to the frequent discriminating inequality between the prosecution and defense in their relative ability to indulge in the expensive advantage of employing experts to testify in their behalf.

A notorious and likely to be celebrated case is now pending in the courts of New York City which fully illustrates this point.

The district attorney, with the city treasury to draw upon, is said to have engaged the services of an array of talented experts whose fame can scarcely be matched. Two are to appear upon the subject of chemistry, two upon that of materia medica, two to take charge of the pathologic aspects, and one is employed to expound the special subject of toxicology. By membership in their faculties the staff will represent the following great institutions: The University of Michigan, the College of Physicians and Surgeons of Columbia University, the University of the City of New York and the University of Pennsylvania. In addition to this a very noted doctor-lawyer has been hired to arrange and adduce the scientific testimony in the case.

On the other hand, and in consideration of such formidable preparation on the part of the People, the pertinent question is very naturally asked by a prominent New York newspaper, "How is the poor defendant to get experts from Michigan and Pennsylvania, the first in their profession to testify for her?"<sup>1</sup>

This unfair relation of the almost always impe-

curious accused in criminal cases is by no means uncommon, and its injustice is too apparent to require extended comment.

It would seem in this era of specialism in study and practice that the line might without great difficulty be satisfactorily established whereby the status of an expert in a given department could be previously obtained and certified. But the standard of qualification obviously must be defined by and through the medical profession in such manner as to command the entire respect of the courts, and merit the approval of the public at large. This, it may be said, has already been practically done, but advantage can never be taken until the system of taking expert testimony has been so radically changed that the proper restriction as to the manner of selection and appointment has been regulated, to the extent that the expert witness shall in all cases be an officer of the court, and occupy a position with reference to the subject concerning which he is to express an opinion of absolute independence and impartiality.

In this view the function of the expert would be advisory in the strictest sense. He would, and should, be the mentor and censor both to the court and jury, and thus would the average jury be relieved of the always too great responsibility of determining upon questions of such scientific delicacy as to require a technical knowledge that presupposes years of study and experience to attain.

Nothing can be more absurd and contradictory to the professional mind than to call together twelve men, selected for the most part *because* of their ignorance and stupidity and their unfamiliarity with the facts and circumstances, and compel them to sit in judgment upon the radical and sometimes chaotic disagreement of opinions of those whom education and years of continuous practical application have qualified them to express. The unintelligent jurymen is thereby exalted to the lofty position of an arbiter upon the points at issue, obliged in the brief period of time to qualify himself as such, and systematically deceived, misled and narrowed as to the aspects of the case which he is permitted to consider under the rules of evidence.

Paradoxical as it may seem, however, there is a strong measure of doubt whether this system of consideration and decision by juries even of the kind referred to can be improved, for the simple reason that no other plan has yet been devised which would not have similar defects and be open to the same, and perhaps greater, objections.

A very distinguished jurist, writing reminiscentially of his experience as associate justice of the United States supreme court in support of the existing trial by jury, declares in effect that the differences and disputes of the members of that august court leading up to decisions do not materially differ from those of the average petit jury, and that notwithstanding their profound legal learning the actuating motives and influences are essentially the same, particularly as to matters of fact.

Furthermore, if reform could be accomplished in criminal jurisprudence by the modification of the jury system it would be impossible as, it is hardly necessary to state in this presence, the right to trial by jury must forever remain inviolate under constitutional provision. For the same reason it may also be

said that the right of a defendant or plaintiff to call his own counsel and witnesses and cross examine those opposed to him can not be denied or in any degree curtailed.

It follows then that if reform in the presentation of medical expert testimony is ever to be accomplished, it can not be by way of any change in the jury system of trial at present in vogue. It is much more possible that it will come through an improved and acceptable method of obtaining, and submitting for deliberation by the jury, the associated scientific facts and relations.

In the judgment of the writer the following propositions would seem to fairly comprehend the circumstances:

1. The appointment of a commission of experts by the court in each case requiring it, the experts to be especially qualified by educational experience as such.

2. The establishment of an educational curriculum and a period of service in each branch of medical science by which the qualifications of an expert witness may be known and certified.

3. Just and adequate compensation commensurate with the character of the service should be awarded, and should in every instance in criminal cases be paid from the public treasury upon the certificate of the presiding judge. In civil cases the compensation might or might not be fixed by the court, but should be taxed as costs to abide the event, or, by agreement, the expense might be equally divided between the contestants in the action.

With these somewhat desultory remarks, for which it is not pretended that they convey any new or original ideas, but that they simply express the individual thoughts of the writer and endorse the views that are commonly entertained among those of the profession whose opinions are entitled to carry the weight of authority, your attention is respectfully invited to a brief history of the movement which is now in progress, and is rapidly assuming influential and promising proportions in the State of New York, looking to the correction of the evils of the prevalent method as far as may be by appropriate legislation.

During the session for 1895 of the Medical Society of the State of New York, a special committee, comprising some of the most noted and competent alienists and medico-legal authorities of the State, was appointed to cooperate with the standing committee on legislation to duly consider the subject and report the most feasible plan of procedure.

Soon thereafter an extensive correspondence was undertaken among the prominent jurists, alienists and medical experts of the country, in order to obtain a symposium of essays illustrative of the relative personal status of the individuals addressed for the subsequent guidance of the committee.

With notable unanimity, the opinions expressed in all the replies received were substantially the same in regard to the main propositions.

All agreed, first, upon the growing necessity for the reform; second, that the true solution of the problem consists in the appointment, by the common consent of the court and the contending parties, of a commission, or a board, of experts, in each case, to act in an advisory capacity in the presentation of the scientific aspects to the jury; and third, that absolute independence can only be secured by an arrangement whereby the honorarium shall be a public charge, the value of the service to be determined by the court,

thus divesting the proceeding of the commercial character so much to be deplored.

The greatest diversity of opinion appeared to be with reference to the appointing power—some advocating that the appointments should be made by the governor, and that the board should be a permanent one; many believing that the State should be restricted for the purpose after the method in common practice in continental Europe. Others thought that a permanent board should be designated by the State Commission in Lunacy and be of a non-partisan character; and still others who expressed the view that the appointing power should be vested in the board of regents of the State university, they to pass upon the qualifications of the incumbents in the same manner that medical practitioners are now licensed after examination by the State board of examiners, and that it be unlawful to designate any person to give expert testimony who does not possess the regent's certificate setting forth that he is duly qualified.

A general commission was suggested, to be permanently established by statutory enactment to represent all departments of science (and perhaps mechanics) upon which requisition might from time to time be made when the occasion should be such as to demand the service of an expert.

A special commission for each case was more commonly advised, to be named by the presiding judge, and to be composed of three or five members, one or two to represent the prosecution, one or two to represent the defense and one to be nominated as the special representative of the court; all questions of a technical nature to be submitted to them and their replies and conclusions to be in turn submitted to the court and jury, any or all of the experts to be subject to subsequent cross examination upon the report rendered should the parties to the action so elect.

With these data at hand, which seemed to contain a complete consensus of the general trend of thought upon the subject, the committee compiled a condensed report in the form of a preamble and resolutions which were promptly acted upon and unanimously adopted.

In accordance therewith, a proposed law was formulated under the intelligent direction of Dr. Carlos F. MacDonald, the president of the State Commission in Lunacy, and its introduction into the State legislature secured by the writer. It is believed that the bill embodies in substance the required measure of reform in criminal cases, recognizing of course the fact that no bill can be drawn which would be entirely free from constitutional restrictions.

STATE OF NEW YORK. No. 1943. Int. 1375. In Assembly. March 26, 1896. Introduced by Mr. Scherer—read once and referred to the committee on the judiciary.

#### AN ACT

To regulate the employment of medical expert testimony in criminal proceedings.

*The People of the State of New York, represented in Senate and Assembly, do enact as follows:*

SECTION 1. Do ever any person in confinement, under indictment for the crime of murder, attempt to murder, manslaughter, arson, highway robbery, forgery or other felony, may desire to present medical expert testimony in his defense, whether of a medical, surgical or chemical nature, he shall so inform the court at the time of his arraignment for trial, whereupon the presiding judge before whom such trial is pending shall appoint such number of experts as he may deem necessary to adequately represent both the prosecution and the defense, and the compensation of such experts shall be fixed by an order of the court at a rate that shall be reasonable for professional services of such a nature. The experts so

appointed shall be persons of repute and qualified in the branch of medical science to which the question calling for expert opinion relates; and shall have full and free access to the evidence adduced on the trial, as well as to the defendant, if the issue involves his mental or physical state. On the completion of their examination, the said experts shall submit to the court for transmission to the jury as evidence a report in writing, attested by their oaths, setting forth their conclusion, together with the facts upon which such conclusion is based. If counsel on either side shall demand it, the experts may be sworn as witnesses, but their examination and cross examination as such shall be limited to the facts and opinion contained in their report to the court.

SECTION 2. All acts or parts of acts inconsistent with this act are hereby repealed.

SECTION 3. This act shall take effect immediately.

It may be surprising to state that at the first hearing before the committee on judiciary to which it was referred, although the bill was carefully scrutinized by the statutory revision commission (the State board of reference upon the phraseology of laws) the advocates of the measure were confronted by a question involving the doubtful constitutionality of the passage relating to the subject of cross examination. Contention was made that cross examination could not be confined strictly to the matters contained in the report adduced, and that the defendant would still have the right to go outside of the report and call witnesses to combat the testimony therein; and in case of his acceptance of the special expert commission such circumstances would place him in the position of attacking the testimony of his own witnesses.

You will agree that this is a knotty point, and observe how difficult a task it is to frame a law that would be entirely free from similar antagonism.

Another objection may properly be mentioned:

In a recent editorial comment,<sup>1</sup> attention was directed to an apparent ambiguity of expression regarding the report of the contemplated special commission, namely: That it does not specify as to whether the experts shall submit their report collectively or as individuals. If collectively, it may still be a question whether a majority and a minority report shall both be permitted, or a unanimous declaration required.

Of course the bill should be amended in this respect.

The proposed law will be modified in a way to meet, if possible, every objection raised, and upon that point it is hoped that some helpful suggestions may be made by the members of this section.

This legislative proposal is now pending in New York with no real expectation that it will be enacted during the current session. That would be almost unprecedented in so important a matter. But it may be written down that no effort will be spared nor opportunity neglected until the desired reform has been achieved.

The contest will be continuous and uninterrupted, and it is expected that the profession throughout the United States will give all aid and support possible, as favorable action in New York will greatly tend to influence similar legislation in all other States of the Union.

By way of comparison, it will not be amiss to introduce at this point the text of a bill which was presented to the legislature of the State of Minnesota several years since (1893), and about the same time in the legislature of Illinois in practically the same form.

This formulation was first reported to the Minne-

<sup>1</sup> American Medico-Surgical Bulletin, Vol. 1x, page 556.

sota State Medical Society by Dr. B. J. Merrin, chairman of the section on medical jurisprudence. The proposition was very carefully studied in connection with the movement in New York State:

*Be it enacted, etc.*

SEC. 1.—In all cases pending in the courts of this State, civil and criminal, before or at the time of the trial of said cases, the judge of said court, when it is made to appear to him that the appointment of experts upon medical, scientific or mechanical questions is desirable, may appoint such experts to examine into the subject matter in controversy, said experts so appointed to be selected in reference to their impartiality between the contending parties; the number of such experts in each case to be fixed by the court.

SEC. 2.—In all cases where experts are so appointed, the court is to fix their compensation, and in all criminal cases direct the payment of the same in the same manner as witnesses on the part of the State are paid; in all civil cases the amount so fixed and determined by the court shall be taxed as disbursements by the successful party.

SEC. 3.—The court may order such experts to examine into any medical, scientific or mechanical question, and after such examination to testify in court in reference thereto.

SEC. 4.—The testimony of said experts so appointed by the court, shall be *prima facie* evidence of the statements and conclusions as to the questions in reference to which said testimony has been given.

SEC. 5.—The court may also fix and determine the amount to be allowed such experts for and on account of any medical, scientific or mechanical examination, analysis or test, which the court may deem advisable to have made, and direct the payment thereof, or permit the taxation thereof as costs as hereinbefore provided.

It is understood that considerable effort was made to secure the passage of this proposal in both the States mentioned, but it was successfully opposed in both instances. The bill has great merit, however, and should have met with a better fate.

It will be noted that it differs from the New York bill in several important respects:

1. It provides for civil as well as criminal cases.
2. It permits of unlimited examination and cross examination of the experts appointed, and does not specify a written report to the jury.
3. It makes provision for the regulation of analyses and tests in all cases requiring it, and also prescribes the payment of adequate fees for the same.<sup>2</sup>
4. It includes questions of a mechanical nature, but does not specifically mention those relating to surgical subjects, although the construction likely to be placed upon the terms "medical" and "scientific" would probably make satisfactory application.

Originality has not been attempted in this paper, nor has effort been made to treat any phase of this absorbing question to any extent exhaustively. It is simply what its title implies, namely, "remarks upon medical expert testimony and proposed relative legislation."

The drafted formulas are placed before the section in the belief that suggestive and critical discussion will lead to conservative results.

Let it be borne in mind that the New York proposal is nobody's pet, and the same may doubtless be said of the one introduced for comparison.

The true motive of all concerned is to secure the adoption of a wise and beneficent measure which will comprehend the requirements of the occasion, correct the prevailing abuses, and elevate our moral standing before the courts to the dignified position to which it is justly entitled.

Reform is urgently needed. The "cause is ripe" and the demand is rife.

## INSANITY IN COURT.

Read in the Section on Neurology and Medical Jurisprudence, at the Forty-seventh Annual Meeting of the American Medical Association, held at Atlanta, Ga., May 5-8, 1896.

BY L. HARRISON METTLER, A.M., M.D.

CHICAGO, ILL.

With the rapid growth of knowledge and the steady development of new forms of industrial activity, the employment of expert testimony for the instruction of the courts is becoming more of a necessity every year. This is admitted by all. The present method of securing this testimony is acknowledged to be both defective and inadequate. On account of this faulty method, expert testimony itself is occasionally most unjustly criticised and ignorantly ridiculed. From the method of its engagement to the system of expert testimony in general the blame has been transferred, and some narrow minded jurists have even cast slurs and insults upon the experts themselves, thus completely losing sight of the real cause of their dissatisfaction, namely, the ancient and absurd method in which the expert is brought before the court. Lord Campbell revealed a partial comprehension of the trouble, when he said that "skilled witnesses come with such a bias on their minds to support the cause in which they are embarked that hardly any weight should be given to their evidence." What gives rise to this bias might have been asked of the noble lord. He insinuates his answer in the statement that they come "to support the cause in which they are embarked." In other words, the expert is a biased individual, just as my Lord Campbell himself would have been, had he been engaged and remunerated by one or the other side in the contest. To secure an unbiased legal opinion from my noble lord, it was necessary for the State to elevate him to the bench and to pay him a wholesome sum out of the public treasury. Experts are human beings with the same human frailties as lawyers and judges, and I have a suspicion that among experts there is a larger, or at least equal number of individuals who honorably decline serving, and who often forego a most tempting fee when they discover that their scientific testimony will be damaging to the parties who have summoned them. As he is now placed the scientific expert is not an *ex parte* witness and Lord Campbell's *biased* insinuations in regard to the honesty of the expert, reflects more unfavorably upon the legal profession and the legislative powers, in whose hands the maintenance of the present defective system so largely rests.

Once a judge of Maine declared that if there be any kind of testimony that is not only of no value, but even worse than that, it is in his judgment that of medical experts, all of which criticism is highly commendable if the honorable judge is at the same time exerting his influence to induce his own guild to institute the needed reforms by which medical expert testimony may be able to exercise its proper function and to reveal to the court the value which the rest of the world recognizes it possesses. A New York judge very *judiciously* classifies witnesses as liars, blank liars and experts, which is all very facetious and may be allowed to pass as a very *judicial* joke. Mr. Weil, a lawyer of some acumen, once said: "The fact is the average lawyer does not qualify himself to examine an expert, he qualifies himself only sufficiently to conceal his own ignorance." I do not think

<sup>2</sup> In New York State the penal code provides for chemical and other scientific analyses upon the order of the court, the compensation to be fixed by the district attorney and paid by the county treasurer upon the district attorney's certificate.

the average medical expert can be charged with such an unwarrantable delinquency.

Maudsley suggested as a means of softening the virulence and disgracefulness of the disputes between lawyers and doctors in our courts, the abolition of capital punishment. In the words of Mills: "Some of our learned judges are not without blame for this state of affairs. The decidedly antagonistic stand which they seem ever prone to take against reputable physicians in *habeas corpus* and other cases in which questions of medical opinion are at stake, has put the profession into such a frame of mind that in Philadelphia—and it may be the same throughout the country—many physicians now refuse altogether to make affidavit." It seems to me that these "learned judges" are so easily biased, considering the freedom from one-sided influences which their position and income enjoys in comparison with that of the experts as it now is, and considering the large amount of honesty of opinion expressed by experts, even under such unfavorable conditions, that these same judges are constitutionally less fitted to administer justice in court than are the experts they antagonize fitted to give scientific testimony.

Those who recognize the faultiness of the present method of expert examination anticipate very little reform for a long time to come. The legal fraternity has almost complete control of the judicature and legislation of our country. The medical profession has comparatively little to do with either. Now the trend of law and medicine are almost in diametrically opposite directions. Legal judgments are founded in large measure upon precedents; they are based upon authority which generally is better the more ancient it is; to a considerable degree the legal mind looks backward for its guidance. On the other hand medicine, being a science, looks forward and to-day recognizes facts and formulates principles that it scarcely dreamed of yesterday. Our modern judiciary system is hoary with age; and its strength and dignity rest largely upon its antiquity. On the other hand much of our knowledge of insanity is of very recent date, being founded upon discoveries in anatomy and physiology made within the last decade. At one time mental diseases were so little understood that there were perforce no experts upon them; their manifestations were simply strange *facts*, the decision of which was as much within the capability of the layman as of a medical man. The acts committed by an individual on trial for insanity could be as well established and the insanity itself (which was necessarily of a gross form) could be as well determined by an ordinary jury as by any body of professional men. The only questions to be solved were the commission of the acts and whether a supposedly sane person would have committed the same acts. The absence or presence of a rational motive and the power to distinguish right from wrong, were the only plausible and apparently reliable tests that could be applied. The psychology of that day was about as well acquainted with insanity as the law itself was; hence it readily acquiesced in the legal tests then formulated. Now, however, all this has been changed, at least in regard to our knowledge of insanity; whereas our system of judicature has remained the same. In regard to the conceptions of mental phenomena, law and medicine started out together upon the same path but the paths soon diverged, and now have become so widely separated that there needs to be an entire readjustment in regard

to medico-legal questions. Medicine recognizes to-day special and complicated forms of insanity. It has discovered since the formulation of the old legal tests, particular varieties to which these tests are wholly inapplicable. It has uncovered the physical lesions for some of them at least. The diagnosis of them is now a matter of greater refinement and depends upon much more subtle symptoms than such signs as the inability to distinguish right from wrong or the absence and presence of certain motives. In a word our system of administration of justice has not kept pace with the progress of science; it has not readjusted itself to the newer scientific state of affairs.

Perhaps the most glaring fault in the present management of expert testimony, is its engagement by the opposing counsel. Human nature has its weakness in scientific men as well as in lawyers and when experts are thus hired they are almost forbidden to be experts by being made partisans. Even were the condition so Utopian that none but honest experts could be secured, that those whose opinions were found to conflict with the interests of the side engaging them would refuse to testify, there would always be some, equally honest, whose opinions would differ, especially upon points of science still open to controversy. They would be engaged and thus the court room would become the scene of a scientific debate much to the dismay and confusion of an uninformed jury. Such is the way things are managed at the present time. The counsel fixes the medical opinions for the court and then hires those experts, or self-styled experts, who will be most likely to support his side of the contest. Between the two sides a rhetorical display of scientific quibbling is presented for the edification of the court and jury; more often a roaring farce is performed; the judge becomes incensed, the jury falls into hopeless confusion, and the few deserving experts in the case are brought to shame and made the victims of most unjust sarcasm. Volunteer experts would be better than those paid like partisans for one side or the other; but as volunteers would be hard to secure, experts paid by the court or government should be employed and only such experts. That would be one step toward the elimination of the partisanship feeling in regard to expert testimony.

But the counsel tell us that their purpose after all in the cross-examination of opposing experts, is the elucidation of scientific *facts* and not the hearing of any scientific *opinions*; that one layman is as capable of deciding *facts* as another; and that a jury of laymen should be the only body to decide upon such *facts*; for the establishment of the truth or falsity or rather the presence or absence of *facts* in the case being tried, is the fundamental object of our great jury system. In the words of Hornblower (Hamilton's System of Legal Medicine, Vol. II, p. 131) "The primary object of expert testimony is not to prove opinions but facts in the shape of rules of science as are generally recognized." And again, the counsel tell us that the present method of engaging experts is the best because it carries out most effectively the great principle in our system of judicature, that every man under accusation has the right to interrogate and to confront his accusers and witnesses. Both of these arguments of defense set forth by our legal friends, are right in principle but wrong in practice as medico-legal questions are considered to-day. When the power of distinguishing right from wrong was the test and apparently the only test of insanity, and

when *facts*, scientific medical *facts*, were scarce in regard to the many mental phenomena of health and disease, the present system of our courts would have been fully adequate to lead to a decision. To-day, however, every intelligent man admits that there are new *facts* revealed by science that none but a skilled specialist can recognize. This is true of all the sciences as well as of medicine. The court, for instance, does not submit to a jury of laymen an abstruse chemic question but takes the facts detailed by an expert chemist and instructs the jury to accept them as detailed. The discovery of arsenic in a man's stomach is not left to a jury to decide, nor is its presence or absence dependent upon any arbitrary legal test, such as the discernment between right and wrong for insanity; but an expert chemist is called and his observations accepted as proof of the presence or absence of the poison. Likewise the decision of insanity in a case on trial should not be left to a jury, because insanity is diagnosed to-day upon finer symptoms than the mere power to discern right from wrong, etc. The *fact* of insanity can be affirmed only by a special student of the disease and the majority of laymen would be confused and embarrassed by what to him would be clear and self-evident. Furthermore, in many cases of insanity the only *facts* comprehensible to a lay jury would be certain strange acts, delusions, etc.; but to the expert those isolated, scattered facts, which would seem to mean so little to the average layman, might indicate a great deal. Hence, while to the jury the experienced expert may be able to enumerate only a limited number of facts within their comprehension, he from a long study of similar cases may be capable of giving a most valuable *opinion* in regard to the sanity of the prisoner. Certain impulses such as homicide in acute mania, suicide in melancholia, certain delusions as that of grandeur in the early period of general paralysis, religious exaltation, illusions and hallucinations in other special forms of mental derangement, may when described to an average jury as isolated *facts* or more general *principles*, bear very little weight, because such a jury has not been impressed with the importance of those isolated facts as evidences of mental aberration, by seeing them repeated and duplicated in hundreds of similar cases. The experienced expert, on the other hand, has seen such and from the few apparently unimportant *facts* is able to give to the court the *opinion* that the prisoner is a victim of one or other form of insanity.

I believe, therefore, most emphatically that an expert should not be put into the position of a *witness*. Often he has witnessed so little in regard to the prisoner at the bar as to render his testimony in regard to the *facts* about that prisoner's mental condition of small worth. The expert should occupy a *judicial* position, so that after a thorough examination of the prisoner, he can give a full and unbiased *opinion* of his mental condition, based upon the thorough examination and his large experience in the study of like cases. The increased refinement in the diagnosis of mental diseases at the present time, demands the exercise of an experienced judicial mind. It asks for something more than the bare statement of a number of isolated facts. A genuine expert is to-day, in the light of our increased knowledge, something more than a witness; he is a judge with an opinion to offer or he is at least an adviser capable of guiding the court's opinion. His worth is much diminished by putting him in the attitude of a mere retailer of certain scientific facts, which

in their isolated presentation may throw but a limited light upon the case in hand.

The same explanation accounts for the inefficiency of the *hypothetic question* as a means of obtaining an expert's opinion. This form of examination prevents the expert from rendering a judicial opinion. As it is now employed it brings into prominence symptoms of little importance and suppresses others that may be of the greatest significance. If it is to be made use of at all (and the instances in which it is of any value are testamentary cases in which the maker of the disputed will is dead), it should at least be worded and presented by the court and not by either of the opposing factions. In the framing of the hypothetic question as it is now done, the partisan spirit enters and so construes the facts of the case as to make them appear otherwise than they actually are. Granting, however, that the question should be framed by the two sides in such a way as to eliminate every suspicion of partisanship, it may be presented to the expert and court in such a manner from the legal or lay standpoint as to be perfectly meaningless or completely unanswerable to the expert. In such a case an expert will wisely decline to say anything, for he will be obliged to keep within the limitations set for him and though he may know that a single word of explanation upon his part would change the whole face of the question, that word will usually not be allowed him. Thus his valuable knowledge will be lost in the trial. If he foolishly attempts to answer the question, and thus more often than is agreeable puts himself in a position not well fortified by his own explanations, he will sooner or later come to grief in the hands of the opposing lawyer, and appear before the jury in a most ridiculous and self-contradictory plight. This is not an uncommon exhibition in our courts, and it is one of the chief causes of the disputes in which experts are held.

I believe that every case in which insanity is entered as a plea should have a separate medical trial. This need not in the least remove the case out of the jurisdiction of the court; for the same judge may preside and in accordance with the result of the medical trial, the prisoner may be sent to an asylum or referred to the ordinary court for a civil trial. In the latter, however, all questions as to the mental condition of the prisoner should be excluded. This would undoubtedly diminish the number of insanity pleas now entered for the defense of criminals. The criminal as well as his lawyer would hesitate before coming under the examination of a carefully selected commission of medical experts; whereas now he is almost certain he can confuse an ordinary jury and so secure a verdict not in accordance with his deserts. The very weakness of the present system is exposed in the enormous number of insanity pleas that are annually brought before the courts. Criminals recognize a source of strength in their own defense, in the difficulty experienced by the average jury in deciding upon a case of insanity. It is the greater misfortune, however, that the disadvantage works also the other way, for it is a notorious fact that the gallows has more than once ended the life of a poor demented creature, irresponsible for his deed and sent into eternity by the unjust verdict of a confused and ignorant jury of laymen. It has been argued that a separate medical trial or examination before a commission of experts would thwart the very purpose of our time-honored jury system, in which a man charged with a

crime is given the privilege of meeting face to face his accusers and of receiving his sentence at the hands of his peers. Now, I maintain that the present mode of examination is the one which contravenes the spirit of this fundamental legal maxim. If a man accused of a crime, enters a plea of insanity as his defense, or if he is suspected of being insane, he for the time being stands as the representative of some one of the many forms of mental disease. In a word, he is, as it were, that disease itself, whether he is attempting to counterfeit it or is actually its victim. It seems to me, therefore, to be a self-evident proposition and one that is almost axiomatic, that in the abstract the peers of such a man are those who know most about the disease which he is manifesting. The latter in their knowledge of it are equally its representatives, and they, like the prisoner, stand, as it were, in its place; certainly more so than any layman who knows nothing about such a disease. There can be no sort of parallelism or comparison drawn, in the abstract, between the victim of an abstruse and delusive form of insanity for which he stands in reality as the living representative, and a body of ignorant, inexperienced jurymen gathered haphazard from out the street, who have probably never seen or heard of the simplest forms of mental aberration and for whom a few hours' hurried explanation of it in a crowded, somniferous court-room can only afford a vague and uncertain opinion. Why, a class of first-year medical students would constitute a better jury than such a one for the trial of insanity, while the trial itself would be more in the spirit of our great jury system, for the medical students would, at all events, have seen a little of the possibilities and probabilities of disease. For a military misdemeanor a soldier is tried by a court-martial, it being understood that his peers are those who know most about the military rules and regulations that he has broken. A clergyman is tried for heresy by his fellows, because they alone are his peers in knowing most about the doctrines which he is supposed to have denied. Likewise a crime done by a supposed lunatic should at least have a separate medical examination to determine at least the lunacy of the criminal, for the legal peers of such a criminal are those who know most about the vagaries of lunacy.

In conclusion, then, I believe that the present method of examining cases of insanity in our courts is unjust because:

1. The engagement of the expert by the opposing counsel is prone to bias the expert and to nullify the truthfulness of his testimony.
2. The discovery of a number of isolated facts (which is the affirmed purpose of an examination in court) is not in the present advanced state of our knowledge of mental phenomena, the most reliable way to diagnose insanity.
3. The value of an expert's testimony is vitiated by the fact of his being placed in the position of a witness to testify to certain isolated facts, instead of the position of an adviser to the court to give his full and unbiased opinion.
4. The hypothetical question hampers even the most learned experts and in the end often places them in a contradictory and absurd attitude from which it is difficult for them to recover.
5. The present system does not carry out the abstract spirit of the law that every man shall be tried by his peers; but on the other hand works injustice in many cases of real insanity and favors the

exercise on the part of criminals of feigned insanity.

6. The old legal tests of insanity, which are of a more or less popular character and were sufficiently adequate for the guidance of the average jury in former times, are not tenable to-day in the advanced state of our knowledge of mental phenomena and their manifestations.

The remedy I have already hinted at consists in the separation of the medical from the civil trial. The former is to be conducted in the presence of the judge by a commission of learned and experienced experts appointed by the supreme court or in any other way that will keep the appointments beyond the influence of politics; this commission to be remunerated by the State in accordance with the dignity and seriousness of its decisions. If the result of this trial or examination by the commission of experts, be that the prisoner is insane, no appeal is to be allowed, but the prisoner is to be removed to an asylum for medical treatment. If, however, the commission decides that the prisoner is not insane, then he is to be submitted to a civil trial in the ordinary way and punished or acquitted in accordance with the verdict.

#### EXPERT TESTIMONY IN DISPUTED CASES OF INEBRIETY.

Read in the Section on Neurology and Medical Jurisprudence at the Forty-seventh Annual Meeting of the American Medical Association, at Atlanta, Ga., May 5-8, 1896.

BY T. D. CROTHERS, M.D.

SUPERINTENDENT WALNUT LODGE HOSPITAL, ETC.  
HARTFORD, CONN.

During the past year several very important cases have brought out the most widely divergent expert testimony, clearly showing the need of new study of this subject.

Disputed cases of inebriety are increasing every year. Not the petty contests of police and criminal courts, where the questions raised are technical for partisan purposes, but facts of great interest and profound questions of science on which large issues turn. In one case, the final disposition of over a million dollars turned on the question of the normal condition of the mind of a testator who used spirits to excess. In another case a forgery which implicated many persons, depended on the judgment of experts relating to the motives of an inebriate. Several murder and homicidal cases have been disposed of on the testimony of medical experts. The final issue of all these cases has been the subject of divergent views in both legal and medical circles.

The usual criticism that expert testimony is purchasable and unreliable to the highest degree, has become a common observation in court rooms. In reality the ordinary expert testimony that is vague and confusing becomes so through the faults of the legal battles of lawyers.

In every case two theories are assumed and the struggle is to prove the one and disprove the other. Facts, theories and statements of every possible character are gathered, grouped and twisted in every way possible for this purpose. Scientific opinions of every description that seem to sustain one view or the opposite, are marshalled and placed in their best form to carry conviction irrespective of the truth. The central object of the opposing counsel is to prove the truth of their side of the question and not to ascertain

the actual facts or principles of equity involved, and expert medical testimony is called for this special purpose. Consciously or unconsciously, the expert becomes a partisan and, with the counsel, believes a certain theory true, and in his efforts to sustain this position, under the cross fire of the opposing lawyers, appears to a great disadvantage. The fault is not that of the expert, it is the vicious legal system of ascertaining facts.

Suppose two physicians enter upon a partisan contest to prove that a given case is one of typhoid or simple derangement of the digestion, and each one gather and twist all possible facts to sustain his theory. The failure of both to secure the real facts and make clear their position would be inevitable. Take these two men in court with care-testing counsel to sustain and coach them. Then have the subject obscure and not clearly defined in fact or theory, and the wonder would be how any truth could be ascertained by such methods.

The present methods of securing medical men to sustain opposite views, by grouping a mass of statements which are half truths and distorted, strained conceptions, and enlisting physicians to defend them by assuming that they are complete facts, is dangerous and utterly subversive of truth. The common experience of presenting to the expert a view of the case which supports the theory the counsel is called to defend, and convincing the expert that this is true, then retaining him on the trial is the beginning. Then the trial begins with the expert in possession of a certain class of facts which he is soon biased to believe.

In the meantime he has fortified these opinions by reading and examination of all the possible authorities, and grouped all the facts which support and make the theory clear. On the trial he hears the other side, but the constant presence of the counsel who is defending the theory he has been retained to support, neutralizes and explains away the opposing facts. Every night the counsel literally coaches the experts by arguments and explanations, and strengthens his former convictions wherever they may have been shaken by other testimony.

Finally, the expert is a partisan who is fully convinced of the truth of the theory he is called to support. He goes on the stand and under the cross fire of counsel fails to make his theory clear, or impress any one with respect for his fairness and scientific accuracy. He is prejudiced from the start; his scientific sense of judicial examination of facts is enfeebled; he has become, unconsciously or otherwise, imbued with a strong bias in the belief of the accuracy of a certain class of facts. Of course the pecuniary fees will in some cases add to this, but in most cases unconsciously. On the stand opposing experts who are equally partisan and confident of the truth of an opposite theory are able to detect and expose the errors of the other. Finally, the expert testimony becomes a mere word battle in which all the energies of each side are concentrated to win their theory. The "hypothetical case," which is supposed to group all the facts in one picture, is made to prove and disprove opposite theories by the merest word juggling, and the emphatic affirmative and negative answers demanded still farther confuse the real facts in question.

There can be no question that the fault is in the system, not in the medical men, who wisely or unwisely

try to reach accurate conclusions along impassable paths and roads of study. The most celebrated cases which turn on medical testimony, and those of minor interest, show the same confusion of means and efforts to reach the facts, and the hope of change and improvement is removed to some future, when medical testimony will be given in commission and on paper, as exhaustive independent studies of the facts at issue.

There is another phase of expert testimony which needs a new study from a different standpoint. I refer to the disputed cases in which the question of how far, and to what extent, has the use of spirits impaired the brain and influenced the act in question. Strange as it may appear, the medical answers to this question are very largely colored by the previous convictions and personal habits of the expert. This is illustrated by life insurance applications in different sections of the country. Certain medical examiners will consider the continuous use of spirits, with an occasional attack of delirium tremens, of no importance as impairing the risk of the life of an applicant. In like manner a noted physician swore that the continuous use of spirits for twenty years would not necessarily impair the capacity of the brain. Of course the honesty of the witness must be assumed, but his prejudice and evident partisan attitude was apparent. We have reached a position now in psychologic research when the paralyzing effects of alcohol on the brain and nervous system can be asserted as an established fact. The fascination which causes it to be repeated and become a daily drink is from its narcotic properties. It brings relief from pain, rest and a sense of comfort which requires repetition and increasing doses to keep up. Its action provokes a desire for more and the injury of to-day seeks relief from the same drug to-morrow. This use may be continuous or in paroxysms, but in all cases there is positive injury, unknown in its nature and extent, until finally it manifests pronounced symptoms of degeneration and disease.

In any given case, where the history indicates continuous or paroxysmal use of spirits for any period of years, the inference of mental impairment and defects will be supported by an appeal to the facts. It may be safely asserted beyond fear of contradiction that no one can use spirits for any length of time and be sane and of sound mind. Any act which is in dispute, performed by a moderate or continuous drinker, is open to suspicion. In the history of any case, if the use of alcohol and other narcotics is established, the expert has a starting point from which to examine and study physical and psychical changes that show the real condition. The study of the drink history is the key that will clear up many of these cases. A practical illustration is found in the famous Ross case. Here, a homicide and suicide was committed, and a will written at about this time was contested. His conduct before and after the will was not unusual, but his drinking history showed continuous use of spirits in large quantities daily. From this it was evident that his mind was enfeebled, and although acting along lines of automatic activity he was clearly unstable and likely to explode any moment into some form of insanity. The more accurately his drink history was known the clearer the insanity of his case became.

The drink history is a very essential factor in the study of the symptoms and is of more importance

than change of conduct, appearance and thought. These may remain substantially the same, or be so concealed as to escape observation.

The mental state of a person at a certain time and in certain circumstances is to be judged from a great variety of conditions. This study should begin with heredity, family diseases, peculiarities and surroundings. Then go on to birth, nutrition, culture, diseases, injuries and surroundings. This leads up to the vast range of influences and their power over the mind and body, and furnishes a comparative clear conception of the physical and mental conditions present. Then comes the question of the disputed act, whatever it may be. Was this natural and along the line of his usual activities? Was the act and its motive reasonable and natural to him? Was it a natural sequel to his drinking history, or any other line of conduct?

These and other questions can only be answered by an appeal to the facts, and this appeal must be addressed not to one side of his physical and mental history, but to all sides. The expert must analyze groups and study all the conditions, and as in the diagnosis of disease, it is a question of facts and their meanings, not of theories or rulings of courts, or law questions. The case is one of murder or crime of magnitude, and the question is the mental state of the man. The legal method is to begin with the act, and go back and forward for evidence to explain it. In other words to first make an exhaustive study of the act, then go back in the history for evidence and indications which would point to this, or go forward for facts which would follow such a deed. If it is a will or forgery, or theft or assault, it is assured the act itself furnishes evidence of the condition of the mind which inspired it. The expert testimony is concentrated on the act; this is the same as requiring the medical man to form an accurate opinion of a typhoid or other case entirely from the present symptoms. To properly realize the state or conditions of the man at the time of the act, a life history must be gathered and studied, particularly the drink history. These facts of heredity of disease, of surroundings, of occupation of manner, of life, of his ambitions and purposes and customs and habits. Then the use and effects of alcohol on his life, and the changes, if any, which followed from its use. These and other contributing and influential forces followed up to the disputed act like links in a chain are all connected and all foreshadow the act in question, and all serve to show the real condition of the mind at the time. With these data to judge from, the experts would find no difficulty in making a correct diagnosis. From this point of view all theories would grow out of the facts, and no questions of gathering facts to support a theory would be thought of, and all studies of the act would follow as a stage in the history of the case.

Conduct and thought are the avenues through which unsoundness of mind is seen, and yet they are only properly compared by a study of a previous history. The continuous use of spirits, as a rule, is manifest in changed conduct and thought, yet this change may not pass the limits which would attract attention. This is seen in states of insanity where a semblance of reason remains, and much of the thought and conduct are apparently sane. To illustrate: A man killed his wife, and the act seemed sane and with motive. His conduct and thought before and after had no appearance of other than conscious reasoning of cause and effect. He was tried and convicted of murder.

The defense of insanity rested on his drinking habits and the coolness of the act. It was treated with contempt. On the second trial a thorough study of the case showed an alcohol and epileptic ancestry. Severe diseases in infancy, neurotic defects and disorders of childhood. Early use of spirits to excess at puberty, then a degree of moderate drinking from this time on. Five years before the crime he suffered sunstroke. From this period on paroxysms of anger and strange impulsive acts frequently occurred, acts without reason at the time, which he manifested much anxiety to explain afterward. The acts were committed in a sudden impulsive way, the explanations seemed an afterthought and an effort to make clear what was unusual and strange before. Some of these explanations were clear and rational, others were strained and peculiar. In all cases there was a suspicious frankness about his statements that suggested some concealed delusion. He used spirits daily in small quantities, and every four or six weeks he would drink to stupor at night in his room. The next day his manner was changed, he was more talkative and excited, and seemed anxious that full explanations should be made of every event and act. In business he was more exact and methodic, and more irritable and intolerant of the errors and failures of those associated with him. He was sentenced to prison for life, and in a few months developed well marked epilepsy. It was evident that for years he had suffered from premonitory epilepsy, and the homicide was the result of this condition.

Recently a postmortem of a man hung for murder revealed a tumor in the brain, which had evidently been the growth of years. The man was an inebriate, had murdered a companion, and exhibited cunning to conceal the crime. His mental condition had been questioned, expert testimony could not define the disease from the act, and no particular history of the case was made. Seen from the facts of the postmortem, the crime was the act of an insane man. A diseased brain unable to reason and control its acts had been misjudged and judicial murder added to the first crime.

In a celebrated case of a clergyman whose conduct and impulsive drinking had been the subject of much social scandal, and on several occasions resulted in imprisonment, a postmortem at death revealed the real causes. A fragment of a ball received in the late war, was found incysted in the skull pressing on the brain. His life had been prominent by great extremes of character and conduct.

An eloquent, model clergyman and a low dishonest inebriate; great intellectual brilliancy and childish dementia, with paroxysmal explosions that were inexplicable. Expert medical studies had failed to detect the physical nature and causes which were clearly manifest by the symptoms. These studies were dismissed with the terms sin, vice, moral depravity, and given over to the devil. Such echoes of the dark ages are fortunately receding and growing fainter, and the medical man of to-day who uses these terms in explanation of strange conduct is sadly belated. The drink history is an unmistakable evidence of degeneration, of disease, of central brain failure to realize and control conduct and acts. While the expert may not be able to trace the exact lines and forms of known and defined insanities, he can always determine general principles of cause and effect. The use of spirits is a specific range of causes deteriorating

and destructive to all healthy normal brain power. The problem is how far the use of alcohol is a cause or a symptom in any case. How far it breaks up and injures the capacity to reason naturally on events and their meaning. This must be determined in each case from the separate facts and history. The expert must start out on a new original study in each case. He must start from the fact that the medical questions in the disputed case, are purely matters of cause and effect. The criminal or unjust act, the strange unusual reasoning, and the suspicion of brain failure are all susceptible of demonstrations from accurate exhaustive study.

An officer in the English India service was a murderer and forger. He was convicted and before sentence was placed under the care and observation of expert asylum physicians. In a few months a well-marked case of general paralysis appeared, and it was evident that the crimes had been committed in the preliminary stage. The experts in this case could not make out the form of the disease from the facts at command, although the evidence was clear that some form of degeneration was present; later and more exhaustive studies revealed the true condition.

The facts I wish to emphasize in this study are on the errors of the present methods of examining medical men in open courts on questions of facts relating to science. The great difficulty is avoiding a partisan attitude and taking sides in a disputed case. The legal methods of, from a brief study of the act in dispute, forming a theory, and bending all energies to support and defend it, are dangerous and thoroughly unscientific. The haste and confusion in which a medical man is expected to study supposed facts and ascertain their real meaning, and prove a hypothetic question, state positive convictions, is utterly subversive of truth. In every case the physician should insist on time and full opportunity to satisfy himself as to the actual conditions present in a desperate case. He should also insist in stating the reasons and facts on which his conclusions are based, and not be constrained to affirmatives and negatives where each answer depends on certain conditions which will vary.

The second fact which should receive prominence is the drink history in a desperate case. Here the same errors prevail. Theories of alcohol and its effects which have come down from the past together with legal conceptions of responsibility, must be put aside as misleading. Has alcohol in any degree raised the vigor and mental capacity of the person who has used it? Has his thought and conduct been more rational and normal from its use? If this can not be answered in the affirmative from the facts the opposite must be true. In all cases the fact that alcohol was used by the person whose mental condition is questioned opens up a new field of study.

Here critical analysis of facts will point out states of poisoning or marked degenerations that exist. Dogmatism here is fatal to the reputation of the expert, he must adhere closely to general principles and appeal constantly to facts. He must examine and reexamine the facts persistently to eliminate all possible errors. The medical expert should take the position of a judge and give the conclusions and the facts on which they are founded, then he rises to the level called for by science and truth. Medical men called to give facts of science in court to-day should keep above the levels of courts and battles of counsel to maintain the power which their position demands.

## THE NECESSITY OF REFORM IN MEDICAL EXPERT TESTIMONY.

Read in the Section on Neurology and Medical Jurisprudence at the Forty-Seventh Annual Meeting of the American Medical Association at Atlanta, Ga., May 5-8, 1896.

BY DANIEL R. BROWER, M.D.

PROFESSOR OF MENTAL DISEASES, MATERIA MEDICA AND THERAPEUTICS, RUSH MEDICAL COLLEGE; PROFESSOR OF MENTAL AND NERVOUS DISEASES, WOMAN'S MEDICAL SCHOOL, N. W. UNIVERSITY, CHICAGO, ILL.

The members of this section, without a dissenting voice, will agree with the title of this paper, and feel keenly the discredit brought upon the profession at every important trial where medical expert testimony is employed.

A trial, as I am writing this, is going on in Chicago in which a dozen medical witnesses are arrayed against each other on the question of the responsibility of a dipsomaniac, one set testifying that he is responsible for the killing of his wife, and the other that he is not. Similar discreditable displays have been witnessed in this city in the Cronin and Prendergast cases; indeed every city and every such trial is a most serious reflection on the integrity and capacity of the medical profession.

Medicine is not pure empiricism. Medical jurisprudence is a great compilation of scientific facts, and their judicious use is essential for the establishment of justice in many cases. Medicine is a learned, as it is a self-sacrificing profession, and under proper protection and with proper legislation, medical expert testimony can be relieved of the stigma that is attached to it. It ought to be no longer possible for lawyers to find physicians, who will have standing in courts, to build up this theory, or that theory of a case, as the necessities of the prosecution or defense may require.

This medical expert testimony is not only condemned by the leading thinkers of our own profession, but the legal profession in this country and Great Britain has been equally emphatic in its condemnation; for example, we find Lord Campbell of England, remarking, "Skilled witnesses come with such bias on their minds to support the cause in which they are embarked, that hardly any weight should be given to their evidence."<sup>1</sup> Again, Judge Davis of this country expressed an opinion that "if there is any kind of testimony that is not only of no value, but even worse than that, it is that of medical experts. They may be able to state the diagnosis of a disease more learnedly; but upon the question whether it had, at a given time, reached such a stage that the subject of it was incapable of making a contract, or irresponsible for his acts, the opinion of his neighbors, if men of good common sense, would be worth more than that of all the experts in the country."<sup>2</sup>

Again, another American judge has spoken almost as strongly: "There seems to be but one opinion as to the fact that this kind of testimony is extremely unsatisfactory. We are more and more confirmed in an opinion that the difficulty comes largely from the manner in which the witnesses are selected. If the State or the courts do not esteem the matter of sufficient importance to justify the appointment of public officers, it is certain the parties must employ their own agents to do it; and it is perhaps almost equally certain that if it be done in this mode, it will produce two trained bands of witnesses in battle array against

<sup>1</sup> Tracy Peer, 10 Clark & Fin., 191.

<sup>2</sup> Neal case, cited 1 Redfield on Wells, ch. iii, 101, par. 13.

each other, since neither party is bound to produce, or will be likely to produce, those of their witnesses who will not confirm their views."<sup>3</sup>

Taylor, in his work on Evidence, observes: "It is often quite surprising to see with what facility and to what extent these views can be made to correspond with the wishes or the interest of the parties who call them. They do not indeed wilfully misrepresent what they think, but their judgment becomes warped by regarding the subject in one point of view, that even when conscientiously disposed, they are incapable of expressing a candid opinion."<sup>4</sup>

In my opinion the time has come for a reformation, and I ask the coöperation of this Section in the efforts that are being made to devise some plan by which the present methods may be improved.

The International Congress on Forensic Medicine, which met in Paris in 1889, representing as it did, the best thought of the times on medical jurisprudence, deliberated thoroughly on this important question, and formulated the following proposition, which was adopted: "To guarantee the interests of society and of the accused, in all medico-legal investigations, at least two experts shall be employed. These shall be appointed by the judge."

Six of the medical societies of Chicago have had the subject under serious discussion, and as a result a joint committee of eighteen was appointed, of which the writer had the honor to be made chairman, and this committee, after due deliberation, have formulated and adopted the following draft of a bill.

A Draft of a Bill for an act authorizing the Judges of criminal jurisdiction in the State of Illinois, to appoint persons to act as expert witnesses:

*Be it enacted by the People of the State of Illinois in the General Assembly represented,* That the Judges of the Circuit and Superior Courts of the State of Illinois, be and the same are hereby authorized to appoint in the month of January of each year, persons who shall act as expert witnesses in the medical and other sciences in giving opinion upon the evidence, as presented in a hypothetical form, of criminal causes that may be on hearing in the courts presided over by the said judges. Such expert witnesses shall hold their said appointments for one year, or until their successors are appointed and qualified. They shall be entered as expert witnesses upon a list of such witnesses kept by the Circuit Clerk, and the said Clerk shall issue a certificate of appointment as such expert witness to the person appointed as above.

SEC. 2. Such expert witnesses shall be citizens of the State of Illinois, and shall be known in the communities where they reside for their professional competency and personal probity, and if physicians, they shall have been at least five years in regular and active practice. When expert opinion is desired in any cause pending in a criminal court, the trial judge presiding in such cause may, at his discretion, summon for duty under this act, such expert witnesses to the number of three. Such expert witnesses shall be paid for their services by the county in which the trial for which they are summoned is held, in such sums as may be named by the judge.

SEC. 3. It shall be the duty of such expert witnesses to give an opinion on the evidence as presented in hypothetical form in the case in which they are called. Such experts shall be subject to cross examination by both prosecution and defense; but such cross examinations shall be limited entirely to the subjects embraced in their opinion.

SEC. 4. In criminal cases previous to trial, if the State's Attorney deems it advisable to have expert opinion, he shall state to the court having jurisdiction of the cause, and the judge receiving such statement may summon expert witnesses to serve under this Act.

This bill with slight amendments passed one branch of the Illinois Legislature, but failed to reach a vote in the other. It met with much more favor than was anticipated and an effort will be made again this winter to secure its passage.

DISCUSSION ON PAPERS OF DRS. SUITER, NETTLER, CROTHERS AND BROWER.

DR. HUGHES, St. Louis, Mo.—I think that the question of expert medical testimony is a far more difficult question to determine by legislative enactment than at first sight appears. The court is undoubtedly entitled to an *amicus curiæ* in every question of mental aberration; the court can solicit counsel, friendly counsel, from science to aid it in forming its conclusions and judgments. The only thing that seems to be in the way is the neglect of legislators and other authorities, to provide means for the compensation of this counsel.

But after you shall have secured for the court all it requires or may ask in these cases, you still have the inalienable right of the individual accused or arraigned to have such testimony as his case, in his judgment or the judgment of his counsel, may demand. He still has the right, after you shall have enacted laws providing for expert medical testimony to be given in the interests of the court for the enlightenment of the court, to as much testimony in his behalf, or that will contribute to enlighten the jury, as may be necessary to accomplish that purpose and to secure his rights before the law. The chief difficulty in this whole question of medical expert testimony is not so much in the fact that the principle of giving expert testimony by experts as such before the jury, and for the consideration of the jury, is objectionable, as in the quality of the expert testimony itself; and the suggestions of Dr. Suiter meets my approbation entirely in regard to the efforts made to determine the quality of experts who shall be admitted to testify. I do not coincide with the views of Dr. Crothers in regard to the general weakness of medical men in their judgments in regard to expert medical questions. I do not consider that a medical mind is naturally less logical or weaker than the average mind. Some medical minds, like a few legal minds, and a great many more clerical minds, are lacking in trained logical discernment. If a man assumes to be an expert, he should think as an expert and cultivate the judicial faculty of mind and not go into cases biased, not decide upon the presentation of the case only conditionally by one side. I have never made any such mistakes as Dr. Crothers is talking about, although I am a western medical expert, and I have never made the mistake of committing myself to an attorney in any question irrevocably. I have taken facts given to me by attorneys and given conditional opinions, for which I have always exacted a consideration for the opinion itself, without regard to the use that might be made of it. I never took a contingent fee in my life. I have taken fees for time of service, conditioned that I might be required for so many days' service, provided the opinion that I had given, and which was paid for at the time, proves to be satisfactory, supplemented by another opinion when all the testimony was in, with the understanding that I was to have all the opposing testimony before my final conclusion was reached, where that was practicable. There is no reason why medical men that aim to be experts in court should not elevate expert medical testimony in such a manner as to stop this outcry against it. Medical men make no more errors in judgments than lawyers. Lawyers say that the errors of medical men are buried in the ground, but the errors of lawyers are before us constantly; the decision of one court is reversed by another, and lawyers have to have a succession of courts, appellate courts, supreme courts, to correct the errors of judgment of the lower courts; and the arraignment does not hold good in regard to medical expert testimony.

The question in regard to the effect of alcohol in questions of mental aberration, is not whether the man has drunk so much or so little, not whether the man has had such and such drinking habits, and then a conclusion that therefore that man must be out of fix mentally; but it turns upon the question of disease which can be established by methods of obser-

<sup>3</sup> Gay v. Mut. Ins. Co., 2 Bigelow, Life Ins. Cos.

<sup>4</sup> Taylor on Evidence, p. 73, par. 50.

vation familiar to all psychologists, neurologists and alienists, and that is the underlying question in all cases of mental aberration, whether it be produced by alcohol or irregular habits or over-strain. The toxic effect of alcohol does not *prima facie* make a lunatic. There must be an inherent instability of nerve element in the organ, brought about by repeated potations destroying the integrity of the cell or neuron that gives final instability to mental operation. And the alienist, interrogating his patient carefully and finding that to be the fact, says to the court that he believes this man is diseased, or is insane and irresponsible, and because he is so diseased that his mental operations are not normal, they are out of harmony with his natural character; and thus the individual is placed in disharmony with his environment. The change has come over that individual by reason of disease, and alcohol has been the exciting and it may be the predetermining effect or the chief factor. The individual that makes a business of going into court upon the hypothesis that because a man drinks whisky and commits a crime he is therefore insane, will be exposed in error by a judicial-minded lawyer, capable of discerning appearances from real facts by the proper logical processes.

The criteria of all mental aberration resolve themselves into the question of disease. If it is not a question of disease, medical men have nothing to do with it before the courts; it is out of the province of the alienist or of the neurologist. If it is only a question of conjecture based upon the knowledge of the man having drunk alcohol, in the case of alcoholic insanity anyone can conjecture that that was probably the reason the man committed the crime. But in every form of mental aberration it is a question of disease, whatever may be the exciting cause. So far as all forms of aberration are concerned, except those rare forms which may be called hereditary, and which even in those instances are marked by a departure from natural habits of thought, feeling or action of the individual, we are enabled by careful interrogation of the patient to establish the systematic evidences of disease in the individual's brain and mind, just as we determine the existence of disease in the body. All disease is a perversion of the physiologic action of the organism or of the organ from the normal; and all mental aberration is that same thing. It obeys a certain law as any other physical disease. The substratum of all mental disorder being physiologic disorder of the brain, you have manifestations just as in any other diseased organ. You come back to the proposition of Cabani and you find it almost the same. We do not say that the brain secretes thoughts as the liver secretes bile and the stomach secretes gastric juice, but it obeys these same laws and it displays thought upon the same condition, and if it is out of order so as to constitute the condition of irresponsibility, the character of the brain's functioning will be so transformed as to make the brain act unnaturally, just as the liver acts unnaturally, the spleen, pancreas or any other organ of the body, the intestinal tract, the bladder, the heart; and that organ will be out of harmony with its environment in the organism. Its functioning will be disturbed in relation to the organism and in relation to the individual's environment, and so will an individual's character be transformed and changed, thus placing him out of harmony with his surroundings. It is not difficult for the average medical expert to detail all forms of mental derangement, whether they are produced by alcohol or other causes in that category, and be able to make the thing plain by the coöperation of the reaction tests applied to the urinary excretions, by the ophthalmoscope and other plans within our reach to confirm the conclusion that that man's brain is deranged, and that the departure from the natural habits of thought, feeling or habit of that individual which attracts our attention is the result of that brain disease. These conditions can generally be placed very plainly before the court by experts, so as to bring conviction to the average jury, and

at the same time reflect a reasonable amount of credit upon our profession and not make the impression that medical men merely guess at these conclusions.

DR. MOYER—The subject can be divided naturally under two heads: 1, that the personal attitude of the medical expert testimony as given in our courts, is defective, inadequate and even offensive in the eyes and to the mind of man; 2, such being the case, the remedies that are proposed to overcome these defects.

Regarding the first proposition, I do not regard the present system of giving expert testimony as nearly as bad as has been stated here. Now and then there is a case presented, in which there has been a gross miscarriage of justice, or perhaps a conflict of the evidence which is simply appalling. Such a case attracts public attention forthwith, and the whole theory of our present medical jurisprudence is condemned. I believe that there are a large number of cases, both civil and criminal, tried in our courts, in which the present system is adequate and effective, in which the truth is ascertained, and just verdicts are rendered. This is the rule; the exceptions to it are the cases which attract the attention of the public and most medical men.

I do not, however, advocate the present system of giving expert testimony as the best, as I think that it is capable of improvement, but we should approach the subject with care, and we should make very short steps in advance, lest we fall into a worse state of affairs than we have now.

If we consider some of the causes by which medical expert testimony is made difficult, I think we can approach the question of reform with a little clearer apprehension. The fault is not all with the method in which experts are summoned; it is not due to the fact that the lawyer goes to the physician's office, explains to him his theory of the case on a partial statement of the facts, secures his testimony, and makes him a partisan. There are other objections and other difficulties that are inherent in the constitution of society and human individuals themselves. Human institutions are not perfect; I do not think that our legislatures are perfect. There is no remedy that can be devised which will bring about a perfect result; the question is whether its defects are to be less than the present system.

The causes of these defects are partially in the nature of things, the defectiveness of individuals, the defectiveness of jurisprudence generally. But there are also defects in ourselves and in medicine. Medicine is not an exact science. The opinions that medical men give in courts are largely based upon judgment and experience. We can only have a perfect medical jurisprudence when we have an exact medicine; that seems a long distance in the future. In view of the fact that medicine is in an inexact state, some subjects almost chaotic, with wide divergences of opinion, we should approach the subject of a remedy with very great care, and an attempt to make a wide and sweeping departure is very ill-advised. We do not know exactly what the truth is in a great many cases, and even though we may agree on the major proposition in a given case as to where the truth lies, there may be a large number of minor propositions admitting of a wide difference of opinion. As long as this is the case it does not behoove us to set ourselves up as judges in a court of law. We do not know enough about medicine yet to do it; we have to improve medicine very much before we can take such a strong ground.

I now pass to a consideration of the remedies which are proposed. These are naturally divided into different classes: those which, according to the continental system, would limit the function of the jury; would make really a jury of experts, not subjecting their opinion to cross-examination, but the jury to take their decision on that part of the case as final. The other system, as has been recited in the bill from New York, and the one from Illinois, consists not in sweeping away cross-examination—limiting it somewhat perhaps as in the case of the bill

from New York—but simply changing the manner in which experts are to be summoned; giving them some definite standing; providing for compensation for these experts, and doing away, so far as possible, with bias among them.

In this respect I agree with the bills that have been presented but I shall never give my consent to any other step in this direction until that has been taken.

As to this New York bill, it does not seem to contain any definition of expert testimony. That would seem to be an important omission. What is expert testimony? Is it opinion testimony; if so, where does the difference between fact testimony and opinion testimony come in? Lay persons give opinions in court; they can give an opinion in most of our States as to the insanity of a person. "Do you think such a person was insane?" It is perfectly competent for any witness to answer that question.

Then, there is absolutely no provision in this bill for another exceedingly important testimony; that is, shall a person who is previously in possession of facts be allowed to give opinions as well? It is proposed to summon into court medical experts, presumably not familiar with the facts in that particular case. (This is provided for in the Illinois law by hypothetic statements.) A man makes a postmortem examination; he is summoned into court, and his opinion, as well as the recital of the facts of the postmortem, are asked for. Perhaps his opinion is more valuable because based on things he sees at the time; better than any subsequent opinion formed by hearing a relation of the facts. In this New York law we are met at once with that question: Shall a man who has previously examined a patient (a blood stain, or the contents of the stomach) be allowed to give his opinion under this law or not; or shall the opinion on the case be solely confined to these experts? Under the New York law the hypothetic opinion can alone be given experts who are all summoned. It seems to me that this is a fatal defect in the drafting of this bill.

DR. HUGHES—Have you been asked on the witness stand to give your opinion hypothetically, and then, in a second opinion, to give your opinion upon all the hypotheses in the case, as well as upon your own information?

DR. MOYER—In Illinois that is a very common form of question. When a postmortem examination is made there may be no man accused, and no man on trial. Is the man who makes that postmortem examination to go into court, and give his opinion as to what the cause of death is? That opinion is formed long before anybody is arraigned for trial. Shall he give that opinion?

DR. A. WALTER SUITER—That is what he made the postmortem examination for.

DR. MOYER—It seems to me, that this is one of the defects in the bill; that a person may be liable to be put in possession of facts long before a trial, for instance, the direction of a bullet wound, the facts of postmortem examination; a stomach is submitted to a chemist for examination, perhaps under the suspicion only that there has been foul play. There is no case in court, there is no man arraigned. Then a man is summoned as a fact witness, and he states what he found at that postmortem examination. Is he to be permitted to give his opinion? It seems to me that that class of testimony is shut out by that bill, and that is the most valuable kind of testimony that comes into a court of law; the opinion formed at the time of personal examination.

Regarding the view of the matter brought out by Dr. Crothers, I think he carries his opinion as to the effect of inebriety too far.

He says that experts are required to make yes and no answers to leading questions. There is no court in any State of the Union where such a practice prevails. He can qualify his answer until his exact idea is placed before the jury.

DR. ROHÉ—I am much more favorably disposed toward this

Act of the New York Legislature that was not passed than Dr. Moyer seems to be. However, it does not cover the subject fully; an additional section would be advisable.

During the past winter it has been one of my duties, as a member of the Committee for the Baltimore Neurological Society to prepare amendments to the Maryland Code, so far as relates to lunacy. When the criminal procedures are against lunatics, or in the cases of suits against lunatics, there are certain means by which the defense of insanity may be brought before the court and tested. It was proposed in these amendments to authorize the court in any case where one was accused or on trial, that the court should be authorized to appoint a commission of three physicians qualified and advanced in medical science, and experienced in the treatment of insane persons, who should go into court and hear the testimony (if it be that the trial were going on), and then consider the testimony, and report to a court, under oath, their findings. If they did not agree, or if the court for any reason were satisfied with the findings of a commission, the court may discharge that commission and appoint another commission, or revert to the old established form of inquiry by a jury. The object was to get a report which was the expression of all the members of the commission, and that that commission could be cross-examined by either the prosecution or the defense. It was not a prosecuting commission or a defense commission; it was a commission of the court itself.

I rather decidedly object to bringing in any question of civil procedure. When a question of money is involved, the person who can get the best lawyers and the best experts, can win the case.

But here is a case where an individual's life is at stake; where the person accused has no money; where the State has to pay expenses. The State ought to select and be responsible for the expert testimony in this case.

DR. MARCY, of Massachusetts—In Massachusetts we are suffering, perhaps more than any other State, from the necessity of reform in this respect. The best men in Massachusetts will not appear as experts in courts. I myself have refused to go into courts except in the defense of another practitioner. I only express the opinion that is common in our State. I am glad to tell you that the legal profession feel it themselves as strongly as we do that something must be done to correct the abuses which have arisen.

In a discussion we had in Boston not long ago the judiciary of the State met some of the very best members of our profession, and this seemed a common ground upon which to meet: that the judges themselves should have a large power in selecting the class of medical experts who should be considered as a sort of judicial body, to which these questions should be referred.

DR. H. S. DRAYTON, of New York—For several years past the Bar Association of New York has been discussing this subject; the Society of Medical Jurisprudence in New York City, also the Medico-Legal Association, and by reference to the proceedings of either of those societies it will be seen that for the last four or five years this matter has been one of constant discussion. It has been under the consideration specially of a commission, and every year at Albany the matter is brought up for discussion in some way.

The matter of a commission appointed by the court in each case seems to be chiefly favored, and yet that is not universally approved. Some favor a commission appointed by the State, but politics would be likely to intervene.

With regard to the giving of testimony in court, I have had a little experience, and I have never been very badly used or abused by lawyers. I remember that celebrated case of Carlyle Harris. Nearly every great man, every physician who stood before the country as an expert, as eminent in his department of particular service, was very seriously treated by

Dr. Sullivan, the prosecuting counsel of the city. Dr. Sullivan, having a good medical education, used his knowledge as far as possible for the purpose of mixing up the professional witnesses, and seemingly did it very successfully. However, I think that Dr. Wood and the other physicians did not suffer very much in the opinion of the communities at large, for the reason that the common sentiment is not so much in favor of the lawyer side of the subject as it is of the medical side.

In regard to answering questions yes or no, a hypothetical question was given to me in a case in Newark, N. J., in a murder case. I had had an opportunity to examine the accused very carefully, and told the lawyers who wished me to testify just my opinion, in fact I wrote it out very carefully and said, "If you are satisfied that that opinion, if ventilated in court, will meet your requirements or your wishes, I will testify." In New Jersey the witnesses in these cases are paid for by the county, and it is not a matter of a fee from the defendants. I testified there, and at the close of my testimony a hypothetical question was administered. I think it was about five minutes in length and I was required to answer "yes" or "no." I answered it practically "no," but I turned to the jury and made a statement. The counsel for the prosecution endeavored to stop me. Then I turned to the Court: "Your Honor, may I be permitted to answer this question in my own way?" He said: "Certainly; by all means explain your views to the jury." In that case I was the only physician on that side who received a fee; my bill was honored without any discount.

In New York I have pursued the same policy; when invited to be a witness, or take part in any case, I have examined the accused, examined into the case, and written out an opinion, and I would suggest that that is a capital thing to do. Your attitude in regard to the case will be clarified, and you will be understood as representing certain opinions.

DR. BISHOP, of Pennsylvania—The question that concerns us most is in regard to the selection of these witnesses, whether these experts should be permanent officers or only chosen for the particular time. I have seen a good deal of legal testimony, having been interested in a good many contests, and I find the great trouble is that the physician when he gets upon the stand is inclined to make a speech. Doctor, preacher and lawyer, when they get in the witness stand, think it is an excellent occasion to air their knowledge and try to make a speech. If they are asked a hypothetical question, and then asked to answer "yes" or "no," all they have to do is to say they do not understand it. If you do not understand a question make the lawyer explain it.

DR. MOYER—Dr. Drayton refers to some difference of opinion as to how these commissions should be appointed, or as to how long they should remain in force. There has been none between those who have taken part in discussing this question. None have ever favored a permanent commission. That is what we know as the continental system. We agree that the best method is the appointment of separate experts by the court for each case.

DR. SUITER—We in the State of New York do not force this bill, and simply want to correct it so as to cover every detail. We are ready to receive suggestions at any time. This is in the hands of some of the most competent experts and alienists in the State of New York, and we are making a determined effort to have this matter corrected in some degree. The question as to whether civil cases should be included in this bill, came up, and for reasons which have been very well stated by Dr. Rohé, the civil cases were left out. We thought this bill would be an entering wedge and there could be subsequent legislation when the proper time came for it.

Dr. Drayton was incorrect in his statement that this subject was being constantly brought up in Albany. I have had charge, more or less, of medical and medico-legal legislation for a great many years in the State of New York, and this sub-

ject has not been brought before the legislature during that time. There is no dispute in reference to the method of appointment, so far as the State of New York is concerned, and everybody is agreed that the appointment should be made by the court and the county bear the expense.

DR. HUGHES—It often becomes necessary for what are some times termed speeches to be made by the medical expert—that is, the elaboration and elucidation of his testimony. No medical expert on the witness stand is obliged to suffer himself to be confined by attorneys to a categorical answer, and whenever an expert permits it, when his meaning can be further elucidated, he puts himself at the mercy of the attorney against him. It is a favorite method of attorneys with experts on the witness stand to propound questions which they think admit only of a categorical answer, and secure only such answers; or questions which they wish to have answered only categorically. The medical expert should always be on the alert for that kind of interrogatory, because it is always the business of the lawyer to make the witness *his* witness; his questions are always so framed, if he be an adroit attorney, so as to favor the point which he wishes to elucidate. It often becomes necessary, then, for the expert to decline to make a categorical answer, and to so frame his answer that it can not be misunderstood, and if this involves making a speech, then he should make that sort of a speech. When I was young in psychiatry and the guest of Dr. Isaac Wray, he told me: "Some day you will be called into court, and I will tell you one thing from my experience, and that is, never to permit a lawyer to compel you to give his kind of an answer, that is, a categorical answer when you know that science requires a more elaborate answer." I have never followed any other rule. I do not think it is necessary for a medical expert, who knows the subject upon which he is testifying, to be outwitted by a lawyer. Of course, if he does not understand his subject up to the degree of enlightenment which his day affords, he ought not to go on the witness stand; if he does so know it, there is no danger of any lawyer knowing more than he does.

I would say that this was an enactment proposed, with this additional qualification put right here in the ninth line (referring to copy of New York law proposed):

"The presiding judge before whom such trial is had may appoint such experts as he may deem necessary to adequately represent both the prosecution and the defence,"

"Not by the recognized legal right of both prosecution and defense to such additional expert testimony as they may deem, with consent of the court, essential to the maintenance of their cause," etc.

A man who is on trial for his life is entitled to all possible defense, and no one can deprive him of the right of summoning individuals to testify in his behalf. If this right were attempted to be abridged by statute, it would have to go to the supreme court, and it would be declared unconstitutional.

In our State the law is defective in regard to compensation, because you can get such expert testimony as you are able and willing to pay for, and the State has to rely on voluntary expert testimony. Thus the State is crippled in prosecuting the case.

We ought to favor this enactment, because it is a step in the right direction, and it does not complicate the question of expert testimony very much. The legislature should have their attention called, and it is proper that this body should call their attention, to the fact that there are glaring defects in the provisions as to the qualifications of medical experts.

**Operation and Cure of Perforating Tumor in the Duodenum.**—Landrerer reports the first case of this kind on record in the *Mittl. u. d. Gr. d. M. u. C.* No. 2. The usual difficulty is in the clinic diagnosis, but whenever an *ulcus ventriculi perforatum* is diagnosed and the operation discloses nothing wrong in the stomach wall, the possibility of a duodenal tumor should be borne in mind.—*Wien. K. Rund.*, No. 33.

## INTOXICATION AND INSANITY.

Read in the Section on Neurology and Medical Jurisprudence, at the Forty-seventh Annual Meeting of the American Medical Association at Atlanta, Georgia, May 5-8, 1896.

BY J. T. SEARCY, M.D.

TUSCALOOSA, ALA.

I will be glad to limit the meaning of the word intoxication, in this paper, to the injurious effects on the cerebrum of toxic agents present in the circulation. Toxic agents in the blood, of course, have their chemic effects upon other structures, but in the ordinary interpretation of the word, the symptoms of intoxication are those that belong to the brain. I will use the word in that sense.

This organ is exceedingly sensitive to the action of certain agents; so much so, in certain instances, that it seems to be the only organ affected, or affected so far in advance of others that their disturbance is not appreciated. The exceedingly soft colloid character of the functioning central parts of its nerve cells and fibers render them the most sensitive of all the structures of the body to some agents; and their excessively rapid functional motion is most delicately disturbed.

The nervous system, indeed the whole body, may be divided into sensating and non-sensating structure. This is only a fact in a comparative sense, because there are no defined limits of the property of sensibility anywhere in the living world. The broad generalization is commonly admitted, that all *living* structures are more or less sensitive. In biology there is an advance of grade in this property as we ascend in the classification of species. Within the body of man the property is more decided and distinct in some organs and parts than in others. The nerve centers particularly have it as their function, and, among them, it improves in delicacy and distinctness until we reach the cerebrum, where its most refined excellence is called consciousness. In man, so "centralized" is the faculty, that all conscious action may be said to be cerebral. Sensibility in the human being is carried to such a degree of centralization that the cerebrum is practically the only sensorium. It is the organ of all "feeling," the physiologic *ego*. The recognition of this as a physiologic fact will explain many phenomena of the brain; in that of intoxication it gives ready explanation to many of the symptoms produced.

In intoxication the conscious feeling of the man is affected and subjectively interests him most. His "feelings" are altered, and he is concerned favorably or unfavorably as he is comforted or discomforted.

In addition to being physiologically the conscious organ, the brain is also the organ that adjusts the entirety we call "the man" to his environment. The other nerve centers have also adjustment as their function, but they adjust the organs of the body internally to each other. The brain adjusts externally.

The comparative excellence of structure and function of one man's brain makes him excellent in his external activities, and the comparative weakness or defectiveness of another man's makes him less excellent or competent. We judge of the integrity and functional capacity of this organ by the *emissions* it makes, which in the aggregate go to make up the exhibitions of the man's intellectual capacity and constitute what we call his conduct and character.

We judge, therefore, of the effect of a toxin and of the degree of intoxication by the man's recital of

his own "subjective" feelings; and we judge "objectively" by the "symptoms" shown in his brain's emissions. The symptoms of intoxication have been discussed in medicine since medicine first began. Because it relates seriously to the transcendently most important organ in the body, it is a live question.

There are a great many agents that act intoxicatingly. Some enter the circulation from within the body, are produced there; others are introduced from without.

We hear much said now-a-days about *auto-intoxication*, by which is meant the intoxication that is produced by toxins produced within the body. The unqualified word intoxication popularly means the series of symptoms produced by alcohol, or some other such agent, introduced from without.

The word *insanity* is more properly a popular or a legal term than a medical one, which fact occasions the trouble often found by doctors in giving a medical definition to it for legal use. Legally, insanity relates to conduct alone, and not especially to the brain condition that produces it. The gradually increasing popular recognition of the fact, however, that all conduct, good and bad, excellent and defective, depends upon brain condition, has led, of late years, more and more to the popular and legal reference of all cases of defective conduct to the medical profession, in the same way other defective functions are referred to them.

Properly, because it is a legal term, insanity simply means that the person has reached such a *degree* of aberrant conduct that he has to be supported, controlled or restrained by others, or by the State—he is disabled to that degree. It is always a question of degree and a matter of opinion. The doctor's opinion is taken as of most value.

Insanity indicates an *extreme* degree of cerebral defectiveness, which implies that there are other grades of impairment above the insane level. This is a fact open to every day verification, and it is a fact particularly related to the subject before us. Intoxication can be shown to be the cause of different grades of defective conduct ranging all the way upward from the insane level.

Cerebral intoxication varies in the person according to two factors or sets of factors; the first is the character of the agent and the amount of it in the circulation; the second is the peculiarity of the particular brain, peculiar in the way of being more or less sensitive to the particular agent, or peculiar in the way of being inherently defective, which abnormality is rendered more apparent by the action of the toxin. In other words, intoxication varies according to the toxin and the dosage, and according to the abnormality or idiosyncrasy of the particular brain.

Subjectively considered, by the man himself, the toxin produces discomfort or comfort. This is the direction in which he first considers it or principally considers it. In the action of many, probably of most toxins, the sentient result is that of less conscious activity, which means less sensation, or a more comfortable state.

Consciousness occurs only when there is functional action going on in the cerebrum; when there is no cellular motion, there is no consciousness; this occurs naturally in sleep and artificially in anesthesia; when the brain is partially rendered less capable of functioning by the chemic action of a drug, there is diminished sensibility—more comfort. Comfort is a

negative condition, meaning no discomfort. Discomfort is a constant or most frequent condition of many brains to whom all cerebral or bodily effort is more or less painful. Cerebral hyperesthesia is a very frequent condition as a part of neurasthenia or cerebrasthenia. In this condition, the over-sensitiveness, in time, is increased by the injurious or chemic effect of the toxin. If the agent simply stiffen or slightly harden the delicate structures so as to prevent or to make less their functional activity, it produces less consciousness—more comfort. This varies with the character of the toxin, but in time produces hyperesthesia or neurasthenia.

In intoxication there is more or less a sense of incapacity, dullness and confusion; sometimes, a more comfortable state because there is lessened sensibility. Sometimes, on the other hand, cerebral effort or activity produces more discomfort, so that, as a sequel to continued intoxication, comes hypersensitiveness with irascibility, irritability, forgetfulness and worry; all exhibits of cerebral impairment. If the person is naturally erratic or peculiar or hypersensitive, he is rendered more so. A cerebrum tending already toward hypochondria, melancholia, mania or paranoia, is more inclined that way. In short, intoxication always injures the cerebrum for the time being, sometimes permanently, and in certain persons increases original defectiveness to the permanency and grade that is called insanity.

Toxins, such as ptomains, leucomains and other toxic albuminoids, arise from the disintegrations of disease in the system; and there are also natural waste products which, if retained in the circulation, prove highly toxic, such for instance as are eliminated by the kidneys, the liver, the bowels and the lungs. Infection comes into the circulation from many directions; the scavenging of the system is most important work on that account.

Microbic disintegration of cerebral structure proper is not often seen. Inflammation of tubercular bacilli occurs in the meninges, and other meningeal inflammations are said to be microbial; cerebral syphilis may be this. Upon the true functioning structures of the cerebrum, however, microbes most often have no direct, but indirect effect by the toxins they produce elsewhere.

Diseases affecting the general system, like the exanthems, fill the circulation with toxins. Some brains are very sensitive under these conditions, and delirium is a consequence; there are always more or less confusion, dullness, listlessness and incapacity, as a consequence of such intoxication. In the extreme of life, *in articulo mortis*, the complete arrest of cerebration from this cause, in a large number of cases, removes the pain and distress of dying.

Cerebral toxicity, from disease in different organs of the body, varies with the organ. Diseases of those organs, whose function it is to remove waste toxic material, are always serious to the brain. The kidneys, liver, alimentary canal, lungs and skin, are organs of this character. We often have the unre-moved waste toxins of the system in the blood added to those directly produced by the inflammatory disease of the excretory organ. Acute rapid disease of such organs often produces delirium; more chronic disease for this reason sometimes gradually induces the more permanent condition of insanity. The delirium and the insanity indicate, usually, brains already sensitive, weak or defective.

In an insane hospital, where the worst cases of defective cerebra are found, it is very easy to note the effects of auto-intoxication. The part the digestive tract plays in the rôle of insanity is often very evident. In conditions of certain forms of dyspepsia, particularly in conditions of constipation or torpidity, auto-intoxication can be shown, and its relief demonstrated by removing the toxin by cathartics and alimentary disinfection. Stercoremia, copremia, and the common condition, "biliousness," afford instances of it.

A large proportion of the insane suffer from some form of nephritis, and to it can be traced many of their more insane periods or "spells," when the already weak or defective cerebrum is made more aberrant by uro-toxicosis.

Toxemia in women, during gestation, and after their confinement, during uterine involution, especially if there is sepsis, and during lactation, is by no means an uncommon thing. Puerperal mania or insanity in some form, is a result in extreme cases. It is a rare thing that the parturient woman shows no signs of intoxication in some of its milder forms.

A long chapter could be written on auto-intoxication. Literature on this subject is getting more and more abundant. I have said enough to show its importance as it relates to insanity.

Intoxication by agents introduced from without is a frequent occurrence and, as it relates to brain hygiene, is little appreciated.

As physicians, we would be very much handicapped in our practice if we did not have cerebral toxins among our medicines. They constitute a very popular line of drugs; popular with the doctor, because popular with his patient. All anodynes and anesthetics are of this class. Most frequently, the urgent symptom to be relieved in our patient is pain or discomfort. Pain is a brain condition. If disturbed or disintegrating action in distal parts can not be conveyed to the sensating brain by nerve lines that we have rendered incapable of transmitting by our toxin, there is no sense of it; or, if we render the cerebrum unconscious by our toxin, we accomplish the same object, there is no pain. We accomplish artificial anesthesia with such an agent as chloroform by a complete suspension of cerebral functions, while the functions of the lower centers, which adjust internal actions, are left to continue. If we push the anesthetic farther we suspend them also, fatally to our patient.

Toxins nowadays are known also to have injurious effects upon peripheral nerves. Peripheral neuritis is now ascribed most often to this cause, in conjunction with exposure, fatigue, or some such condition which renders these nerves more sensitive to the toxin. Peripheral pains, such as make so prominent a symptom in grippe and dengue, probably have this source—headaches, sometimes.

I believe it is true, under certain conditions or with some toxins, toxicity can be of the peripheral nerves at the same time and by the same agent that the cerebrum is affected. The difference between an anodyne and an anesthetic may be this; the one affects more generally the nervous system, the other principally the cerebrum. This distinction is necessarily not well drawn. It is a good hypothesis, however, that anodyne or anesthetic effect in the relief of pain or discomfort occurs by the arrest of the function of the transition of motion along nerve lines or, most fre-

quently, by the arrest of conscious motion in the cerebrum. The anodyne, cocain, administered hypodermically, hardens chemically the nerve lines leaving the locality, so there is no transition of motion to the sensorium from the part, and no pain; though later, we have its anodyne effect on the cerebrum, obtunding in a general way the sense of disintegrating action, or pain.

The effects of alcohol, on the other hand, generally begin in the cerebrum; though we do have local anesthesia in the stomach, and in time, in some cases, neuritis in the periphery as an effect of it. We may correctly suppose that whenever we arrest or abate pain with a toxic agent, we do it most often in the brain by hardening the axis-cylinders of nerve lines, or the central part of nerve cells, in this way preventing or lessening their functional motion. A good deal is being written to show the changes in the nerve cells of the cortex, in the way of enucleation, diminution in size, and changes in length and shape of processes by the continued use of certain toxins. Degeneracy of axis-cylinders in nerve lines elsewhere is also reported. The cerebrum (the sensorium) is the most important organ that suffers; it is impaired by the excessive or the continued use of anodynes and anesthetics, in numbers of instances.

In many persons the effect of the continued use of such agents on their peculiarly susceptible or defective cerebra is so injurious as to increase the original condition of over-sensitiveness to neurasthenia, or to carry their original defectiveness or weakness to the stage of permanency and degree called insanity. The continued use of such agents as luxuries, because of the artificial comfort they give, works wide-spread harm. The popular and extensive use of alcohol and nicotin as luxuries, not to mention other toxins, leads to increase of cerebral and neurotic defectiveness and disease and, in some, induces the extreme cerebral condition of insanity. A narco-maniac or an inebriate, in the large majority of cases, has had an original defect of brain, preceding his drink habit, that has been rendered more decided by repeated intoxication. The brain is a very much abused organ, and one sorely omitted in our private and public sanitation. In the use of such agents as luxuries, the brain effect is the one sought after, and in proportion to the amount taken and the length of time, injury is done. Intoxication, owing to inherent peculiarities, is more injurious to some brains than to others.

#### DISCUSSION.

DR. FREDERICK PETERSON of New York—I think this question of intoxication as the cause of insanity bears strong testimony to the progress of psychologic medicine of late years, because of the increase in the number of the cases which are put under the heading of toxic insanities. Formerly by toxic insanity we meant merely alcoholic insanity, or insanity due to lead and other poisoning, or cases of bisulphid of carbon poisoning, etc. But since the investigations in regard to the toxins manufactured in the body, we have come to look upon a large number of other cases that were formerly considered idiopathic or without etiology, as cases of toxic insanity. Beside, I think it is now pretty well believed that many cases of recurrent and of acute mania and cases of melancholia and hypochondriasis may properly come under that heading. The means of discovering whether it was really due to auto-toxicism are not always efficient. In certain cases that are due properly to putrefactive or fermentative changes in the intestinal contents, we have the means of ascertaining, sometimes by testing the urine. Usually the discharges from the bowels give no par-

ticular evidence of auto-intoxication, although in cases where there is intestinal intoxication we do sometimes find that there are periodic attacks of gaseous diarrhea. Our chief proof, however, of this probable etiology of many cases of melancholy and mania, is in the treatment by intestinal antiseptics and diet. I think the chief means of treating these cases is by a properly regulated diet, milk, vegetables, etc., by the washing out of the stomach and intestines with hot water, and by the use of certain antiseptics, like salol, given in fairly large doses, two hours after meals. I have found that remarkable success could be attained by such means.

### CONTROL OF TUBERCULOSIS FROM A STRICTLY MEDICO-LEGAL STANDPOINT.

Read in the Section on Neurology and Medical Jurisprudence, at the Forty-seventh Annual Meeting of the American Medical Association, at Atlanta, Ga., May 5-8, 1896.

BY CHARLES WILSON INGRAHAM, M.D.  
BINGHAMTON, N. Y.

How far can legal measures, whether municipal, State or National, be carried to control tuberculosis? This is now one of the leading questions before the medical profession in this and in other civilized countries. That decisive legal interference will be necessary before tuberculosis can be brought under control, there is no doubt. In the minds of all, physicians, legislators and tuberculous invalids themselves, who have given the question more than ordinary thought, the necessity of legal control is realized. It is estimated by competent authorities that 450 persons die every 24 hours in the United States from tuberculosis. A disease which is responsible for a human fatality so large and so continuous should be classed with dangerous contagious affections, as one requiring the strictest hygienic management designed to minimize the infection arising from each individual case. No one expects to obtain a complete destruction of tubercular infection as it is generated, and only a comparative control of the infection may be expected at best. The medical profession is unanimously agreed that it is not the tubercle bacillus alone which is responsible for the immense mortality of tuberculosis. It has been proven repeatedly that a certain percentage of human beings are more or less completely immune against tuberculosis, and such may be repeatedly exposed to the infection of the disease in a concentrated form and still escape contracting it; while again a certain percentage—and unfortunately it is a much larger percentage than the former instance—become affected from comparatively slight exposure to infection. So, therefore, constitutional idiosyncrasy, not always synonymous with constitutional degeneration, is an important factor, though tuberculosis can not develop even in the most susceptible without the presence and activity of the tubercle bacillus. It will require generations, even though the most corrective modes of living are carried out, to eliminate hereditary tendencies to tuberculosis to a noticeable degree, and the most that we can do in this generation is to initiate a movement in the right direction and leave future generations to do the rest. What we can not do as regards decisive constitutional improvement, we can do as regards the infection of the disease.

The question is, how far can the Government carry legal measures designed to control tuberculosis, and not infringe upon the natural rights of American citizenship. We can not, nor is it necessary to treat

the tuberculous patient as though he were a leper, but we can, I believe, form and apply a legislation which shall be just to the consumptive and the public, and at the same time have the desired effect of controlling tubercular infection.

There is scarcely an intelligent person of the present age who does not thoroughly understand that tuberculosis is a contagious disease, but for all this the public at large do not seem to comprehend the necessities of the situation with the keenness that they appreciate the contagious nature of smallpox and diphtheria, and until they do we can scarcely expect them to make any decisive changes in their present customs regarding tuberculosis. Tuberculosis is such a common disease that laymen, as a rule have but little fear of it from a contagious standpoint, and look upon those who demand that strict means be employed to destroy the contagious elements as alarmists, or as individuals who wish to increase the misery of unfortunate invalids. At the present time there is little encouragement returned to those who endeavor to inform consumptive invalids of the dangers which they, through carelessness, expose others. That the majority of consumptive invalids are a danger and menace to health and life in their respective neighborhoods can not be doubted, and yet it is easily possible for them to overcome any and all dangers. Intimate knowledge of the disease fosters intelligent action and cooperation. Therefore it should be the effort of every physician to do all in his power to disseminate appropriate information among his tuberculous patients.

With this brief introduction I will come at once to the main consideration of my paper, namely, what legal measures are necessary in order that we may immediately effect a reduction in the prevalence of tuberculosis, eventually gain control of it, and finally exterminate it; that is, exterminate it so far as is possible to exterminate an infectious disease. There are *five* measures of leading importance which must be adopted and enforced before we can expect to see tuberculosis controlled.

1. The strict registration at the office of local boards of health, whether country, village or city, of all residences in which consumptive invalids reside, in order that such residences and surroundings may be thoroughly disinfected after the removal of such invalids, before the house, apartment or room is reoccupied.

2. Systematic monthly inspection of all factory employes, to exclude from factories tuberculous workmen, which is necessary, not alone as a means of protection to fellow laborers, but to increase the chances of recovery of the sick ones who might in their desire, and oftentimes necessity to labor and earn, sacrifice their only chance of recovery. Factory infection is a prominent source of disseminating tubercular disease, and I have in mind several large manufacturing establishments to which I have distinctly traced the cause of many cases of tuberculosis; not to confinement associated with factory work, but to infection deposited in and about the floors, machinery and furnishings.

3. The thorough instruction of all tuberculous invalids capable of affording personal medical attendance. Experience has shown that family physicians have thus far not accomplished as much as might reasonably have been expected, in impressing upon the minds of consumptive patients the necessity of destroying all infectious matter. I believe it is neces-

sary for the health officials to assume the entire responsibility of instructing this class of consumptive invalids in all the details outside of medical treatment, concerning their disease. I think family physicians will welcome the day when the health officials assume this responsibility. It would not in any way infringe upon their professional relations with their patients, and would relieve them of a great anxiety.

4. The next measure I would suggest is the erection of State hospitals for the *compulsory* care, treatment and education of the indigent class of consumptives. By education I mean their instruction in hygienic matters, not alone as concerns tuberculosis, but in every sense of the word hygiene, as applied to everyday life. By the indigent class, I mean those invalids who can not afford suitable medical attendance and necessary medicines, and nourishing preparations upon their own responsibility. Persons who in health would be capable of caring for themselves and families in comfort, might, being afflicted with tuberculosis, become so reduced financially as to be classed in this instance, as indigent. In these State hospitals there should also be *sentenced* by health officials for a greater or less term, according to the seriousness and persistence of their offense; those persons not eligible from financial circumstances, who might persist in carelessly exposing others to the infection of tuberculosis, for without doubt many consumptives who even with a competent knowledge of the infectious nature of their disease would not exert any effort to protect others. Unless the State hospital plan for the care of indigent tuberculous persons is instituted on a National scale, we can not hope to gain any apparent control over the disease, for the majority of such indigents in their ignorance and carelessness scatter sufficient infection to perpetuate tuberculosis, though all other sources were perfectly eliminated.

5. My final suggestion is the extermination of tuberculosis from among dairy and stock herds, in order that human beings may not be exposed to the disease through the medium of meats and milk. This portion of the subject is receiving active attention at the hands of many of the State boards of cattle commissioners and State boards of health, but they are greatly handicapped in their work, and until the measures previously enumerated are attended to, they can accomplish but little to control the spread of tuberculosis among cattle. When the cattle commissioners go into a dairy herd and slaughter one-third, two-thirds or more, as the case may demand, their efforts may be compared to the surgeon who has by active means, healed an external ulcer or sinus due to constitutional causes, without removing the constitutional cause; the ulcer is sure to break out again, and so is tuberculosis in the dairy herd, for it must be remembered that the cattle become diseased principally through the carelessness of human beings, and so long as the present condition of affairs is allowed to continue, the control of tuberculosis in dairy herds will be an impossibility, and all efforts toward such control an immense and unnecessary expense to the government.

This then is the brief summing up of what I believe to be necessary, and I see nothing in any of the five measures advocated which would in any way infringe upon the legal rights of individual consumptives, under the laws of the United States. The medical profession must not wait for the politicians to inaugurate suitable medico-legal measures as regards tuber-

eulosis. If we await action from purely political sources we will live to see the ratio of deaths from tuberculosis doubled. The AMERICAN MEDICAL ASSOCIATION, as the greatest representative body of physicians, is an appropriate organization to take the initial steps. There is no doubt as to their ability to do what is necessary to be done.

### SURGERY OF THE NASAL VESTIBULE WITH REFERENCE TO CERTAIN FORMS OF STENOSIS AND FACIAL DISFIGUREMENT.

Read in the Section on Laryngology and Otology, at the Forty-seventh Annual Meeting of the American Medical Association, at Atlanta, Ga., May 5-8, 1896.

BY ROBERT CUNNINGHAM MYLES, M.D.

Professor of Otology and Adjunct-Professor of Rhinology and Laryngology at the New York Polyclinic; Surgeon to the Nose and Throat Department of the Church Infirmity and Dispensary; Assistant Surgeon to the Nose and Throat Department of the New Amsterdam Eye and Ear Hospital; Member of the American Laryngological, Rhinological and Otological Society; Academy of Medicine; American Otological Society; County Society.

NEW YORK.

The surgery of the nasal vestibule has not received that serious and careful attention which its importance demands. Abnormalities in this region not only obstruct the gateway to physiologic respiration, but also disagreeably alter an otherwise pleasant facial expression. Frequently operative procedures achieve a cosmetic result which were intended only to relieve nasal stenosis. It would be well to define the nasal vestibule as being that part of the nasal fossa which extends inward from the margins of the anterior nares from one-half to seven-eighths of an inch. Nearly all of this part of the nasal fossa is lined with scaly or pavement epithelium, and the balance of the nasal membrane is covered with ciliated and non-ciliated columnar epithelium. Attempts to enlarge the lumen of the vestibule by excision of the surface tissue, excluding a part of the septum, almost invariably produces the opposite results, by narrowing it. The contraction is usually due to the large amount of fibrous tissue in the membranes beneath the pavement epithelium. I have seen many cases in which the patients have been made worse by operations, where the surgeons did not recognize nor consider these principles, and the results were especially bad in those cases where the amateur or persistent rhinologist worked under the theory that the way to make a hole larger was to bore off or excise its walls; but the theory worked with the logic of the Irishman's ditch—"the more he cut off it the longer it got."

In former times when the electric trephine was used much more frequently than now, it was not uncommon to see cases where the membrane, and sometimes a part of the bone, had been removed from the floor of the nose, at the point where there is an elevation caused by that part of the nasal process of the superior maxilla, which extends downward and inward to the anterior nasal spine. In these cases the cicatrized membrane forms in a web-like manner across the floor, and extends from the septal wall across to the outer side beneath the junction of the ala and the nasal process. This condition greatly diminishes the ingress of air and the egress of secretions. I soon learned that any attempts to relieve the condition by cutting or excision only made it worse. I adopted the method of passing a small trephine through the band, along the floor, and afterward inserting a string or a small tube, leaving it in for a few months, until the healing was complete; carrying out the process used

in piercing the ear lobes. When practical it is best to leave the tube in place for about six months, until the elements of the tissues shall have become absorbed and fixed. It is a simple matter to remove the bridge-like band by making a section on either side with a Grafe knife, and afterward insert a Berens cork or an Asch's perforated tube for a week or two. The results have been almost invariably good, usually leaving a little excess of elevation of the floor at the point.

I have had three cases of complete occlusion of the vestibule: One the case of a girl 18 years of age, who informed me that her left nostril had always been stopped, and that she had only been able to force a little air through the right side. Examination demonstrated a membranous occlusion about one-third of an inch within, extending from the superior part of the vestibule, near the upper lateral cartilage, down to the floor. There was a pin-hole perforation through the one on the right. After using cocain locally and hypodermically, I cut through the membrane, which was about one-quarter of an inch thick, above and below, put in the rubber tubes, and finally cut away the tissue from top to bottom. I placed three rubber tubes, successively, side by side, sewed them together, and introduced them into the fossa; they were worn for a few months with most excellent results.

One of the cases was in a man 17 years of age. He was unable to breathe through either nostril, although a little air could be forced through the right one. I opened the right nasal fossa, after the manner described in the other case; the membrane was about an inch thick and extended from the floor to the anterior end of the middle turbinated body; the fossa remained patulous and satisfactory. On the left side, after cutting through the fibrous web in the vestibule, I found that the fossa was obliterated, and the space from the anterior to the posterior nares, and from the middle turbinated body to the floor, was filled with fibrous and cartilaginous tissue. I trephined and cut through about two and one-half inches of solid adhesive tissue; this caused severe pain, the cocain crystals and deep injections did not seem to obtund the parts effectively. I had no trouble in keeping the parts beyond the vestibule open, as they have no tendency to adhere or contract when they are not in contact. The vestibule was kept open by the usual method. The patient's general health improved rapidly; he slept well; the nervous system recovered from an extremely depressed state.

I will not have much to say concerning procedures for improving the general appearance of the nose, for the subject is of sufficient importance to require an individual paper.

There are two methods which are being employed: one, the implantation of metal plates and supports; the other is carried out by cutting or sawing the bones, cartilages and tissues, removing some parts, transposing others, and fixing the parts temporarily with apparatus, until they are permanently fixed by inflammatory adhesions, caused by the fractures or the incision into the parts.

Dr. John O. Roe of Rochester is a pioneer in the latter method, and it has been my fortune to see some wonderfully artistic work which had been done by him.

There is a great field for exercise of genius in the department of cosmetic nasal surgery, and the question as to whether the progress will be made through the surgery of the external nose, or through the vestibule, is to be decided in the future. I think that

the avenue will be through the anterior nares, on account of the external scarring.

There are certain forms of partial stenosis which are due to deflections of the anterior part of the triangular cartilage within the vestibule of the nasal fossa.

For several years past I have been operating for the relief of this class of vestibule stenosis with satisfactory results. There are two conditions which usually confront us in these cases; first, a projecting anterior extremity of the triangular cartilage, which extends across the vestibular space and approaches the margin of the ala; the second condition embraces the various forms of deflections with more or less thickening of the convex side of the cartilage. Since so many authors have written extensively and advocated various methods for relieving this latter condition, I have decided not to discuss the subject on account of time and the length of the paper that would be required to treat it in a manner its importance demands.

In those cases which come under the head of the first condition, the space between the ala and the projection is so narrow that when inspiration takes place in a rapid manner the atmospheric pressure forces the ala against the cartilage. These patients become accustomed to contracting the muscles on the side and front of the face for the purpose of pulling the ala away from the cartilage. Others sleep with the hand on the cheek, instinctively elevating the ala. This condition may be overlooked, especially when the nasal speculum is introduced, consequently it is well to test the inspiratory capacity without it, with the mouth closed, and also with each nostril respectively closed.

I have attained but little success in attempting to replace this tip by fracturing the convex cartilage in the opposite nostril, and afterward maintaining the segments in position with mechanical appliances until union takes place.

The operation consists of first carefully cleansing the vestibule and then making it aseptic with solutions of 5 per cent. carbolic acid and 1-1000 bichlorid of mercury. After this the anterior part of the fossa, posterior to the vestibule, is carefully packed with bichlorid and iodoform cotton. Extreme precaution is used in regard to asepsis in everything. A perpendicular incision is made about two or three millimeters posterior to the margin of the projecting cartilage. The incision is usually about an inch long and extends down to or near the floor. The perichondrium and the mucous membrane are dissected from both sides of the cartilage, and a piece about ten to fifteen millimeters in length and two to four millimeters in width is removed with great care, especially in reference to making a counter opening in the membrane. I never remove the anterior upper part of the cartilage, which is left for the purpose of sustaining the tip of the nose in its proper position. Delicate knives, periosteal elevators, Dr. Noye's eye speculum, a small needle holder, the smallest size curved needle, and a pair of self-registering rat-tooth forceps are the most essential implements. I have found in certain cases a small knife with short, lateral curve very useful in making the transverse cut for severing the cartilage. The wound is very carefully cleansed, all blood clots and ragged edges are removed and the parts are brought together with very fine silk sutures. In the majority of these cases the wound unites by

first intention and the after-treatment consists of filling the vestibule with aseptic cotton, and leaving it in place from two to three days. The results are beneficial from a respiratory sense; the appearance is much improved, and a decided improvement in the quality of the voice usually follows.

Another form of vestibule stenosis, which ought to be placed in the second class, is caused by a deflection, and circumscribed ecchondrotic growth or enlargement on the convex side of the triangular cartilage, can be relieved by this method of sub-perichondrial dissection. In case 3 the atmospheric pressure has caused a depression in the space between the upper and lower lateral cartilages; the stenosis was almost complete when he applied to me about one month since. I dissected out a large growth, which was situated on the septum opposite the depression, and three-quarters of an inch from the margin of the anterior nares. Cocain made the operation painless. The wound was brought together with four stitches; it united by first intention; in five days the dressing was left off and a small glazed line was all the evidence to indicate the place of operation. The stenosis was relieved and the breathing through the nostril was comfortable.

#### DISCUSSION.

DR. JOHN O. ROE, Rochester, N. Y.—The point that Dr. Myles has made in regard to the ill-advised attempts frequently made to enlarge the vestibule of the nose by cutting out the interior of the passage, is well taken. This procedure invariably results in decreasing the size of the opening instead of enlarging it, for the reason that when a portion of the constriction is cut away, the circumference of the uncut portion is correspondingly lessened, and when the cut edges become coapted during the process of healing, the lumen of the passage is made smaller. The vestibule of the nose may become narrowed by a variety of causes. In those cases in which it is obstructed by an exostosis which we frequently find in the floor of the vestibule, this exostosis should be removed subcutaneously in order to leave the mucous membrane uninjured, thereby avoiding the contraction of the passage. This is best done by making an incision in front of the eminence down to the bone and raising the mucous membrane together with the periosteum over the entire elevated portion of the exostosis. By cutting through these tissues on the posterior side they can be raised out of the way and the bony growth removed either by drill or saw. When this is completed the mucous membrane of the periosteum can be replaced, leaving the passage of the nostril unobstructed. The vestibule of the nose is often very much narrowed by the collapse or dropping inward of the alæ of the nose from a weakening or partial paresis of the dilator naris muscles, thus allowing the ala to be drawn inward against the septum during inspiration, thus increasing the obstruction to ingress of air. I have removed this difficulty by making one or two incisions through the cartilage of the ala, and inserting a dressing into the nostril sufficiently large to distend the alæ quite widely until the cut made through the cartilage has become firmly healed and fixed in this position, thereby maintaining the nostril freely open and preventing the collapse of the ala on inspiration. I was also much interested in Dr. Casselberry's paper on the reduction of spurs of the nasal septum by electrolysis, although I have never employed that method. I have not done so for the reason that I have always disposed of spurs and ridges of the nasal septum by what seems to me to be a very much easier and simpler method—by simply cutting the spur away. If the spur is located on the cartilaginous portion, I employ a suitable small cartilage knife for its removal, and if

located on the osseous portion of the septum I remove it with a saw or the Curtis drill. I have not attempted the more complicated methods because my patients do not object to having these obstructions removed in this manner. In the case of removing a small enchondroma, it can be so easily and quickly done with the knife that if the parts are thoroughly anesthetized with cocain the patient is neither alarmed nor incommoded by the operation, and sometimes scarcely realizes that anything unusual is taking place. In regard to the danger of denuding the parts of mucous membrane, I have never experienced any difficulty in this respect after a cutting operation, if but a limited portion of the membrane is removed. Even in some cases where quite an extended area of mucous membrane is removed, I have observed it from day to day spread over the parts when maintained thoroughly aseptic, so that in a short time the site of the operation, from the loss of the mucous membrane, could not be perceived. After the use of the cauterizer, however, I have observed extensive scars and areas in which the mucous membrane had been replaced by fibrous tissue, thereby causing much annoyance from the dryness of the nose and the formation of scabs and crusts over the parts in which there were no mucous glands to lubricate the part.

DR. MAX THORNER, Cincinnati, Ohio.—I would like to refer to Dr. Myles' paper. The obstruction of the nasal vestibule is by all means the worst thing that can happen after operations. In the operation advocated by Dr. Myles I think we have means to prevent such occurrence. One case I had was that of a young man who had been kicked on his nose by a mule, and there was entire occlusion of the right nostril. I made the incision and occlusion followed, and it was as bad as before, if not worse. Later on I made a flap from the upper lip, turned it upward into the nose and sewed it to the inner surface of the ala nasi, after having loosened it from its adhesions. Then I packed the nostril with iodoform gauze. The result was not an ideal one, but the improvement was great and permanent.

DR. HANAU W. LOEB, St. Louis, Mo.—I was impressed with the statement of Dr. Myles in regard to maintaining an opening. I remember one case in which there was complete stenosis as a result of smallpox; there was complete adhesion of both edges to the septum. To maintain the opening I used two rubber tubes, which were made after the fashion of Simrock's spectrum. These were worn without discomfort for six months, later being worn only at night, and at present there is a complete opening.

## NASAL HYDRORRHEA.

Read in the Section on Laryngology and Otology, at the Forty-seventh Annual Meeting of the American Medical Association, held at Atlanta, Ga., May 5-8, 1896.

BY D. BRADEN KYLE, M.D.

PHILADELPHIA, PA.

True nasal hydrorrhea is an exceedingly rare condition, not being mentioned in many of our works on nasal diseases. It is true there are many conditions which simulate this, but the well authenticated cases are rare. Let us first review the subject as to cause.

No special lesion can be named, the peculiar discharge being present under so many different conditions. It may follow trauma, with escape of cerebrospinal fluid, but probably an injury of that degree would prove fatal. It may be associated with nasal growths, as polypi, but in the one case thus far reported Bosworth thinks the polypi were the result and not the cause. Nerve lesions, as involvement of the fifth pair; this would act in two ways, both nerve influence and blood supply would be altered and the condition would properly constitute a reflex neurosis. Carious teeth and cerebral lesions may be exciting

causes in the same way. Malaria in the chronic form; the repeated chills driving the blood to the internal organs and chronic congestion, in addition to the general anemic condition produced, with the necessarily lessened vascular tone, may cause the entire mucous membrane to become cyanotic. Atrophy of the optic nerve existed in at least one case. Hardie quotes seven cases in which optic atrophy existed, but does not give the references.

The cases in which no mention of any circulatory lesion is made and some lesion, as of the ethmoid or antrum existed, does not prove it the cause, as these lesions may be present without true nasal hydrorrhea.

In reviewing the cases thus far reported, it is my purpose to exclude all, excepting those cases, the reports of which include the clinic history, and in which the hydrorrhea existed independently of any associated nasal lesion. After a careful search of the literature on the subject I have been able to collect twenty-seven cases; sixteen collected by Bosworth, with two reported by him; three by C. E. Bean; one by A. R. Anderson; two by Hardie and Wood; one by Keiper, one by Emory Jones, and the one reported in this paper. The following is a tabulated list of the cases thus far reported:

The first sixteen were collected by Bosworth, and the seventeenth and eighteenth were reported by him.

Bosworth in his text-book very properly divides the reported cases into two classes: 1. Those in which the escape of fluid is passive and painful and which phenomena he explains by involvement of the trifacial nerve. 2. Those in which the fluid gives rise to intense irritation. Yet this does not differentiate as to the irritating nature of the fluid, but is rather a classification as to symptoms and not varieties. A review of the cases reported gives such a variety of causes that a classification would be impracticable.

The history of the case I wish to report is as follows: Two years ago the patient—male, aged 40, first presented himself for treatment. His general condition was fairly good. For about six months he had had a profuse watery discharge from his nostril, which was, when he presented himself for treatment, constant, but which at first had occurred at usually irregular

intervals; sometimes as often as three or four attacks daily. The discharge was clear and profuse, although no definite estimate of amount could be made, the reaction was alkaline; it gave the patient a sensation as of strong salt water snuffed within the nostrils and was very irritant, not only to the mucous membrane, but also to the muco-cutaneous surfaces. The attacks at first were usually preceded by headache and severe sneezing, which came on suddenly and without warning, and were followed by profuse discharge. With the beginning of the discharge both the headache and sneezing were relieved.

An examination of the nostrils during the attack showed the mucous membrane of the anterior cavities swollen, edematous and boggy, often entirely obstructing nasal breathing. The membrane did not present the appearance of acute hyperemia, but more that of a chronic congestion, being of a dull bluish-red or pink tinge. The naso-pharynx and pharynx were slightly involved, but not to the extent of the anterior passages.

On examination between attacks, the mucous membrane, though slightly edematous, was paler, the color apparently being due to a pigment deposited within the cells (which later proved to be the case); the membrane on pressure was soft and boggy, and pressure left indentations, which slowly filled, a characteristic of passive congestions. The naso-pharynx was slightly paler than during the attack. This condition continued for several months, the attacks becoming more irregular, yet more frequent until when he had been under my observation for five months the discharge was almost continuous. The general appearance of the patient was that of a severe attack of hay fever. There was no evidence of antrum or ethmoid disease.

I had the eyes examined, with negative results. I made careful and repeated examinations of the urine, suspecting possible uric acid diathesis, but while the urine was of a rather low specific gravity, from 1.012 to 1.018, the chemist analysis revealed nothing except a low per cent. of urea, but by the increased amount of urine the total daily excretion was from four to five hundred grains. Microscopic examination showed no casts, but many leucocytes, and desquamated epithelial cells, which, from their shape and condition, being water-soaked, evidently came from high up in the urinary tract. During this time, although I had tried every known remedy, he gradually and persistently grew worse. In looking up the literature of the subject, I noticed malaria mentioned as a possible cause, and on questioning the patient, he said that one year before the beginning of the attacks, he had had malaria. I also discovered that before living in Philadelphia he had been in a distinctly malarial district. While at the beginning his general condition was good, during this time he was losing flesh, although not rapidly. I then examined his blood for evidence of malaria.

The blood examination showed, by the Thoma-Zeiss hemocytometer, 4,800,000 red corpuscles per cubic millimeter; white, 8,000. Hemoglobin, by Von Fleishl's hemoglobinometer, was 60 per cent. of normal. There was considerable free pigment. The red corpuscles, while about 3,000,000 showed almost a normal appearance, the remaining 1,800,000 were irregular, crenated and corrugated, some few showed segmentation and the peculiar kidney-shaped corpuscles were present. The leucocytes were normal.

Careful examination did not show much, if any, enlargement of the liver and spleen.

Tube inoculations had been made repeatedly from the nasal secretion and while growths showed many bacteria present, yet never was there present any but what had been found in other conditions, or the ordinary bacteria found in abnormal discharge from the nares. The only one present which is decidedly irritating was the streptococcus, although out of repeated inoculations this particular germ was found only twice and then not in any number, thus excluding bacteria as a probable etiologic factor.

A small piece of tissue was removed from the left nostril, and hardened in picric and chromic acid solution, infiltrated with acacia, frozen and cut. The sections showed a small round cell infiltration of the submucosa, and dilated vessels with thinned walls. The epithelial layer was desquamated, the cells showing cloudy swelling and granular and hydropic change; the connective tissue cells were pigmented.

After the blood examination, as the patient told me quinin made him nervous and irritable, I gave him bromid of quinin, in 5 grain doses every four hours and in addition 1-16 grain of the double sulphid of arsenic, which is a so-called alterative tonic. This treatment internally, with local applications of benzo-inol, to which had been added to each ounce menthol 2 grains and oil of sandal wood 3 drops, was kept up for over two months. The patient after two weeks showed slight improvement and at the present time, while not entirely relieved, is comparatively well. The attacks are very slight and usually follow exposure or over-exertion.

From a review of the cases, I think the majority, at least, belong to the second class and that in these if not in all nasal hydrorrhea is a symptom or local manifestation of a constitutional condition. I regard the constitutional lesion as varying, but in the second class of cases, in which the one reported belongs, as usually associated directly or indirectly with some circulatory lesion in which the venous return is impeded, producing in the nasal mucous membrane a cyanotic condition, analogous to congestive lesions in organs, as the lungs, liver and kidney, largely made up of mucous membrane, and not necessarily the site of acute local inflammatory conditions. Mucous membranes, when repeatedly congested, tend to remain so, allowing the leakage of serum into the perivascular tissue which, when near the surface, becomes edematous and the epithelial cells undergo, in their effort to elaborate the excess of fluid, hydropic degeneration; the membrane relieving itself and again becoming infiltrated, accounting for the recurring attacks. Practically the condition may exist in any mucous membrane as is shown in the case reported by Miles, in which this condition existed in the mucous membrane of the intestines. The lymphatic supply may be involved as shown in one of the cases reported by Miles (Trans. Internat. Ophth. Congress, Heidelberg, 1888). Because of the intra-vascular pressure the tissue would undergo simple atrophy and impair to a great extent sensation, and cases with this induced condition must not be confused with those properly of the first class.

Owing to the varied symptoms and etiologic factor, no regular plan of treatment can be formed; but each case must be treated as to cause, and irritation during the attack should be relieved by sedatives.

## UNCOMMON ACCIDENTS FOLLOWING OPERATIONS IN THE NOSE AND THROAT.

Read in the Section on Laryngology and Otology, at the Forty-seventh  
Annual Meeting of the American Medical Association,  
at Atlanta, Ga., May 5-8, 1896.

BY MAX THORNER, A.M., M.D.

PROFESSOR OF CLINIC LARYNGOLOGY AND OTOTOLOGY, CINCINNATI COLLEGE  
OF MEDICINE AND SURGERY; LARYNGOLOGIST AND  
AURIST, CINCINNATI HOSPITAL, ETC.  
CINCINNATI, OHIO.

It is now almost ten years that the late Professor Nussbaum commenced his monograph "On Accidents in Surgery" with these words: "Of surgical accidents, avoidable ones as well as unavoidable, there are so many, that if one would attempt to enumerate them all one would hardly know where to begin and where to end. Unfortunately, owing to human vanity, almost exclusively successful cases are reported, while unfortunate events are not published, although one unfortunate accident is often more instructive than ten successful cases." Such considerations have prompted me to report to you to-day a number of accidents following operations in the nose and throat, which have happened during the last eleven years. I do not attempt to enumerate all or even the majority of undesirable sequelæ that I have seen; but I purposely omit all such cases, as are frequently observed and have often been described, for instance lacunar tonsillitis or pharyngitis following intra-nasal operations; acute purulent otitis with or without complications, adhesions forming in the nose, epistaxis, etc. But I shall confine my remarks to a few cases which are rather remarkable on account of their rarity.

*Case 1. Functional aphonia, following cauterization of the pharynx for chronic follicular pharyngitis.* The patient was a young lady, 18 years old, who was studying elocution. She was referred to me on account of her voice failing during any prolonged attempt at loud reading or speaking. She had a well developed chronic lateral and follicular pharyngitis, and some remnants of adenoid vegetations, in cushion shape, at the vault of the pharynx.

Treatment consisted mainly in galvano-cauterizations, repeated at intervals of from eight to twelve days. One day, after a number of treatments had been given with a very noticeable improvement of the voice, a large hypertrophied follicle, situated nearly in the center of the posterior pharyngeal wall was cauterized, when suddenly the patient said in a whisper that her voice was gone. There was complete aphonia. I was naturally alarmed. Upon laryngoscopic examination the image was found to be the same as in functional aphonia; the vocal cords approximated during an attempt at phonation for an instant, but separated again at once. This condition lasted for a few days, when it vanished almost as suddenly as it had appeared, without any special treatment. There was at no time a recurrence of this reflex phenomenon, although the same treatment was continued for some time, with the result of entirely restoring the voice of my patient. This patient was a strong and healthy young woman, and did not at that or any time thereafter belong to the great army of hysteric women.

*Case 2. Temporary amaurosis following cauterization of the nose.* Mr. J. H., 40 years old, was under my care about ten years ago for nasal polypi. A great many of them were removed by the cold wire snare. When the nose was thoroughly cleared there remained a few very small ones in the crevice between lower and middle turbinated bodies, which could not be engaged in the snare. I decided to destroy them with the galvano-caustic burner. One day, following such a treatment on the previous afternoon, Mr. H. called on me in great excitement, telling me that he could not see with the right eye, the side operated upon. The eye, upon examination, did not show any difference from the normal; he could discriminate between light and dark, could see objects held closely before his right eye, but could not count fingers at a distance of five feet. Ophthalmoscopic examination was entirely negative. Vision improved after five days and was gradually and entirely restored within four or five weeks.

*Case 3. Loss of memory following an insignificant operation in the nose.* A boy of about 16 years of age, from one of

the interior towns of Ohio, was operated upon for almost complete nasal obstruction. There was a marked deviation of the septum and enormous hypertrophies of the lower and middle turbinated bodies. These hypertrophies were removed at intervals of from four to six weeks, the boy returning to his home after each operation. After two or three operations had been done, without any untoward symptoms, the boy returned for another operation. This time I succeeded in removing but a small piece, the size of a green pea, from the middle turbinated. There was but moderate hemorrhage, but as the boy had just passed through an attack of tonsillitis, I decided not to do any more. I saw him the following day at 10 A.M., found him apparently in good condition, and he left on an afternoon train. When he arrived home about four hours later, he was in an almost absent minded condition. During the night the family physician telegraphed me to inquire what anesthetic had been used. I learned the following day from a letter of the physician that the boy had a high temperature when he arrived, his conjunctiva were hyperæmic, pupils dilated, he was complaining of headache, and above all was absolutely unconscious of everything that had happened since he left home. The pain and fever subsided within two days; the pupils became again normal; but the loss of memory remained for about six weeks, during which time his mental activity was very much impaired. Gradually during the course of the next two or three months, all his mental faculties returned, although the memory remained sluggish for some time. When I saw him several months thereafter, he was in perfect health and his parents had the courage to have the treatment continued, which was thoroughly successful without any further accident.

*Case 4. Intubation in an adult followed by a fatal edema of the larynx after extraction of the tube.* J. B., 18 years old, had been suffering eight years from what was considered asthma, the dyspnea having increased of late to an alarming extent. The history was entirely negative; syphilis could not be traced. The patient appeared to be in great distress. His respiration was labored, noisy and accelerated; on exertion his face had a livid color and was covered with a cold, clammy perspiration. The stenosis of the larynx was extreme. The ventricular bands were greatly thickened and the vocal cords buried in masses of infiltrated tissues. The encroachment on the lumen of the larynx increased in the subglottic space, the opening for breathing being scarcely the size of a thin lead pencil.

The smallest tube of the intubation set for adults was introduced without any difficulty. It was well oiled and the larynx had been previously anesthetized with a 5 per cent. solution of cocain. The tube is somewhat larger than the largest tube of the set used for children. The patient could readily breathe through the tube and complained of no pain. It was my intention to permit the tube to remain in the larynx for twenty-four hours, but on the following morning, about fifteen hours after the introduction, the patient returned and begged me to remove the tube. He stated he was greatly annoyed by it and could not take any food whatever. I extracted the tube without any difficulty, with the understanding that it was to be reintroduced in the evening. The patient was greatly relieved, was able to take some water, and left my office after a few minutes feeling comparatively comfortable. About fifteen minutes later he was found dead on the sidewalk, about a half square from my office. He had walked about one and a half squares when he felt bad and asked the driver of a passing wagon to take him to my office. Scarcely had he been seated when he fell back and died before he could be lifted from the wagon. A physician who happened to pass there shortly afterward found no sign of life.

The unfortunate accident can be easily explained. After the pressure exercised for fifteen hours by the tightly fitting tube upon the infiltrated tissues had been suddenly relieved a subglottic edema ensued causing a fatal issue within a short time. This rather unusual case teaches us a lesson to keep a patient upon whom intubation for a chronic stenosis has been practiced, under strict surveillance for some time after the extraction of the tube.

*Case 5. Severe spasmodic cough and neuralgia after a nasal operation.* Miss B. K., aet. 24, consulted me on account of excessive sneezing which had been troublesome for several years, but had become well-nigh exhausting of late. The anterior and lower portion of the left middle turbinated was enlarged to almost the size of a cherry, of a deep purple hue, and touching the septum. Upon the lightest touch with the probe an excessive fit of sneezing was sure to follow, which would immediately stop after the application of a 4 per cent. solution of cocain. This hypertrophy was removed with the cold snare. One half hour after the operation the patient had a most severe attack of coughing, a symptom which was

entirely new, and not long thereafter a most intense neuralgia of the left side of the face developed; nothing short of morphin and chloral hydrate would give her rest during the following night. The neuralgia lasted for several days when it gradually disappeared, while the spasmodic cough vanished only after two and one-half weeks. There was no local condition present that could account for it, the wound having nicely healed without any disturbance and without further interference. There was afterward no return of these symptoms, nor of the sneezing.

These few cases are reported simply for the reason that they appeared to me somewhat unusual. In fact all of them at the time, when my experience was less, were rather alarming, although fortunately, with the exception of the fourth case, they ended well. Yet, as any one is likely to meet at any time with accidents which are not common, and which can not be expected according to our usual experience, I thought these cases, collected at random from my note book, of sufficient interest to be placed on record.

#### DISCUSSION.

DR. J. E. LOGAN, Kansas City, Mo.—I have had some experience similar to Dr. Thorner's. My patient was similarly affected with this extreme irritability of the nostrils and experienced a great deal of the same trouble of excessive sneezing. I only refer to the case to make this suggestion, that in most of these cases the focus of irritation is in the anterior chamber. I have found that the application of the galvanic cautery to the middle turbinate has brought me better results than complete or partial removal with the snare. In this patient I removed considerable portion of the middle turbinate and packed with iodoform gauze, and for several months afterward the patient had a disturbed sense of smell. He was troubled with the odor of iodoform for months. It disturbed me, and while in New York I had him go to a friend of mine and he confirmed my opinion that it was due to the very nervous temperament of the patient. The sneezing did not return, but the perverted sense of smell remained for six or seven months.

Accidents liable to happen as the result of operations in the nasal cavity are many, for the reason that the nose and throat, especially the laryngeal cavity, are the seats of great reflex action, more so probably than any other cavity of the body and I am not surprised that the removal of the enlarged follicle was the cause of the aphonia. I have found the cause of this sudden aphonia to be very hard to explain. In the case in which there was involvement of the cords without loss of muscular power it would lead me to suspect hysteria; the cords would be under the control of the patient to a certain extent. I have had this experience with hysterical patients.

DR. W. E. CASSELBERRY, Chicago, Ill.—I wish to say in support of Dr. Thorner, that I believe one may have temporary impairment of the voice reflexly produced by operations on neighboring parts independently of a suspicion of hysteria. In one case of combined operation for tonsils and adenoids on a boy 5 years of age, the tonsils being removed with the cold wire snare, after the operation he spoke in a high unnatural voice, which lasted for about six days, when he gradually regained his proper tone. It could not be ascribed to other than irritation of peripheral nerves.

In reference to the case involving the middle turbinate body, I would ascribe the loss of memory to the use of cocain. I have seen some curious temporary mental effects produced by it. In regard to the middle turbinate body, I would say that while I have advised operations upon it under certain conditions, I think we should be cautious. From the intimate association of the vessels of the middle turbinate body with the cerebral meninges, it is perhaps surprising that serious results should not be more frequently encountered. Operations upon this body should be restricted to those cases in which there is a very clear and decided indication therefore.

DR. CLINE—In Dr. Thorner's case in reference to the aphonia

I am inclined to think that it was the result of the cocain. I recall three similar cases which I think were due to it. One, a man of very nervous temperament whose sphincter muscles were paralyzed for several hours. He also seemed to be unable to speak, which I attributed to the cocain. I am not in favor of the free use of cocain unless I know my patient.

DR. THORNER—The discussion has been partly diverted to cocain poisoning which I did not consider. The operation which caused the temporary loss of memory was done on the soft parts of the middle turbinate and not on the bone itself. Operations on the middle turbinate are much more dangerous than on the other parts. If you will examine the connections closely you will readily see that it is a dangerous place to operate and the wonder is that we do not have accidents more frequently. As to the operation for the removal, I always prefer the cold snare. This simply cuts away the bone as clean as can be done. The old way of tearing out is certainly dangerous. The galvano-cautery is also very dangerous here. I have heard of a number of deaths that were the result of cauterization. And how many are not reported? There are others who favor the removal with the cutting forceps, which if properly done is also well adapted for operations of this kind.

The principal danger of operations in this vicinity lies in the anatomic relations. We have the immediate region of the orbit separated from the ethmoid cells by the lamina papyracea. We have also the nerves and blood vessels passing through the foramen opticum, through the fissura sphenoidalis, etc. The roof of the nasal cavity is thin and separates it from the brain. And yet there are and will be cases which must be operated upon.

DR. JOHN O. ROE, Rochester, N. Y.—In regard to the case in which the effect of the cocain seemed to be quite unusual, I am also of the opinion that all the manifestations were the result of cocain. Some patients are so extremely susceptible to its influence that all sorts of neurotic manifestations are caused by it. Notwithstanding this fact I daily use cocain in my work freely and indiscriminately without the slightest bad results. With patients who are so extremely susceptible to cocain we must use it with great care. In the case of a patient under my care not long ago, one single drop of a 4 per cent. solution put into her nose would cause agitation of the heart, and a few drops would cause extreme dyspnea, so much so that suffocation would seem imminent. I was obliged to resort to general anesthesia in order to perform the necessary operation in her nose. I find that by giving these patients quite a large dose of tincture digitalis a short time before employing the cocain and giving whisky in sufficient doses to very nearly intoxicate, this susceptibility to cocain is overcome, so that all these unpleasant symptoms and cocain complications are entirely obviated. In the case of the patient just referred to, I have had occasion recently to do a slight operation on her nose, and by the use of digitalis and whisky I was enabled to use all the cocain necessary to complete the operation without pain. In regard to the cerebral complications resulting from operations in the nose, I have observed in the cases reported, that these complications more frequently result from operations upon the middle or superior turbinate bone than in any other portion of the nose. These bodies are a portion of the ethmoid bone, which is closely connected with the cranial cavity, and it is for this reason that under certain conditions disturbances in these parts may be transmitted to the meninges.

DR. ROBERT C. MYLES, New York, N. Y.—As for the fainting from the use of cocain I think it is very common. I have adopted the plan of preventing the solution from extending over a larger area than that on which I intend to operate, and I believe a strong solution is better than a weak one. I also employ the reclining position as a remedy. I have noticed in a number of cases that were in the incipient stage of fainting, when they were placed in the horizontal position they recov-

ered at once. Sometimes a hot room will cause fainting. A peculiarity is that there is very little absorption about the tongue and throat, but in the nose it is very rapid. In regard to operating on the middle turbinated I think that the old way of tearing the body away with forceps is unsurgical and unsafe. The membrane continues through the cribiform plate into the cranium, and it is remarkable that serious consequences are not reported more frequently. The turbinated body can be removed neatly and effectively with the ethmoid clippers or scissors and a cold wire snare.

**A CLINICAL STUDY OF TWENTY-ONE THOUSAND CASES OF DISEASES OF THE EAR, NOSE AND THROAT.**

BY SETH SCOTT BISHOP, B.S., M.D., LL.D.

Surgeon to the Illinois Charitable Eye and Ear Infirmary; Professor of Otolaryngology in the Post Graduate Medical School and Hospital; Professor of Diseases of the Nose, Throat and Ear in the Illinois Medical College, etc. CHICAGO.

The following statistic table of 15,300 cases, combined with a table of 5,700 cases already published, represent the records of 21,000 treated during the past seventeen years at the Illinois Charitable Eye and Ear Infirmary in Chicago. The following table was compiled for me by my assistant, Dr. Charles L. Enslee.

My first classification was instituted for the purpose of establishing a basis of calculation of the influence, if any, exerted by occupation, age or sex in the causation of diseases of the ear, nose and throat.

The condition of each patient at the time he first presented himself at the clinic is presented to determine the relative frequency of the different diseases.

As is common in charity hospitals, a considerable number of those who applied for treatment belonged to that class of laboring people who have no definite trade or fixed occupation. In order to facilitate investigation and simplify the tables as far as possible, all those occupations that were closely related to each other in nature and effects were grouped under one heading. For example, under the classification of clerks were embraced salesmen, bookkeepers, office employes; etc.; with teamsters were grouped car drivers, peddlers, etc.; cooks and bakers were classified together; brass molders, iron molders, etc., were classified with iron workers; plumbers, gas and steam fitters appear together; such closely allied occupations as stone cutters, stone masons, bricklayers and plasterers in which the influences and exposures are very similar, are grouped together under the head of day laborers, a term borrowed from the laborers themselves.

The combined tables show that of the 21,000 cases, there are 11,119 patients with occupations, classified under twenty-eight headings. Of this number, 3,813 had out-door work and 7,306 in-door. About 34 per cent. are out-door occupations and 66 in-door; or about twice as many in-door occupations as out-door.

The largest number of any one class were in-door workers, 3,045 domestic servants. Next in order were about half that number of the out-door class, or 1,508 day laborers. Then follow groups of the next highest numbers; 858 clerks, 460 iron workers, 452 carpenters, 400 sewing women, 378 factory workers of all kinds, all in-door occupations before we reach the out-door class again in going down the scale.

While the great stores and factories furnish a large number of patients, the homes contribute 5,615 females, including the servants, seamstresses and

women without occupation, or more than one-fourth the whole number of the combined tables. These facts are significant when we take into account the slight difference between the number of males and females affected under the age of 15 years. Out of 6,162 children under 15 years of age there were 1,484 boys; and 1,590 girls between the ages of 6 and 15 years; and 1,641 boys and 1,447 girls under 6 years.

THE ABBREVIATIONS EMPLOYED ARE:  
W. No.—whole number.  
Ext.—diseases of the external ear.

F. B.—foreign body.  
 In. C.—inspissated cerumen.  
 Fur.—furuncle.  
 Ac. R.—acute inflammation of the right middle ear.  
 Ac. L.—acute inflammation of the left middle ear.  
 Ac. 2.—acute inflammation of both middle ears.  
 Ac. S. R.—acute suppurative inflammation of the right middle ear.  
 Ac. S. L.—acute suppurative inflammation of the left middle ear.  
 Ac. S. 2.—acute suppurative inflammation of both middle ears.  
 A. S. & N.—an acute suppurative inflammation of one middle ear, with a chronic non-suppurative inflammation of the other.  
 C. N. R.—chronic non-suppurative inflammation of the right middle ear.  
 C. N. L.—chronic non-suppurative inflammation of the left middle ear.  
 C. N. 2.—chronic non-suppurative inflammation of both middle ears.  
 C. S. R.—chronic suppurative inflammation of the right middle ear.  
 C. S. L.—chronic suppurative inflammation of the left middle ear.  
 C. S. 2.—chronic suppurative inflammation of both middle ears.  
 Au. P.—aural polypus.  
 M. D.—mastoid disease.  
 Int.—diseases of the internal ear.  
 D. M.—deaf mutes.  
 N. Ph.—naso-pharyngeal catarrh.  
 Ad.—adenoid growths in the vault of the pharynx.  
 Hy. T.—hypertrophied tonsils.

Of all these children 3,037 were girls and 3,125 boys, leaving a difference of only 88 more males than females under 15 years. Between the ages of 6 and 15 years there were 106 more girls than boys. Under 6 years there were 194 more males than females.

Sex seems to have no influence in the production or prevention of diseases of the nose, throat and ear. It appears that up to the age of 15 years both sexes suffer nearly equally. Possibly a reason for this may be found in the similarity of the lives and habits of the sexes during this early period. But the classes of society that afford clinical material at the medical charity institutions are such that necessity requires them to abandon the pursuit of an education at about the fifteenth year, and to enter upon bread-earning vocations. Thenceforth the divergence in habits and environment increases. The males are either out of doors more than before, or confined chiefly to mercantile houses and factories. The females become domestics, clerks, shopgirls and seamstresses.

An interesting question pertains to the relative frequency of diseases of the right and of the left ear, and of diseases of one ear as compared with diseases existing coincidentally in both ears. The above table shows that in acute inflammation of the middle ear there is but a very slight difference in the frequency of involvement between the two ears, and both ears were affected in 24 per cent. of all the cases. In acute suppuration of the middle ear again there is too little difference between the two ears to take into account. In 15 per cent. of all these cases both ears were involved.

In the 5,849 cases of chronic non-suppurative inflammation of the middle ear the two sides were about equally affected, but a great contrast is now offered in the relative frequency with which both ears are involved in the various middle ear diseases, for in this instance nearly 82 per cent. of all the cases presented bilateral aural affection. Sufficient importance must be attached to these undeniable figures in formulating our prognosis when only one ear is already diseased, for it follows, almost as the night the day, that if one ear has become seriously affected, especially with the sclerotic form of dry catarrh, the other becomes subject to the same destructive process.

In chronic suppurative otitis media the two ears suffer nearly equally, and it appears that both ears are simultaneously affected in a little more than 60 per cent. of the cases. In 3,149 instances of unilateral diseases of the ear, there was an excess of only 37 cases of the right over the left. This fact is mentioned particularly because the opinion has often

been expressed that one ear was much oftener affected than the other, some specialists believing that the right was affected, by far, more frequently than the left ear.

The tables show that about 13 per cent. were afflicted with nasopharyngeal diseases, but the actual number would be much in excess of this figure. The Infirmary being an eye and ear hospital strictly, not as great prominence has been given to the nose and throat affections as would be desirable, this part of the diagnosis sometimes being entered on the patient's cards instead of upon the record books.

About 0.8 per cent. had diseases of the mastoid process, which was nearly twice as prevalent in males as in females.

Deaf mutes formed about 0.5 per cent. of the 21,000 cases. There were three times as many males as females.

The largest number of any one class of diseases were 8,858 with chronic non-suppurative inflammatory processes of the middle ear, or 42 per cent. of the whole number. Next in numerical order come 3,664 cases of chronic suppurative inflammation, or 17 per cent.; and the next highest number, 1,010 cases of acute suppuration, or 5 per cent.

Children under 15 years of age constitute about 29 per cent., or more than one-fourth of the whole number of cases. Very many of them dated back to attacks of scarlet fever, measles and the earaches, and "running ears" of infancy, so that a much larger percentage than appears should probably be credited to the period of childhood. Only a small proportion of the children were brought for treatment during the acute stage of inflammation. Only about 10 per cent. were acute cases, leaving 90 per cent., or nine times as many who had not applied for treatment until the inflammation had reached a chronic stage. Indeed, only 13 per cent. of the adults were seen in the acute stage of their troubles.

Columbus Memorial Building.

## ELECTROLYSIS IN THE TREATMENT OF DETACHED RETINA.

Read in the Section on Ophthalmology, at the Forty-seventh Annual Meeting of the American Medical Association, held at Atlanta, Ga., May 5-8, 1896.

BY W. T. MONTGOMERY, M.D.

CHICAGO, ILL.

Within the past few years various remedial agents have been advocated with more or less enthusiasm in the treatment of detachment of the retina. One of the more recent of these agents, and one which from its action and the nature of the disease seemed to promise as much or more than any other treatment, is electrolysis. One of the most full and encouraging reports on the application of electrolysis in detachment of the retina, is by Dr. Terson, and was published in the last July number of the *Annales d'Oculistique*. Dr. Terson reports twelve cases treated with one recovery which had lasted nine months, and five improvements which had persisted for from two to nine months. Within the last six months four cases of detachment of the retina have been treated in the Illinois Charitable Eye and Ear Infirmary, two by myself and two by Dr. B. Bettman. In the treatment of these cases we, in the main, followed the recommendations of Dr. Terson. Positive electrolysis was used; the eye was punctured by the strong platiniridium needle at some point of the sclerotic corresponding to the detach-

ment and a current of five milliamperes applied for a period of one minute. The eye was thoroughly cocainized so that the puncture was made without pain, but when the current was turned on the patients complained of severe pain. In Case 2 the pain was so severe as to prostrate the patient and he absolutely refused to submit to it again. In Case 1 the pain was severe enough to bring out beads of perspiration. The after-treatment consisted of the instillation of a 1 per cent. solution of atropin sulphate, the compress bandage and rest in bed for one week. No noticeable reaction followed treatment in either case.

*Case 1.*—Andrew J. F., age 29, mechanic, Norwegian, July 30, 1895, was admitted into Ill. Charitable Eye and Ear Infirmary. Patient states that the sight of his right eye has always been poor, V = bright light = amblyopia. Eight days ago was struck on the left eye with a piece of wood, and this eye has been almost blind since. On examination, external appearance of eye normal. The ophthalmoscope shows large blood clot in vitreous. Vision—fingers at six feet. Pressure bandage applied, and small doses of hydrargyrum bichlorid and potassium iodid was ordered, and the patient kept quiet. August 30, patient was discharged with V = 20/30, some small floating opacities of vitreous remaining. September 30, patient was readmitted with extensive detachment of the retina. V motions of hand in temporal field. Patient says his sight failed suddenly the day before. Ophthalmoscope shows almost complete detachment, only a small area of nasal portion remaining. Treatment: rest in bed, bandage and hypodermic injections of the muriate of pylocarpin, saline cathartics. October 15, no improvement. Electrolysis used. Bandage and quiet. October 25, no change. Needle used again, but owing to breaking of wire in holder battery did not act and operation resulted in simple evacuation of subretinal fluid. December 5, patient thinks he can see better. Field is enlarged but can not distinguish objects. Electrolysis again used. December 15, field and vision not so good. Is now about as it was before electrolysis was used. Patient was transferred to Dr. W. H. Wilder, who injected sterilized rabbit's vitreous, according to Deutschmann. Violent reaction followed, but this subsided within a week. There was no improvement of vision. Jan. 7, 1896, patient discharged as incurable.

*Case 2.*—M. C., age 65, laborer, American, was admitted into Infirmary Oct. 23, 1895, with umbrella detachment of retina of right eye. Left eye lost from the result of an injury years ago. Present trouble came on suddenly three months ago. No history of an injury or previous trouble. V = motion of hand. Electrolysis used November 6. No improvement. Electrolytic needle used again, but as in Case 1, the battery did not work, the result being only puncture of sclerotic and escape of subretinal fluid. December 5, patient thinks he sees a little better, but we can not detect any change in the detachment. Patient refused to submit to further operative treatment, and was discharged at his own request. Feb. 14, 1896, patient readmitted with acute glaucoma, which he states came suddenly one week ago. Pupil widely dilated. T + 3. Eye totally blind. Pain excruciating. February 27, pain continues. Eye excised.

*Case 3.*—P. L., age 40; laborer, Irish, was admitted into Infirmary Dec. 30, 1895. Left eye blind for three years as the result of an injury. Vision of right eye began to fail three months ago. On examination cornea clear, pupil dilated, numerous floating opacities in vitreous. T—1. No distinct vision and only poor perception of light. Detachment of the retina in upper and temporal portions. Pilocarpin treatment used until Jan. 10, 1896, without any improvement. Electrolysis used. The eye was bandaged and patient kept in bed. January 25, no improvement. Electrolysis again used, making three puncture. March 25, still no improvement. No further treatment.

*Case 4.*—M. B., age 67; farmer, Irish; admitted Dec. 26, 1895. Right eye normal. First noticed flashes of light in left eye three weeks ago. Eight days ago he suddenly noticed cloud before eye, as he expressed it. On examination, cornea clear, pupil dilated. T—? Detachment of retina above, hangs down and nearly covers optic disc. No distinct vision. The pilocarpin treatment was used without benefit. Jan. 20, 1896, electrolysis, single puncture. February 15, no improvement. Electrolysis repeated, the sclerotic being punctured three times at this sitting. March 22, no improvement. Patient discharged by request.

The cases we have reported were all of extensive

detachment. Only one, Case 1, can be claimed as presenting conditions fairly favorable for successful treatment. This patient was young, his general condition was good and the detachment recent when the electrolysis was first used. Of the other cases, their ages were 65, 40 and 67 years and the detachment had existed from one to four months. If we are warranted in drawing any conclusions from such a meager report they would be: 1, that the treatment is exceedingly painful, but is not immediately followed by severe reaction; 2, that it is valueless as a curative agent in detachment; 3, it may be a factor in exciting inflammatory glaucoma, as occurred in Case 2.

## THE ABUSE OF WATER IN SURGERY.

BY EDWIN WALKER, M.D., PH.D.

EVANSVILLE, IND.

The art of antiseptic and aseptic surgery has advanced with the science of bacteriology. Surgical technique has changed as our knowledge of germ life has advanced. While some observers before Lister seemed to have had a vague idea of the relation between wound infection and microorganisms, to him belongs the credit of putting first the knowledge, scanty as it was, into a distinct shape and to practice antiseptic surgery. He acted on the knowledge at that time and his failures were in a great measure due to the lack of that information we now possess. He supposed the chief source of infection was from the air. Tyndall's observation seemed to prove this, consequently he bent his energies to devise a means of purifying the atmosphere.

Only a few years ago, when operating rooms were small and the air was laden with carbolic spray, the operator and patients were deluged with antiseptic solutions. These stood in puddles on the floor so that one had to wear rubber boots or wooden shoes. I have seen a carbolic spray play directly in an abdominal incision for an hour. Great emphasis at that time was placed on the preparation of the room in which the operation was to take place. The walls were wiped down and the floors scrubbed with antiseptic solutions. Since, however, we have found that infection from the air is very little, and the number of organisms contained in it is so small that the danger is practically *nil* when compared with other modes of access, viz.: hands, instruments, dressings and fluids during the operation. Experiments have shown that even in apartments where decomposing fluids are present, as in water closets, the number of microorganisms in the air is very small. This knowledge has led to the abandonment of cumbersome methods, and little by little we have evolved a simpler and more reliable technique.

Perhaps no greater change has occurred than in the use of water and antiseptic fluids. Many accidents were due to the over-use of the latter, and they were responsible more than anything else for the tardy adoption of antiseptic surgery. Many deaths charged to the new method were due to ignorance of principles and excessive use of poisonous agents. This subject has been fully discussed and the danger fully set forth by many observers; still we find surgeons who think it necessary to irrigate a clean wound or wipe it out with sponge or gauze, moistened in some antiseptic solution. The danger of infection from the air is very slight, and if the hands of the surgeon, his instruments and sponges, have been rendered strictly

aseptic, the introduction of antiseptic fluid in the wound is entirely superfluous. It has been proven that blood serum is a reliable antiseptic, which is non-irritating and makes the very best covering for a cut surface, and it is fully able to render harmless all the germs that will enter the wound from the atmosphere. An antiseptic solution, or even water, is not only unnecessary but absolutely harmful. Bichlorid solutions produce superficial necrosis and any fluid damages more or less the integrity of the tissues, besides they furnish the very moisture necessary to the development of the bacteria. I do not wish to dwell at any length upon this branch of the subject, for I believe that most surgeons have long since abandoned the use of antiseptics during operations. I have referred to it because recently I have seen surgeons insult clean wounds in this manner. I heard not since, that a surgeon of some prominence in this State filled wounds with protonuclein, thinking thereby to hasten union. It seems almost incredible that anyone would introduce dead elements to replace the living; for even if protonuclein does contain the corpuscular elements, they certainly could not be as reliable as the fresh blood.

It is especially with regard to the use of water that I wish to speak. Most surgeons have within the last few years much curtailed its use. Landerer in 1889 recommended wiping with dry bichlorid gauze and packing the wound carefully to control hemorrhage and remove all surplus blood, so that the wound would be dry when it was time to close it. The dry method has been adopted partially at least, by most surgeons and is considered by all a marked advance. Few, however, fully appreciate the extent it should be applied and many operators still use too much fluid, too much irrigation and too much wet sponging. In most recent articles I find irrigation recommended after many operations, which in my experience have done better without, and we will have much better results when we abandon irrigation except in those cases where mechanically, it is impossible to remove foreign substances or septic material in any other way, and these cases will become gradually less as we apply efficient means of drainage and keep the parts dry afterward.

The first objection against water is that, as ordinarily obtained, it is not sterile. When emergency operations are undertaken, boiled water is rarely at hand, and if it is it has to be cooled with water that has not been boiled. Washing the wound with water that is not sterilized is a hazardous proceeding and is liable to carry more infection than it washes out. The following, taken from Warren's pathology, page 787, fully expresses the idea: "A cubic meter of air may contain from 1,000 to 20,000 germs, but in a drop of putrefying fluid millions of bacteria may exist. Schimmelbusch reckons that the number of germs that settle upon a space a decimeter square amounts to about sixty or seventy during one-half hour's time in V. Bergmann's operating theater. In a cubic centimeter of water of the river Spree, which flows past the clinic, it is estimated there exists about 27,000 germs. Assuming, now, that a boatman should injure his hand and should wait one-half hour in the clinic before it is dressed, he would receive upon the surface of the wound, covered probably with a blood clot, between sixty and seventy bacteria. If, however, he attempted to 'cleanse' the wound in the Spree water and bind it with a dirty handkerchief, the number of

organisms that would come in contact with the wound would amount to probably between thirty and forty millions."

I know it will be argued that water is easily sterilized by boiling, but unfortunately we usually have to delegate that part of the work to some one who is uneducated in aseptic methods. Who of us has not in our haste, after carefully boiling the water, found it too hot for use, cooled it with plain water, and then to ease one's conscience a few bichlorid tablets were dropped into it; or having directed some one to get the water ready, have seen the temperature tested with a dirty hand or it is brought in a vessel which has been in service in every branch of household life. It is practically impossible, even with trained help, under the most favorable circumstances, to attain absolute asepsis, and when that part of the work devolves on those who are not especially trained it is sure to fail.

To test this subject I had three trained nurses prepare three pitchers of water, telling them that it was to be used for an operation. They each washed out a pitcher with sapolio and scalded it with boiling water, then after boiling the water thoroughly for one-half hour poured it into the pitcher, and covered it carefully with a clean towel. The result of a bacteriologic examination by Dr. Kerth, showed germs in two of them while one was sterile.

If we have prepared our hands and instruments and the skin of the patient properly, in any clean operation, dry wiping with sterilized gauze will remove all blood and render the wound dry and clean. Blood clots and the tissue which may be cut away, can be removed without one drop of moisture, and these wounds will heal more kindly and are less frequently infected than where water is used.

Thus far I have only spoken of clean wounds, but I believe the same is true of infected wounds and in cavities, mucous and serous, where infection exists prior to the operation. I do not speak dogmatically because sufficient experience has not been collected to fully establish the fact, but from my observation dry sponging has been more efficient than irrigation. I do not include in this assertion, cavities, sinuses, etc., which mechanically are almost impossible to clean without water. When this is the case, after thorough washing, the parts should be dried and efficient drainage established and dry methods employed afterward.

In operations in the uterine cavity the same general rules should be followed. After curetting for endometritis or removal of the products of conception before the third month when not infected, I never irrigate. Since abandoning washing out with antiseptic fluids, my cases have done much better. The packing remains sweeter and the discharge following is less. Twice in the past year I have been compelled to empty the uterus at the second month for vomiting. (I may add by way of parenthesis, that they were the only two cases in which I have had to resort to this measure.) In both, the os was dilated by steel instruments, and with the curette and Martin's forceps the fetus and membranes were removed, the cavity wiped out with sterilized gauze and packed with iodoform gauze. This was done under strict aseptic precautions. In neither case did the temperature rise to 100, or was the pulse at any time above normal. After the third month and where infection has occurred, it may be better to irrigate in some cases,

on account of the difficulty of removing all foreign matter without it. I have, however, treated a large number of this class entirely by the dry method with most satisfactory results.

It is possible, rapidly and thoroughly, to remove all debris even in quite a large uterus with the finger, a dull curette and curetting forceps. I have not had the accidents so often spoken of in this connection, due to instrumental interference. The unfavorable sequence (pelvic inflammations, etc.) are often due, to the forcing of pus through the tubes by the irrigation. I have known peritonitis to follow irrigation of the uterus several times. I am very partial to the use of Martin's heavy forceps in these cases. With them the uterus can be more rapidly emptied than by the curette alone, and in many cases they are more efficient than the curette or fingers. I have never had any unfavorable results from them. So far, I have not treated the infected puerperal uterus by the dry method, nor has it to my knowledge been employed by any one, but it has been so successful in my hands in smaller infected uteri, that I shall try it the next case I have to treat.

Formerly I performed operations on the cervix, vagina and external genitals under constant irrigation with antiseptic solutions, and later with sterilized water, as was the general custom. The later works on gynecology (Keating and Coe) recommend it. Since adopting the dry methods my results have been much more satisfactory. So much so that I have entirely abandoned irrigation in all operations on the genital tract. No water, not even a wet sponge is used. I use irrigation to cleanse the parts before the operation, but after the first cut, not a drop of water is used.

Irrigation in the abdominal cavity, while still employed by many operators, has been entirely abandoned by a large number. It seems impossible to wash out with any degree of thoroughness the abdominal cavity. In aseptic cases it is certainly superfluous, and in pus cases the careful protection of the cavity by gauze, and wiping out with the same material, has been more satisfactory in the hands of many. Careful, thorough work renders irrigation superfluous except in rare instances. The dry method seems to me more rational, and in my experience has been attended with better results. This method possesses great advantages to the surgeon who does much of his work in their patients' homes. He can pack his bag with everything he needs thoroughly sterilized, and after he has disinfected his hands, use absolutely nothing on the premises. When I go from home to perform surgical operations, I take everything I need except the water to wash my hands, and I think by this method I exclude many avenues of infection. If antiseptics or water are used, it adds that many more chances of trouble. The instruments should not be immersed in any fluid for the same reason. Simplicity all along the line is the watchword, and every additional detail may furnish a loophole for the entrance of the enemy. A fair trial will convince any surgeon of the superiority of the dry method.

**Magnan's Sign in Chronic Cocainism.**—Ribakoff has had occasion to observe a couple of cases of severe chronic cocainism in which Magnan's sign was the predominant symptom. This is a hallucination of the cutaneous sensibility, characterized by the sensation of a spheric foreign body under the skin, varying in size from a grain to a nut. This sensation is peculiar to this intoxication and its differential value should be more generally recognized.—*Gaz. d. Osp. e d. Clin.*, August 4.

## EXPERIENCE OF AN AMERICAN PHYSICIAN IN MEXICO.

A CASE OF MALIGNANT EDEMA—A MEXICAN FUNERAL.

D. H. GALLOWAY, Ph.G., M.D.

CHICAGO, ILL.

The patient was a laborer, 38 years old, who had received a crushing injury to the foot from a car wheel, which passed over it high up on the instep. The accident happened on Sunday and he arrived at the hospital Tuesday afternoon, sixty hours later, after a journey of 200 miles.

The injured foot had been wrapped in cotton waste, such as is used about the engines for cleaning purposes. I sent for a Mexican physician and then prepared to operate, with the assistance of a couple of servants. I put the patient to sleep with chloroform, changed to ether and then gave the cone to one of the servants. The leg was prepared for amputation just above the ankle, the operating table being outside the house in the shade of the building. As I began to operate the Mexican doctor arrived and greatly to my relief took charge of the anesthetic. I placed the instruments in two basins on two chairs so that I could reach them without much difficulty, as I had to procure my instruments as well as do my own sponging. In one pan I had a knife, a saw, a pair of artery forceps and a needle threaded with silk. The other pan contained a few other instruments which I thought might be needed. As the bone was sawed through the doctor took it in his hands to lay it down thus getting them covered with blood and pus. I picked up an artery and put on a ligature and then looked for more but could not find any. The doctor noticing my difficulty, wiped his hands on the patient's clothing and swept his fingers over the stump in search of other vessels which might need tying. As he also was unsuccessful, I motioned (we could only communicate by signs, as I could not speak Spanish and he could not speak English and we had no interpreter) to him to loosen the Esmarch bandage so that we might find the other arteries by the bleeding. He did so but no blood appeared, even downward stroking of the leg failed to reveal any spots bleeding sufficiently to require tying. The wound was then closed in the usual way with silk sutures, a drainage tube put in and a dressing put on. Before closing it however, I irrigated very carefully with a solution of bichlorid of mercury, in the hope that I might remove the infection implanted by the doctor's hands and with the expectation that I would discover, at least, a second artery that would need a ligature. We now turned our attention to a rather insignificant injury in the other leg, a triangular wound of the skin over the thickest part of the calf, exposing the muscles which appeared to be uninjured. This was carefully washed out with a bichlorid solution and an iodoform dressing put on. On Wednesday I repeated the irrigation of this wound, which seemed to be in good condition. On Thursday the dressing was saturated with a bloody fluid and I irrigated it several times with hot bichlorid solution. Friday the discharge was more copious and the leg slightly swollen. In washing it, I separated the muscles with my fingers and irrigated very thoroughly between them. All day the swelling increased so that at 4 o'clock the leg seemed ready to burst with the tension and it was almost black. Bloody fluid ran in a stream through the mattress to the floor. Several incisions were made from the knee to the ankle, the

first one was three-quarters of an inch deep and gaped nearly two inches.

My Mexican friend predicted that the patient would die before morning but suggested that he have some medicine. At my request he wrote a prescription which I took to the drug store. The druggist gave me two bottles full (one was not large enough); one held about twenty-four ounces and the other sixteen ounces. Directions: half a teacupful every three hours.

Amputation was out of the question, and the patient died the next morning, five and a half days after the injury. The stump of the amputated leg was healing well with very little suppuration.

Never having seen a Mexican funeral, I thought this a good opportunity to do so. The patient died at 4:30 A.M., and at 7:30 the Mexican physician wrote out an application for a burial permit. This I took to the "civil judge," who copied the document entire into a large book. He then asked my name, age, birthplace, whether married or single and the number of children I had. The last question followed the previous one, though I had just said that I was unmarried. I signed my name to what he had written in the book, paid \$1.25 and was given the permit. This was taken to the custom house, endorsed by an official there and we were free to proceed with the funeral. A coffin was obtained for \$2.50. It was made of light wood, painted black and trimmed with white stripes. A cross was painted on top and "1893" on the head end.

The body was wrapped up in the sheet on which it lay and put into the coffin. Four cargadores, hired for the purpose (at 50 cents each), put it upon their shoulders and took it to the graveyard. In twenty minutes we arrived at the "Cemetery of the Angels." This is surrounded by a high stone wall through which we enter by an iron gate under an imposing stone archway. On passing this gate we came into an enclosure of, perhaps, five acres, containing quite a number of monuments. This was the "yard of the first class." Walking through this we passed by another gate into a second enclosure of about the same size constituting the "yard of the second class." The entire surface of the ground here was level except for irregular piles of earth here and there, and bare except for seven or eight small mesquite trees. Not a spear of grass! Not a flower! Near the middle there was a row of ten open graves, about five feet deep and separated from each other by about a foot of earth. The loose earth was piled up in a windrow at either end of the row of graves. Here the bearers set down their burden. An attendant, who had followed from the entrance with two short ropes and five shovels, took the permit, the coffin was opened for his inspection but he disdained to look. The lid was put on again and fastened with two or three small nails driven in with a small stone picked up near by. The coffin was then lowered into the grave nearest the path and the five men began shoveling in the dry earth, talking and laughing, meanwhile; but about what, I did not know.

While they were thus engaged I employed myself examining the mound of earth under my feet. I was standing on a human femur. On looking more carefully I found that the earth was covered and filled with human bones! A tibia, a scapula, a radius, half a dozen ribs in a pile, part of a pelvis, bones of hands and feet without number! Easily fifty bones in sight without disturbing the earth a particle! Meantime

the grave was full, no mound being made, one of the cargadores said "lista" (ready or done), and we turned away. The burial over, the funeral services ended! Antonio Hernandez under the sod! No, under the sand, gravel and the bones of his predecessors in this particular spot. Four hours before, he began his last long sleep, now begins his last long rest (?) No, five years hence his bones will be notified that their lease is up and they must move. The landlord wants the ground for another tenant. Then his skull, perchance, may sit on a pile of earth, as two skulls sat to-day, and watch his successor take his place. The bones of his hands and feet will be a part of the earth which fills the grave over the newcomer.

I made inquiries and found that this cemetery was eighteen years old and that every five years the ground is reopened for new burials. The bones are supposed to be gathered up and deposited in a trench dug for that purpose, but that many of them are returned to help fill up the newly opened grave, I, myself, witnessed. The rich buy lots and dig graves eighteen to twenty-four (!) feet deep, in order that their bones may not be exhumed in the next turning up of the soil.

What an impression is made on one accustomed to the orthodox funeral at home! The darkened room or church, the expensive felt-covered silver-trimmed coffin, the crape, the flowers, the people with their sympathy and tears. The pall-bearers, dressed in black, with white gloves and bared heads. The hearse with its somber plumes and black horses, the long procession of carriages; the cemetery, with its trees and grass, flowers and monuments; the throng of people about the open grave, the measured tones of the minister repeating the solemn burial service, all culminating in the "ashes to ashes, dust to dust," as the clods roll in upon the coffin.

To one who carried such an impression of what a funeral ought to be, the Mexican way seemed forbidding enough.

But is not that, in some respects, a better custom than ours? The object in putting a body into the ground is, or ought to be, to resolve it into its elements. There it is put in as light a coffin as possible and buried in dry soil where disintegration will rapidly take place. Here we put it in a strong, sometimes a metallic, coffin and inclose this in an outer box; thus retarding decomposition as much as possible. There a funeral costs \$6 or \$7, here even the poor will spend \$100 or \$200 on a funeral, for coffin, carriage, flowers, etc., even when they are too poor to pay the doctor or even buy the decent necessities of life. If prejudice is so great that cremation can not soon be made general, people might, as a step in the right direction, be compelled to use coffins of wickerwork or very light wood so that nature's work of purification might be facilitated, and not retarded.

In five years, buried in Mexican soil, the body disappears, except the bones. Investigations in our cemeteries would reveal a very different condition. We should not regard with such horror the customs of other people without considering the end sought. The feeling of abhorrence we have for new or strange customs is only relative and disappears when we become accustomed to them, particularly if any good end is attained thereby.

As I left the cemetery I was approached by the attendant with a request for money to buy pulque for himself and the cargadores. Returning to the

hospital, I took the mattress, bedding, dressings and indeed everything combustible which had been about the patient, into the back yard, saturated it with kerosene and burned it. The room was scrubbed, then washed with a solution of carbolic acid and left open and unoccupied for some time. There were other patients in the hospital who had wounds, but none of them became infected.

200 Oakwood Boulevard.

## A NEW FIGURE-OF-8 PEDICLE LIGATURE.

BY F. SHIMONEK, M.D.  
MILWAUKEE, WIS.

The following pedicle ligature is, so far as I know, original:

I have used it with much satisfaction for the last nine months. It is an improvement upon the old

FIGURE 1.

Worrlieh ligature, because it can be quickly tied, whether it be used singly or as a continuous ligature; for very broad pedicles only one knot is required; the

FIGURE 2.

threads cross naturally when passing through the pedicle. It is better than the Tait ligature because of its applicability to any breadth pedicle and can be safely tied, and without any trouble whatever.

An armed needle is passed through the pedicle, as

shown in Fig. 1. That part of the ligature passing through the eye of the needle is withdrawn from it, as shown in Fig. 2. We now have the needle and ligature passing through the same opening in the pedicle, and yet are independent of each other. Take that part of the ligature corresponding with the handle of the needle, carry it half way around the pedicle and pass it through the eye of the needle as shown in Fig. 3.

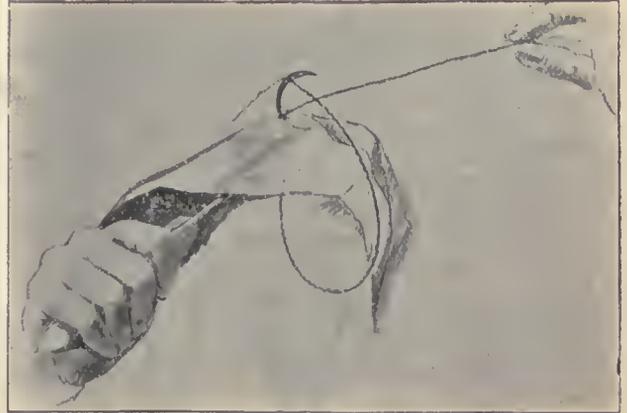

FIGURE 3.

Now withdraw the threaded needle from the pedicle, thereby forming a loop upon one side of the pedicle, the ends passing and crossing through the same opening appear upon the other side and may be tied,

FIGURE 4.

as shown in Fig. 4, or, in a very broad pedicle that can not be securely tied with one figure-of-8, the needle may be passed through the pedicle at a distance of one-half inch or more, threaded with one of the free ends, then unthreaded of that end and again threaded

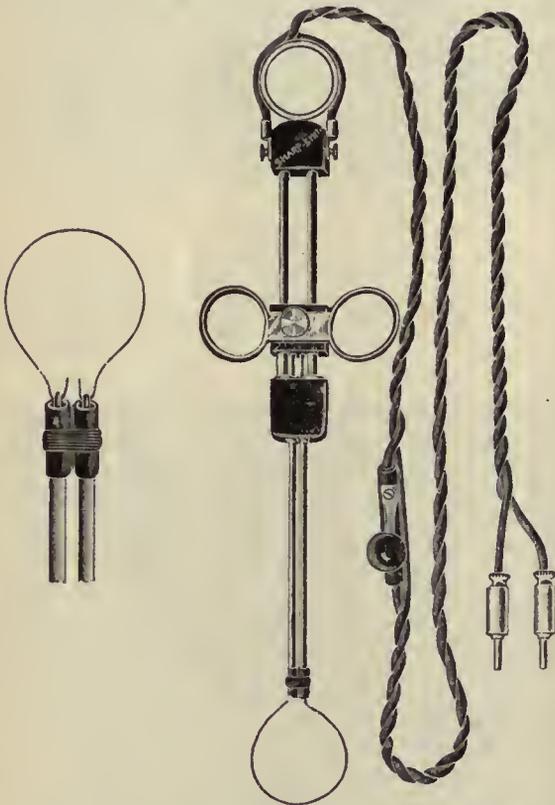

with the other one, and so on, until the entire pedicle is encompassed and the free ends tied.

307 Grand Avenue.

### A HANDY FORM OF HOT SNARE FOR TONSILLOTOMY.

BY HENRY GRADLE, M.D.  
CHICAGO.

It is acknowledged by many throat surgeons that the galvano-cautery snare is the best instrument for the removal of tonsils, because it acts very efficiently and prevents bleeding. Any one who has used either the hot or the cold snare for tonsillotomy has been able to observe that the wire loop slipped over the tonsil, after the latter has been pulled forward with a tenaculum or appropriate forceps, will grasp a larger portion of it than can be sliced off with any form of

guillotine. But with slight experience the snare will be found even more thorough than the use of bistoury or scissors. The cold wire, however, is quite painful and with a Wyeth's snare it may even happen that the wire is pulled out of the stylet instead of cutting completely through the tonsil, if the gland is fibrous in consistency. The hot wire on the other hand cuts its way as easily as a sharp knife, even if only a dull red heat is employed. As this degree of heating is sufficient to stop all bleeding it is unnecessary to bring the wire to more than a dull red glow and indeed we only inflict more pain and produce a slower healing wound by heating the wire beyond this point. Since the current raises the wire progressively to a higher temperature as the loop gets shorter, it is best to press on the key and accordingly close the current in an intermittent fashion. The wound heals a little more slowly than a clean cut with the knife. But if the wire is not unnecessarily hot I find the wound entirely cicatrized

in from five to ten days, according to the size, which is perhaps, two days more than for a corresponding tonsil cut with the knife.

The hot snare prevents bleeding entirely. If a few drops of blood appear they are due to unsuccessful grasping with the tenaculum. However trivial the bleeding may be in most tonsillotomies, anyone who has ever worked over one of the "exceptional" cases of tonsillar hemorrhage can appreciate the advantage of a bloodless operation. Even if fatal cases are very rare, annoying bleeding from tonsil cuts is not uncommon, especially in adults.

My reasons for devising a new instrument are the weakness of the ordinary snare canulæ and especially the loss of time incurred in wiring the hot snare as it is found in the market. I have hence designed a snare for tonsillotomy, which, however, can be used for any other purpose where straight and not very thin tubes are applicable. It consists of a handle made of two parallel brass bars, 11 cm. long, mounted in rubber blocks at both ends. A third rubber block slides along the bars when guided by the fingers inserted through the rings on the block, while the thumb rests in the ring at the rear end of the handle. The sliding block holds two insulated steel stylets which when pushed forward, protrude through the two canulæ in front of the handle just far enough to allow a wire to be slipped through the eye in each stylet. The two canulæ, 9 cm. long and 2.5 mm. thick, are insulated by separation along their length and by a soft rubber tube slipped over the end, while their ends are strengthened by wire wound around the rubber insulation. Steel (piano) wire is a better material for the loop than platinum on account of its stiffness. The instrument can be used with a loop nearly 11 cm. in circumference, but this size is rarely required. If a few suitable lengths of wire are prepared with their ends bent sharply, as shown in the accompanying cut, the burnt or softened wire can be replaced in a few seconds.

As shown in the figure the current enters the instrument through the cords permanently attached beside the rear ring, passes along the brass bars to the stylets directly through metallic contact in the front block as well as indirectly through the canulæ to the stylets and wire loop. Good connection is thus assured. I have not been able to devise a better place for the key which establishes the circuit than in the length of the cords twelve inches from the handle. Experience in over twenty-five operations has taught me that this arrangement is a practical one. The hand which seizes the tonsil with the tenaculum (put through the wire loop) presses the button as soon as the loop is in place.

The instrument has been made for me by Messrs. Sharp and Smith of this city.

### SELECTIONS.

**The Less Frequent Hazards of the Bicycle; Defects of the Tandem Wheel.**—The editor of the *Boston Medical and Surgical Journal*, July 23, comments upon some of the less common accidents of 'cycling as follows:

"Although the worst casualties usually occur to riders going at high speed, there are certain conditions which render falls even when going at a low rate of speed serious and disfiguring. Of these the principal is that in a large number of cases, particularly those which are due to suddenly running into an obstacle, the weight of the head and body being carried

high, and the legs arrested by the handle bars, the head, and particularly the face, is the first to reach the ground. A man taking a 'header' from a horse starts from such a height that he may turn a complete somersault and land in a sitting posture, but the bicycle is so low that the victim strikes the ground face first, and when he has plowed over a few yards of gravel or pavement, his physiognomy is usually somewhat altered. A particularly dangerous accident is the breaking of the front fork of the wheel. Here the victim never has time to get his hands before his face, and fracture of the nose and jaw with serious laceration of the soft parts almost invariably results. These falls are so quick that before a man has time to let go of the handle-bars his face strikes the ground. In fact in headers from the bicycle generally, there is no time to let go of the handle-bars in order to protect the face. Sprained wrists and broken arms are therefore comparatively rare, while broken noses and serious lacerations of the face, mouth and eyelids are common. Bruises, sprains and abrasions of the shoulders occur if the face escapes. The danger of the breaking of the front fork is especially great in the case of the tandem wheel, where the fork has to bear the weight of two instead of one, and the danger from any flaw in the steel of which it is constructed is consequently greater. The writer has recently seen two young women who were seriously disfigured by falls due to the breaking of the front forks of second-grade tandem bicycles. The moral for young men who wish to give their sweethearts a taste of the joys of riding tandem would seem to be to buy none but a first-grade wheel and take the front seat yourself. Although accidents to the face, head and shoulders are the more common, fractures of the legs and bruises and sprains of the knee occasionally result from bicycle accidents, and internal injuries are by no means unheard of. A case of rupture of the pancreas due to a blow in the epigastrium by the handle-bar has recently been reported. The bicycle is proving itself so important a means of providing fresh air and healthful exercise to a vast number of people that the good done by it greatly overbalances the harm resulting from occasional accidents, most of which can be avoided by careful riding and by the selection of a well-constructed, standard wheel."

**Fifty Cases of Pernicious Anemia.**—The London *Lancet*, August 29, refers editorially to the work done in recent years in the elucidation of pernicious anemia, and analyzes the report by Dr. Richard C. Cabot of Boston on fifty carefully studied cases of that affection. The *Lancet* commends Dr. Cabot's work in regard to the corpuscular changes, especially as to coloration and shape. The observer has not found the pallor of the corpuscles equally marked in all cases. Where deformities in shape were present one of the commonest is the absence of any central biconcavity, the corpuscles being swollen up and taking appropriate stains in a smooth, even manner quite different from the normal corpuscle.

"Variations in shape (poikilocytosis) were more apt to be present, if at all, toward the fatal end of the case. Of thirty-six cases in which this point was noticed ten showed little or no variation from the normal shape. The deformities when present usually belonged to one of a few types such as are usually pictured in connection with the disease. The racquet-shaped and sausage-shaped cells were specially common. These variations of shape were not commoner in pernicious anemia than in any severe case of secondary anemia or chlorosis. This opinion coincides with that of other modern observers, although at one time it was held that the condition of poikilocytosis was one peculiarly characteristic of the pernicious form. According to Dr. Cabot's experience, the distorted forms of the red corpuscles were not infrequently absent in pernicious anemia—in more than one-fourth of his series. The variations in size were more constant than deformities. They were present in 90 per cent. of these cases, both microcytes and macrocytes being seen. Here, again, Dr. Cabot corroborates the writings of other authors. Most of the latter, however, lay more stress on the large numbers of microcytes which are usually seen, frequently in groups of twenty or more together, while macrocytes, as a rule, are only present in small numbers. The increase in the average diameter of the corpuscles was present in eighteen of this series, so far as could be judged by measuring a few corpuscles in each case and then endeavoring to apply the standard so obtained to a large number, a method easily adopted in ordinary clinical work. Very frequently the large corpuscles showed the lack of biconcavity mentioned above. The Ehrlich-Biondi method, which was used in all these cases, stains normal red corpuscles straw yellow.

In nineteen cases of the series there were present certain red cells which contrasted distinctly in color with the clear yellow of the surrounding corpuscles. The color of these atypically stained cells varied through various shades of brown to purple. This reaction is not so well known as the other properties of abnormal red cells and is worthy of further investigations. In only one of the thirty-five cases examined were nucleated red corpuscles wanting. In the thirty-four others there were seen from 1 to 568 nucleated red cells in the space covered while making a differential numeration of 1,000 white cells. As many as nine different varieties of nucleated red cells were noted in addition to the cells with dividing nuclei (some of them of normal size, some as large as any megaloblast) and cells showing karyokinetic figures. In no case was there observed any sudden and marked increase in the number of normoblasts, such as has been mentioned by some writers as a point of favorable import. As a rule, the number of megaloblasts steadily increased as the patient grew worse, while the relative proportion of normoblasts diminished. Cases where the whole number of nucleated corpuscles, or the proportion of megaloblasts, was relatively large seemed to be neither better nor worse off than those where only a few were to be found, but on the whole it is to be concluded that an increase of these cells in the blood of any one case is a bad sign."

**Galvano-Cautery in Uterine Surgery.**—Dr. Charles Jewett, in the *Brooklyn Medical Journal*, September, offered some remarks on the claims of cautery in the treatment of uterine cancer and of procidentia. These remarks were made in the course of a discussion before the Brooklyn Gynecological Society on true and false methods in this branch of surgery. Dr. Jewett contended that the cautery had not received the attention that it deserves. The first and most obvious advantage is its complete antiseptis, an attribute that can not be marred by the carelessness of either the operator, assistant or nurse. In certain cases, no doubt all the diseased and infected tissue can be removed, and the results reported by Dr. John Byrne and his associates commend the operation as one deserving to stand side by side with hysterectomy until experience has proven that hysterectomy gives better ultimate results than the mere removal of the diseased tissues with the cautery knife." The cautery knife is, too, a very valuable adjunct for at least the first step in vaginal hysterectomy. It frequently makes this part of the operation a bloodless one, and it obviates the necessity of hemostatic sutures in the vaginal wall at the close of the operation. It is one which I have used with satisfaction. Theoretically, total ablation, on the other hand, appeals to the judgment of the surgeon in cancer of the uterus, as it does in cancer of other organs. In carcinoma of the breast the surgeon considers it necessary to remove not only all the diseased tissue, but the entire mammary gland, and with it the pectoral muscles and all of the lymphatic glands that are known to be or that might be involved. A similar rule is enforced in the treatment of cancer generally. If there is any criticism on the Doctor's method it is the uncertainty that the operation reaches all the infected tissues of the uterus. With reference to the theory offered as to the action of the current on the structures left behind, I can not agree with him. The current which runs through the cautery knife passes from one pole of the battery to the loop or knife and back again to the other pole of the battery, none going out into the tissues. I assume that the galvano-cautery does not differ in effect from any other kind of cautery. The action of the instrument must be simply that of a hot knife or iron. The tissues are disinfecting, the cancerous elements are destroyed, only so far as the slough goes; at least that is my belief. The use of the cautery in the treatment of procidentia is a method we are familiar with through the teachings of Dr. Byrne. No doubt the results are quite as permanent as in many cases of ventral fixation and of most other operations for the purpose. The effect, I take it, of the knife is to set up an inflammation, with resulting proliferation of tissue, which blocks the pelvis and holds the uterus up. The inflammatory products must be absorbed in time—I am glad to know it is ten years in some cases—but ultimately we must expect the uterus to come down again."

**The Medicine of Life Insurance is yet in its Infancy.**—The editor of the *Medical Examiner* offers the following thoughts upon the higher plane of insurance :

"Insurance medicine is yet in its early stages. Within the last fifty years it has made great advances. There is no doubt that in the course of time, for that is a great element in the collection of statistics of this character, greater accuracy will be reached in everything relating to the medical phase of life insurance. The best medical men of the profession are needed and sought for to act as examiners—men who are capable of accurate observation and of securing accurate records. While the first is possible, the latter is not always so, as applicants will not state or do not know the facts in all cases. Conclusions drawn from inaccurate data are themselves defective, and allowances in practice must necessarily be made. But no department of an insurance company is beyond the reach of law. If the status of a company as reported to the insurance department of a State, is found to be below the required standard, the causes are immediately sought for and the appropriate remedy is applied. If the medical department in any part of its organization is found to be at fault, then the State will require such changes to be made as will remedy any defect discovered. These defects are so far-reaching and cumulative that they can not be otherwise than disastrous if allowed to exist. The medical department of an insurance company is one of the necessary and important divisions of its organization. Upon its efficiency and integrity depends the very existence of the company."

**The Narrowing Field of the General Practitioner.**—The following is a portion of an essay by Dr. Onslow Gordon of Brooklyn in *Weir's Index*, inculcating a higher self-confidence and a less constant reliance upon specialists. He holds that specialism is overdone to an extent injurious to general medicine, and a concert of action is needed. He further says :

"Within comparatively few years the field of the general practitioner has been very much narrowed, and present indications point to still greater inroads upon his field of usefulness. Should he be crowded into such narrow quarters that he will be unable to exist, the fault will be largely his own. It requires but a moment's reflection to convince one that the number of good, all-around physicians is rapidly growing smaller and that the tendency is toward specialism. While I have nothing to say against specialism in medicine, and would not wish to go back to the time when there were no specialists, as we owe very much to them, and there are certain lines along which they can do better work than the man who tries to cover the whole field of medicine and surgery, I think that the general practitioner is too dependent upon them at the present time. A very large number of physicians (especially the younger members of the profession) are doing a larger business as distributors of cases than as practitioners of medicine; they shake the bush and the specialist gathers the fruit.' There is not a member of this Association that has not repeatedly seen the specialist called upon to open a simple abscess, remove wens, dilate for anal fissure, remove tonsils, ingrowing toe-nail, perform circumcision and do an innumerable number of operations that the family physician should blush to decline. All surgical cases are sent to the surgeon, gynecologic cases to the gynecologist, throat and nose work to the laryngologist, heart and lung affections to the chest specialist, nervous diseases to the neurologist, diseases of the rectum to the rectal specialist, genito-urinary ailments to the genito-urinary surgeon, joint and bone diseases to the orthopedic department, eye and ear troubles (however slight) to the ophthalmologist, and skin diseases to the dermatologist; we can also find specialists who will call us good fellows if we will turn over our stomach, kidney and hernia cases; yet there are very few specialists who will decline to treat a patient, no matter what his ailment may be, if the money is in sight. While the people of moderate means still tolerate the family physician as an obstetrician, the more favored in worldly goods are looking for a specialist when an accoucheur is desired. If matters continue on these lines, the specialist, or more properly speaking, the general practitioner, will leave for himself possibly acute coryza and constipation. The tendency to rely on the specialist has grown to such an extent that there are many physicians who will not remove a retained placenta, suture a recently lacerated perineum, however simple, open an abscess or venture a diagnosis in any obscure case. It is the custom of the times that makes them hesitate to rely more on their own judgment and call into action the ability their patients have a right to expect them to have. It has been well said, 'The wise and brave conquer difficulties by daring to attempt them.' Perhaps the time will

come when the general practitioner will be consulted only as to the advisability of calling a specialist and whom to call. All this can but tend to belittle the family physician in the eyes of his patients, limit his ability and impair his usefulness, to say nothing of his loss from a financial standpoint. The physician who has no confidence in himself can not expect others to trust him with their lives. I believe there will always be room for the well-equipped general practitioner, unless he persists in turning away all of his most interesting cases. By so doing he will help educate the rising generation to believe that they are to depend on the family physician to treat slight ailments only."

**The Lancet on the Health of Chicago.**—The London *Lancet* for August 29 has the following interesting annotation about Chicago's health, taking up anew, although in an incidental manner, the thread of certain investigations that were made by that journal in 1893, at the time of the great exposition. The annotation opens by referring to the report, printed in April of that year by a special *Lancet* committee, or "Sanitary Commission," of inquiry concerning the water supply of Chicago, and says :

"When, three years ago, we undertook an investigation into the drainage and water supply systems of the city of Chicago we acted primarily in the interest of our own countrymen who, in the year 1893, were visitors to the great exhibition; but as we then remarked, the matters examined were of even more abiding importance to the residents in Chicago than to her visitors, and it was very gratifying to us to gather from the way in which our action was received by the city authorities that they took the same view. Since that date our own opportunities of collecting information concerning the sanitary history of the city have naturally been occasional only, but we have from time to time heard with a lively interest of the progress of the large engineering works required to secure efficient drainage on the shores of Lake Michigan and the effective use of the boundless supply of excellent water which the lake brings to the city's door. A return from the Bureau of Vital Statistics, for a copy of which we are indebted to the courtesy of the Commissioner of Health, shows that the effect of the water supply upon the health of the city is made the subject of constant and watchful attention and certainly the results of the observations made illustrate in a very striking manner the close—we might even say exact—relation between the two. This is well exhibited by a diagram which accompanies the Commissioner's report for the month of June last in which the mortality rates from intestinal diseases for six months are collected. Upon this diagram one curve shows the varying condition of the water supply, the badness of the water in the sense of pathogenic quality being measured by the height of the curve in successive weeks; a second curve shows in the same way the weekly series of mortality rates due to typhoid fever; and a third a corresponding series of mortality rates due to other acute intestinal diseases, such, apparently as enteritis, gastro-enteritis and diarrhea. Between the water curve and the second mortality curve the correspondence is most striking. The water supply was at its worst in the week ending December 28 last; the mortality from intestinal diseases was greatest in the following week. The water curve shows culminating points in the weeks dated January 25 and February 15, in each case followed by a maximum point in mortality from intestinal diseases a fortnight later. A marked amelioration in both conditions is indicated throughout the month of March, but in April, May and June the water supply became again pathogenic and within a week the mortality curve exhibits a corresponding increase, both curves approximating closely to that reached by them respectively in the month of January. In fact, the dependence of the one upon the other might almost be expressed by a mathematic formula. In the case of typhoid fever the correspondence is not so close and the difference is characteristic. The bad water maximum of December is followed after an interval of five weeks by a typhoid fever maximum in the end of January, and although the typhoid curve does not respond with the same precision as the curve of other intestinal diseases to the water maximum of the following April there is a traceable rise in typhoid fever mortality during June and it is matter of common observation that this disorder is less rife in the spring than in the after part of the year. Altogether the statistics produced from the health department of Chicago are most suggestive, eminently instructive and of much more than simply local significance."

**Clinic Teaching in the Modern Hospital.**—The *Sanitary Journal* of Glasgow, June, 1896, considers the subject of ampler provision for the use of clinic material at the infectious disease

hospitals, especially in new hospitals and in respect of the plans of proposed hospitals. The writers say:

"The primary duty of laying down the best known conditions by which the hospital may be rendered the best possible instrument for the treatment of disease being fulfilled, there remains to be recognized the clear duty of rendering it also an efficient teaching institution. I regard this duty as a very close second in importance to the first. Ten years ago scarcely one and one-half per cent. of the medical graduates of Edinburgh had obtained their knowledge of fevers from clinic study. It has only been since the treatment of infectious disease was taken over by the city that anything like general attendance at fever clinics has been given by the students of our medical school. Such attendance has now been made compulsory by the medical authorities. In the new hospital, we shall, I feel sure, as heartily afford facilities for clinic instruction as we have done hitherto in the old building.

"What I desire mainly to urge with regard to the hospital as a teaching institution is that, in constructing our new hospital, the city will have a unique opportunity to render, at a comparatively trifling cost, one of the most valuable services to the Edinburgh school of medicine that it has ever received. That service lies in providing adequate laboratory accommodation for bacteriologic research, and for the investigation of the whole natural history of all kinds of febrile disease. The Edinburgh school has never yet been able to take its proper place in relation to this all-important field of inquiry. The prosperity of its medical school tends, in no small degree, to the general prosperity of the city. Whatever, therefore, the city may do to promote the interest of the medical school, famous as it has been and is still, will be in reality a contribution to the best interests of the city itself. Down to the present time almost all the material which our increasing fever hospital affords for scientific investigation has gone to waste. Notwithstanding what has been generously provided by the Royal College of Physicians at its own charges, we have no adequate means of conducting such systematic inquiry as that which is carried on in the principal medical centers of the continent. The opportunity to meet this great defect now lies to our hand. In every well-appointed fever hospital on the continent, but especially in Germany, well-equipped laboratories are found, where students and graduates conduct methodic and patient investigation into every aspect of every kind of infectious disease. There is also provided a museum for the preservation of preparations made by the investigators, and there is, likewise, adjoining the laboratories, a well constructed postmortem room with the requisite appliances. Let it be the graceful part of the city to provide the necessary accommodation for the purpose now pointed out, which it is in a position to do in the simplest, most economic and yet most effective way. It may be assumed that the medical school will not be slow to do its part in making the best use of facilities so provided."

## PRACTICAL NOTES.

**Dry Heat of High Temperature in the Treatment of Chronic Joint Affections.**—The apparatus which Dr. Wm. E. Wirt employs consists of a copper drum twelve inches long and nine inches in diameter, fitted at each end with a wooden ring and a hood of thick rubber. Having protected the back of the knee with cotton, it is enclosed in the apparatus, and heat applied to the outside by means of a Bunsen burner. Most patients tolerate a temperature between 250 and 300 degrees F., provided three holes are made in the drum to secure proper ventilation and so keep the air dry. This treatment gives immediate relief to pain and increases temporarily the mobility of the joint.—*Boston Med. and Surg. Jour.*, September 10.

**Modern Treatment of Progressive Polyarthritides Deformans.**—Physicians are too much inclined to consider this disease incurable. Its pathogenesis is still obscure, but it is probably due to some infection which rapidly localizes itself in the nervous system. It attacks both adults and young people, starting with one or two acute seizures, develops from below upward, attacking symmetrically the articulations of the members and then of the trunk, but scarcely ever causes visceral lesions. The usual internal remedies for rheumatic or gouty tendency, salicylate of soda, preparations of colchicum and alkalins in large

doses, usually fail to produce any effect in this disease. The only internal medicines which prove effectual are iodine and the iodids combined with preparations of arsenic. It can be commenced with small doses of iodid or tincture of iodine, taken in the middle of the two principal meals, 4 to 5 and even 10 drops of tincture of iodine in a class of wine or of *eau sucrée* or syrup of bitter orange peel in water. Or else a teaspoonful of the following: Two grams each of potassium iodid and sodium iodid in 120 grams of dist. water. After fifteen days of this treatment it is to be suspended and a teaspoonful of the following taken in the same way with the meals in a tablespoonful of iodotannic syrup: Sodium arseniate 0.05 gram in 120 grams of dist. water. The sodium arseniate can be replaced by Fowler's solution taken in progressive doses, increasing from 3 drops at each meal to 6 drops and then decreasing a drop a day until the original dose is reached. This treatment is to be continued several months, alternating the arsenical medication with the iodids. If, as sometimes happens, the iodid is not borne well, the tolerance can be increased by associating with it belladonna and arsenic in the following proportions: Potassium iodid, 4 grams; sodium arseniate, 0.02 gram; neutral sulphate of atropin, 0.001 gram, and 120 grams of dist. water. Take one teaspoonful in the middle of each of the two principal meals, in half a glass of Vichy water (Hauterive). In combination with this internal medication there should be external treatment to ward off the threatening ankylosis in the joints. They must be frictioned with a stimulating liniment, and as the frictions are to be made daily, irritation of the skin should be carefully avoided. The following is a good liniment for this purpose: Liquid ammonia, 50 grams, with 100 grams each of balsam of Fioravanti and spirit of lavender. The frictions may be followed by slight massage, but it is best not to massage the articulations and avoid imparting too active movements to the diseased joints. The different methods of electrization have all proved impotent, even long continued currents applied to the atrophied muscles consecutive to arthritis of this kind. Alkaline and saline baths, very hot and prolonged, sometimes produce good results, as also hydromineral treatment at Aix-la-Chapelle, Dax, Saint-Armand, Ragatz, Bourbonne-les-Bains, Bourbon-l'Archambault, etc. But in the torpid periods of the disease, to combat the articular deformities and restore mobility to the ankylosed members, mud and sand baths are excellent. These have been recommended for many years, but it is only comparatively recently that the establishments at Dresden (Dr. Fleming), Kostritz near Leipsic (Dr. Sturm), at Berlin (Dr. Grawitz) and especially at Lavey in Switzerland (Dr. Suchard), have really rendered these baths practicable. The Grawitz method enables baths to be taken at home in an ordinary bath tub at 122 degrees, but the best results are obtained at Lavey where the establishment is fitted up with appliances for whole or partial baths of sand, evenly heated to 122 and 140 degrees, absolutely free from gravel, clay, calcareous or organic matters. The partial baths are considered best as they do not debilitate. These baths produce an excessive cutaneous secretion which has been found to benefit to a surprising degree sciatic and chronic rheumatism and gout. They also modify very favorably cases of arthritis deformans. The Lavey water is also beneficial in rheumatic disorders.—*Rev. Int. d. M. et d. Ch.*, August 20, from the *Gaz. hebdom.*, May 24.

**Influence of Cold Baths on the Circulation.**—A series of experiments on typhoid fever patients and persons in health, as well as numerous experiments on animals, lead Breitenstein to assert that the number of corpuscles in the blood greatly increases in the course of a cold bath, but as this can not be due to the formation of new corpuscles, it must be that corpuscles more or less stagnant in the viscera and other interior portions of the organism, are drawn to the surface by the effect of the cold bath.—*Revue Int. de M. et de Ch.*, August 25.

**Abortive Treatment of Coryza.**—Lermoyez orders a snuff made of hydrochlorate of cocain, 50 centigrams; menthol, 30 centigrams; salol, 5 grams; boric acid, 20 grams. A large pinch of this snuff, finely pulverized, every hour. Or a spray of a tepid and boiled solution of hydrochlorate of cocain at 1 per cent. every two or three hours. He also recommends a snuff powder, slightly antiseptic but not irritating, made of hydrochlorate of cocain, 50 centigrams; menthol, 25 centigrams; salicylate of bismuth and sugar of milk, each 5 grams. Brand's method is to wet a piece of blotting paper every hour with 10 drops of the following mixture: Pure phenic acid and liquid ammonia, each 5 grams; alcohol at 90 degrees, 10 grams; acq. dest., 15 grams, and inhale it a few seconds.—*Gaz. Méd. de Liège*, August 27.

**Vaselin in Erysipelas.**—Koester has been using vaselin in erysipelas for three years and studying its effects as compared with other remedies. He announces now that it is fully as efficacious as the rest, the fever lasts no longer, the lesions extend no more and the complications occur with no greater frequency. It is therefore much to be preferred, as it is so simple, and has none of the inconveniences inevitable with toxic and irritating substances.—*Revue Int. de M. et de Ch.*, August 25.

**Maragliano Serum in Tuberculosis.**—The *Gaz. degli Osp. e delle Clin.* of Milan, is constantly publishing reports of the results of treatment of tuberculosis with the Maragliano serum, and one cure after another is described, although the concession is made that the cure like the disease itself, is slow. The graphic reports certainly establish the fact that the fever disappears with the use of the serum, and Prof. Mascei concludes a recent address on the subject with these words: "The dizzy rate of progress at this end of the century in all that regards therapeutics is shaking up old bones and revealing new ideals. Genius and perseverance have enabled Behring to cancel Napoleon's denunciation of medical science as he stood at the bedside of his nephew dying of diphtheria: 'This terrible scourge to humanity is a disgrace to science.' As an Italian, as a physician, as a man, I prophesy that the anti-tuberculosis serum is destined to as great a fate as the diphtheria antitoxin and that the name of Maragliano will rank in time among those of the great benefactors of humanity, Jenner, Lister, Pasteur and Behring."

**Radical Cure of Hydrocele.**—Incision with partial removal of the sac is to be resorted to when the sac is found to be thickened, or where it protrudes far into the inguinal canal. A modification of this operation is suggested, which it is believed will greatly simplify the usual procedure: It is performed by making a free incision over the long axis of the tumor, dividing the structures down to the sac, at the same time being careful not to open it. By means of an Allis's dry dissector, the scrotal tissues are quickly separated from the tunic, which is left slightly adherent posteriorly; this being the portion of the sac which covers the cord and is not disturbed. The sac is then made tense, fixed by means of a tenaculum, opened by a touch of the knife, and the fluid allowed to escape. The sac, having been thoroughly dissected from the scrotal tissue, is removed in a single piece by means of the curved scissors. The bleeding vessels are ligated and the wound dried. Should there be much hemorrhage from the edges of the cut sac, it must be controlled by a continuous suture passing completely over the margin. The portion of the tunica vaginalis lying over the cord is swabbed with carbolic acid, the wound irrigated with 1 to 1,000 bichlorid solution, a small drainage tube inserted, and the parts closed by silkworm-gut sutures. An antiseptic dressing is then applied. The drainage tube is removed after twenty-four hours; the sutures after the seventh day.—Dr. Orville Horwitz, in *Jour. of Cut. and Genito-Urinary Dis.*, September.

**To Remove Fish Bones From the Throat.**—Fish bones can sometimes be expelled from the throat by giving from four to six ounces of milk, and forty minutes later an emetic dose of zinc sulphate. The vomit of coagulated milk carries the bone before it as a rule.—*General Practitioner*, July.

**Alcohol in the Treatment of Carcinoma.**—Dr. H. C. Howard reports satisfactory results from hypodermic injections of absolute alcohol, to which, if there is an open ulcerating surface, is added from 15 to 25 per cent. of tannic acid; this solution is also employed as a dressing to the surface. Of carcinoma of the breast he says: "I have employed this treatment in ten cases. Nine of the patients recovered and are in good health; in one case secondary extension to the liver took place. In these cases, it is my custom to pass the needle through and below the tumor and during the retraction of the needle to inject ten or fifteen minims of absolute alcohol into the tumor. This injection is repeated in four or five points in the tumor. The injections are repeated at intervals of two or three days and the time required for the complete removal of the growth is ordinarily about three months."—*Medical Standard*, Sept.

**Treatment of Hemoptysis.**—Letters addressed to representative physicians of Chicago, by Dr. Robert H. Babcock, requesting a statement of their treatment of pulmonary hemorrhage, elicited twenty-seven replies from which the following summary was tabulated: Eighteen insist upon absolute physical rest in recumbent or semi-recumbent positions, and three added that they permitted no talking. Cold to the chest is ordered by thirteen, usually in the form of ice. Nine administer opium and eight morphin hypodermically. Ergot is employed by fifteen, a few however stating doubt as to its utility. One administers Tancret's ergotin subcutaneously in doses of from 6 to 8 minims. Eleven are positive that ergot has no efficacy in controlling pulmonary hemorrhage. Six make use of acetate of lead, either with or without opium; two, tannic acid; two, gallic acid; one, dilute sulphuric, and another aromatic sulphuric acid. Six prescribe ipecac—five, the syrup, and one the powder in an emetic dose after the manner of Trousseau. Four give aconite, and two veratrum viride. Salt is recommended by seven, one of whom administers the salt freely, either by the mouth in water or in the food, or by the rectum (ʒj of salt to ʒj of tepid water), or subcutaneously in the form of a normal salt solution. Four advise mild laxatives, but do not specify the one employed, with the exception of the advocate of salt, quoted above, who recommends phosphate of soda because "of the physiologic fact that the phosphate present holds the other salins in solution, thus making the common salt taken more effective." One only employs sprays to the larynx and trachea of solutions of "liquor ferri subsulphatis, 10 to 20 m. to ʒj, or the tincture of the chlorid of iron, from 20 to 30 m. to ʒj of water, repeated three or four times daily. One says he uses phenacetin internally, depending upon the cause of the hemorrhage, and (after the attack) rest, light diet, and tincture of iron internally. Two speak of employing ligatures to the extremities, close to the trunk, during the attack, one specifying slight constrictions of the lower extremities to prevent the return flow of blood to the lungs. Dr. Babcock states that for the hemoptysis of active hyperemia, he quiets the cough—preferably by phosphate of codein,  $\frac{1}{4}$  to  $\frac{1}{2}$  grain hypodermically, or  $\frac{1}{2}$  to 1 grain by the mouth; prescribes syrup of ipecac in frequent doses until nausea is produced; and orders an efficient but not severe aperient, preferably Hunyadi or Rubinat water. If the hemorrhage arise within a cavity and be profuse, he orders the immediate injection hypodermically of one-fiftieth or even one twenty-fifth of a grain of sulphate of atropin. This dose promptly produces pronounced physiologic effects, but is not dangerous, and the initial increase in the heart's rate and vigor is offset by the vasomotor paresis occasioned, which diverts the blood to the periphery.—*Medicine*, September.

THE  
Journal of the American Medical Association  
PUBLISHED WEEKLY.

SUBSCRIPTION PRICE, INCLUDING POSTAGE:

Per Annum, in Advance . . . . . \$5.00  
Single Copies . . . . . 10 Cents.

Subscriptions may begin at any time and be sent to

THE JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION,  
No. 61 Market Street (Occidental Buildings), Chicago, Illinois.

MEMBERSHIP IN THE AMERICAN MEDICAL ASSOCIATION.

This is obtainable, at any time, by a member of any State or local Medical Society which is entitled to send delegates to the Association. All that is necessary is for the applicant to write to the Treasurer of the Association, Dr. Henry P. Newman, Venetian Building, Chicago, Ill., sending him a certificate or statement that the applicant is in good standing in his own Society, signed by the President and Secretary of said Society. Attendance as a delegate at an annual meeting of the Association is not necessary to obtain membership.

On receipt of the subscription the weekly JOURNAL of the Association will be forwarded regularly.

Gentlemen already members of the Association should send their annual subscription to the Treasurer, or direct to the JOURNAL office.

All communications and manuscript of whatever character, intended for publication in the JOURNAL, should be addressed to the Editor, and all communications relative to the business of the JOURNAL, proof sheets returned, or in regard to subscriptions, should be addressed to THE JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION, 61 Market Street (Occidental Buildings), Chicago.

Original communications are only received with the understanding that they are exclusively contributed to this JOURNAL.

INFORMATION WANTED.

It would greatly facilitate the prompt delivery of the JOURNAL to those members of the ASSOCIATION living in large cities, if they would kindly furnish this office with their street address in those cases where it is omitted from the wrapper of their JOURNAL, as we have been notified by the postmasters of the larger cities that second-class mail matter not having street address, would be placed in the general delivery to await call.

SATURDAY, SEPTEMBER 26, 1896.

THE LANGUAGE OF MEDICAL TERMINOLOGY AND  
MEDICAL CONGRESSES.

An Eastern medical weekly (published at a center of culture with a university richly endowed in all its departments) editorially endorsed the cant of an English pedant against the use of Greek in medical terminology on the ground that: "Even when scientific coinages have been adopted into the language of the people, it is not always certain that men of fair culture correctly analyze them into their original constituents and real significance." This is clearly an apology for the "fair culture" of the following review of a "quiz compend" in the same number of this weekly: "There is a tendency to the use of Latin headings for familiar diseases which is to be deprecated, stomatomyosis for instance might well be written 'thrush' and 'coprostasis' might be simplified into 'lead poisoning.'" The "fair culture" which could turn into Latin such familiar Greek as stomatomyosis and coprostasis and could mistranslate the last into "lead poisoning," is one evidently not possessed by the vast majority of regular (American) physicians who, whether classically educated or not, have a sufficient working etymologic knowledge of Greek to avoid such blunders. The widespread nature of this working etymologic knowledge of Greek, a credit to the United States, argues for Greek as the international medical tongue. The English medical pedant, so admirably quoted in the weekly of "fair culture" aforesaid, argues against the growing use of Greek in scientific terminology, with the futile British

cant crushed by Macaulay (seven decades ago when he foresaw the conquest of Latin by Greek in scientific terminology) with the following vivid logic (*Edinburgh Review*, February, 1826): "The vocabulary of Latin is miserably poor, and its mechanism deficient both in power and precision. The want of the definite article and of a distinction between the preterite and the aorist tenses are two defects which are alone sufficient to place it below any other language with which we are acquainted. In its most flourishing era, it was reproached with poverty of expression. CICERO, indeed, was induced by his patriotic feeling to deny the charge. But the perpetual recurrence of Greek words in his most hurried and familiar letters and the frequent use which he is compelled to make of them, in spite of all his exertions to avoid them, in his philosophic works, fully prove that even this great master of the Latin tongue felt the evil which he labored to conceal from others.

"The Latin language is principally valuable as an introduction to the Greek, the insignificant portico of a most chaste and majestic fabric. On this subject our confession of faith will, we trust, be approved by the most orthodox scholar. We can not refuse our admiration to that most wonderful and perfect machine of human thought to the flexibility, the harmony, the gigantic power, the exquisite delicacy, the infinite wealth of words, the incomparable felicity of expression in which are united the energy of the English, the neatness of the French, the sweet and infantine simplicity of the Tuscan. Of all dialects it is the best fitted for the purpose both of science and of elegant literature. The philosophic vocabularies of ancient Rome and modern Europe have been derived from that of Athens. Yet none of the imitations have ever approached the richness and precision of the original. It traces with ease, distinctions so subtle as to be lost in every other language. It draws lines where all the other instruments of the reason only make blots. Nor is it less distinguished by the facilities which it affords to the poet. There are pages, even in the Greek dictionaries, over which it is impossible not to glance with delight. Every word suggests some pleasant or striking image, which wholly unconnected as it is with that which precedes or that which follows, gives the same sort of pleasure with that which we derive from reading the Adonis of poor Shelley, or from looking at those elegant though unmeaning friezes in which the eye wanders along a line of beautiful faces, graceful draperies, stage chariots, altars and garlands."

With the nineteenth century evolution of science, Greek, in the contest for existence in scientific terminology, conquered Latin (once the dominant language of culture) as the fittest to survive. That this victory of Greek will continue there seems no reason to doubt. Greek owes its dominance in science not to

the cloistered scholar but to the working scientist for the practical reasons laid down by MACAULAY, whose prophetic notions as to Greek have been more than fulfilled. Greek has naturalized itself in every European tongue as the language of science; even German terms give way to it in all but nativistic German cant.

It is an open question whether the very qualities which render Greek of such value in scientific terminology do not unsuit it for debate, which to-day seeks expression in terse terms. The dominance of English is due to its monosyllabic peculiarity, in which it surpasses all Caucasian tongues. The readiness with which English, adopting loan words, modifies them to its own terse grammatical forms, aids its progress. It is intruding even on the French in France as witness les "five-o'clockers" (women attending 5 o'clock teas), and la "struggle-for-existence." English orthography and pronunciation are its chief defects. Here Greek as a practically dead tongue (destitute of the shiftings due to evolution) has an advantage somewhat offset by differences between British and European continental pronunciation; differences daily becoming less. Greek is not taught as a colloquial but a literary language, which unsuits it for debate. French, the language of diplomacy, as we have repeatedly said, has the enormous advantage (for medical congress) of being a tongue in which foreigners understand each other better than they do native Frenchmen. Italian has the great advantage of approximation to phonetic orthography, but lacks the terseness and energy of French and English. German is widely known as a literary tongue to medical scientists but is involved and open to orthographic and phonetic objections. The difficulties in the way of one language for medical congresses are such as can only be removed by evolution. On this the growth of English-speaking communities must exert an enormous influence. The attempt to found a world language (volapük) on English by German philologists, is a recognition of this influence which must increase with scientific development in North America, Australasia, South Africa and India. Greek will, however, remain the language of scientific terminology. The international medical spoken language will take many decades to produce and meanwhile international medical congresses will probably continue to be polyglot, notwithstanding the ease with which French could be made available for these gatherings.<sup>1</sup>

#### THE MICROBE AS A FACTOR IN EVOLUTION.

The beneficent as well as maleficent microbe has at last achieved recognition as a factor in human evolution, of which fact a recent review by Prof. E. RAY LANKESTER of a work by a Mr. ARCHIDALL REID ("The Present Evolution of Man," Chapman & Hall,

1896) in the September number of the *Fortnightly Review*, is in evidence. Mr. LAWSON TAIT, many years ago, wrote a paper showing that the law of natural selection appeared to be suspended in the case of man, and Mr. REID, independently recognizing this fact, seeks to find the real agencies that take its place. War, exposure, famine, the struggle with wild beasts, all the elements that entered into the evolution of the savage or primitive man are ineffectual now, and the survival of the fittest must depend on other determining causes than those that so obviously prevail throughout the animal kingdom. Mr. REID finds the chief desired factors in the germ diseases which are now in all parts of the world producing changes and a selective process "tending to the evolution of new generations of men endowed with other qualities than those possessed by the rejected of this agent." Tuberculosis, syphilis, and all the other civilized scourges introduced among and decimating or exterminating the native races of various portions of the world, are there, as elsewhere, only culling out the unfit and leaving their survivors in a higher, or better, or more resistant stage of physical development. What we have long called acclimatization is, according to this author, only a synonym for evolution, and when applied to races instead of individuals is solely the result of the accumulation of hereditary inborn variations.

Whatever of truth there is in these ideas is not new to the medical public, but as applied to evolution it seems to have struck so eminent a biologist as Professor LANKESTER as a novelty. We have long recognized the fact that many non-self-protective infections appear to produce a racial immunity, that familiarity with them breeds a sort of physiologic contempt, and that this is an important element in the adaptation of the species to its special environment. But its relation to general racial evolution or devolution has not so far been a question of very great medical interest.

Disease germs are, however, not the only apparent evils from which Mr. ARCHIDALL REID sees beneficent results to the race, he finds alcohol and opium also elements in the improvement of mankind by their selective action in removing the unfit from among us. In this he is not original; the same idea has been offered by others, notably, by Dr. BERRY HAYCRAFT in his work, "Darwinism and Race Progress." Like all other human vices or weaknesses these bring on individual degeneration and weed out their victims, but that any race becomes immune to their effects is something that so far has not been satisfactorily proven. The findings of the English opium commission, which seem to be taken as gospel by the author and his critic, as to the habituation of the Indian races to opium, were too clearly "for revenue only" and have been riddled by competent authority in India itself. There has been as yet no such convenient authoritative government statement in regard

<sup>1</sup> See the JOURNAL, Vol. XXV, p. 1065. "The International Scientific Language."

to alcohol and his argument as far as this agent is concerned rests only on assumptions.

The question of human evolution under present conditions is, as Professor LANKESTER admits, a very complicated one, and no single cause or series of such can be made to cover all the possibilities. The fact that evolutionists are looking to medicine and pathology for suggestions and theories which, while novel to them, are familiar to the physician is worth a passing thought.

#### THE SECOND STATE HOSPITAL FOR THE INSANE OF MARYLAND.

Another pariah has been redeemed from opprobrium as a social outcast. The bars and shackles which restrained the sufferer with a mind diseased, have been relegated to the scrap heap upon which thumb-screws and branding-irons have been cast. The creature, formed in the physical image of the God of the Universe, no longer wallows as swine, nor crawls on hands and knees with the beasts of the field, chained by the waist, like Nebuchadnezzar. The "lunatic asylum" has given place to the State hospital, under the superintendence of medical men of the highest professional attainments. The higher medicine of the close of the nineteenth century, which has made State boards of health, State boards of medical examiners and State licensing boards the arbiters of proficiency and responsibility, has lifted the attending physician of the asylum for the insane from the status of a subservient to the steward, manager or executive officer, by whatever title known, to the supreme control and direction of the hospital in which the most pitiable of afflicted invalids are sought to be restored to health, or tenderly cared for when unable to care for themselves.

The medical control of these institutions has brought about a complete revolution in their administrative systems with new methods of hospital construction. Dr. P. M. WISE's notable work in this direction in the St. Lawrence State Hospital at Ogdensburg, N. Y., upon which Governor MORTON has set the seal of approval by appointing him to the head of the Lunacy Commission, is about to be further developed in the Second State Hospital of Maryland, for which the ground has only recently been broken. To the enlightened and progressive late governor of that State, the Hon. FRANK BROWN, and his successor, the Hon. LLOYD LOWNDES, the one a democrat and the other a republican, and to an enlightened and liberal General Assembly, in which party lines and interests were for the time ignored, is due the projection of an institution in which the physician will have the untrammelled opportunity of carrying to its highest possible development the modern rational view of the treatment of insane invalids.

When the necessity for accommodations for the

insane of the State, beyond the capacity of the hospital at Spring Grove, near Catonsville, Md., which was completed for occupation in 1872, compelled the legislature to make provision either by the enlargement of the existing institution or the creation of another, it judiciously consulted the superintendent in charge for the past five years, Dr. GEORGE H. ROHÉ, and wisely determined upon a new establishment, and after constituting a Governing Board of Managers, consisting of the governor, State treasurer and State comptroller, as ex-officio members, with six colleagues to serve six years, two being renewed every second year, intrusted to them the selection of a site and the determination of the character of the new institution. In the matter of site they associated with them a professional advisory board consisting of Dr. ROHÉ as chairman, Prof. HENRY M. HURD, of Johns Hopkins Hospital, and Dr. JAMES F. MCSHANE, health officer of Baltimore, with regard to the sanitary and other requirements of the contemplated structure. The result has been the acquisition of the Patterson estate of Springfield, an ancestral domain of 728 acres near Sykesville, on the Baltimore and Ohio railroad, about thirty miles from the city of Baltimore—an ideal locality for the purpose as to elevation, diversified surface, abundant water supply, drainage facilities, amount of arable farm land, accessibility with isolation, well wooded and traversed by rapid brooks discharging into the Patapsco river, with an attractive landscape and as equable climatic conditions as are to be found within the State.

The old Patterson manor-house has been converted into quarters for the superintendent, an annex wing containing the senior assistant's and secretary's quarters, offices, board rooms, visitors' rooms, store-rooms, etc., pertaining to the general administration. The distinctive professional feature of the new establishment is to be the erection of independent groups of hospital buildings, the number of these groups being indeterminate and dependent entirely on the future needs of the State. The several groups are to occupy elevations at considerable intervening distances, and each is to be complete in itself as to the accommodation and care of its invalid inmates, the preparation of food, messing, attendance, etc., with quarters for physicians and attendants, the latter not being allowed to live in the patients' buildings, where they are only when actually on duty, and where they are consequently not permitted to sleep or loaf. The first of these groups is that now under construction on a hill about twelve hundred feet east of the superintendent's quarters, and consists of three detached pavilions and a fourth or "service building." Each pavilion will contain from fifty to seventy-five beds, with common living rooms entirely apart from the dormitories, and a significant departure has been made in the very large proportion of general dormitory space to single rooms.

The practice of isolation is not to be encouraged. The asylum notion is to be subordinated to the hospital idea, the inmates being taught to consider themselves only as sick persons under treatment for remediable ailments. Every inmate who can be employed outdoors will be put to work at farm labor, or during bad weather will be given occupation with others as assistants in the kitchens, store-rooms, laundries, stables and workshops, and all required to go into the wash-rooms after their work and before entering the dining or living rooms. During the summer they will be required to bathe outdoors in an artificial lake along with the attendants or a medical officer. The pavilions are two-storied, and a most commendable feature are the fire escapes—short, wide stairs completely inclosed by brick walls, large enough to empty the several wards in two minutes. Two of the fire escapes in each building are to be used frequently as means of egress, in order to familiarize patients with their purpose.

The first group of buildings is to be completed and occupied before ground shall be broken for the second, thus permitting improvements in plan, the desirability of which experience may demonstrate, and a similar course will be pursued with the third, fourth and as many subsequent groups as may be required, the extent and conformation of the grounds making this possible. Thus it may be claimed that it is an institution that will never be completed while the probabilities of advance and development exist, since in the distant future, when the latest child shall have outstripped the eldest, the latter may be demolished to give place to a better.

When it came to be known that the patrimony of one of the aristocratic families of the State was to become a "lunatic asylum," the sentiment of the neighborhood was outraged, many of the residents being in real dread of the fancied dangerous element coming among them. Curious visitors and tradesmen after a while found the farm and tenant houses on the estate occupied provisionally by persons whom they supposed to be all employés, and only later discovered to be chiefly lunatics—the dreaded "madmen," and saw the customary operations of the cultivation of the extensive fields performed by men whom from their dress they learned to recognize as wards of the State. Admiration for the humane methods they saw in operation followed upon the sense of security from possible danger from the crazy folk; the local dealers and shopkeepers profited by the vicinage of a large able-bodied community, until now all classes are proud of the splendid establishment which they foresee is to be one of the most notable of its kind in the world.

We have felt it due to the profession that this admirable and satisfactory consummation of the modern idea of caring for the insane should be made known. by this brief sketch of its details,

looking upon it as a matter in which every member of the ASSOCIATION should feel the highest pride, and as further illustrating the ability of medical men to exercise administrative and executive functions as well as the merely therapeutic and sanitary duties of State and National establishments. This has long been the practice in the United States Army and Naval Hospitals, and the United States Government Hospital for the Insane, although not many years ago a retrograde attempt was made by the Navy to transfer the executive control of these to officers of the line, in face of the unsatisfactory working of this plan in certain European services; but it is now so well understood in this country by educated laymen legislators, that the proper care of the sick involves something more than the mere administration of drugs, and that the subject of expenditures for quarters, food, fuel, light, clothing and attendance is a necessary element of that care and is, therefore, the proper function of the medical officer and one he can only properly perform unhampered, that no fear need be entertained that his right to do so will ever again be questioned. Of this the prospective success of the Second Hospital for the Insane of the State of Maryland, under its able, energetic and progressive superintendent, Dr. ROHÉ, in whom the State authorities have shown their confidence by intrusting him with its erection, development and control, gives additional assurance.

#### THE DISFIGUREMENTS OF SMALLPOX.

In the last volume of the St. Thomas Hospital Reports, Dr. ROBERT CORY contributes an interesting line of proof as to the condition, as to vaccination, of persons who are scarred by smallpox.

We are apt to forget how great a blessing vaccination is until an outbreak of smallpox opens our eyes to the terrible nature of the disease from which the labors of JENNER protected us. Even those who live through the sufferings of variola not infrequently bear traces of the attack in loss of sight or painful disfigurement for life. Noticing the tendency to belittle the value of vaccination, Dr. CORY commenced in November, 1884, his investigations with the intent of placing on record the result of his labors. In 1888 he had collected notes of 152 cases, which he published in the "Transactions of the Epidemiological Society" of that year. Up to the time of writing he had collected 448, of these, 210 were admittedly unvaccinated before their attack of smallpox, or 46.87 per cent., and these admittedly unvaccinated people had smallpox at the average age of 6.58 years. Continuing he remarks:

"This age is indeed high when compared with the average age individuals were attacked with the disease in the last century; however, there are three circumstances to be borne in mind. First, the greatly

diminished prevalence of smallpox in the present day to that which obtained in the last century. It follows, therefore, that the opportunity to become affected is accordingly not so great, and this would delay the average age at which unvaccinated individuals contract the disease. Secondly, a large proportion of the unvaccinated individuals die of the disease, and these would, in the main, be infants; hence, we have a considerable portion of the youngest eliminated by death. And thirdly, only those who have been obviously pitted with smallpox are dealt with in this paper."

The editor of the *Medical Press and Circular*, thereupon offers the following comment:

Of those who professed to having been vaccinated 23.44 per cent. had no scar of vaccination. And, as a matter of fact 70.31 per cent. of those pitted by smallpox bore no evidence of having been vaccinated. Now, as Dr. CORY says, the proportion of the unvaccinated to the vaccinated in London is not more than 5 per cent., yet we have seen that people pitted with smallpox are to the extent of 52.51 per cent. unvaccinated. If there be no protective power in vaccination, how can this be explained? We think our readers will agree with the author of the paper—that vaccination is a marvelous preventive of smallpox, and that his labors have done much to demonstrate the fact.

## CORRESPONDENCE.

### Professional Complaints.

In a timely article of the *Medical and Surgical Reporter*, with the above caption, the writer touches upon many points which might be amplified almost into treatises.<sup>1</sup> The inspiration of the editorial is a symposium by six teachers in a contemporary popular magazine regarding the hardships of their position in life, the emphasis being upon the monotony of their vocation, inadequate pay and the influence of politics. Of the first of these complaints, we are called upon to say but little inasmuch as a grievance it is common to every pursuit; of the second, the complaint of our own profession, is entitled to more consideration, while the third seems never destined to be divorced from the growing paternalism of all institutions.

Our writer says very truly: "We believe there can be no dispute that the professional class is too large. Our own profession numbers at least twice so many men as are needed to care for the health of the country; the legal profession, even with its many collateral opportunities, is overcrowded, and a considerable share of the clergy are a dead weight on society. . . . In professions like that of the teacher which can be filled with comparative ease from without, candidates inevitably tend to become the puppets of outside politics and the man who prefers to stand upon his own merits becomes unpleasantly aware of the pernicious tendency. On the other hand, the professions at whose entrance greater barriers are erected, like our own, or the ministry or the military are pervaded by a tendency to the development of an intra-professional intrigue which perhaps gives rise to more feeling and has as great disadvantages as the methods often brought to bear to secure advancement in the profession of pedagogy. Such things are no doubt regrettable, but so long as the supply is greater than

the demand and the spirit of competition for mere place is so keen there is no remedy."

By way of corroboration rather than addition, we may continue the subject with other pertinent reflections, chief among which are the reports of absurdly large incomes. These partake of the egotistic form and indirectly, as intended, furnish pabulum for public gossip. A little analysis of the factors at once exposes the fallacious statement. Every physician's duties are more or less personal, in truth do not belong to the class that can be made available by the labor of others. Here at once is a limitation to anything beyond a mere living. The temptation to embark in enterprises based upon the honesty of promoters is strong we know, but all faith in the childlike blandness of human nature is doomed to discomfiture. As such the physician should content himself with his lot in life, that of being "passing rich" upon a moiety, of taking the consequences of what his business friends not unjustly style foolish philanthropics, and in order to avoid the sneers of his brethren we might even advise him to cherish some variety of code in secret. What else can he do but be content, he can not hope for wealth, inasmuch as he is destined to end his career, if long enough, with a salary or sanitarium. But hold, virtue is its own reward and the much quoted "room at the top" converges into an apex upon which an equilibrium can with difficulty be maintained. At all events, what one of all our host would enjoy a solitude where our ambitions could be no better satisfied?

UMBRA.

## BOOK NOTICES.

**Index-Catalogue of the Library of the Surgeon-General's Office, United States Army. Authors and Subjects. Second Series, Vol. i., A—Azzuri.** Washington: Government Printing Office. 1896.

This volume, according to Deputy Surgeon-General D. L. Huntington, includes 6,346 author titles, representing 6,127 volumes and 6,327 pamphlets. It also contains 7,884 subject titles of separate books and pamphlets, and 30,384 titles of articles in periodicals. The value of the Index-Catalogue to medical science can not be over-estimated, and it is pleasant to know that the work is appreciated in Europe as well as in America. Congress, in making annual appropriation for this work, has acted wisely.

The arrangement of the volume is the same as that of the first series.

**Tenth Annual Report of the State Board of Health of the State of Ohio for the year ending Oct. 31, 1895.** Columbus: 1896.

This volume shows that this Board is keeping pace with the sanitary advances made in other States, but they are seriously handicapped by being without any proper system of vital statistics. "No one," says the report, "knows the number of deaths or the number of births that occurred in Ohio during the past or in any other year. Thousands die and thousands are born of whom no official record is made or can be obtained. Crime is made easy, the settlement of estates and legacies difficult, and a study of the causes of death and means for their removal impossible from the lack of such records." The work is edited by Dr. C. O. Probst, the efficient secretary.

**Food in Health and Disease.** By I. BURNEY YEO, M.D., F.R.C.P., Professor of Therapeutics in King's College, London. New (2d) edition. In one 12mo volume of 592 pages, with 4 engravings. Cloth, \$2.50 Philadelphia and New York: Lea Brothers & Co., publishers. 1896.

This book, which for some inscrutable reason appears to have been dipped in an indigo pot, is a valuable reference book for all interested in practical dietetics. Indeed, it might be fairly claimed for this study that every rational human being is practically interested in the subject, some of them intensely so. A work therefore upon such a subject naturally has a very wide circle of readers. Dr. Yeo has divided the work into two principal parts, the first of which relates to the food in health, giving its

<sup>1</sup> See also this JOURNAL, August 8, "Medical Grievances."

nature, origin and purpose, classification, nutritive value and uses of the different classes: Animal foods, vegetable foods, beverages and condiments, et cetera. The second part treats of food in disease, in general, and with reference to particular diseases, artificial digestive agents, hospital dietaries, sterilization and Pasteurization of milk, and concluding with select recipes for invalid dietaries and a copious index. No general practitioner can afford to be without a good work on dietetics, and this of Yeo's takes rank with those of the higher order.

**A Manual of Materia Medica and Pharmacology.** Comprising all Organic and Inorganic Drugs, which are and have been Official in the United States Pharmacopeia, together with important Allied Species and Useful Synthetics. For Students of Medicine, Druggists, Pharmacists and Physicians. By DAVID M. R. CULBRETH, M.D., Professor of Botany, Materia Medica and Pharmacognosy in the Maryland College of Pharmacy, Baltimore. In one handsome octavo volume of 812 pages, with 445 illustrations. Cloth, \$4.75. Philadelphia and New York: Lea Brothers & Co., publishers. 1896.

This work treats of official drugs; those once official and subsequently dropped; allied species of organic drugs and the unofficial synthetic compounds. The work is thus seen to cover a somewhat different field from the ordinary work on materia medica. Botany has been fully drawn upon in the description of medicinal plants, and the illustrations are superb. We think the author has made a serious mistake in ignoring the Centigrade thermometric scale and the metric system of dosage. The author says this was not done to disparage the metric system but because the old apothecaries weight is still universally used. This will indeed be news to the Committee on Revision of the Pharmacopeia. If all books were constructed on this principle no reform could ever be effected, or any advance made in the methods of scientific knowledge. We regret this the more as the step is deliberately taken in the face of the movements now going on in Great Britain, and the past decisive action of all our own scientific bodies.

From other standpoints the book can not be too highly commended.

**The Methodical Examination of the Eye,** being part 1 of a guide to the practice of ophthalmology for students and practitioners. By WILLIAM LANG, F.R.C.S., Eng. Cloth, pp. 96. London and New York: Longmans, Green & Co. 1895.

This work was written for the instruction of the surgeon who is beginning the special study of ophthalmology and as well for students. It is well illustrated, and its teaching is sound.

**A Pictorial Atlas of Skin Diseases and Syphilitic Affections,** in photo-lithochromes from models in the museum of the Saint Louis Hospital, Paris, with explanatory wood-cuts and texts. By ERNEST BESNIER, Physician to the Saint Louis Hospital, Member of the Academy of Medicine, President of the Dermatological Society of France; A. FOURNIER, Physician to the Saint Louis Hospital, Professor of the Faculty of Medicine, Member of the Academy of Medicine; TENNESON, Physician to the Saint Louis Hospital; HALLOPEAU, Physician to the Saint Louis Hospital, Member of the Academy of Medicine, Professor agrégé of the Faculty of Medicine; DU CASTEL, Physician to the Saint Louis Hospital; with the cooperation of HENRI FEULARD, Curator of the Museum, formerly Chef de clinique of the faculty at the Saint Louis Hospital; Secretary L. JACQUET, Médecin des Hôpitaux, formerly house physician to the Saint Louis Hospital, secretary of the Dermatological Society of France. Edited and annotated by J. J. PRINGLE, M.B., F.R.C.P., Assistant Physician to the Department for Diseases of the Skin at the Middlesex Hospital, London. London: The Rebman Publishing Co., Ltd., 11 Adam Street, Strand, Philadelphia, Pa.: W. E. Saunders, Publisher, 925 Walnut Street. For sale by subscription only. Part 4. Price, \$3 a part.

The contents of this volume consist of four plates: Mycosis Fungoides, Psoriasis, Tubercular Leprosy of the Face, Mycosis Fungoides, and various illustrations accompanying the text. We know of no work which will bring before the reader the magnificent models in the museum of the famous Saint Louis Hospital, so well as these. The coloring is very close to life

and is an aid to diagnosis alone; even without the explanatory text it would take the highest rank.

**Hare's Practical Diagnosis.**—PRACTICAL DIAGNOSIS. The use of Symptoms in the Diagnosis of Disease. By HOBART AMORY HARE, M.D., Professor of Therapeutics and Materia Medica in the Jefferson Medical College of Philadelphia, Laureate of the Medical Society of London, of the Royal Academy in Belgium, etc. In one octavo volume of 566 pages, with 191 engravings and 13 full-page colored plates. Cloth, \$4.75. Lea Brothers & Co., Philadelphia and New York. 1896.

There are few medical subjects Dr. Hare has not written upon, and his flowing pen not only ornaments the topics touched, but he seems always to hit upon the most practical way of conveying instruction. We recently had the pleasure of noticing a work on diagnosis, in which chemistry of the normal and pathologic fluids, was made to assume the chief rôle in diagnosis. Here we have a work in which semeiology, the visible symptoms with which we are confronted, is made to tell the story of the patient's pathologic condition, the natural or Hippocratic method. The work is profusely illustrated and the illustrations are fine. The title of the volume is not a misnomer in this instance, for it is indeed a *practical* diagnosis. An excellent index concludes the volume.

**A Vest-pocket Medical Dictionary.**—Embracing those terms and abbreviations which are commonly found in the medical literature of the day, but excluding the names of drugs and of many special anatomic terms. By ALBERT H. BUCK, M.D. New York: William Wood & Co. 1896.

This is truly a vest-pocket book, being 3½ inches long, 2½ inches wide and ⅝ inch thick! This little book will be found an excellent one for student's use. There may be critics who would object to see "Paget's Disease of the Nipple" defined as an "eczema," or the statement that "pyo-nephrosis" is a necessary or common sequence of hydronephrosis; and above all, students should be taught the etymology of words used in medical science, altogether omitted from this little lexicon. Nevertheless its form is most convenient, and it is destined to be immensely popular. We therefore urge the author to include the etymon of each word in the next edition.

## PUBLIC HEALTH.

**Typhoid in Kankakee (Ill.) Insane Asylum.**—It is reported that there are thirty cases of typhoid fever at the Illinois Eastern Hospital. Impure drinking water is supposed to be the cause.

**The Female Criminal and the Prostitute.**—The new book with this title completes Lombroso's remarkable work on the "Criminal," which is already a classic in anthropology. It is divided into several parts: The normal woman, the criminal woman, anthropometric and pathologic anatomy, biology and psychology of the female criminal.

**Ontario Boards of Health Must act for Themselves.**—The Ontario court of appeals holds, in the case of Township of Logan v. Hurlbut, decided in June, 1896, that, under the laws of that province, where members of a local board of health allow a person suffering from an infectious disease to go into an adjoining municipality, they are liable to repay to that municipality moneys reasonably expended in caring for the sick person and preventing the spread of the disease.

**Oblo Law as to Public Buildings, Extended.**—Section 2572 of the Revised Statutes of Ohio has another time been amended, in this instance extending the penalties which it denounces for not providing proper exits, means for extinguishing fires, or not having the required inspector's certificate relating thereto, to the owner or person having control of any college, academy, seminary, infirmary, sanitarium, children's home, or other building used for the assemblage or betterment of people, in a municipal corporation, or in a county or township of the State, which county or township provision is also a new introduction

to the section, and will equally apply to the owner or person in control of a hospital, medical institute, asylum, opera house, hall, theater, church, or school house, previously being the persons mentioned in the law.

**Tobacco and Cholera.**—A recently published report of investigations of the effects of tobacco during the epidemic of cholera at Hamburg states that there were no live microbes after twenty-four hours in the cigars made up with water containing 1,500,000 cholera microbes to the cubic centimeter. There were no traces of microbes to be found in any of the cigars manufactured at Hamburg during the course of the epidemic. The microbes die in half to two hours exposure to tobacco smoke, Brazil, Sumatra or Havana tobacco. The smoke of any cigar kills the microbes. The smoke kills in five minutes all the microbes in the saliva. Another fact established is that none of the persons employed in the tobacco factories at Hamburg, contracted cholera.—*Gaz. degli Osp. e delle Clin.*, August 20.

**Typhoid Fever Cause by Ice Cream.**—According to the *Boston Medical and Surgical Journal*, August 27, a considerable, but not widely extended, outbreak of typhoid fever occurred during the latter part of July in the town of East Barrington, N. H. The cases were all traced to a single source. The first case was an unrecognized one, the patient being unwell but helping about the house and doing part of the milking. It is supposed that he must have in some way contaminated the milk, as by going to stool and not washing his hands before returning to his milking. The water supply was carefully examined and found to be all right. On Friday evening a party was given at the house and the guests were given ice cream made at home from the milk supply above referred to. Within the next ten or fourteen days fourteen of the guests came down with typhoid fever—eight in the town of Barrington, of whom one died; two in Lee; one each in Dover, Rochester and Woodbury, N. H., and one in Haverhill, Mass. All of these out-of-town cases were guests at the party. No other cases occurred in the town, and all were partakers of the cream.

**The Offensive Water-Supply of Brooklyn.**—The *New York Times*, September 5, refers as follows to the water-supply of Brooklyn, that has been the source of numerous complaints during the past two months: "The people of Brooklyn will read with a feeling of relief that the reports which show that at last both the Department of City Works and the Health Department are engaged in a thorough investigation concerning the condition of the water-supply. The engineers are inspecting the several sources from which water comes, and the Health commissioner has been authorized to spend a little money for the chemic and bacteriologic analyses which are needed. The examination of the water in the reservoir of final distribution seems to prove that the supply has not been polluted at the sources, but is affected injuriously after it has passed into the mains and delivery pipes.

"In some parts of the city the water has been bad for many weeks. It may not have been loaded with the germs of the so-called water-borne diseases, but it has been repulsive in appearance and odor and clearly unfit to be used. It is probable that the health of the people has suffered but little by reason of the presence of the objectionable matter in the supply, but even if this matter be only a vegetable growth the accumulation of it in a condition of decay should be prevented, because the presence of it can not be beneficial and may be injurious to consumers. With respect to the treatment of this problem there has been inexcusable delay. It is admitted by the Department of City Works that the water has been in this bad condition for about two months. The facts now disclosed by recent inquiry might have been ascertained some weeks ago. They should be used promptly and with energy now and the good name of the Brook-

lyn water-supply should be restored if an effective method of purification can be devised."

The Mayor of Brooklyn has given to the Department of Health, from the emergency account, the sum of \$3,000 to be expended upon a survey of the water-sources, reservoirs and conduits. It is believed that the city authorities have been awakened to the importance of a permanent bureau of water-investigation—both chemic and bacterial—to be located upon the water-shed, and at some distance from the city. It is the estimate of those who are expert in the establishment of such a laboratory that not less than \$20,000 will be needed, in the first year, for plant and running expenses. It is probable that this grant will be made, and be placed in the hands of the Department of Health.

**Higher Education in Missouri.**—State Superintendent of Schools, John R. Kirk, who has just finished the examination of applicants for admission to the medical colleges in the cities of St. Louis, St. Joseph and Kansas City, has made his report public. The examinations were carried on under the direction of the State Board of Health and were the result of the agitation last winter against the wholesale graduation of licensed physicians who were incompetent to practice their profession and were a menace to the public health. Although the examinations prescribed by Superintendent Kirk were not severe and were calculated to test the student's general information, and did not require a technical knowledge of any of the branches touched upon, over one-half of the prospective medical students failed to pass them. On this account the outlook for a large or even fair matriculation of students for the coming year is very poor. Of the three cities visited by Superintendent Kirk, only twenty-four applicants took the examination, and of these only eleven succeeded in passing. Last year at this time there were nearly 100 freshmen already admitted to the three medical colleges in Kansas City alone. Dr. Willis P. King, secretary of the State Board of Health, who has been more instrumental perhaps than any other member of the board in securing the new regulations, defended it with much vigor.

"I am heartily in favor of the new system," he said. "It can not help but effect a great and beneficial change in the present way of turning out incompetent doctors. We have in this State between fifteen and eighteen so-called medical colleges. That is a third more than in the State of New York and twice as many as there are in any other State. Our schools have been like brick mills. All that was necessary was enough mud, and the doctors were manufactured as fast as the machines could be operated. I look for many of these little institutions to close, for the licensing of young and incompetent men to go out into the State and experiment on helpless citizens is a crime and an outrage which I propose to try and stop. There are too many incompetent physicians now, and the rapid overproduction of them is alarming to one who knows what butchery and death their ignorance can cause. The State Board of Health will keep up its fight, and in time we hope to rid the State of this class of practitioners."

Other States would do well to follow the example of Missouri.

**Medical Diplomas in Michigan.**—A great many inquiries are received at the department of State in regard to the existence of a law providing for the registration of physicians, and frequent questions are asked as to the validity of certain diplomas, issued without examination or residence, and ostensibly entitling their possessors to the right to practice in Michigan. As an example of this class of correspondence, the following extract from a letter received by Secretary of State Gardner from a Canadian attorney, may be quoted:

"Is it necessary for a physician to register with any State medical association or council before he can lawfully practice medicine in your State. Is the diploma of the Wisconsin Eclectic Medical College, of Milwaukee, conferring the degree of M. D. (without residence or examination), upon a pharmacist duly licensed by the province of Ontario, sufficient in and by itself, to permit its holder to practice the profession of medicine, in all branches, in your State?"

The reply of Secretary Gardner contains information of interest to the holders of fraudulent diplomas, as well as to the county clerks who have in many cases registered them, supposing such registration compulsory under the law, although well knowing the fraudulent character. The reply was as follows:

"Registration of diplomas is required only in the office of the county clerk. No State board or council passes upon the validity of diplomas. There is nothing in the law requiring or authorizing a county clerk to register a bogus diploma, *i. e.*, one issued without residence or examination. The act refers to the 'graduate' (presumably in the usual sense), of any legally authorized medical college, and elsewhere provides for the return by supervisors of graduates of 'regularly established and reputable colleges.' To this category the possessor of a diploma issued by a fraudulent institution evidently does not belong."

## ASSOCIATION NEWS.

### Section on Obstetrics and Diseases of Women.

Milo B. Ward, Chairman, Topeka, Kan.; George H. Noble, Secretary, Atlanta, Ga.; Executive Committee, Jos. Eastman, Indianapolis, Ind.; F. H. Martin, Chicago, Ill.; J. T. Johnston, Washington, D. C.

As an effort has been made to keep a mailing list of the members of the AMERICAN MEDICAL ASSOCIATION interested in the Section on Obstetrics and Diseases of Women, please be kind enough to publish a notice to the effect that all members desiring to participate in the proceedings or to attend the meetings of this Section should send their names and addresses to the undersigned, as no communication concerning papers, program, etc., can be had with members not upon the proposed list.

Most respectfully,

GEO. H. NOBLE, Sec'y, 186 S. Pryor St., Atlanta, Ga.

Other medical journals please copy.

### The Ophthalmologic Section Reprint.

Gentlemen desiring to subscribe for the reprint of the Ophthalmologic Section, 1896, will please send their names to this office at once. Unless seventy-five subscriptions are received the volume will not be printed.

## SOCIETY NEWS.

**Utah State Medical Society.**—The second annual meeting of the Utah State Medical Society will be held at Salt Lake City, Utah, October 6 and 7. Program: Address of welcome, Hon. Heber M. Wells, Governor of Utah; The etiology and management of suppurating pleurisies, Philo E. Jones, Salt Lake City; Amputation of thigh for tuberculosis of knee joint, with cases, H. J. Powers, Ogden; When and how should the State assume sanitary control in new settlements? Maj. A. C. Girard, Surgeon U. S. A.; Neurasthenia, R. W. Fisher, Salt Lake City; Auto-intoxication, Augustus C. Behle, Salt Lake City; Suppurative Keratitis, S. L. Brick, Ogden; A report of some cases of skin grafting in the treatment of burns and ulcers, S. H. Allen, Provo; Lead poisoning, K. A. Kjos, Salt Lake City; Irregularities of typhoid, Chas. F. Wilcox, Salt Lake City; Evolution and revolution in pelvic surgery, H. D. Niles, Salt Lake City; Hysterectomy, F. S. Bascom, Salt Lake City.

**National Association of Nurses.**—A convention representing different training schools and alumnae associations, met September 2, in order to organize an association of nurses, which shall cover the United States and Canada. A constitution was drafted which will be submitted to the different bodies represented for their ratification. The object of the proposed association is to unite, protect and elevate the profession of nursing, and in drawing its outlines those of the medical associations have been to some extent copied, and the preamble of the AMERICAN MEDICAL ASSOCIATION largely

drawn upon. The training schools and alumnae associations included in this convention were the Royal Victoria; the Toronto General; the Massachusetts General; the New Haven; Presbyterian of New York City; Bellevue, and the New York; the Brooklyn City; the Orange Memorial; the Pennsylvania; University of Pennsylvania, and the Philadelphia; the Johns Hopkins; the Garfield; the Rochester City; the Illinois; the Farrand; and St. Luke's, Chicago.

**Virgolia State Medical Society.**—This society began its twenty-seventh annual session at Rockbridge Alum Springs, Va., September 8-10, with a large number in attendance. The session, was opened by an address of welcome from Hon. A. H. Graham, of Texas, on the part of the Springs management. This was followed by an address to the public and profession by Dr. C. T. Brady of Marion, Va. His subject was "Moderation and Aim in Education." The speaker dwelt with especial emphasis on the importance of universal temperance and the avoidance of excesses in youth. Other interesting papers followed. The officers chosen for the ensuing year were President, George Ben. Johnston of Richmond; vice-presidents, W. C. Day of Danville, T. W. Simmons of Martinsville, L. H. Keller of Luray; recording secretary, Landon B. Edwards of Richmond; corresponding secretary, Jno. F. Winn of Richmond; treasurer, Richard L. Styll of Hollins. J. Allison Hodges was elected to deliver the address to the public and profession at the next annual session at the White Sulphur. Dr. Hunter McGuire's prize of \$100 for the best essay on the status of serum therapy was awarded to Dr. Charles M. Blackford of Lynchburg.

**Wayne County Medical Society.**—At the regular meeting of the Wayne County Medical Society, Thursday evening, September 10, Dr. R. Harvey Reed read a paper on "Malignant Neoplasms." The meeting was well attended. Dr. Theo. A. McGraw, in discussing the subject, said: "The subject of malignant neoplasms is such a large one that one hardly knows where to begin in discussing it. It has been the prevailing opinion, until very recently, that all of these troubles arise exclusively from local conditions or local irritations, and that there is nothing constitutional about a cancer or sarcoma or any other tumor in the beginning; that is to say that whatever is constitutional is the result, not the cause, of the affection. I think that modern pathologists will hardly concur now in the theory of the purely local origin of cancers and tumors without being able, nevertheless, to closely define what there is in all neoplasms that is constitutional. I believe that there is something constitutional in every neoplasm or growth, not only of a malignant form, but of a so-called local or benign form, and that the origin in some way takes place directly from the cells which compose it, and that they begin to grow rapidly. I can conceive no other way to account for the growth of any tumor unless there is that loss of control upon that part of the organism so that the cells multiply and the part enlarges and grows just so fast and no faster, in other words, the control which allows of tissue growth just sufficient to the needs of the organism; in the case of benign tumors the check on multiplication is not so entirely lost as in some forms of malignant growths. When we have a growth of any tumor, it means that whatever it is that keeps away or retards growth in that part, has been lost or has been weakened, so that my conception of a tumor is something constitutional. Now the Doctor has described very well the different forms of malignant growths to which we have to adapt our means of treatment. The only treatment in my estimation is complete and thorough extirpation. Toxin has been tried in malignant tumors of every description in St. Mary's Hospital, and in private practice, and in no one case have we had any success whatever. I was talking with some New York surgeons when we had them here, and their report was that no one excepting Dr. Coley had

had any success with toxins in the treatment of malignant growths. Now I do not think just as Dr. Reed says, viz., that there is one case in a hundred curable by this morbid treatment, but the future may open up the possibility to us of something good. As far as our present knowledge is concerned there is just one thing to do with a malignant tumor, and that is to extirpate it, and extirpate it thoroughly, and if there is one need that modern surgery has now it is the perfecting of radical methods of operation. The surgeon does not see all cases of cancer or sarcoma. Why, just take cancer of the neck of the uterus and turn it over to the surgeon. He operates and expects to cure his patient. The surgeon should always be consulted in cases of malignant growths; the sooner the better; the earlier the more chance for final cure and the saving of life."

Dr. Hal C. Wyman said: "I would like to call attention to some successful methods and some unsuccessful ones. The particular notion in regard to cancer, and I use the term in a general sense, is that it is something that is to be helped by some irregular or clandestine method or operation, and for that reason quacks thrive. It is my belief that the regular physician may accomplish a great deal by constantly preaching the absolute necessity of early operation. If he will call up to the minds of the laity or patients suffering from carcinoma or sarcoma, that under modern methods of asepsis, and under anesthesia, the removal of these growths, when done early, is not fraught with much danger to life, or with any pain; in other words, that the removal of these neoplasms, when done by a scientific surgeon, is not essentially dangerous. If he will bring out these facts prominently before the public we could see these cases earlier and could have the privilege of removing tumors in time. The early removal of these tumors frequently leads to their non-recurrence. Even when they reappear a second time or a third time, or even a fourth time, removal has finally been followed by non-reappearance. I can see the necessity for the public to understand the need of early operation, and if they would only realize the fact that under anesthesia there is no pain and almost absolute safety, and also that with asepsis the danger from the wound is only a minimum, they would appear earlier for operation. So far as the operation is concerned it may be performed, except in rare cases without much danger, and it is the duty of every medical man to use every means in his power to secure an early operation. I am sorry that the profession is so at sea in regard to the matter, but we may find something in the future that will be of service to us. I can see the possibility of some antitoxin for cancer, like the diphtheritic antitoxin, and one which may take the place of operation. I would not say one word against the endeavor that is being made to find a cure. I think when a physician allows one of these cases to leave his hands and turns it over to the quack, he does wrong. I am glad that we have a little hope in regard to the possibility in the near future of the discovery of some toxin or antitoxin which will prove curative."

Dr. R. Harvey Reed, in conclusion, said: "You are all well aware of the fact that cancer and consumption have from the most ancient times been looked upon by the laity as incurable, and that is the reason why, as my friend, Dr. H. C. Wyman, says, these patients go to the quacks, because the quacks hold out luring inducements, the like of which we are not permitted to advance on account of our medical ethics. I hope that whatever I have said here to-night will stir up the profession to investigate this matter, and above all means do not turn over these cases to some one who knows nothing about handling them, and above all things do not allow them to go to the so-called quacks. It is the combined study, the combined work upon these diseases, that helps us in the treating of them. I believe that in the study of these diseases that we should, as do our explorers of the North Pole, keep right on, no matter what the result. In other words, keep right on till you get there."

## NECROLOGY.

CHARLES H. CHALKLEY, M.D., at Richmond, Va., of inflammation of the brain, September 13, aged 36 years. He graduated from the Richmond College and entered the Medical College of Virginia, from which he graduated in 1880. Soon after he became a physician, he was appointed adjunct professor of chemistry at the Medical College of Virginia. He held this position until the University College of Medicine was established when he accepted the chair of chemistry and also became professor of medical jurisprudence and toxicology, which he held up to the time of his death. He also held the professorship of chemistry at the Mechanics' Institute.

F. W. HANCE, M.D., a pioneer physician of Freeport, Ill., at his home in this city September 16, of heart disease. He was born in Ohio in 1822 and was graduated from the Medical Department of the University of Pennsylvania in 1849. He came to Freeport in 1853. He was elected mayor of the city in 1864 and also served as president of the Second National Bank.

D. J. MOSHER, M.D. (Detroit Medical College, Mich., 1869), at Norwich, N. Y., September 8.—Orin M. Ward, M.D. (Bellevue Hospital Medical College, New York City, 1877) at Duncan Falls, Ohio, September 14, aged 45 years.

JAMES EDGAR CHANCELLOR, M.D., at Charlottesville, Va., September 11. He was descended from a long line of Americans of English descent—the lineage running back to 1066. When Gaultier le Chancellor, as law officer of the crown, crossed over to England with William the Conqueror, as his chief legal advisor, the surname of Gaultier was dropped and it came by successive changes to be written Chancellor. From this family the name of the town of Chancellorsville is derived, a town made famous by the sanguinary conflict which took place there during the recent civil war. Dr. Chancellor was born in Chancellorsville, Va., Jan. 26, 1826; was educated at the classical Academy at Fredericksburg, Va.; matriculated as a student of medicine in the University of Virginia, session 1846-47, and graduated from the Jefferson Medical College, Philadelphia, 1848. Immediately after graduating he entered into an active practice, locating in his native county, at Chancellorsville. Subsequently he removed to Courtland, the county seat, where he enjoyed a large practice up to the outbreak of the civil war. In 1861 was commissioned assistant surgeon in the Confederate Army, and assigned to duty at the General Hospital, C. S. A., at Charlottesville, Va.; was commissioned full surgeon in 1862. In the spring of 1864 he was sent to the battle-fields of Wilderness, Spottsylvania Court House, and Richmond, as a member of the reserved corps company of surgeons.

In October, 1865, he was made demonstrator of anatomy in the Medical Department of the University of Virginia, which position he filled until shattered health, from a dissecting wound, necessitated his resignation in 1872. He was a member of the Medical Society of Virginia since 1871, and its president in 1883; permanent member of the AMERICAN MEDICAL ASSOCIATION since 1875, and the American Public Health Association since 1878. In 1885 he served as professor of diseases of women and children in the University of Florida at Tallahassee, and also filled the chair of anatomy in the same school; he resigned both chairs and, returning to Virginia, was appointed by the governor a member of the State Medical Examining Board in 1890. He has made frequent contributions to the literature of his profession, among which are named "An exhaustive paper on the origin and use of natural mineral waters of the United States;" "Ancient medicine, its history, etc.;" "Cremation and inhumation compared;" "Uses of iodoform in specific diseases;" "Removal of fibroid growth involving right parotid gland," 1863.

WILLIAM HENDERSON WILKES, M.D., died in Waco, Texas, August 14. He was born in Raymond, Miss., in 1833, and

enlisted in the Confederate Army as a private, from which he was retired with the rank of Brigadier-General. In 1868 he began practice in Waco, where he remained with the interval of a year during which he was a professor of obstetrics and diseases of children in Kansas City. In 1882 he was elected mayor of his city, and in 1885, was reelected. In 1888 he declined the chair of the theory and practice of medicine in the Texas Medical College in Galveston. In 1891 he became president of the Texas State Medical Association. In April of the present year he again became mayor of Waco, and died in office after an illness of six weeks. He was a graduate of the University of Nashville in 1855.

WILLIAM M. McLAURY, M.D., at New York City, September 8, of cerebral hemorrhage. He had been in poor health for some time. Dr. McLaury was graduated from the University of the City of New York, Medical Department, in 1860. He was a member of the New York County Medical Society, the Academy of Medicine, the Physician's Mutual Aid Association, the Northwestern Medical and Surgical Society, New York Society of Medical Jurisprudence and New York Academy of Anthropology.

WILLIAM CRANCH BOND FIFIELD, M.D., at Boston, Mass., of heart disease, September 10. He was born Aug. 27, 1828, in Weymouth, Mass. His family traced its ancestry beyond even early colonial days to England, where it gave the name to the town of Fifield. He was a graduate of Phillips Exeter Academy and of the Harvard Medical School in 1851. He went to England and took the full course in the Royal College of Surgeons. He was a licentiate of the Royal Ophthalmic Hospital and a member of the American Medical Society of Paris. From the beginning of his practice in Boston over forty years ago he took a high position in the profession. For fifteen years he was on the staff of Boston City Hospital and was on the consulting staff at the time of his death. He had also long been a fellow of the Massachusetts Medical Society.

EDWARD S. FARRINGTON, M.D., at New York City, September 7, aged 31 years. He was educated at Yale, and was a graduate of the College of Physicians and Surgeons of New York, class of 1892. Dr. Farrington was connected with the outdoor work of Bellevue and New York Hospitals.

WILLIAM R. BRICKER, M.D. (Medical Department of the Western Reserve University, Cleveland, Ohio, 1857) at Shelby, Ohio, September 7. He was among the oldest citizens of Shelby, practiced his profession there over 50 years, having celebrated his 51st anniversary September 5. He was born in Schaefferstown, Pa., October 6, 1820.

ALEXANDER H. McADAM, M.D. (Department of Medicine of the University of Pennsylvania, Philadelphia, 1863) at Philadelphia, September 9, aged 57 years. He was, for seven years, physician of St. Mary's Hospital, and since 1869 had been prominently connected with educational matters in Philadelphia.

WILLIAM M. KELLY, M.D. (Medical College of Indiana, Indianapolis, 1870), at Knox, Ind., August 28.

## MISCELLANY.

**For the Deaf and Dumb of Ohio.**—The law has been amended so that it now provides that no person shall be received in the institution for the education of the deaf and dumb of that State under 7 (instead of 8) years of age, or remain there longer than twelve (instead of, as heretofore, ten) years.

**The Megaloscope.**—The *Ungarisches Archiv f. Med.* No. 3, describes an instrument constructed on the principle of the telescope which magnifies the objects shown by the endoscope. The illustrations are specimens of the work of the megaloscope showing the finest details of various sections, urethritis granulosa, etc., in the natural tints.—*Wien. k. Rund.*, No. 33.

**Ohio Charitable Societies Can Sell Real Estate.**—Section 3,794 of the revised statutes of Ohio, providing when and how religious societies may sell, exchange, or mortgage their real estate, whether held in trust or not, has been amended, among other respects, by extending its application to any charitable society or association, and this whether the trustees are willing to take steps in the matter or not.

**Contrast Staining.**—Bacteria and cell-nuclei can be differentiated rapidly and easily by first staining the prepared dry section with a diluted watery solution of methylene blue, then rinsing it in water and after drying, placing it in a watery solution of eosin, 0.1 to 100, for one minute to a minute and a half. The eosin drives out the blue and takes its place in the tissues, while the bacteria retain the blue longer. This method is recommended in the *Deutsch. med. Woch.*, August 20, as exceedingly simple and sufficiently accurate for general purposes.

**Ink for Writing on Glass.**—*Nouveaux Remèdes*, August 24, describes a new ink that will write on glass, and can take the place of paper labels on bottles, etc., as it is indelible. It is made by dissolving 20 grams of brown lacquer (not heated) in 150 c.c. of commercial alcohol, and mixing this, a drop at a time, with a solution of 35 grams of borax dissolved in 250 c.c. of distilled water. It can then be colored as preferred; 1 gram of methylene violet, for instance, will produce a handsome ink.

**A Child in Legal Definition.**—In a case brought under a statute "for the prevention of cruelty to children," the supreme court of Georgia holds, *Collins v. State*, that the word "child" as used therein, means one of tender years, or a person between infancy and youth, and that a male person who has attained the physical strength and stature of manhood, and who is "almost as large as his father, but not quite as strong," is not a "child," in the sense in which the word is used in such law.

**Confirmation by Bacteriologic Diagnosis of Epidemic Cerebro-Spinal Meningitis.**—When Heubner announced his discovery on the living of the microbe of this disease, he remarked that lumbar puncture would become still more important as a means of differentiation. Fürbringer now reports several cases diagnosed by lumbar puncture promptly and accurately, with the discovery of the meningococcus intracellularis in the spinal fluid. The cultures showed the characteristic diplococci enclosed in the capsules which refracted the light like a halo around them. The cocci were often assembled in four, six and eight pairs, especially in the older cultures. The median dividing line in the pairs of cocci forming tetrads was very distinct and noticeable. Gram's solution usually decolorized them like the gonococcus, but occasionally the microparasites partially retained their coloring.—*Deutsch. med. Woch.*, August 20.

**New Jersey Law as to Indigent Insane Amended.**—The New Jersey statute of 1895, respecting hospitals for the insane and the admission of indigent patients thereto, was amended by an act approved March 26, 1896, omitting, in the first part of Section 1, the clause apparently tending to restrict its application to any county "in which there is a hospital for the insane," and providing that application for an investigation of a case may be made not only to any judge of the court of common pleas in such county, as heretofore, but also to any judge of a criminal court established in a city of the first class in such county, while police justices are deprived of jurisdiction.

**Provision for Ohio's Aged Deaf and Dumb.**—A law was passed in Ohio, April 27, 1896, providing that any incorporated association organized for the purpose of providing a home for aged and infirm deaf and dumb persons may enter into a contract with the board of county infirmity directors of any county for the care and maintenance at such home of any aged or infirm deaf and dumb person who may be an inmate of the county infirmity or who may, under the laws of the State, be entitled

to admission thereto. And in every such case the county in which such infirmary is situated shall, during the period such person may remain in such home, pay to such association, annually, a sum equal to the per capita cost of maintaining inmates in the infirmary of such county.

**Decision Relative to License to Practice in Colorado.**—Attorney General Carr has recently decided that the State Medical Board of Colorado has no right to revoke a license to practice except after conviction of some penal offense.—*Denver Med. Times*, September.

**Improvement in Transportation of the Wounded.**—Meyer of Berlin, has invented a new spring floor for ambulances which rests on four rubber balls  $1\frac{1}{2}$  cm. thick and  $12\frac{1}{2}$  cm. in diameter. The balls are filled with air and held in place by bowl shaped rests above and below fitted with springs. There can be two of these floors, one above the other to secure extra elasticity.—*Deutsch. med. Woch.*, August 20.

**Traces of Poisons in Normal Urine.**—Kossa accidentally noticed indications of poisons in normal urine, and further investigations confirmed this experience, disclosing traces of arsenic, copper and mercury in the urine of numerous healthy individuals examined. He is inclined to think that these substances are not totally eliminated by the organism, and that in time the accumulated amounts might have an important bearing in certain medico-legal cases.—*Wien. kl. Rund.* No. 33, from the *Ungar. Arch. f. Med.*, No. 3.

**Petroleum from Linseed Oil.**—The paper read by Professor Sadtler at the recent A. Ph. A. meeting was a record of some very interesting experiments upon linseed oil. It was shown that by subjecting this oil to destructive distillation, under pressure, various products identical with certain petroleum hydrocarbons can be produced. This fact is of greater significance than is at once apparent. It bears directly upon and affords proof of one of the two theories regarding the origin of petroleum. These theories are, one that petroleum is of animal, the other that it is of vegetable origin. Possibly both are true. Without discussing the theory of animal origin, Professor Sadtler's results would seem to prove the theory of vegetable origin. *Pharm. Era*, September 10.

**Ohio's New Execution Law.**—By law passed at the recent session of the Ohio legislature, the mode of executing a death sentence must, in every case, for a crime committed after July 1, 1896, be by causing to pass through the body of the convict a current of electricity of sufficient intensity to cause death, and the application of such current, it says, must be continued until the convict is dead. This must be done by the warden of the Ohio penitentiary, or by a deputy, not only within the walls of the penitentiary at Columbus, but also within an inclosure so constructed as to exclude public view. Moreover, all such executions or electrocutions, must take place before the hour of sunrise of the designated day.

**Healing of Wounds among the Negroes of Africa.**—A surgeon writes to the *Deutseh. med. Woch.*, August 20, from Kamerun, expatiating upon the almost miraculous way in which the wounds of the negroes there heal without complications. He describes a dozen cases of severe wounds, among them five received while out on an expedition, compelled to march through pouring rain with no food but wild bananas, and exposed to the constant fire of the natives at close range, the bullets often nothing but scraps of iron so that the wounds resembled those made by an explosion, and with no surgical attendance for twenty-one days, as it was not a military expedition. The recoveries were rapid and complete with no complications; in some cases a surprising lack of sensitiveness in the parts wounded. He is inclined to ascribe this extreme power of reaction to a race peculiarity, as the absence of wound infecting bacteria in the primeval wilds is not absolutely estab-

lished, although they must certainly be rare. In fifteen months of residence there he has never heard of such a thing as puerperal fever, and has only had one phlegmon in 906 patients treated. He remarks in conclusion that the surgeon in West Africa is certainly justified in proceeding with the utmost audacity in the conservative treatment of his black patients.

**Russian Jury Discounts Expert Testimony.**—In a recent case where a young wife admitted killing her husband, it was brought out that she had a sister who evinced a sudden aversion to her husband on the night of her marriage, and, thereafter being placed under medical observation a report was rendered by the expert that she had probably committed the crime while suffering from the psychologic equivalent of epilepsy, it being observed that she frequently suffered from such complete absences that she did not recognize those around her and that in these instances there was a complete failure of the reflex action of light upon the eye; yet, notwithstanding this expert testimony, she was placed on trial by jury, convicted and condemned.

**Ohio Institutions to be Inspected.**—An Ohio law was passed in April, 1896, which provides that every private or public hospital, reformatory home, house of detention, private asylum and any institution exercising or pretending to exercise a reformatory or correctional influence over individuals in the State of Ohio, shall be open at any and all times to the inspection of the commissioners of the county in which such institution is situated, or the board of health of the township, or other municipality in which any such institution is situated. It also makes it the duty of each and every county commissioner to visit, unannounced, every such hospital and other institution in his county at least once in every six months, to note the sanitary condition thereof, and the condition and treatment of the inmates thereof. And it shall be the duty of the county commissioners to file a full and complete report of the investigations of such institutions with the prosecuting attorney of the county, which report shall be open to the examination of the public. Any official agent or employe, or other person refusing to permit or in any manner interfering with the inspection of any such hospital or other institution, by the county commissioners of the county, or by the board of health of the municipality in which the same is situated, shall be deemed guilty of a misdemeanor, and shall, upon conviction, be punished by a fine of not less than \$25, or six months' imprisonment, or both, and for each subsequent offense a fine of not less than \$100 and six months' imprisonment.

**The Peppermint King**—According to the *Chemist and Druggist*, July 25, Mr. H. G. Hotchkiss of Wayne County, New York, bears appropriately the above title. About fifty years ago that gentleman kept a store at Phelps, near the Wayne County line in the peppermint belt. Mr. Hotchkiss had taken peppermint oil from farmers in payment for goods until he had on hand so much of it that he would lose money if he could not dispose of the lot for \$1,000. The problem was to find a market for all that oil from an unknown peppermint-producing district. He put his oil in tin cans and took it to New York City. None of the drug houses would buy it, because they did not believe that it was pure. This emergency brought the business ability of Mr. Hotchkiss to the surface. The now old-fashioned 21-ounce, lipped ink bottles had just come in and Mr. Hotchkiss purchased a lot of them, removed his peppermint oil from the tin cans, and after satisfying himself that it was as pure as any oil then on the market, placed it in the bottles, hermetically sealing them, and consigned the oil to a house in Hamburg, naming his price if the oil was accepted. At the end of several months' waiting Mr. Hotchkiss received a draft for the amount he had asked for his oil and an order from the Hamburg house for another consign-

ment. Most of the oil was sold back by the German firm to the dealers in New York who had refused to have anything to do with it when Mr. Hotchkiss offered it to them at first hand. The demand for Wayne County oil grew so rapidly that the cultivation of peppermint became the chief occupation of the Wayne County farmers. Mr. Hotchkiss gave up all other engagements and devoted his whole attention to the growing and distilling of peppermint. The average annual yield of peppermint oil in Wayne County is now 150,000 pounds, nine-tenths of which is controlled by the Hotchkiss family of Lyons. Mr. Hotchkiss still packs the Wayne County oil in bottles made after the exact pattern of the bottles in which his original shipment to Hamburg was packed in 1844. For years the Wayne County oil was considered by the trade superior to all others, but the distinction between Wayne oil and Michigan oil has now been dropped from most of the New York price lists.

**Are Deaths from Aesthetics due to Failure of the Respiration or of the Circulation.**—Despite the dicta and the experiments of Surgeon-Colonel Lawrie of the British army to the effect that the breathing claimed the undivided attention, the *London Lancet* has been engaged in a series of exhaustive inquiries. The members of its commission have investigated 716 deaths from chloroform.

The report presents three series of cases: Series A, derived from the report of the Committee of the Royal Medical and Chirurgical Society, contains 86 cases of death under chloroform; series B, derived from an analysis of the fatalities recorded between the years 1860 and 1891 in various British and foreign publications, contains 596 cases, and series C, derived from the inquiries made by circulars, contains 27 cases from hospitals and 7 from private practice. All these were carefully examined in such a way as to eliminate, as far as possible, the personal belief of the examiner, and to preserve only what had been placed on record by competent persons who were present when death occurred. According to this testimony, in the 716 deaths from or during the administration of chloroform, the pulse was observed to fall first certainly in 183, and probably in 44 more, or more than 31.5 per cent. The respiration was noted to fail first in 73 cases, and probably in 7 more, or only about 11 per cent. Both functions are said to have failed simultaneously certainly in 58 cases and probably in 19 more; and in 322 the point was not noted with sufficient accuracy to justify the statement of any conclusion. But the fact remains that, in nearly one-third of the whole number of fatalities, the recorded opinion of those present was in favor of the result having been due to the failure of the heart rather than to failure of the respiration. It is pointed out, also, that experiments on animals are apt to be misleading, because the subject selected would usually be healthy, while most human subjects in the operating room are diseased. It is suggested, also, that deaths during surgical operations not of a severe kind sometimes occurred before the discovery of anesthetics and were vaguely attributed to shock. The cause, whatever its nature, probably still exists, and its victims are charged to anesthetics. The objection to ether as an anesthetic by most English surgeons has been based chiefly upon the slowness with which it operates and the distress which its administration causes to many patients. Both these disadvantages have now been overcome by combining nitrous oxid with the ether fumes until unconsciousness is produced. Instead of the ether cone an apparatus similar in some respects to that in a well-equipped surgeon-dentist's office is employed. The patient breathes easily into the mouthpiece, the first three or four inhalations being of the gas alone. The ether fumes are gradually substituted. In two minutes the patient is unconscious, and there is no choking or distress such as the ether alone often produces. The latest report upon the possible dangers of chloroform is likely to lead to the rapid introduction in this country of this new and safe form of anesthesia.

**To Recover Medical Expenses.**—In cases of personal injury of a plaintiff through the negligence of a defendant, the supreme court of California says that there is no doubt but that, under a proper pleading, the injured party may recover for such necessary medical expenses as he may have become liable to pay though not in fact paid before suit brought. But the allegation of the complaint must correctly describe the expense as to being one that had been paid or simply incurred. Thus, the court reverses, in *McLaughlin v. San Francisco & S. M. Ry. Co.*, decided July 31, 1896, a judgment for the plaintiff, holding that evidence that the plaintiff had incurred a liability to

pay \$750 was not admissible under the allegation of his complaint that in attempting to be cured he had necessarily expended, in doctor's bills, the sum of \$750.

### Hospitals.

THE VIRGINIA HOSPITAL, Richmond, Va., which has undergone most extensive repairs and improvements, after having obtained a handsome and commodious addition, is receiving patients again, after having been closed since July 1. The entire building has been remodeled, and taken in connection with the commodious "John Pope Annex" just completed, makes this one of the most modern and best equipped hospitals in the South.

NEW YORK FLOATING HOSPITAL WORK.—There were 46,253 women and children carried on the Floating Hospital during the season of 1896. More than seven hundred cases of severely sick children were treated in the wards without a death taking place on board.

## THE PUBLIC SERVICES.

**Army Changes.** Official List of changes in the stations and duties of officers serving in the Medical Department, U. S. Army, from Sept. 12 to Sept. 18, 1896.

Captain William B. Davis, Assistant Surgeon, is relieved from duty as Attending Surgeon and Examiner of Recruits in New York City, to take effect upon the completion of his examination for promotion and ordered to Fort Brady, Mich., relieving Captain Charles Richard, Assistant Surgeon. Captain Richard, upon being thus relieved is ordered to New York City as Attending Surgeon and Examiner of Recruits.

Captain Louis Brechemin, Assistant Surgeon, is relieved from duty as Attending Surgeon and Examiner of Recruits, Baltimore, Md., to take effect on completion of his examination for promotion, and ordered to Fort Sherman, Idaho, for duty.

Captain W. Fitzhugh Carter, Assistant Surgeon, will be relieved from duty at Fort Sill, Oklahoma Territory, Oct. 1, 1896, and ordered to Baltimore, Md., as Attending Surgeon and Examiner of Recruits.

First Lieutenant William E. Purviance, Assistant Surgeon, is relieved from duty at Fort Sherman, Idaho, and ordered to Fort Columbus, New York, for duty relieving First Lieutenant Thomas J. Kirkpatrick, Jr., Assistant Surgeon. Lieutenant Kirkpatrick, on being thus relieved, is ordered to Fort Douglas, Utah, for duty relieving First Lieutenant George D. DeShon, Assistant Surgeon. Lieutenant DeShon, on being thus relieved is ordered to Washington Barracks, D. C., for duty.

**Navy Changes.** Changes in the Medical Corps of the U. S. Navy for the week ending Sept. 19, 1896.

Medical Inspector Daniel McMurtrie, promoted to medical director from September 8.

Surgeon L. G. Heeneberger, detached from naval hospital Wldow's Island, Maine, ordered home, and then await orders.

### Change of Address.

Brooks, S. D., from St. Louis, Mo., to U. S. Marine Hospital, Port Townsend, Washington.

Hull, Geo. S., from Chambersburg, Pa., to Pasadena, Cal., Box 176.

McGahan, C. F., from Bethlehem, N. H., to Aiken, S. C.

Pritchard, W. B., from 347 W. 58th street, to 105 W. 73d Street, New York, N. Y.

Reichman, Max, from 624 S. Center Avenue, to 616 W. 12th Street, Chicago, Ill.

Woodbury, Frank, has returned to his office and residence at 218 S. 16th Street, Philadelphia, Pa.

### LETTERS RECEIVED.

Ayer, N. W. & Son, Philadelphia, Pa.; Alma Sanitarium Co., Alma, Mich.; Alta Pharmacal Co., St. Louis, Mo.; Allenburger, C. A., Shelby, Neb.

Blodgett, F. J., New York, N. Y.; Battle Creek Sanitarium, Battle Creek, Mich.

Christopher, H., St. Joseph, Mo.; Cantrell, G. M. D., Little Rock, Ark.; Cleaves, Margaret A., New York, N. Y.

## ORIGINAL ARTICLES.

### OTO-MASSAGE IN SUPPURATION OF THE EAR; ITS VALUE FOR THE RELIEF OF DEAFNESS AND IN THE TREATMENT OF THE SUPPURATION.

Read by title in the Section on Laryngology and Otolaryngology, at the Forty-seventh Annual Meeting of the American Medical Association, held at Atlanta, Ga., May 5-8, 1896.

BY LOUIS J. LAUTENBACH, A.M., M.D., Ph.D.

Surgeon to the Pennsylvania Eye and Ear Infirmary; Nose and Throat Physician to the Odd Fellows' Home; Late Chief of the Eye Clinic of the German Hospital, etc.

PHILADELPHIA, PA.

Upon several occasions I have presented various aspects of oto-massage, but, beyond having noted in one of my papers that I considered the deafness occasioned by suppurative disease of the middle ear peculiarly favorable in its reaction to massage, I have not publicly considered suppurative disease in connection with the subject. I have often been asked the value of the method in the deafness and tinnitus, the results of suppurative disease. On expressing my opinion that it was of especial value in both conditions, I have naturally been led to explain why this was the case.

In considering the value of massage in the treatment of cases of suppurative disease or of the defects from suppurative disease, the subject naturally divides itself into two parts: 1, the consideration of its application and value in cases undergoing suppuration; 2, its importance in those in which the suppuration has ceased, deafness being present with or without tinnitus.

Eliminating for the present all the acute suppurative cases, those attended with extreme pain and swelling of the parts, we will study a typical case of chronic suppurative disease. It will present, in addition to the discharges, which may be meagre or profuse, watery or ropy, colorless, pustular or bloody, a greater or less degree of deafness with or without tinnitus, accompanied usually by a full or swollen feeling within the ear, with perhaps a little tenderness and with occasional attacks of pain.

The usual treatment for such cases has been careful cleansing of the meatus and middle ear, usually by syringing with warm or medicated water, followed occasionally by cleansing with peroxid of hydrogen solution, and then after thoroughly drying the ear with cotton and perhaps using the Politzer bag or the Siegle speculum, or both, the insufflation of some drying or absorbent powder, such as aristol, iodoform or boracic acid. The ordinary mild cases are apt to do fairly well under such routine treatment, especially if it be persisted in, and they often develop a decided improvement in hearing, as well as a marked diminution and, frequently, an entire cessation of the ear discharges.

In contradistinction to this the dry method is used by many. The meatus is carefully wiped out with

cotton, after which, if a probe can be passed through the perforation, the middle ear is cleansed as thoroughly as possible. Then by means of the Politzer air bag and Siegle speculum, the discharges lying low down in the ear are forced toward and through the perforation in the membrane and the middle ear and meatus are again cleansed with dry cotton, after which drying powders are used.

An objection to be urged against the first method above outlined is the syringing of the ear. In my opinion this, in many cases, prevents the cessation of the discharge; the water or medicated liquid finds its way into the deeper parts of the ear and not being removed, lies there and acting as a foreign substance, excites irritation and inflammation in the surrounding tissues and thus increases the amount of the discharge. Of late, the dry method has come more and more into vogue. It has the advantage of removing foreign matters from the ear cavity without subjecting the ear to the possible disadvantages of having the pus replaced by other foreign particles. But both methods fail in entirely removing the exudated materials from the middle ear cavity—the former method washing out much of the discharge and diluting the rest—the latter removing considerable but allowing some of the discharge to lie on the floor of the tympanum, as well as leaving a layer of the discharge adherent to all the surfaces and an especially large amount to remain in the attic and on the ossicular structures. In these cases to remove the discharges which otherwise are irremovable I employ massage instruments, using them as cleansers and dryers of the middle ear cavity. To illustrate this method of using massage I will briefly outline the treatment of an average case of middle ear disease with suppuration. Finding that I am dealing with a case of suppuration of the chronic type, I dry out the meatus with a cotton-covered probe and if the perforation in the drumhead be sufficiently large to allow of it, I by the same means cleanse the middle ear as much as I am able, then by the Siegle speculum I suck out as much of the pus as possible and dry the meatus once more, then I inflate with the Politzer bag and force out a little more discharge, which I remove with the dry cotton. I then apply to the patient a pneumo-massage apparatus of medium strength and gradually increase the suction. I succeed in drawing into the meatus and about the perforation of nearly, if not, all of the discharge which may have adhered to the crypts and along the walls of the middle ear. After drying with cotton, I once more use the pneumo-masseur and again dry, after which I use the drying powders or astringent antiseptics, if any of these be necessary. If the ear discharge be too thick or too firm for removal in this manner I then soften the discharge by the use of 3 per cent. solution peroxid of hydrogen, after which I proceed as above outlined.

In using the pneumo-masseur for the purpose of

removing the adherent discharges from the middle ear cavity, I try to use it as forcibly as necessary without in any way imperiling the integrity of the structures, especially avoiding the production of any hemorrhage. I have found by experience that I can usually commence with an exhaust pressure of two ounces to the square inch, and gradually increase it to about half a pound to the square inch, often as much as a pound, and rarely up to two pounds to the inch. With an exhaust from half a pound to a pound, the discharges are usually quickly removed, in from three to ten minutes, 300 or less strokes per minute usually sufficing.

Previous to my using the metronomic masseurs, I endeavored to accomplish this same effective cleansing by the use of the Siegle speculum but, necessarily, the results were indifferent. Since I have used the pneumo-masseur in the manner described I find that I can stop the suppuration more quickly than formerly, and often accomplish this result without any therapeusis to the ear whatever. This, however, is not usually the case, and to a considerable extent I rely upon stimulating and drying powders in connection with thorough cleansing and drying.

In acute cases I apply the suction massage just as soon as is possible, believing that adhesions, ulcerations and destruction of the tissues result often from the pressure of the discharge, from its direct corrosive effect and its fermentative results as well as from the progress of the inflammatory affection.

As soon as the pain is sufficiently allayed so that the treatment is bearable, I apply to the ear either the metronomic ear masseur or a little electric suction pump and clear the middle ear of all its discharges and accumulations. By securing a clean surface early in the course of the disease I hasten reparative action and avoid the ofttimes destructive effects of the decomposition of unhealthy pus.

These ear discharges lying in the middle ear, envelop the ossicles, fill up the space between the promontory and the membrane, and generally occupy all possible spaces, gluing all together. As a result of this we have occasioned abnormal adhesions between the ossicles and between the ossicles and the surrounding walls, as well as occasionally ligamentous bands between the membrane and surrounding structures; again, in other cases, the disease results not in a tying together of the various parts, but a rending asunder of normal structures, in ulcerations, necroses and sloughings.

In the one case we have ankyloses, adhesions, abnormal growths and thickenings followed often by sclerotic changes, in the other we have necrotic changes with often loss of one or more of the ossicles or greater destruction of the tympanic membrane or ulceration of the mucous lining of the middle ear with inflammation extending, perhaps, into the mastoid or involving the internal ear. It is on account of these often serious results that there is an urgent necessity for prompt action, with the idea of restoring the parts as soon as possible to as nearly a normal condition as can be attained. It is therefore necessary if anything can be gained by pneumo-massage, to apply it as early as is admissible.

In some cases I have used the masseur during the acute stage of the attack with marked benefit, allaying the pain and for the time being increasing the amount of suppuration and apparently shortening the attack. I presume the reason for this is that

much of the pain in these cases is occasioned by the retention of the discharges, the tissues being filled with discharges which, finding no outlet, have commenced to burrow more and more deeply, the infiltration ever extending, and when the pressure from the central inflammatory area is released by means of the exhaust apparatus, the tissues adjoining empty themselves of their contained discharges, thus relieving much of the abnormal tension of the surrounding infiltrated zone, the lessening of the pressure relieving the pain, and the frequent application of the method tending to prevent extension of the inflammation.

From my experience with this method of cleansing the ear, I am convinced that there would be fewer cases of secondary involvement of the internal ear if the practice above outlined was more generally followed. When we consider that the cases of internal ear disease are the most difficult and unsatisfactory with which the ear surgeon has to deal, the necessity of their avoidance is evident. I know of no other measure of relief which exercises such a powerful influence in the avoidance of this complication.

I very much desire to go more deeply into the subject and illustrate it by cases, but I find this to be impossible as I wish to refer to another aspect of the matter, the improvement in hearing brought about by oto-massage in suppurative cases as well as in cases of deafness occasioned by suppurative disease.

Strange as it may seem, I have found in no class of my chronic ear cases such marked improvement of impaired hearing as in those in which the defect was caused by suppuration. Sclerotic changes are rare in these cases until long after the subsidence of the suppurative disease. I will refer to two such cases of deafness, the result of suppurative disease. Two years ago I reported the case of a woman 38 years old who had scarlet fever in her first year. When I saw her the ears were discharging and there was very poor hearing power. After she had been using the massage treatment for some months, not only did the discharge stop, but the hearing improved so much that she had no conscious difficulty in hearing conversation; the watch being heard twenty inches ( $\frac{20}{2}$ ) from the ear. The progress of this case was a steady gain in hearing power from the commencement. From the time of my report to the present there has been no diminution in hearing power.

I will briefly note another case. Miss C. M., 15 years old came to me Dec. 1, 1894, for chronic suppurative disease of the left ear. There was a large perforation and a fair amount of whitish discharge, not very gluey. There was no watch hearing on contact. I treated her ear without massage and succeeded in about four months in stopping the suppuration, but the perforation did not heal. I endeavored during another two months to heal the perforation, without success. The hearing distance had improved at this time to hard contact hearing for the watch. I then endeavored to restore the hearing by means of massage, using the pneumo-masseur, but especially the phono-masseur, neglecting the perforation, hoping it would heal spontaneously. Now, after ten months of such treatment (one visit per week), she hears the watch at ten inches, the perforation remaining unhealed.

In these cases the two kinds of massage are valuable—the phono to stimulate the nerve, which is more easily accomplished in such cases by reason of the

perforation allowing the sound to be carried more directly to the internal ear—the pneumo-masseur being used to break down adhesions and restore abnormal or diseased parts to more healthy action by reason of the stimulation thus produced.

To indicate the value of phono-massage, the following experiment will serve. April 26, 1896, I tested the hearing of the right ear of Mr. C. M., aged 28, and found it to be for the watch one-quarter inch. His is a case of old suppuration with bone involvement—one which has gone on for twelve or fifteen years and which he thought was incurable. The strong pneumo-masseur was used on his ear for forty minutes with the result that the hearing for the watch was increased to one and one-quarter inches. This increased hearing usually gradually disappears unless the treatment is regularly applied. If this be done it usually increases, the amount depending on the nature of the case. This immediate increase in hearing is a very frequent experience in my work, and one which I usually secure except where there has been most extensive destruction of the middle or internal ear structures. In dry suppurative cases where I do not succeed in producing an almost immediate temporary increase in hearing distance, my conclusion is that permanent results are very difficult to attain.

In conclusion the facts may be summed up as follows: In acute suppurative conditions, pneumo-massage should be tried and if the application be not too painful it will relieve the swelling and the severity of the inflammatory pain and shorten the attack; the purpose of this suction massage being to remove from the ear all possible suppuration and thus, by relieving the tension, lessening the frequency of ulcerations and necrotic processes and preventing adhesions and deep infiltrations of the surrounding tissues.

In cases of suppuration that have passed the acute stage the pneumo-masseur is to be used for the purpose of relieving the ear of its discharges and for the relief of extreme tension, preventing ulcerations and necroses, as well as to overcome the formation of adhesions and for the stretching, absorption and destruction of these adhesions when formed, and to stimulate the drumhead and its connecting structures to normal, functional action. The phono-masseur is to be used in these cases for the purpose of restoring to the ear nerve and its terminals the normal tone and overcoming the sluggishness to response engendered by inaction and disease.

In cases of deafness following upon suppurative disease the pneumo-massage is useful for limbering up the diseased and stiffened tissues, to restore their normal action and tone, and to break or stretch abnormal adhesions, to overcome ankylosed joints and give to the ossicles their normal motion, while at the same time improving the circulation of all the middle ear structures—the phono-massage being again used for its effect upon a sluggish, diseased and non-responsive nerve ending.

1723 Walnut Street.

**Intravenous Injections of Sublimate in Ocular Affections.**—Angelucci has found rapid and thorough recovery follow the use of intravenous injections of 20 centigrams of sublimate and 60 centigrams of chlorid of sodium, in 100 grams of distilled water. The dose increasing from 2 to 16 milligrams. The cases favorably affected were all of syphilitic origin: Iritis, irido-choroiditis, papillo-retinitis, etc., but the results were negative in all non-syphilitic troubles.—*Revue Gen. d'Ophth.*, August 31, from *Arch. di Ottalm.*, No. 3.

## STRICTURE OF THE UPPER PORTION OF THE TRACHEA SUCCESSFULLY TREATED BY DIVULSION THROUGH THE LARYNX.

Read in the Section on Laryngology and Otology, at the Forty-seventh Annual Meeting of the American Medical Association, held at Atlanta, Ga., May 5-8, 1896.

BY JOHN O. ROE, M.D.

ROCHESTER, N. Y.

The following case of stricture of the upper part of the trachea, due to organic contraction, can not, on account of its rarity, fail to be of interest.

On November 23, 1895, Miss D., aged 27 years, was referred to me on account of frequent and urgent attacks of dyspnea, which had for a considerable time been exceedingly distressing to her. She gave the following history: In March, 1888, she had a severe attack of diphtheria, from which it was thought at the time she had fully recovered. During the following year, however, it was noticed that she had edema of the feet. The edema was found to be associated with albuminuria and was ascribed to that cause. Notwithstanding this she enjoyed a fair degree of health.

In October, 1890, she became hoarse nearly every day as evening came on. This hoarseness continued until December, when she began to have considerable difficulty in breathing. The family physician found a swollen condition of the larynx, which he regarded as a consequence of the albuminuria. He treated her with steam inhalations, compelling her to remain in bed for about three months continuously with the object of maintaining a uniform temperature and preventing her from contracting cold. During this time her health was very good and she gained ten or twelve pounds in weight; although she had one or two severe attacks of dyspnea, lasting three or four days at a time. These were attributed entirely to the renal disturbance, since albumin and casts were found in the urine.

After a time the dyspnea subsided and in April, 1891, she began to go out. Shortly after, however, she took cold, and had another severe attack of dyspnea, lasting several days. As warm weather came on her dyspnea disappeared. Her voice during the period, since her first attack of hoarseness, had remained quite clear.

In August, 1891, she went to Canada and remained there until fall, feeling quite well. She continued to feel quite well during the fall, but during the winter she had frequent attacks of dyspnea, very similar to those of previous winters. During the following summer she had no special difficulty in breathing, although during July, August and September she was aphonic.

During the fall of 1892, she had at times much difficulty in breathing, and that winter she spent in Southern Pines, South Carolina, where she gained much in general health. Her breathing, however, was not materially improved, although the atmosphere there was remarkably dry. She came home May 1, 1893, and during the following summer was quite well, having little or no difficulty in breathing.

During August the cartilaginous portion of her nose began to diminish in size and for about a year afterward there was a gradual settling of this portion of the nose. During November, 1894, she had inflammation of the right lung, which nearly proved fatal and very much increased her difficulty in breathing.

During the following winter her dyspnea was frequently very urgent. These attacks of dyspnea were aggravated very much by accumulations of mucous below the obstruction in the trachea, which she had great difficulty in expelling. After expulsion of these accumulations her respiration was for a time very much improved. As the warm weather came on, her dyspnea diminished, and during the summer of 1895 she was quite free from it, and felt very well. As in previous years, when the cold weather came on, her trouble increased, and last October her dyspnea became very urgent, although her voice remained quite clear.

On November 23, when she came under my care, there was found on examination a chronic subglottic laryngitis, with considerable infiltration of the subglottic region. About three-fourths of an inch below the larynx there was an annular constriction, which appeared something like a membranous formation. Notwithstanding the fact that no history of syphilis could be obtained, as the girl's character was beyond question, the sinking in of the nose appeared more or less positive evidence that the trouble was of a specific nature.

Previous to the time that her nose began to diminish in size, her dyspnea was attributed entirely to the albuminuria, and she was treated accordingly; but after this manifestation it was thought that a specific trouble must be the cause of the difficulty. Since it seemed so certain that it must be of that nature, I placed her upon an antisiphilitic treatment, in both large and small doses, but with no benefit whatever. In fact, the dyspnea was aggravated by it, whereas iron and strychnia improved her condition.

Locally I attempted to reduce the subglottic laryngitis by sprays and insufflation of a power composed of tannin, sugar of milk, and a small quantity of morphia. This appeared to lessen the subglottic congestion, but had no effect in lessening the constriction in the trachea.

On December 4, the dyspnea became so urgent that suffocation seemed imminent, necessitating either tracheotomy or intubation of the larynx. The latter was resorted to and the tube was retained for two days, when it became so irritating as to require removal. It had the effect, however, of so enlarging the constriction that the dyspnea for a considerable time entirely disappeared. The constriction gradually returned, and in February it again became necessary to introduce the tube.

As the tube was being introduced by the aid of the mirror, she suddenly threw her head forward, bringing the end of the tube quite forcibly against the anterior portion of the trachea. As she jumped back, the tube was brought out. She at once, however, experienced complete relief from her dyspnea, and on the examination of her larynx, I found that the tube had broken down the anterior portion of the constriction so that the lumen of the anterior portion of the trachea was quite free.

Seeing that this constriction could be disrupted, I introduced a pair of Grant's forceps, with blades closed, until they passed below the constriction. I then opened the blades until the widest portion of them nearly filled the trachea. Holding the handles firmly I drew the blades up in the constricted portion, so dilating it as to break down much of the posterior portion of the constriction and leave the trachea quite free. As the glottis did not permit the forceps to open wide enough to fully break down the stricture,

I had a pair of dilating forceps with double-jointed blades so constructed as to increase the expansion of the lower blades to the full width of the trachea and to completely obliterate the stricture.

Since that time the constriction has shown little or no tendency to return. An occasional dilatation of the trachea with the forceps is sufficient to maintain the opening. The respiration and voice are quite normal. By following up the dilatation of the trachea in this manner when there is a tendency of the constriction to return, I have every reason to believe that a permanent cure will be effected.

This has been to me an exceedingly interesting case, being one of chronic subglottic laryngitis, to which was added organic constriction in the upper part of the trachea. This case is of special interest on account of the uncertainty as to the exact cause of the condition, and also on account of the history of repeated attacks of dyspnea extending over so long a period.

How much of this trouble we may ascribe to albuminuria, it is difficult to say. We all recognize the condition of edema of the larynx and aphonia, associated with albuminuria, which we term albuminuric aphonia, and we know that specific taints uncontrolled by ordinary antispecific remedies may excite all sorts of conditions. Subglottic laryngitis is a disease that is not of frequent occurrence, and is therefore not commonly met with in our daily work. We know, however, that its cause is frequently involved in obscurity, although it is usually associated with lymphatic affections and the conditions termed scrofula; that it occurs usually in young females from fifteen to twenty-five years of age, and that the treatment which proved serviceable in this case is the one that is recognized as the most beneficial in simple chronic subglottic laryngitis. Simple absorption of the tissues of the nose without ulceration results only, so far as I am aware, from a specific cause. We must therefore believe even in the absence of every other manifestation that the underlying cause was a latent hereditary taint of a specific character which produced the subglottic laryngitis and ulceration of the upper portion of the trachea and the resulting stricture, as well as absorption of the tissues of the nose.

#### DISCUSSION.

DR. J. E. LOGAN, Kansas City, Mo.—Is it not probable that this case is more or less of a specific type? The Doctor states that it was simply a settling of the cartilaginous septum unattended by any ulceration, and that the bony septum was intact. This would make it a very peculiar and interesting case. I have seen many of those cases which had no evidence of external ulceration, but there would be an ulcerated condition of the septum.

#### A FEW REMARKS ON THE CLINIC USE OF ORTHO- AND PARA-CHLORO-PHENOL.

Read in the Section on Laryngology and Otology, at the Forty-seventh Annual Meeting of the American Medical Association, at Atlanta, Ga., May 5-8, 1896.

BY CONRAD BERENS, M.D.

ONE OF THE WILLS HOSPITAL SURGEONS. PHILADELPHIA, PA.

In the *University Medical Magazine* for October, 1894, there is a brief note of reference to ortho-chloro-phenol, quoting N. Simanoffski, who is reported to have used it for reducing hypertrophies of the mucous membrane overlying the inferior turbinates of the nares. Simanoffski made but a preliminary report, and referred also to para-chloro-phenol. The endorse-

ment of ortho-chloro-phenol was of such a nature that I was induced to make some trials with it, as well also as of para-chloro-phenol. Ortho-chloro-phenol is a heavy limpid liquid of exceedingly irritating and pungent odor. It is rapidly soluble for clinic purposes in glycerin, and from this may be reduced in strength again and made soluble in water. For clinic purposes the para-chloro-phenol, which occurs in amorphous crystals, is best used by fusing to the end of a probe. In my work I have fused the crystals to silver. Para-chloro-phenol is not so satisfactory clinically, and is very much more cumbersome and inconvenient in its application. The conclusions of Schourmo in regard to its irritating properties, particularly in laryngeal conditions, are fully borne out by clinic experience. There is no denying the correctness of the statement of Spengler (*Brit. Med. Jour.* 1896, No. 1,827), as to its antiseptic properties, but I would take issue with him as to its efficacy compared with ortho-chloro-phenol. My experience having taught me that the latter is just as active an anesthetic, and is a very much more convenient form for clinic purposes. The use of ortho-chloro-phenol for the reduction of engorgement of the erectile tissue overlying the inferior turbinates is much more satisfactory than the cauterization—with less destruction of tissue and less intense reaction. In acute engorgement of the erectile tissue, I have found nothing more satisfactory than its application by means of a small dossil of cotton dipped in the drug and applied antero-posteriorly to the parts after they have been prepared by the use of cocain. The effect of the cocain having passed off after the thermo-electric cauterization has been applied, patients as a rule complain of intense pain, and frequently of epistaxis, not to mention the enormous inflammatory swellings and frequent adhesions to the septum. Ortho-chloro-phenol is slightly anesthetic, and this anesthesia is more persistent than that of cocain. As a consequence after the action of the cocain has passed off that of the ortho-chloro-phenol continues, and the patient reacts without any inconvenience. There being less inflammatory reaction it is natural that there should be less deeply seated initial lesions, but the drug has no place in the treatment of true hypertrophy, or hyperplasia of the region under discussion. In ulcerous conditions more especially of the septum nasi, the application of the glycerole of ortho-chloro-phenol 10 per cent. has invariably proved satisfactory in my hands. In ozenatous conditions after freeing the nares from the offensive accumulations, and thoroughly cleansing the nasal mucous membranes with dry absorbent cotton, I have found nothing that will so quickly remove the offensive odor of the disease as two or three applications of 10 per cent. ortho-chloro-phenol in glycerin. In these cases I persistently but very gently rub the solution over the diseased parts, and the patient is much gratified by the sudden removal of the offensive odor of the disease. I have yet to see however a case cured by the application of this or any other drug; that is, having no longer necessity for any applications to the nares. In laryngeal conditions I found that it will not in any sense take the place of ichthyol or iodoform as a local application. If a caustic effect is required, as for instance upon deeply seated ulcers or upon granulations in the pharynx, it is not to be considered, as its effect is too mild to be taken into consideration. In laryngeal diseases the results of persistent application have not

lead me to resort to its use excepting in the event of failure of lactic acid, ichthyol or boro-glycerin. In three out of fifteen cases of laryngeal tuberculosis in its very incipency, I have found ortho-chloro-phenol, in full strength, to give better results than any other local application. In two instances, most gratifying results were obtained by the application of 10 per cent. ortho-chloro-phenol to large ulcers of the epiglottis, both occurring in cases of advanced tuberculosis.

For the removal of growths of any sort in the larynx, I would not encourage the use of the drug, as it is not only slow, but also liable to cause acute inflammatory reaction—in one instance, giving rise to very severe dyspnea. In aural diseases its use has been attended by more gratifying results than those gained by the use of any other drug. The application of a pledget of cotton saturated with the 10 per cent. of the glycerol of ortho-chloro-phenol to an incipient furuncle of the external canal, in many instances has resulted in the abortion of the disease, while no dressing has proved more satisfactory after I have been compelled to open the furuncle in the canal. Though I have used a dossil of cotton saturated with it as a dressing after opening the furuncle I have never yet seen a recurrence of the disease at a sufficiently early date to warrant me in believing that there had been any material allowed to remain in the ear disinfected. A small pledget of cotton saturated with the solution and applied to the point of attachment after removal of polypi of the external canal, has always proved effectual both in destroying the extremely offensive odor, and in encouraging a rapid healing of the parts. In suppurative otitis media it has proved exceedingly effectual in 10 per cent. in glycerin. I will cite but one case as an illustration of many. Miss E. M., aged 22, applied to me in July, 1893, with chronic suppurative otitis media of the right ear; more than two-thirds of the inferior portion of the membrana tympani had been absorbed. The suppuration had continued with more or less severity and an offensive odor, since the early childhood of the patient. I employed every method for the relief of the symptoms and checking the disease, even curetting the floor of the middle ear, where the disease seemed to be confined, the attic not appearing to be involved. Boro-glycerin in 50 per cent. solution, ichthyol, nitrate of silver, zinc, nitrate of sanguinaria, douches, powders as iodoform, aristol, etc., were used without result. The discharge continued to be offensive and muco-purulent in character, no matter how thoroughly the application at the previous visit had been made. In December, 1894, after having thoroughly cleansed the parts I inserted a pledget of cotton saturated with 10 per cent. ortho-chloro-phenol in glycerin. The patient was instructed to return the following day. To my surprise the entire appearance of the parts had changed, the mucous membrane had become more healthy in appearance, and the discharge had lost its odor and golden yellow color. In five days and after three applications the discharge entirely ceased, and has not recurred since, excepting in the spring of 1895, when the patient was attacked by an acute rhinitis, and three days afterward complained of discharge from the ear. A single application of ortho-chloro-phenol caused this to cease after twenty-four hours, and there has been no discharge since. The patient, as a rule complains of considerable burning pain on the first introduction of the cotton saturated with the

drug, but this rapidly subsides and leaves a sense of comfort. It has been my custom to dress the ear daily, or not later than every other day, and in no instance of chronic suppurative otitis media have I had any but the most gratifying results in its use. In acute suppurative otitis media I have found that in any strength it seems to aggravate the disease. The greatest objection raised to the use of the drug comes from the patient, who complains of its odor. Even weak solutions of the drug unquestionably give rise to an all-pervading and pungent smell that is more penetrating than that of iodoform. This objection, particularly in the application of the drug to the ear, may readily be overcome by closing the external meatus with a small piece of absorbent cotton. In conclusion then, I have no hesitation in recommending the further clinic use of ortho-chloro-phenol in the belief that it will prove a valuable addition to the pharmacopeia of the rhinologist and aurist, and prove itself worthy of the fullest confidence, especially in those cases where the commonly resorted to medicaments have not only failed to relieve the patient, but have disappointed the expectations of the surgeon.

### THE ELECTRO-CAUTERY SNARE AS AN EXCISING AGENT IN DIS- EASES OF THE NOSE AND THROAT.

Read in the Section on Laryngology and Otology at the Forty-seventh Annual Meeting of the American Medical Association held at Atlanta, Ga., May 5-8, 1896.

BY HANAU W. LOEB, A.M., M.D.

Professor of Diseases of the Nose and Throat, Marion-Sims College of Medicine, Surgeon to the Nose and Throat Department of the Rebebah Hospital, Missouri Pacific Hospital, East St. Louis Protestant Hospital, Grand Ave. Free Dispensary, etc.  
ST. LOUIS, MO.

It is only a natural sequence which impels one who has given the electro-cautery snare a trial for the treatment of one of the various conditions for which it is recommended, to extend its application, to find new uses and to confirm those whose work has forced them to admit its growing utility. Especially is this to be expected in view of the recent improvements in electric appliances.

At the meeting of the AMERICAN MEDICAL ASSOCIATION at Detroit in 1892, I presented an electric snare which I had devised, and stated its indications and uses in nose and throat diseases. Since that time I have, by greater opportunity, enlarged its sphere of usefulness and fixed my own views in favor of a wider range of application of the electro-cautery snare in nose and throat affections. From its very nature it is adapted for amputation or excision. Any organ or growth or portion thereof which can be engaged within the snare may be removed, without danger of hemorrhage, for not only will there be less hemorrhage than when a knife or cold snare is used, but absolutely no bleeding in the vast majority of cases.

The snare, which was exhibited before this body four years ago, I again present though it is unmodified, except, that in order to accommodate the increasing field of application, it has been made in two sizes. By reason of its ready separation, its simple construction and its constituents, it is easily cleaned. Being covered with hard rubber it is not open to the objection which the old time snares received on account of their lack of cleanliness.

Until over three years ago, I relied upon the ordi-

nary galvanic and storage batteries, without complete satisfaction; constant attention was required to keep them in order and even when the greatest care was observed the battery would often fail at the critical moment.

In December, 1892, I began to use the Aloc converter and since that time I have never been subjected to any annoyance on the part of the appliance supplying the current. The converter is applicable only to the alternating current and is similar in its design and purpose to the transformers which are now used to reduce electricity of high electro-motive force to a lower tension.

The instrument which I have, reduces the voltage from 104 to 1, 1½, 2, 3, 4, 5, 6, 7, or 8 volts, and is therefore suitable for the cautery or the light.

In construction, it consists of iron core with a large primary coil of fine wire and a smaller secondary coil. The ratio of turns of the wire in the primary and secondary coil will depend upon the transformation required. Thus when the voltage of the house current is 104 to secure one volt the primary would have 416 turns to 4 of the secondary; for 2 volts the ratio

would be 416 to 8, for 4 volts, 416 to 16; for 8 volts 416 to 32. From 4½ to 6 amperes are required for the proper action of the snare with No. 5 piano wire (½ mm. in diameter).

Lichtwitz<sup>2</sup> describes a fairly elaborate instrument which he uses and which he presents as one by means of which the quantity of electricity may be measured. He finds that ten amperes are necessary for ordinary tonsils and twelve for the larger, when the wire used is ½ m.m. in diameter.

There are several very good appliances in use for utilizing the constant current which alone is available in some cities.

It therefore follows that at the present time no one need deny himself the use of the electro-cautery snare on account of electricity producing apparatus; for, whether the current be alternating or direct the supply will be reliable and precise. For some years a valid objection was entertained to the platinum wire on account of its lack of firmness. Since iron or steel wire has replaced it however, the same degree of stiffness of the loop is obtained whether the cold or hot snare be used.

The electro-cautery snare is from the very nature of things of but recent use. So far as I can learn Middledorf<sup>3</sup> was the first to employ it in the removal of tonsils.

According to Kijewski and Wroblewski<sup>4</sup> the galvano-cautery snare was used by Koehler and Korzeniowski<sup>5</sup> to remove a large polypus which filled the entire nasal cavity. Voltolini,<sup>6</sup> in his great treatise upon the galvano-cautery considered the value of the snare lessened by reason of the insufficiency and inconstancy of current.

Since the publication of this work and especially since the introduction of an apparatus which provides for the regular and certain supply of electricity, this and the somewhat similar objection of Beverly Robinson<sup>7</sup> are answered. So satisfactory has been this answer that the advocates of the electro-cautery snare have increased immensely, until they include many who are willing to replace by it many operative procedures which legend and practice had almost established forever. In fact the most enthusiastic advocates are those who have had most experience with it and its greatest opponents are generally those who have used it infrequently or not at all.

Thus Sendziak<sup>8</sup> complains that Jurasz, after employing the electro-cautery snare in only two cases, came to the conclusion that it was inconvenient, painful and disagreeable to the patient on account of the odor it leaves.

The electro-cautery snare has been recommended and employed in the following diseases of the nose and throat:

1. Nose: *a*, anterior and posterior turbinal hypertrophies; *b*, polypi and other benign growths; *c*, malignant neoplasms; *d*, spurs.

2. Rhino-pharynx: *a*, polypi; *b*, fibromata.

3. Pharynx: *a*, hypertrophied tonsils; *b*, tonsillar neoplasms; *c*, palatal neoplasms; *d*, elongated uvula; *e*, hypertrophied lingual tonsils.

4. Larynx: *a*, neoplasms.

#### I. NOSE.

1. *Anterior and posterior turbinal hypertrophies.*—In these conditions the electro-cautery snare is almost ideal, permitting the operator to remove quickly the redundant and hypertrophied tissue by means of an operation which is bloodless notwithstanding the great vascularity. It is quite as easy to engage the hot as the cold snare and the celerity, the painlessness and freedom from hemorrhage should commend the former over the tedious cold snare.

Sajous<sup>9</sup> prefers the electro-cautery snare for posterior turbinate hypertrophies, stating that it is necessary to use a rhinoscopic mirror in order to see the seat of operation. I consider that this is not only unnecessary, but awkward. A far better plan is to place the finger in the rhino-pharynx and thus guide the loop over the hypertrophied tissue.

McBride<sup>10</sup> says it should be used whenever the tissue can be engaged and Greville MacDonald<sup>11</sup> prefers the electro-cautery snare for the removal of large pieces of the turbinated in spite of the objection that it induces considerable inflammation in the neighborhood from the generation of steam and that the cicatrization is delayed. I can not permit this objection to go unchallenged for at least in my own cases it has not been revealed. Among the laryngologists who consider the cold snare as superior for anterior and posterior hypertrophies, may be mentioned Onodi,<sup>12</sup>

Zwillinger,<sup>13</sup> Polyak,<sup>14</sup> Eaton,<sup>15</sup> Hack,<sup>16</sup> while Baumgarten<sup>17</sup>, Schmidt<sup>18</sup> and others commend the hot snare.

2. *Polypi and other benign growths.*—The essential advantage of the electro-cautery snare in the removal of polypi is the fact that so many may be removed at one sitting; whereas it requires considerable time to dispose of a number by means of the cold snare; with the hot snare it is only the question of a few minutes. The smaller instrument which I have devised is quite as convenient and easy of application as any cold snare, and one needs only inquire of a patient who has had both methods applied, to learn that the hot snare is far more agreeable, less painful, more rapid, less bloody and more preventive of recurrence. So far as the inflammatory and infective sequelæ are concerned after a thorough trial of more than four years, I am convinced that they are no greater in one than in the other. In one single case, an acute otitis media followed the separation, doubtless influenced by the unwarrantable exposure to which the patient subjected himself. The operation was performed in the morning and before night the patient had permitted himself to be drenched by rain several times. He failed to report at my office until the fourth day after the operation. I feel therefore that the hot snare may be held blameless of this result. Surely the lessened time of operation should make infection less apt to occur than with the cold snare with which too often no aseptic and antiseptic precautions are taken.

McBride<sup>10</sup> in this connection makes the assertion that it is better to use the electro-cautery snare, when it is desired to remove all the polypi at one sitting. Ingals<sup>19</sup> uses the electro-cautery snare but prefers the cold, while Greville MacDonald<sup>11</sup> claims that there is no advantage over the cold snare, while there is the greater disadvantage of inflammatory action induced by heat and steam generated by the hot wire.

In answer to this, it may be stated that the heat and steam which MacDonald and others claim are generated will not produce any bad results if the snare is properly applied and used. If the wire is drawn tight the tissue which is influenced by the heat will be so constricted and the time of its application so insignificant, that it can have but little influence in this regard. It is often difficult, sometimes impossible, to observe the cauterized stump, demonstrating that at least in many cases the effect of the heat and steam is *nil*.

Schmidt<sup>18</sup> states that after using the cold snare for three years he returned to the electro-cautery. This, I am sure, will be done by many if they give the latter a fair trial. I am inclined to agree with Ball<sup>20</sup> and others that cauterization of the base resulting from the galvano-cautery ablation of polypi is productive of good results. In keeping with the progress of rhinology, I do not believe that mere cauterization of the base will prevent recurrence. Indeed my common practice now is to remove all larger polypi with the hot snare, and if the bone is found affected the smaller polypi with the diseased bone are then removed.

The electro-cautery snare is also available for the removal of other benign growths in the nose, and I have used it with good effect in fibroma, adenoma and papilloma. In one case of fibroma which projected from the rhino-pharynx, the vascularity was very great, the growth bleeding upon the slightest provocation; yet, the electro-cautery snare caused the loss of but a few

drops of blood. In the case of adenoma I first used this instrument but in the later recurrences abandoned it, since on account of the softness of the tissue and slight amount of blood which was lost, I could operate quite as well with forceps.

Zarniko<sup>21</sup> inclines to the cold snare for removal of inflammatory fibroma, claiming that if it is applied as he suggests, the loss of blood will be inconsiderable.

3. *Malignant tumors*.—The electro-cautery snare has in this class but a limited range, which is in the direction of securing a portion of the growth for microscopic examination.

4. *Spurs*.—Although advocated by a number of laryngologists, I have never taken kindly to this form of treatment. The saw, drill and curette are eminently more satisfactory. The electro-cautery snare is by no means as free from objection in operations upon bone and cartilage as upon softer tissues.

## II. RHINO-PHARYNX.

1. *Polypi and fibromata*.—These may well be considered together as the terms are used interchangeably by many. In appropriate cases the belief seems to be fairly general that the hot snare is of greatest service, although the electrolytic treatment seems destined to overshadow all other forms, except where a more serious operation is indicated. However, many still maintain the superior value of snaring where this is possible. Thus Michelson<sup>22</sup>, Lincoln<sup>23</sup>, and Schmidt<sup>25</sup> report cases of rhino-pharyngeal fibroma treated in this way. I have used the electro-cautery snare in two cases of rhino-pharyngeal polypi with success and without return. In a case of rhino-pharyngeal fibroma with projections into the nasal cavity I snared off as much as was possible to reach with the instrument. On the whole the efficiency of the electro-cautery snare in rhino-pharyngeal tumors depends upon the possibility of engaging the growth in the loop and its extent and attachment.

## III. PHARYNX.

1. *Hypertrophied tonsils*.—In the removal of hypertrophied tonsils, the electro-cautery snare has received greater attention than in any other affection. After this method was introduced, according to Lichtwitz<sup>2</sup> the operation lost caste but was revived through the writings of Knight, Loeb, Garel, Schmidt, Heryng and Sendziak. All of these continue to favor the electro-cautery snare except Knight, who writes<sup>24</sup>, after a complete résumé upon the subject of hemorrhage following tonsillotomy that he favors the guillotine.

Flatau<sup>25</sup> intimates that those who have experienced serious hemorrhage after tonsillotomy are much inclined to replace the tonsillotome with the electro-cautery or electro-cautery snare and McBride<sup>10</sup> states that its use is only justifiable in preventing hemorrhage, which he states is a rare contingency. Bresgen<sup>28</sup> dismisses its consideration with the remark that there is no reason for its use as it does not prevent hemorrhage. Bosworth<sup>27</sup> objects to the procedure on the ground that it requires ten to fifteen minutes and Potter<sup>28</sup> advised that the snare be not adjusted too deeply on account of the sloughing beyond the seat of cauterization.

Ingals<sup>19</sup> favors the cold snare. On the other hand there is a great array of experienced advocates of electro-cautery tonsillotomy. Lichtwitz<sup>2</sup> is strong in his preference. Yerwant<sup>29</sup> states that it is more prudent to use the electro-cautery snare in adults so as to obviate hemorrhage. Heryng<sup>30</sup> has given his evidence

in its favor for hard fibrous tonsils, extensive hypertrophy and hemophilia. Sendziak<sup>18</sup> advocates it forcibly and conclusively, stating that any one without prejudice will be entirely satisfied with this method. Schmidt<sup>18</sup> favors the electro-cautery snare beyond all other tonsillotomy instruments. He denies that it requires a longer time than the operation with the tonsillotome and insists that it is to be preferred on account of the certainty that hemorrhage will not occur. Huguenin<sup>31</sup> advises the use of the electro-cautery snare whenever tonsils are pedunculated and Helot<sup>32</sup> also prefers this instrument. There is to my mind no question as to the safety of galvano-cautery tonsillotomy so far as hemorrhage is concerned. A few cases of hemorrhage following this operation have been reported, but never a serious one. They could all probably be explained upon a satisfactory basis. In more than 300 tonsillotomies with the electro-cautery snare I have never observed a loss of more than a few drops of blood. In only one case was there a secondary hemorrhage, which doubtless resulted from a lack of attention on the part of the patient. I think this will compare favorably with the experience of those who use the knife or tonsillotome. In fact the proof is stronger when it is considered that the hemorrhage would be far greater if the advocates of the knife would remove as much as is ordinarily removed with the galvano-cautery snare.

Numerous instances of hemorrhage after tonsillotomy attest to the possible seriousness of such an occurrence. Heryng<sup>30</sup> collected fifty-nine cases of severe and even serious hemorrhage; other cases have been reported by Blairs,<sup>33</sup> Fuller,<sup>34</sup> Catuffe,<sup>35</sup> Moure,<sup>36</sup> Thorner,<sup>37</sup> Jessop<sup>38</sup>, and Lennox Browne.<sup>39</sup>

Another great advantage which the galvano-cautery snare possesses over the tonsillotome consists in the large amount of tonsillar tissue which it is possible to remove and the precision of the operation which makes it possible to remove just what one desires. With the tonsillotome the amount of tonsil removed is purely accidental. If the instrument possesses a fork or lifting device, the amount will depend upon the pulling power of the fork, which to the surgeon can not be known until after the excision. If there is no fork, the pillars of the palate will limit the removal; and therefore it must be very exceptional to remove the entire tonsil. Quite different is it with the electro-cautery snare. It is my custom to pull the tonsil from its palatal bed by means of a pair of sharp-toothed forceps and then engage the wire so that it is possible to remove the entire tonsil. I have again and again made so complete an excision that not a vestige of tonsil tissue remained. This I do not consider a dangerous practice; at least it has been eminently satisfactory up to the present time. I can corroborate the experience of Schmidt,<sup>18</sup> who states that he has frequently seen enlarged tonsils of which one-fifth only had been removed by previous tonsillotomy.

As to the great length of time which some writers maintain is necessary in operating with electro-cautery snare, the expression is born of inexperience, for no one who undertakes it a number of times can fail to acquire sufficient dexterity to operate with celerity. It never should require more than one minute, providing the apparatus is in proper working order; considering the improvements that have been made, nothing short of this is to be anticipated. On the whole it must be admitted that the electro-cautery

snare is to be commended for the removal of hypertrophied tonsils in that it obviates all danger from hemorrhage and makes the operation one of precision, not one of the purest guess-work.

Even in tonsils which are impacted between the palatal pillars it will be found of service, since in almost every case it will be possible to pull out a portion and engage it in the snare, thereby not only securing the advantage of cauterization, but also the removal of a portion of the hypertrophied tissue.

2. *Tonsillar neoplasms.*—Any tonsillar growth which has not involved and attached itself to neighboring structures is susceptible of excision with the electro-cautery snare. This does not imply that the mere removal with the snare will constitute a cure for such an affection. However, if the growth involves the tonsil alone, and the entire tonsil is removed, the method should offer at least as good a result as any other. In a case of lymphosarcoma of the tonsil I snared off a large piece of the tumor for microscopic examination, without causing any hemorrhage and without influencing the growth of the tumor. Wolfenden<sup>10</sup> states that he removed a sarcomatous tonsil by means of the electric snare, and I consider it a procedure which should be utilized in the earlier cases.

3. *Palatal neoplasms.*—Tumors of the palate which may be engaged within the loop are suitable for removal with electro-cautery snare. I have used it twice for palatal papillomata.

4. *Elongated uvula.*—In my previous paper<sup>1</sup> I called attention to removal of elongated uvula by means of the electro-cautery snare, which I had practiced for some time. Shortly after this DeBlois<sup>41</sup> in a paper before the American Laryngological Association, took a similar position. Lennox-Browne<sup>42</sup> states his preference for the galvano-cautery where the uvula is thin, but he does not specify the snare. He operates by pulling the uvula downward and cutting it with the galvano-cautery where he desires. On the other hand Morgan<sup>43</sup> and Ingals<sup>19</sup> prefer the cold snare. That hemorrhage is a possibility, one needs only to refer to the paper upon this subject written by Morgan<sup>37</sup> in which attention is called to a great number of instances of uvular hemorrhage collected from ancient and modern medical literature.

Besides entirely preventing all possibility of hemorrhage the hot snare operation finds an indication in the ease with which the uvula can be engaged, the perfect stump which remains, the smaller amount of pain succeeding the operation as compared with ordinary uvulotomy. It is my practice after the uvula has been properly cocaineized to permit it to fall into the loop and after deciding exactly where the section is to be made, to draw the wire tight and send the current through. So pleasing are the results from this method of operating, that I now use no other plan.

5. *Hypertrophied lingual tonsil.*—My own experience in this particular affection is confined to one case; however, it seems to offer an inviting field at least. Sendziak<sup>8</sup> commends it highly.

#### IV. LARYNX.

1. *Neoplasms.*—Some writers are disposed to favor the electro-cautery snare in these affections, but it seems to me that there are serious objections on the score of inaccessibility, impossibility of keeping the site in perfect view, the danger of inflammatory reaction and the possibility of the excised tumor falling

into the larynx. These are, however, the judgment of opinion rather than of experience.

In conclusion I desire to state that the electro-cautery snare has a possible indication in laryngeal tumors and nasal spurs; an inviting one in hypertrophied lingual tonsils, palatal, tonsillar and rhinopharyngeal growths and a certain one in the removal of hypertrophied tonsils and turbinates, nasal polypi and elongated uvula.

#### DISCUSSION.

DR. W. E. CASSELBERRY, Chicago, Ill.—I think the success of treatment by the electro-cautery snare depends very largely upon the perfection of one's apparatus. I think that Dr. Loeb deserves a great deal of credit for having designed an apparatus by which he can gauge and perform these operations with facility. He is fortunate in having his converter and an alternating current. I have been unable to find a satisfactory galvano-cautery rheostat by which to use directly the Edison or continuous current, so I use the storage battery. I use for this purpose the double American cell, keeping it stored constantly by the Edison current in connection with my light so that the flow of the current from the battery seems to be uniform. I am not accustomed to take out nasal polypi with the cautery snare. I formerly did it but have stopped for the reason that it makes the nose sore. I can remove about as many as I care to at one sitting with the cold snare. I remove tonsils in adults sometimes by the cautery snare. It has the advantage of avoidance of hemorrhage and the disadvantage of making a very sore throat. I think, to remove the uvula by the cautery snare, I must make a more painful wound than by the usual method.

DR. HANAU W. LOEB, St. Louis, Mo.—I expected to hear more criticisms than have been made and I think perhaps they

would have been deserved, for I am sure that my love for the electro-cautery snare has made me rather dogmatic. I use a better instrument than those usually employed. Most of the instruments have too large a handle and are too heavy, but I have somewhere in the gray matter of my brain a little handle in view which will greatly obviate this trouble.

I think Dr. Casselberry deserves a great deal of credit for his faithful work with that abominable machine, the winding cautery snare. I use the McIntosh handle, which has a sliding arrangement by which the loop is tightened in a moment.

It is unfortunate that in so many cities the direct current is still used. Since the consolidation, however, of the Edison and Thompson companies, they are not using them so much, and soon the alternating current will be utilized in all of the larger cities. In reference to trouble from cauterizing the adjoining part, if the wire is drawn tight before sending the current through this will be obviated. The trouble with the instruments is that you have to pass the wire through the cannula and then back again. In mine there are two perforated wires which are threaded like a Sajous snare.

There is no question but that in many cases the inflammatory reaction from the electro-cautery is greater than the cold snare, for the reason that the surface is free from all germs; since I have become more familiar with the use of the instrument I have severe inflammatory results less frequently. It is the best in operating upon the uvula because one is not required to pull down the tip in any way. I simply let the uvula fall into the tip and turn on the current. In the scissors operation you are apt to cut off more than is necessary of the mucous membrane, and in addition the inflammatory results are greater. I have presented this paper because there is a scantiness of literature in regard to the cautery snare for operations in the nose and throat. I hope that when we next speak on the subject, I will have more in favor of it.

## ON BONY GROWTHS INVADING THE TONSIL.

Read in the Section on Laryngology and Otology, at the Forty-seventh Annual Meeting of the American Medical Association, at Atlanta, Ga., May 5-8, 1896.

BY ALEX. W. STIRLING, M.B., C.M. (EDIN.);  
D.P.H. (LOND.)  
ATLANTA, GA.

The cases which I bring before you are interesting, I think, from the points of view of both the anatomist and the practical surgeon.

The first is that of a young lady of excellent personal medical history. Her only complaint had been slight chronic hypertrophic rhinitis, and for a few years some enlargement of the tonsils, especially the right, both of which secreted caseous matter and were at times a little painful. The inferior turbinated bones and the varicose veins of the lingual tonsil had been cauterized by one throat specialist, another had cauterized her right tonsil, and a third had cauterized cysts in both.

When tired she frequently complained of pain which she believed originated in the right tonsil and radiated thence to the mastoid and the right nasal bones, as well as to the right eye and shoulder. When squeezing out secretion she could feel a local tenderness in this tonsil.

On examination with the finger I was able to make out a hard immovable mass coming from behind the tonsil forward underneath it to the level of its anterior surface, but forming practically part of its substance. Its point is rounded, apparently about one-eighth of an inch in diameter, but becoming broader and somewhat flattened laterally as it extends outward, backward, and slightly upward. The finger pressed in front enters an angle formed by it and the inferior maxilla, and when pressed behind it enters another angle formed by its approximation to the right side of the vertebral column. The tenderness felt on pressure appears to be due to the nipping of the tonsillar mucous membrane between the finger and the hard body.

Nothing of the kind can be discovered on the left side.

The second case consulted me on account of large polypi of both nostrils from which she had suffered for years. She is 64 years of age, has asthma and a weak cardiac muscle, but otherwise is in good health. There is nothing of note in her family or personal medical history. On examining her throat I observed a slight protuberance just above and in front of her right tonsil. With the finger I found it to be nearly the same as that described in connection with Case 1, with the following points of difference. In the second case it exists on both sides, though it is not quite so prominent upon the left side; it is also higher, farther forward, perhaps a little thinner, and with a more apparent upward direction.

The growth is quite immovable, and there is no unnatural tenderness on examination. The patient has never had the slightest trouble with her tonsils. I have been able to examine the throat of one of her daughters, but could find nothing unusual there.

The third case is a brother of Case 2, aged 65. He likewise has been free from throat affections or any infirmity which might have a bearing on this subject. On both sides he has the same peculiarity, but differing from the previous cases in that the hard masses are altogether in the posterior part of the tonsils, are much longer, reaching a full finger breadth below the level of the lower tonsillar border, are perhaps rather more slender and, for nearly half an inch of the lower end on either side, cartilaginous to the touch and movable.

The question now arises, what are these substances? They are evidently not tonsillar calculi, because they have none of their characteristics except tenderness. In view of the fact that they have given rise to no symptoms whatever in two cases, and from their formation, position, and immobility, it seems to me certain that they are not the result of disease, but that they are rather congenital peculiarities, having however a distinct interest in cases of disease in their neighborhood.

In endeavoring to come to a decision relative to their origin, let us examine the bony structures from which they might arise, for they can be nothing else than bone. They all arise on the outer side of the throat, and it may be from the lower jaw, the vertebral column, or the base of the skull. If they came from the lower jaw to which they closely approximate, they would move along with it, but not one of them does so. They do not come from the bodies of the vertebrae, because the finger can exclude these. The pterygoid plates are too far forward; the spines on the posterior extremities of the wings of the sphenoids are rather less unlikely, but they too are somewhat too far forward and are distant. It is much more likely that the growths are simply prolongations of natural prominences than entirely new formations; by a process of exclusion we are limited to the transverse processes of the vertebrae and the styloid process.

The tonsil is situated on the level of the upper part of the body of the axis or of the disc between it and the atlas. The transverse process of the axis is small and does not move on rotation of the head. The bones under consideration do move along with the head on rotation, and come into much greater and visible prominence when the head is turned toward the side opposite to that under examination.

We are therefore reduced to the atlas which is as

regards rotation of the head a part of it, and the styloid process. To which of these the bones belong is a question of interest chiefly in view of the possibility of their becoming carious or involved in an operation; for disease affecting the styloid process might spread to the main body of the temporal bone, and the delicate structures in relation with it, and if the atlas were in any way injured at least a serious condition of things might arise.

Upon this atlas, kindly lent to me by Dr. Grandy, with this skull, the posterior limb of the transverse process which ought to, but does not, join with the anterior to complete a foramen, is nearly an inch in length, and were it longer would reach the region of the tonsil if its curve were continued, or were a little accentuated; and its direction would correspond fairly well with that of the growth especially of the first case.

The direction and size of these growths afford no satisfactory point for differentiation. Neither does the movement of rotation, and the only way to distinguish between them, of which I have been able to think, is that the skull proper moves when the head is nodded, which is not the case with the Atlas. These bones move with the head on nodding, and I therefore conclude that they are styloid processes. Other arguments in favor of this view are the presence of cartilaginous terminations in the case of the male patient, and the well-known variability in length of the styloid processes. I have been able to obtain little or no assistance from literature in making my diagnosis. Among the books on anatomy and diseases of the throat which I have been able to consult, I have found only one reference to such a condition as this. A few cases of exostosis of the bodies of the vertebrae, having no resemblance to these, have been recorded. Three widely-known specialists on throat diseases with whom I have been in correspondence, and one of the most experienced of European anatomists have all informed me that they have never seen such a condition as I described to them.

The one reference to any such which I have seen is in Scheeh's book on diseases of the mouth, throat and nose. He refers to a case "described from the anatomic point of view by W. Gruber," and another from a clinical aspect by Lücke, while Weinlechner is said to have broken away a piece of bone which caused inconvenience in swallowing. These are recorded as abnormally long styloid processes.

This condition of the tonsil is not to be looked upon as a mere anatomic curiosity, for in two at least of my three cases an attempt at tonsillotomy might have been met with considerable difficulty had a correct diagnosis not been previously made, and it might be of consequence in other operations in that region. As regards treatment, there is no necessity to interfere in the cases of the elderly people. The tonsils are troublesome in the first case, and it is a question whether removal of part by the guillotine, cautery or otherwise, or even the breaking up of it with a blunt hook might not result in so tightly stretching the mucous membrane over the bone as to produce pain or even ulceration and exposure of the osseous tissue. Personally, unless in case of urgent necessity, I should be averse to removal of the latter on account of possible secondary mischief in the bone, or of interference with the attachments of muscles and ligaments.

#### DISCUSSION.

DR. W. E. CASSELBERRY, Chicago, Ill.—I saw these very interesting cases. The first case to which he has reference, is

a very distinct pointed prominence on the right side occupying the location of the anterior pillar, which covers it more than the tonsil, although when it is stretched forward the tonsil will cover it. The curvature inward and the position would satisfy me that it was a styloid process turned inward toward the throat. The other case had much the same condition but is not so pronounced. The committee agreed that the case was an abnormal styloid process. It is of some importance in connection with possible operations on the tonsils. In regard to operating, laryngologists should take palpation more into consideration. Upon palpation they would discover that there was something of a hard nature and would be warned against operating. I do not think anything serious would occur if an operation was attempted; I think the instrument in both cases would slide over the projecting point rather than go through it. I would not make a tonsillotomy in that case or cauterize it, because the somewhat enlarged tonsil affords a useful padding to the short-pointed projecting styloid process.

#### PORTABLE COMPRESSED AIR APPARATUS AND NASAL SAW.

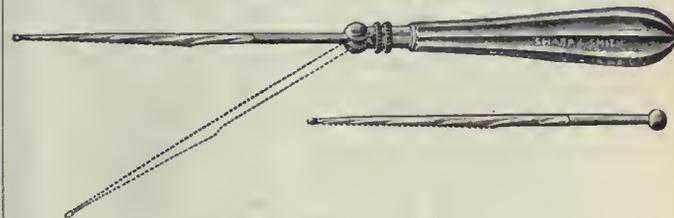

Presented to the Section on Laryngology and Otology, at the Forty-seventh Annual Meeting of the American Medical Association, at Atlanta, Ga., May 5-8, 1896.

DR. E. FLETCHER INGALS, Chicago, Ill., presented a portable compressed air apparatus, with the following remarks: This is a compressed air apparatus designed for treating patients where

Portable Air Compressor, One-quarter Size.

we are obliged to carry an apparatus with us, as for instance in going to theaters to treat actors; or for the use of patients who need a high air pressure for making applications to the

Adjustable Saw, One-half Size.

larynx or Eustachian tubes. It consists of a cylinder eight inches in length and three and a half inches in diameter, capable of withstanding eighty pounds pressure. The cylinder has a movable head that will slide in so that the spray tube, pump and all other parts of the apparatus may be placed inside the cylinder when not in use. To use it the head is drawn up against a rim with a rubber washer and quickly fastened by clamps that make it air-tight. The air tube is one and a half

feet in length, so that the patient can hold the cylinder in the lap while the application is being made. A bicycle pump is employed, which is of convenient size to go inside the cylinder when packed, but is of sufficient size to enable one to easily obtain forty pounds pressure. The cylinder filled with compressed air by this means holds sufficient to throw a strong spray the length of time necessary for treating five or six patients.

The price of this first apparatus, without a case was \$15, but as more are made the manufacturers say they can be furnished in a leather case with space for a reflector, throat mirrors and extra solutions, if desired, for \$15. The case complete with the extra space for other instruments will measure only eight and one-half inches in length, four inches in width and five inches in height, or without space for head mirror will measure eight and one-half inches in length, four inches in width and four inches in height.

Dr. Ingals also presented a nasal saw with an adjustable handle that could be set at any angle. The instrument was provided with two blades, one to cut forward the other backward. It had proved very satisfactory. It was made entirely of metal.

### HYSTERIC DEAFNESS.

Read by title in the Section on Laryngology and Otology, at the Forty-seventh Annual Meeting of the American Medical Association at Atlanta, Ga., May 5-8, 1896.

BY H. V. WÜRDEMANN, M.D.

Director Wisconsin General Hospital and Secretary of the Association; Oculist and Aurist to the Milwaukee Children's Hospital and to the Milwaukee County Hospital for the Chronic Insane.  
MILWAUKEE, WIS.

That protean affection, hysteria, may be considered a purely functional disease. There is, however, usually some concomitant affection or lesion which may be deemed to be the cause. This may excite a local hysteric attack in a patient predisposed by mental or moral influences. Some actual injury or shock to the part is in many cases the predisposing cause for the local manifestation. Affections of the sight are frequently seen; indeed, in most hysteric persons it is possible to find some defect of the visual field.

Hysteric deafness is very rare. In the *Medical News*, Feb. 14, 1891 I reported such a case. Since that time two more have come to my notice:

*Case 1.*—Hysteric deafness and blindness in a woman after injury to the head.

Aug. 29, 1892, a woman, age 42, was sent to me on account of monaural deafness. She gave a history of a railroad accident a few days before in which she had been struck on the left side of the head; had been prostrated and in bed after arrival in this city. She claimed to have had severe pain in the left ear the day before and discovered that this was totally deaf.

*Status Presens:* Patient very nervous and excited. There was a contusion with swelling over the left orbit and malar bone of same side, which patient thought was broken, but examination showed no evidence of fracture. The vision of this eye was slightly reduced for distance and she claimed that she was not able to read ordinary print. Objective examination of the eyes was negative; the refraction and fundus normal; pupillary reaction and pupils normal. Contraction of the visual field on the affected side. Examination of the ear showed a normal drumhead and no visible cause for the pain or deafness. She could only hear loud sounds on this side. That of the right was normal. Tuning fork placed on vertex was heard only on the right side and not at all on the left by aerial or bone conduction. There was no tinnitus or aural vertigo at this time. Two days later the left ear appeared totally deaf. She complained of great pain in the back and leg of this side and of hyperesthesia. She asserted that the whole of this side was weaker than the other. Objective examination showed left hemihyperesthesia and a questionable hemiplegia. Treatment advised was absolute mental and bodily rest with bromid of kalium and valerian. Diagnosis at the time was hysteric deafness, the locality of the functional disturbance being probably influenced by the character and

place of the contusions. A prognosis was given of probable recovery either after the effect of the primary shock had passed away or after the lapse of some weeks.

One month later I examined her again, finding that she could hear a loud voice but could not understand spoken words on the left side; hearing on right side normal as on first examination. Objective examination negative. Tuning fork only heard on the right when placed on the vertex. She was excitable and had an anxious countenance and complained of pain in the back of the head with creepy sensations and weakness on the left side of the body. Also had pain in the ear and roaring sounds which were immediately relieved by weak galvanic electricity. Patient had a fainting fit in the street car on returning home from my office. The vision was blurred for reading in both eyes in a few minutes. There was now no contraction of the visual fields and the vision was normal for distance. About three months later the railroad company having settled with a moderate sum for damages, the hearing gradually came back to the affected side, and examination one year later showed that it was normal.

*Case 2.*—Hysteric deafness and blindness in a child after pulling the ear.

Nov. 9, 1893, an anemic child, aged 11, had trouble at school several weeks before when the teacher pulled her right ear. She became totally deaf on that side and partially so in the left within a few hours; complained of her sight and was light shy. Was given near-sighted glasses (—1 D.) by a jeweler, with which she claimed she could see better, and without which she kept her eyes closed.

*Status Presens:* The child was apparently apathetic and stolid. The right concha was red and exquisitely tender to the touch caused, as I observed, by furtively pulling the ear when she thought she was not being watched. The membrana tympani were normal. She has slight hypertrophic rhinitis for which the mother had been douching the nose with a syringe and salt water. Patient could not understand what her mother said, although she had been shouted to for a couple of weeks, but she was apparently observant of our conversation. On taking the child aside I found that she understood me when I talked in an ordinary tone of voice. All tests for hearing were useless.

Her vision was R. and L. 6-18 with her glasses and without them she would not read any letters. I explained the case to the mother and commenced at once to make a decided mental impression upon the child, *i. e.*, to hypnotize her. I told the mother in the child's presence, in a manner to give her the impression that I did not wish the patient to hear what I said, "that I was about to do an operation that would cure her at once." The child seemed apathetic but responded to the usual hypnotic suggestions and on brisk Politzerization with chloroform vapor, could immediately hear ordinary conversation, her mother's voice as well as mine. Hearing tests showed that she could hear the acometer, the watch, whisper, voice and tuning fork at a normal distance and in a normal manner: besides this she could read all the test letters to 6-VI without glasses. These were taken away from her, but a subsequent examination showed that the eyes were 1 D. hyperopic. The child would not allow of a second Politzerization without hypnotic influence, but the effect of the one given was sufficient to cure the case. Tonic treatment was instituted, and as long as the case was under observation (six months) no return of the hysteric symptoms recurred.

I can not ascribe either of these cases to malingering entirely, although in many cases of traumatic hysteria there is a tendency toward deception. It is probable that the disturbances of special sense in both cases were entirely beyond personal control and were only to be cured by outside suggestion. The first case would not submit to such treatment, but in the second it was thoroughly successful. I have seen other cases of hysteria relieved in quite as remarkable a manner.

805 Grand Avenue.

*Amblyopia Consequent to Chronic Endometritis.*—Monte Mor describes in *O Brazil Medico*, August 1, a case of almost total blindness accompanying chronic uterine disturbances. Dilation and curettement with antiseptic injections, etc., cured the endometritis in fifteen days, and with it the amblyopia. He queries whether the visual trouble could have been of hysteric origin, but adds that the duration, over a year, argues against this supposition.

## THE ANATOMIC CHANGES IN TWO CASES OF RETINAL DETACHMENT.

Read in the Section on Ophthalmology, at the Forty-seventh Annual Meeting of the American Medical Association, at Atlanta, Ga., May 5-8, 1896.

BY ROBERT L. RANDOLPH, M.D.

BALTIMORE, MD.

I have selected these two cases as being fairly typical of the two principal conditions leading to retinal detachment: first, a spontaneous detachment due to fibrillary degeneration of the vitreous body, and the second case was one where a small round-cell sarcoma had led to propulsion of the retina away from the choroid.

In case one the detached retina as it sprang from the papilla appeared like a funnel having a neck about one-fifth of an inch long and which at this distance from the papilla commenced to assume the funnel-like shape. The retina was detached below, all the way around to the ora serrata. Above at a point one-sixteenth of an inch posterior to the ciliary muscle it was lying in position. From this point it turned backward and then passed directly down to a point which lay in the pole of the lens, and from here took a course forward and then upward and finally lost itself in the ora serrata. That part of the funnel which had an upward direction was thrown into numerous and intricate folds and enclosed in its meshes a mass of vitreous body, while that part which passed below was composed of the entire thickness of the retina which appeared quite normal. The peculiarity of this portion was the absence of folds. The inner surface of the retina at the widest part of the funnel was covered with a thick mass of vitreous body and the angle which was formed by the ciliary body in front and by the retina behind, as it fell backward and downward from the ora serrata, was filled with coagulated material and fine fibrillæ, which latter passed forward and served to form numerous bridges across this angle. The ciliary processes were covered posteriorly with several layers of the vitreous fibrillæ. The zonula was not distinguishable as such, it no doubt being merged into the vitreous fibrillæ. That portion of the vitreous lying between the retina and choroid was empty. No doubt we had a fluid here during life. At some points anteriorly could be seen what are described by Nordenson as the choroidal tufts, which appeared like little bridges uniting the retina and choroid. There was nothing worthy of note about the choroid and the same could be said of the ciliary body, iris and lens. There was a great quantity of material in the interior chamber which was probably transudate, coagulated by the hardening process.

*Microscopic Changes.*—The changes in the retina were very noticeable and particularly in the anterior part of the eye. The anterior portion of the detached retina was the seat of the most marked degenerative changes, the retina itself resembling closely a reticulated tissue in which there was hardly a trace of the several layers. Posteriorly it was easy to recognize the several layers but they gradually disappeared toward the ora serrata and the only evidence of a layer was a single row of granules which marked the course of the external granular layer. The layer of rods and cones was intact in several places but this condition was usually found in the posterior half of the eye. At those points where the retina was thrown into very intricate folds this layer was more apt to be

absent, but even in this situation it was sometimes present. In those situations where the layer of rods and cones was absent its place was filled by a mass of albuminous drops, which were arranged in layers one on top of the other. On the inner surface of the retina one could see the meshes of the vitreous fibrillæ, which appeared to be exercising traction upon the surrounding retina. This layer of fibrillæ was tolerably rich in nuclei. In one place the retina had curved around so as to form a loop, on one side of this loop all the layers were to be seen with the exception of the ganglion cell layer. The layer of rods and cones could be plainly seen as well as the external limiting membrane. On the opposite side of this loop the only layers which were present were the external granular and the external molecular, the latter to a very limited extent. The inner layers in this situation had been pulled out of all shape by the vitreous fibrillæ. The external granular layer presented generally a very irregular border line appearing at points as papilla-like projections, due I think to the folding of the retina. The layer which occupied the usual position of the nerve fiber layer and which to a large extent was that layer, was the seat of numerous nuclei. The radiating fibers of Müller showed generally a wavy course. The line of demarcation between the ganglion cell layer and the nerve fiber layer was difficult to make out. This was no doubt to be attributed to the traction exerted upon the nerve fiber layer by the fibrillæ and also by the very irregular course followed by the radiating fibers. As a rule the ganglion cells had dropped out of the section and it was impossible to identify this layer. An examination of the neck of the detachment, or as I have called it, the neck of the funnel, showed no remains of the vitreous body.

This neck appeared to be a mass of connective tissue in which it was impossible to distinguish any of the retinal layers though it seemed to be made up largely of the granular. At the papilla there was no semblance of the retinal structure. There was too at this latter point a notable absence of blood vessels. Upon the neck of the detachment on all sides there were resting several layers of albuminous drops. The fibrillæ were for the most part devoid of nuclei. They often appeared as though they came directly out of the retina and made their way into the vitreous body or as though they were prolongations of the radiating fibers, so intimate was their connection with the latter.

*Choroid.*—On the inner surface there were several layers of albuminous transudate resting on the pigmentary layer of the retina, which layer had remained behind as it usually does in such cases. Increased nucleation was everywhere present throughout the choroid, and further than the points just mentioned; there was nothing noteworthy in this part of the eye. The vitreous body was entirely wanting in the posterior part of the eye. Just behind the lens it seemed to be transformed into granular debris devoid of fibrillæ, while in other portions it was composed apparently of the fibrillæ which have been described. The lens, iris and ciliary muscle were normal.

The chief points then about the pathologic anatomy of this case were: 1. The widespread atrophic degeneration of the retinal layers and especially of the layer of rods and cones. As a general thing the granular layers were the only ones which were preserved. 2. Swelling of Müller's fibers. 3. The presence of

albuminous drops in various localities, especially between the choroid and retina and along the neck of the detachment, and finally the transformation of the vitreous body into the fibrillæ.

The second case was that of a boy aged 7 years who came to the Johns Hopkins Hospital early this spring. His parents had taken him to an oculist several months previously and at that time his eye was not thought to be in a serious condition. He had been complaining for the last three weeks of severe pain in his right eye and his parents had noticed a whitish yellow reflex from this eye. This was very noticeable when he came to the hospital. The tension of the eye was decidedly elevated and the conjunctiva was injected. Vision in this eye was completely gone. I advised enucleation and the eye was removed the following day. The macroscopic condition was as follows: The tumor involved almost the entire nasal half of the retina, filling up that side of vitreous space both above and below. It extended backward and seemed to proceed from the nasal side of the optic nerve and, advancing into the vitreous, stopped at a point about a quarter of an inch posterior to the lens. Over the area occupied by the tumor there was no trace of the retina to be seen. On its free side the growth was quite nodular and one of the nodules projected across to the temporal side of the eye and almost reached the retina on that side. The retina in the temporal side of the eye was completely detached.

Microscopic changes: The tumor was scant in intercellular substance and was made up of small round cells. Blood vessels were quite numerous and they were usually filled with red blood corpuscles. Large areas of the growth failed to take on the hematoxin stain but stained with eosin. These were evidently necrotic areas. Hemorrhages were frequently seen. Wherever the tumor was present the retina was indistinguishable, the tumor having grown into it. The tumor cells were found in the optic nerve as far back as a quarter of an inch from the papilla. The vitreous body had been crowded over to the temporal side of the eye and transformed into the characteristic fibrillæ, which were exerting traction upon the retina and had pulled it into intricate folds in the anterior portion of the eye and just behind the lens the traction was enough to pull the retina backward to such an extent that there was only a short, narrow bridge separating the latter from the growth. The layer of rods and cones was nowhere visible, and as in the first case, the ganglion cells had dropped out of the section. The internal and external granular layers were clearly definable from the equator around to the ora serrata. The retina posterior to the equator was very much thickened and broken down, failing to stain. At one point only, and for a very short distance, the external limiting membrane could be seen. The fibers of Müller were somewhat swollen and had a wavy course, which more or less disturbed the position of the retinal layers. The choroid nearly everywhere had been attacked by the growth; large and small heaps of sarcoma cells were present in this coat, and generally they were resting under the pigmentary layer of the retina, which latter was pushed up. This condition extended around as far as the ciliary region on the nasal side and on the temporal side a short distance from the papilla. There were no albuminous drops. The principal changes in this case were the conver-

sion of the vitreous body into fibrillæ and the atrophic degeneration of the retina in the anterior part of the eye.

It would seem then that fibrillary degeneration of the vitreous body is to be found in both classes of cases. In the case of spontaneous detachment it was evident that the fibrillæ were largely concerned in pulling away the retina from its normal position and from the arrangement of the retinal folds shrinkage or contraction from within must have been going on. In this case there was a considerable exudate consisting of albuminous drops resting on the membrana limitans externa, which exudate no doubt played a part in separating the retina and choroid. These two conditions would explain the detachment in the first case and similar ones. In the second, the presence of the sarcoma was sufficient to lift the retina from its position, though even here it was clear that the retina was subject to a force from within which helped to pull it still further away from the choroid. I failed to discover a rent in the retina in either case.

In conclusion, then, the most striking anatomic change in these two cases was the fibrillary degeneration of the vitreous body, a condition which I think is found more or less in every case of retinal detachment, and which probably is the chief element in the pathogenesis of the disease.

#### ETIOLOGIC FACTORS, OTHER THAN MYOPIA, IN THE PRODUCTION OF RETINAL DETACHMENT.

Read in the Section on Ophthalmology, at the Forty-seventh Annual Meeting of the American Medical Association, held at Atlanta, Ga., May 5-8, 1896.

BY H. O. REIK, M.D.

Assistant Surgeon, Baltimore Eye, Ear and Throat Charity Hospital and Assistant in Ophthalmology and Otology, Johns Hopkins Hospital.  
BALTIMORE, MD.

Of all cases of retinal detachment, between 40 and 50 per cent. occur as the result of high degrees of myopia with the severe choroido-retinal changes that attend this refractive condition. In most of these cases the separation occurs spontaneously, but even in those in which it is the direct or immediate result of traumatism the eye has been previously prepared for this accident by the weakening of its tissues. In a study of the other 50 or 60 per cent. we are compelled to attribute their origin to quite a variety of causes.

The first of these to consider, because of its frequency, is trauma. Whether the eye be myopic or hypermetropic, diseased or healthy, a wound and particularly one that penetrates the sclerotic and choroidal coats, may give rise to intraocular changes that result in disorganization and separation of the choroid and retina. A myopic eye, or one that is the subject of choroidal or retinal disease, is predisposed to detachment, and in such cases often a very slight blow will produce very serious consequences. Any severe blow, or injury about the head, may produce detachment, and Dr. Maher has reported a case which he believes, and with apparently good reason, to have been caused by the use of forceps at birth.

The next largest number of cases are the result of pathologic conditions of the choroid or retina produced by those diseases of the kidneys which may be grouped under the general title of albuminuria. It is not uncommon to find associated with Bright's disease a retinitis or choroido-retinitis with more or less

impairment of the vision, and in a small percentage of these cases detachment takes place. The anatomic seat of the eye lesion in this disease is probably the blood vessels, and as the supply vessels of the retina are end arteries any interference with their function is not compensated for as readily by collateral circulation as would be the case in other parts of the body. So, almost always an extensive edema of the retina exists, which, owing to the loose attachment of that tissue, gives rise to the production of delicate folds in the membrane and later these may amount to a positive detachment, with its tendency to spread over the greater part of the fundus. Occasionally, however, the detachment is brought about in a different way. The vessel walls are sclerosed and weakened by the general disease, and any influence which tends to suddenly increase the blood pressure causes a rupture of the vessel wall with consequent hemorrhage, and the blood clot, if it be sub-retinal, produces a mechanical separation of the retina from its bed. It would appear from the cases reported that detachment occurs most frequently in that class of kidney troubles in which we have to deal with what is known as the small granular kidney. As very many of the reports, however, do not state the pathologic nature of the kidney lesion, it is difficult to arrive at any definite conclusions in this direction. The above supposition, however, is what one would naturally be led to expect, as it is in association with the small atrophic kidney that retinitis albuminuria is most common. Just as the retinal inflammation may occur in any form of nephritis, either acute or chronic, so may detachment be the ultimate result.

The class of cases which probably offers us the most favorable prognosis is that occurring in the albuminuria of pregnancy, for here, if necessity arises, the cause of the disturbance may be removed, and with that element withdrawn there is a remarkable tendency to spontaneous recovery. There seems to be no particular time in the course of pregnancy when we may anticipate retinal complications, as retinitis has been observed in every month, yet it is probably most liable to occur in the latter part of gestation, when the greatest tendency to general edema exists. Schoeler reports cases of two sisters, both of whom suffered during pregnancy from detachment of the retina without any signs of albumin or retinitis.

The following case of retinal detachment was related to me by Dr. Randolph. It is especially interesting as having occurred during labor. The woman was the mother of eight children and always had easy labors. Just before the birth of the ninth child her physician had made a thorough examination of her urine but had not discovered anything pathologic. The labor was an exceedingly painful one and lasted for twenty-four hours. At the height of one of her pains, and just after she had made a violent effort, she noticed that everything became blank before her right eye. Since then she has been practically blind in that eye. When seen by Dr. Randolph there was nearly complete detachment of the retina in the right eye, the left eye being quite normal. The case was seen a few days after the labor. I think that the violent efforts and straining which she was constantly making led to a rupture of one or more of the retinal vessels which discharged their contents beneath the retina, thus forcing the latter away from the choroid, producing a detachment. When we consider the

frequency of subconjunctival ecchymoses following great efforts at stool or in children with the whooping cough, it is not strange that hemorrhage from the deeper vessels of the eye should have followed the violent efforts of a woman in labor.

A few cases of detachment due to diabetic retinitis have been reported, but such cases are extremely rare, as diabetes is but seldom complicated by retinal disturbances.

Galezowski found it, I think, in about 2 per cent. of his cases; syphilis is given as the cause, and the same writer reports four cases the apparent result of sympathetic ophthalmia.

Dr. Mathew Owens of Brisbane, reported in 1884 two rather peculiar cases of double retinal detachment occurring in previously healthy eyes, as the result of sunstroke. Both men were cattle rangers and the sunstroke was followed immediately by detachment. The men were young and there was no history of any diseased condition that might have predisposed them to detachment. In considering the cases Dr. Owens offers the following as a possible explanation: "It was shown by Boll that eyes which have been exposed to the influence of various colors are affected very differently as regards the pigment epithelium layer. If eyes have been exposed to red or yellow, or kept in darkness, the pigment layer is quite easily separated from the retina, but not so if exposed to white, green or blue. The retina and pigment are so closely united that they can not be separated. . . . The eyes of both patients had been exposed for some hours to the sun's glare, retinal hyperemia was present, sunstroke came on; the sinuses of the brain being engorged there was an impediment to the return of the blood to the brain from the congested fundus, effusion of serum took place, and the retina was quite ready to be detached because its pigment layer had been exposed to the yellow glare of the dried up ground." It is a rather unique explanation, and one which in my opinion is somewhat forced.

Erysipelas of the face and neuralgia of the fifth nerve in a small number of cases, have appeared to be the cause of retinal detachment.

Separation may be produced mechanically by hemorrhage or by sero-purulent exudates such as occur in purulent choroiditis or in phlegmon of the orbit. Tumors in the choroid or retina, or a cysticercus developing beneath the retina may also be causative factors. The tumors are usually glioma, or choroidal sarcoma.

In every case of detachment the cause should be determined, if possible, because of its important bearing on the treatment. Rydel has given statistics to show that 5 per cent. of all our blind have become so from retinal detachment. Despite the greatest care taken, however, in examining these cases, there still remain a large percentage in which no cause for the lesion can be ascertained. In these cases the patient usually gives the history of having been perfectly healthy, with an eye that was either emmetropic or hypermetropic, and no exposure to injury of any kind. The first symptom is a slight cloudiness of the vision, or a limitation of some portion of the visual field. It is not attended by pain and it is only the loss of vision, more or less complete, that causes the patient to consult an oculist. Some have thought that disturbances of the sexual nervous organization might be an explanation of a few cases, and in that connection quote Hutchinson as saying that "sexual abuse may produce

degeneration of the vitreous," but I can find no case recorded where there is any conclusive evidence of this having been the cause. Sudden suppression of the menses may result in hemorrhage, and that in detachment.

The pathology of this affection has not been satisfactorily explained. It was formerly held that the retina was pushed forward by a transudation from the choroid. This hypothesis now has few adherents.

A second theory, now generally known as the Leber-Nordenson, and which is the one most generally accepted, attributes the attachment to traction from the vitreous side. The active cause here is held to be a shrinking of the vitreous, which ruptures the retina and permits the fluid from the vitreous cavity, pressed out by the contracting tissues, to pass through the rent into the subretinal space.

This hypothesis assumes not only a shrinking of the vitreous, but an adhesion between the vitreous and retina and a rupture of the retina previous to its detachment.

That rupture of this membrane necessarily precedes its detachment I do not believe. I can not see the need of this supposition in regard to a tissue so loosely attached to its bed as is the retina, and, furthermore, if it does always occur we should be able to see it in a greater number of cases. In a very large percentage seen, even in early stages, it is impossible to find a rupture and even Leber, who considers it so important to his theory, found it positively, in relatively fresh cases, in only about 50 per cent.

It may be that in some cases, at least, the change in the vitreous humor is a chemic one, which leads to an interchange of fluids between that body and the blood vessels of the choroid, and that detachment is produced in accordance with the diffusion theory. This theory, so ably advanced by Raehlmann, has not received the consideration it would seem to merit.

Though the immediate cause of displacement is so obscure it is probably safe to say that the vitreous is always the seat of pathologic alteration, though such changes may not be, and often are not, apparent by ophthalmoscopic examination. One can hardly conceive, except in case of intra-ocular growth, or of subretinal hemorrhage, of detachment occurring when the vitreous is of normal consistency and exerting its usual pressure on the surrounding parts.

## TREATMENT OF DETACHMENT OF THE RETINA.

Read in the Section on Ophthalmology, at the Forty-seventh Annual Meeting of the American Medical Association, at Atlanta, Ga., May 5-8, 1896.

BY CASEY A. WOOD, M.D.  
CHICAGO, ILL.

Without taking your time with a historical sketch of the various remedies employed in the treatment of detachment of the retina I may say that the earliest efforts of the ophthalmic surgeon were directed to puncturing the subretinal sac, as it was found that this usually brought the displaced membrane into its normal position. As, however, the detachment was found to occur a second or a third time or, indeed in many cases, as often as it was replaced, various expedients were resorted to with the hope of rendering the cure permanent.

Before speaking of these matters in detail let me remind you that replacement of the membrane does not necessarily mean a restoration of the lost visual

function, although it is a *sine qua non* of that restoration. Nor do the visual acuity and the extent of the visual field form a proper measure of the success of a remedy for detached retina *as such*. A badly damaged retina (as in the long standing cases) perfectly replaced may give results much less satisfactory to the patient than an imperfect replacement of an otherwise healthy membrane—such as we commonly find in recent examples of this disease.

I pass over the treatment by rest in bed, with or without such adjuncts as bandages, the local use of eserine and atropin, the internal administration of salicylates, purgatives, diaphoretics, potassic iodid, pilocarpin injections, starvation, iridectomy, sclerotomy and puncture of the sclera, to take up certain other surgical proceedings that are now claiming attention as being more or less novel.

I had been attached for nearly a year to Professor Schöler's Klinik in Berlin when he first began to experiment with intra-vitreous injections of iodine in this disease. Consequently, I have had excellent opportunities of observing its effects. Although much was hoped and expected from the procedure and a number of cures have certainly resulted from its use, the evidence is on the whole against it as a dangerous and by no means certain remedy. That numerous eyes have been entirely lost from the employment of Schöler's method, I am obliged to confess, and I do not think that, even in its modified form, one would be justified in employing it. Most of you will also recollect Gelpke's experience. The patient, a healthy man, 66 years of age, with detached retina, received under strict precautions a vitreous injection of three drops of iodine mixture. *In two days he had a purulent choroiditis* and in six days he died of acute meningitis.

Other less active and more certain expedients may be employed to produce all the effects which Schöler claims for the iodine injections. We may dismiss, also, as needless and dangerous, the injection of irritating fluids—such as potassic permanganate, suggested, I think, by Darier—through a puncture in the sclera. To this category, too, belong De Wecker's device of a gold suture and Galezowski's catgut suture, all three intended to produce local inflammatory areas and so bind choroid and retina together.

Wolfe of Glasgow, made a long incision (6-10 mm.) through the sclera, the underlying conjunctiva being pulled away by hooks, and so obtained free and continued drainage of the subretinal fluid. In fifteen eyes he had improved vision (lasting five months to a year) from  $\frac{1}{2}$  to 1-50; in five cases the results were *nil*, and in two instances the eyes were lost. Even when performed under strict aseptic precautions the danger of infection through these large wounds must be considerable.

Gillet de Grandmont first advised electrolysis of the subretinal fluid. Simi of Florence, among others, has successfully tried this method in a case of recent detachment, using a 5 milliampère current for sixty seconds, and two weeks subsequently the same current for seventy seconds. There were signs of reaction in both iris and vitreous and the exudation disappeared, but the detached portion remained opaque and was clearly outlined from the healthy retina by a pigmented line.

Terson of Toulouse, from a study of twelve cases in which he employed electrolysis of the post-retinal fluid, believes that the method of Gillet de Grandmont

with a single needle attached to the positive pole is superior to those of Abadie and Schöler, the latter of whom employed the bipolar plan—making two punctures in the globe.

*Posterior Ophthalmotomy.*—Galezowski<sup>1</sup> formerly relied on iodine injected into the post retinal pocket (1886) with aspiration of the contained fluid. If necessary he followed this with a catgut suture, passed like De Wecker's earlier gold stitch, through all the eye coats. This latter procedure usually succeeded in binding the retina to the choroid but as it was followed in two instances by severe intraocular inflammation he abandoned it in favor of the operation which he now recommends as free from danger and quite as successful. He calls it posterior ophthalmotomy. The instrument used is in the form of an arc of a circle, like a curved needle, so that a sufficiently large puncture and counterpuncture can be made and a sufficient number of retino-choroidal cicatricial points produced to keep the detached membrane in place when it has once returned. He has already followed this plan some seven times—in five cases with partial, in two with great success. In one instance of a man aged 50, with a double detachment, of long standing on the left side, but recent on the right, he obtained a complete cure in six weeks. The linear cicatrices could be made out with the mirror; the visual field and central acuity were very greatly increased.

Probably the most recent, original and important contribution to the rational treatment of retinal detachment has been made by Deutschmann of Hamburg, which first appeared in his *Beiträge zur Augenheilkunde*, although he has since (in May, 1895) given an abstract of the brochure in the *Deutsche med. Wochenschrift*. He prefixes the account of his methods by a reference to Erik Nordenson's work with Leber.

Apart from certain rare forms of the disease, detachment is due not so much to a primary deposit of water from the choroid behind the retina as to the dragging upon this coat by a diseased and shrinking vitreous. The detachment is merely one of the signs of the vitreous disease. Nordenson shows that without losing its transparency the vitreous develops a fibrillar quality, decreases in volume and in shrinking allows the vacant space to be filled with serous liquid. This change in the consistence of the vitreous body is not unfrequently accompanied by proliferation of the vitreous elements as well as by a chronic inflammation of the choroid. Portions of the thickened vitreous remaining firmly attached to the retina are, with it, liable to be dragged toward the center of the posterior chamber. Deutschmann's first proceeding, which he names *Netzhautglaskörperdurchschneidung*, is intended to sever all connections between the shrinking vitreous and the retina, to allow of a free communication between the posterior chamber and the serous collection behind the retina, to empty the latter space so that the freed retina may return to its normal position, and lastly, to produce adhesion between choroid and retina at certain points; these indications are met by the following operation: The previously atropinized eye is cocainized and a double edged knife, of the Graefe pattern, is introduced at the chosen spot, the conjunctiva being pushed to one side. It pierces all the ocular coats, sclera, choroid, and the detached retina. Thence the knife is passed

obliquely through the vitreous mass until it touches the opposite wall of the bulb. It is now carefully moved to and fro toward either side making a vitreous dissection and is finally removed, and a light occlusive and antiseptic bandage applied. Slight hemorrhage occurs at the point of entrance of the knife and inflammatory action is set up about the incision points in both choroid and retina. This latter process is relied upon to permanently fix the retina to the choroid and so resist any subsequent pulling of the vitreous.

The patient is now kept in bed for eight to fourteen days, until the ophthalmoscope shows that the case is cured. The atropia is continued for several weeks longer. When the retina does not lie perfectly flat on the day after the operation, a delay of a few days may be made in the hope of its complete return to the normal position. If this fails the same procedure is to be resorted to, as often as is required, until the desired effect is obtained. Deutschmann has operated ten times upon the same patient with good results at last. He thinks that repeated thrusts of the knife are safer than, and as effective in inducing a sufficient degree of adhesive inflammation between the retina and choroid as the application of the Paquelin or electro-cautery point to the sclera, or, piercing that also, to the choroid and displaced retina beneath.

He refers in his short article in the *Deutsch. med. Woch.*, to eleven patients treated by him, to date. Upon four the Paquelin cautery was employed and the sclera pierced. Of these four, two were partially relieved and two not benefited. Of the remaining seven, where the cautery was omitted, total replacement of the retina was obtained in six instances, with decided improvement in vision. This satisfactory condition has persisted in one case for four years, three cases two years, one case one year and one five months. In the case, where least benefit accrued, only one operation was made, the patient declining further interference.

The author advises this operation in those more favorable cases, where the displacement is recent and not too widespread and where disease of the coats is not advanced.

In another class—in their nature more hopeless—he has employed quite a different and novel remedial process, which he styles "*Kaninchenlaskörpertransplantation*." This was first tried on a patient 28 years of age, with bilateral detachment of the retina. The left eye had suffered a sudden and total separation of the retina from the choroid. The eye was soft and vision was reduced to perception of light in the upper part of the field. Both anterior and posterior retinal spaces were filled with a sero-sanguineous fluid. Deutschmann removed this bloody serum and with an ordinary hypodermic syringe injected into the empty vitreous cavity the freshly prepared, aseptic vitreous of a young rabbit, diluted with a  $\frac{2}{3}$  per cent. solution of common salt. The addition of the sterilized salt solution was intended to allow of easy flow of the vitreous as well as to act as an irritant and bind the choroid to the retina. The result was marvelous. The operation was performed Feb. 4, 1894. On April 28, V =  $\frac{1}{20}$ ; on July it was  $\frac{1}{7}$  and Jäger No. 3. F. of V. for white was uncontracted and has so continued.

Deutschmann has, to May, 1895, performed this operation on six patients and seven eyes, and in four obtained results that hitherto would have been regarded as impossible. In all, central vision before the operation was reduced to perception of light or

<sup>1</sup> Galezowski: Mem. et Bull. de la Soc. frs. 1895, p. 170.

shadows and most of them were cases of total detachment.

In case 2, which was of many years standing, there was beginning secondary cataract; V = eccentric finger-counting at four feet. Result: Useful central vision, replacement of the detached retina and enlargement of the eccentric field to twice its previous size. Case 3, total detachment from injury. V = hand movements. Visual result not very encouraging. V = finger counting at 2 and 3 feet eccentrically.

In the other cases the result was uniformly favorable. The patients have been under observation for from a year in Case 1 to five months in Case 6 after the replacement of the retina. This operation may have to be repeated two or even three times and it must be remembered that an inflammatory reaction follows each injection.

Detachment of the retina does not occur often in this country, but I have on my records six cases that consented to be treated for a sufficient length of time to make my experience with them worth mentioning. The treatment for two scleral punctures, one iridectomy and the other three had prescribed for them continued rest in bed with pilocarpin injection. Only in one case, treated by puncture and pilocarpin, was there a permanent cure, the retina being replaced, the visual field expanded, and the central vision now equals finger counting at seven feet, although at one time it was reduced to perception of light. This continued for nearly a year, when I lost sight of the patient. My experience of this disease in my own practice, public and private, and in that of others lead me to think, with Bull of New York, that we have as yet discovered no better device than that resorted to with occasional success by the older ophthalmologists, viz.: rest in bed, bandages, atropin and the internal use of some absorbent. Instead of the long continued use of pilocarpin, especially when that drug is ill borne by the patient, we may substitute soda bicarbonate and potassic iodid, well diluted with water. In all recent cases where the eye is quiet and there is no vitreous strand to sever, conjunctival puncture of the sclera may do temporary good and vision may be improved. Division of fixed membranous bands in the vitreous may be done without causing much reaction and may prevent extension of the disease. He does not approve of Schöler's method.

In conclusion, this review of the treatment of detached retina would be incomplete without a reference to spontaneous cures. Many such cases are recorded; indeed one may safely say that of all the histories of cures, temporary and permanent, at least 10 per cent. were accomplished without treatment. So numerous and well authenticated are they that I think that a large percentage of the results obtained after iridectomy, after removal of the lens, from the use of atropin, bandaging, pilocarpin, etc., even some cases of cure following posterior operation, are really brought about by local and general rest—by putting patients in such a position that they can not by over exertion of any kind make a bad matter worse. The retina, having meantime broken loose from its connections with the shrinking vitreous, returns to its natural position—and the treatment, medical or surgical, receives the credit.

## REPORT OF A CASE OF RETINAL DETACHMENT AND EDEMA OCCURRING IN CHRONIC BRIGHT'S DISEASE.

Read in the Section on Ophthalmology, at the Forty-seventh Annual Meeting of the American Medical Association, held at Atlanta, Ga., May 5-8, 1896.

BY LOUIS F. LOVE, M.D.

OPHTHALMIC SURGEON TO ST. MARY'S HOSPITAL, HOUSE OF GOOD SHEPHERD, ETC.  
PHILADELPHIA, PA.

When we take into consideration the blood conditions existing in albuminuria, it seems strange that the occurrence of retinal edemas and detachments are not more frequently found. The vitreous body is undoubtedly nourished from its surroundings, and Raehlman long ago demonstrated that by injecting strong saline solutions into the vitreous he was able to produce retinal detachment and that the fluid secreted was densely albuminous, so that it seems rational to say that any cause which produces profound changes in the circulation would interfere with the balance of osmosis between the vitreous body and the choroidal vessels. I believe that by a careful chemic and microscopic examination of the general blood conditions, especially the liquor sanguinis, we might be able to benefit, at least, some of our patients to whom we are at present useless. In detachments taking place in high myopias or resulting from inflammatory conditions, this line of investigation would be of no avail; but in those cases arising without apparent cause, such as we occasionally see in emmetropic eyes, that such a research might be of use. This case is reported for the reason that it is not only rare, but because of the unusual prolongation of life.

C. D., a short, stout woman, aged 54 years, applied for treatment Oct. 26, 1892, giving the following history: Had always enjoyed good health. Lately slight headaches and dyspnea upon exertion. She is the mother of five children, three living, no miscarriages, menopause at 46. Four years ago her vision in her right eye failed suddenly. About two weeks ago she noticed a dimness in the left eye. The present eye conditions were as follows: O. D. V. = counting the fingers at ten inches. O. S. V. =  $\frac{2}{8}$  + S. 2D. =  $\frac{2}{8}$  + S. 4D. type 1D. 12c to 25c. The eyes are rather deeply set, ocular and tarsal conjunctiva pale, the arcus senilis well marked above, the color of the irides brown, right pupil 3 mm. and very sluggish to light; left pupil about 2½ mm., active to light. Anterior chambers shallow, strong reflexes from both lenses. Right eye Tn — left Tn.

Ophthalmoscopic examination O. D: A few very fine floating vitreous opacities; the nerve decidedly atrophic; the vessels diminished in size and a retinal edema extending well out when an extensive retinal detachment was plainly seen superiorly and inferiorly, giving the characteristic delicate gray undulating tremulous protruding membrane. The vessels could be traced from the papilla out into the detachment, and in places showing sharp bends and partially hidden from view by the folds of the separate surface. The disc is seen best with + 3D., the detachment with about + 7D. Left eye lens seemingly hazy, disc very red gray, veins slightly enlarged, arteries normal in caliber, carrying poor blood, a large area of hemorrhagic extravasation in the macula region and a few white plaques found just above the disc. H. = 4d.

Examination of the urine was as follows: Straw color, acid, specific gravity 1018; albumin in moderate

This is the proper season to increase the membership in the ASSOCIATION. Let everyone secure one!

amount, no sugar; microscopic examination hyalin casts, pus cells and few blood corpuscles.

The patient was under the care of Dr. J. C. Wilson, who saw her on four or five occasions, between Nov. 1, 1892, and March of the following year. His report to me was as follows: There was cardiac hypertrophy, accentuation of the aortic second sound and slight pre-tibial edema. She improved in respect to the headaches and restlessness while under treatment by strychnin and nitroglycerin, together with a carefully regulated dietary.

The woman was not seen again until Nov. 6, 1895, three years after the first examination. O. D. V. = light perception only. O. S. V. =  $\frac{2}{7}$  + S. 2D. V. =  $\frac{3}{8}$ . Ophthalmoscopic examination shows vessels thread-like in the right eye, apparently similar conditions of retina as existed when first seen. The left eye, the nerve quite gray, vessels about normal in size, in the macula region a brownish black area, and above the disc there are characteristic changes of an old retinitis Brightii. The patient states that her general condition is about the same, enjoying fairly good health; she has taken no treatment since March, 1893, but adheres somewhat to the regulated dietary as ordered by Dr. Wilson.

1762 Frankford Avenue.

DISCUSSION ON PAPERS OF DRs. RANDOLPH, REIK, WOOD,  
AND LOVE.

DR. J. A. WHITE, Richmond—In considering the etiologic factors of detachment we are to some extent groping in the dark. Apart from myopia, tumors, subretinal hemorrhages and effusions, I do not think we have any very sure foundations for explaining the many cases we meet with where there is no apparent cause whatever. It is important to know the cause in order to decide upon the method of treatment, but in many cases this can not be established. When we come to consider the treatment we are still as badly off as we were many years ago. The old treatment of rest, diaphoretics, pilocarpin, etc., give us as good results to-day as any of the operative procedures. It is only in the recent cases of detachment that we have had any satisfactory results from any of the methods. I have tried rest, iridectomy, sclerotomy, paracentesis and sclero-puncture. I do not advise operative measures except in recent cases where the macula is involved, and even then I do not if there exists a condition likely to lead to hemorrhage. Electrolysis may be a good thing; certainly much has been claimed for it. The galvano-cautery is too dangerous, and should be placed in the same category as the injections of iodine. Deutschmann's method has been mentioned, but neither he nor anyone else has had sufficient experience with it to warrant very favorable reports. One method that has not been mentioned here is that of Strau. He frees the conjunctiva from the sclera over the site of the detachment, makes three little slits in the sclera, and then unites the conjunctiva over this with sutures and allows it to heal. He then makes injections in this region of a 1-5000 bichlorid solution, and has claimed very good results. It is simply an experiment, like all the others, and may be discarded. I have not tried the injections of rabbit's vitreous according to Deutschman. I have watched a few cases in private practice from their start. One was in a physician and associated with myopia. He has a low grade of myopia and wears a -2.50 D for distance, and with it has had for fifteen years almost perfect vision. Recently he said that he had a little spot in his eye; I paid no attention to it, thinking it simply a *musca volitans*. Some time later he complained of an increase of this spot, but I could not find any opacity with the ophthalmoscope. Later a slight spot became visible, looking like a floating string, and I then told him that his vitreous

was undergoing liquefaction, though he never had any alteration of the refraction or any changes in the choroid that I could determine. Soon I noticed a secondary detachment, and although we gave treatment by rest, pilocarpin, etc., at once, in sixty days the detachment was absolutely total. He from the first refused an operation, because he was well acquainted with the subject, and knew the slight chances of success.

DR. LYMAN WARE, Chicago—I did not for a moment question the correctness of the report of Dr. Terson's cases, but I was not convinced that electrolysis was the cause of the result. Is the using of a positive pole a rational treatment? One of the first things settled in regard to the use of electricity was that the positive pole produced coagulation and the negative pole diffusion. Would not absorption be best brought about by the use of the negative pole? The fact that we have such a variety of treatments offered shows that none are very satisfactory.

DR. A. R. BAKER, Cleveland—I wish it were possible to make a more scientific classification of these cases. In the case of hemorrhage, tumor or trauma the detachment is simply an incident, and in those cases produced by Bright's disease, if the cause could be removed the case would recover. Formerly I made a sclero puncture, but lately I have omitted that. Besides rest I give them diaphoretics, and in some cases we have found considerable benefit. One case where there was almost complete detachment in one eye existing for a number of years was followed by detachment in the other eye. I kept him under treatment for six months, and discharged him with fairly good vision. About three years later I found him back in the hospital, blind and without any prospects of recovery. Treatment is very unsatisfactory.

DR. G. E. DE SCHWEINITZ, Philadelphia—I would deprecate the report of cases of retinal detachment submitted to operative interference, before sufficient time has elapsed to test the sufficiency of their cure. I would suggest that Deutschmann's result in human beings with injections of sterilized vitreous be repeated in animals.

DR. D. S. REYNOLDS, Louisville—I am unprepared to accept the details of the pathologic changes described by Dr. Randolph. It is by no means clear that the drawings furnished are sufficiently accurate to support the accompanying descriptive language. The normal retina can not be shown to contain pigmented layers, yet Dr. Randolph's report contains a reference to that impossible condition. In my own experience results have been in some cases very encouraging at first, but in a few months fatal relapses have occurred. In persons under fifty years of age, in good robust general health, medicinal treatment often yields brilliant results, but in nearly all cases subsequent return of the detachment of wider areas surely comes on in due course of time. I have seen it most always in myopes, but never in any but progressive cases. My attempts at operative treatment have yielded results in no wise more encouraging than that by the salicylates, pilocarpin and the iodids, with rest in bed. Much remains yet to be done before we may claim any permanent recoveries from any treatment.

DR. R. L. RANDOLPH—While nothing positive has been added to the therapeutics of this subject, I think we have gone over the whole field thoroughly, and it is always a help to know the present status of any subject.

DR. A. R. BAKER, Cleveland—The question has often been suggested to my mind whether we have detachment in this class of cases. I have seen but few except in high degrees of myopia, and become so accustomed to think of it in this way that I have almost quit looking for any other cause.

DR. F. W. HIGGINS, Cortland, N. Y.—In looking up the subject of edema of the retina in Bright's disease, I noticed one cure reported by Brecht (*Archives f. Oph.*, Vol. xviii, 2, p. 102) of marked detachment of the retina in nephritis. He considers it very rare and due to some predisposition.

## THE USE OF CAUSTICS FOR EPITHELIOMA OF THE LIDS.

Read in the Section on Ophthalmology at the Forty-seventh Annual Meeting of the American Medical Association held at Atlanta, Ga., May 5-8, 1896.

BY FRANK TRESTER SMITH, A.M., M.D.

PROFESSOR OF DISEASES OF THE EYE, CHATTANOOGA MEDICAL COLLEGE. FORMERLY ASSISTANT SURGEON NEW YORK OPHTHALMIC AND AURAL INSTITUTE. CHATTANOOGA, TENN.

This subject was suggested by the following case which came under my observation.

Frank S., age 64, of Chattanooga, at the age of 43 had had the right eye destroyed by an explosion. The ball was shrunken and the lids adherent, so that this eye was entirely useless.

The left upper lid presented an ulcer about one-third inch in diameter covered with a dry scab; on the inner and outer sides there appeared to be a blister. The trouble began twelve years ago from a small scab which was picked off from time to time and the ulcerated surface had gradually grown larger. A few days before, some empiric had made an application which had caused the ulcer to double in size, after which the borders had become blistered. A soothing application was prescribed with the idea that the blisters would disappear, but the bases became hard and the contents gelatinous. The case did not improve after several weeks' treatment. The diagnosis of epithelioma was made, and an operation, consisting of the total removal of the inner half of the lid and supplying its place by a plastic operation, advised. The patient was myopic and presbyopic. Left vision 20-200 with 2 dioptry concave lens 20-70. While preparing for the operation the patient came under the care of an empiric who by means of some caustic, apparently destroyed the pathologic growth, and it was replaced with a smooth cicatricial tissue, leaving the lid intact and much more useful and ornamental than any plastic surgery could have devised.

The case suggests that in some cases of epithelioma of the lids, especially where we can not operate, that caustics should be used. In this case the pathologic tissue extended so as to require the removal of the entire thickness of the lid by any cutting operation, and any surgeon would certainly have removed at least half the lid and even then there would probably have been a reappearance of the tumor. Nearly all this was removed and the lid left in good shape, with the loss of a small amount of tissue, by the use of caustic in unskilled hands. It can but suggest that if the caustic had been carefully and thoroughly applied the cancer cells would have been thoroughly destroyed.

Dr. A. R. Robinson, of New York, called attention to the advantages of the use of caustics in the treatment of cutaneous epitheliomata in an instructive paper read before the Tri-State Medical Society of Alabama, Georgia and Tennessee in 1895. For use about the eye he recommended a solution of chlorid of zinc in a 20 per cent. solution of cocain.

The objection to the use of caustics, in this location, is that some of it may come in contact with the eyeball and cause ulceration. For this reason these growths are removed by cutting.

The advantages of the caustic over the knife are that there is usually less destruction of tissue, and with the destruction of the same amount, the result is surer, because the necrosed tissue is surrounded with an inflammatory zone and the products of the

inflammation tend to destroy the pathologic cells for a distance beyond the part extirpated. This is more likely to be the case if the wound is allowed to suppurate, as it is generally conceded that the toxin of germs which produce suppuration are destructive to the cells of epitheliomata.

Some of the caustics have an elective action on the cancer cells. This is notably the case with arsenious acid, which should be used weaker than in Marsden's paste; three parts of acid to two of gum acacia. It is said this will not attack normal tissue for twenty hours. It is believed that by having the case under constant observation during the application, that caustics can be used safely on the lids, in many cases, to the advantage of the patient. I am aware that this position is opposed to that of most oculists but I have been told that some of the members of this Section have used caustics instead of the knife. However, I have been unable to find any literature on the subject.

## MEDICAL PARIS.

NOTES FROM MY SKETCH-BOOK.

BY L. HARRISON METTLER, A.M., M.D.

CHICAGO, ILL.

In his powerful romance, "Les Mystères de Paris," Eugene Sue, who, by the way, was a physician and the son of a physician, paints a vivid picture of Parisian low life, locating most of his scenes in the crowded tenements and narrow alleys which once occupied the ground now covered by the immense buildings of the Hotel Dieu. When these buildings were constructed, only a few years ago, the remains of the historic Hotel Dieu, as well as many another ancient landmark, were swept out of existence. The Ile de la Cité, with the noble old cathedral of Notre Dame, the gruesome Morgue, so strangely fascinating to Dickens, the Hotel Dieu, so often pictured in history, poetry and romance, the Palais de Justice, the oldest monument in the city, and the matchless Sainte Chapelle, the gem of medieval architecture, constitutes only a small section of modern Paris, but it is the richest in historic lore and romantic anecdote. In one of the ancient streets, now vanished on account of the encroachments of the Hotel Dieu, dwelt the shrewd physician, Theophraste Renaudot, who, in 1630, printed the first Parisian newspaper, *La Gazette de France*. The wily Theophraste had observed something of the power of human curiosity and had cunningly undertaken to gather news from all quarters for the amusement of his patients. Of course his clientage rapidly increased and in a short time he was more in fashion than any of his practicing brethren. But all Paris could not be expected to be on the doctor's sick list at the same time, and were even such a pleasant thing possible his suite of apartments would not be able to accommodate such a glorious rush of practice. Accordingly the doctor decided to publish weekly some fly-sheets, containing the latest news from other countries. For this he needed a license and obtained it *cum privilegio* in 1632. The success of the venture surpassed the most golden dreams of even the medical imagination. Similar fly-sheets had already been issued in Venice, for which a small coin, *una gazzetta*, was asked, whence comes the name of our modern gazettes.

One day as I was coming out of the Hotel Dieu, a student, with whom I happened to get into conversa-

tion and to whom I had just mentioned several special clinics which I had learned were to be given, asked me where I obtained my information in regard to all these things. Of course I told him and then wondered if old King Clovis did not turn over in his grave to think that a Chicagoan must needs inform a descendant of the proud Franks in regard to his cherished Maison Dieu. The Hotel Dieu Hospital, or God's Hostelry, known in early history as the Maison Dieu, is said to be the most ancient hospital in Europe. The actual date of its foundation appears to be in doubt, though there are reasons for thinking that it had its origin under Clovis, King of the Franks, who flourished during the latter half of the fifth century. Saint Landry, who was Bishop of Paris about the middle of the seventh century, is the reputed founder. It is probably this hospital that is mentioned under the name of St. Christophe in a char-

chapels on the river bank. For nearly a hundred years after this it was woefully neglected, but when Louis XI. ascended the throne its prosperity revived. This king did much to favor it, and built the exquisitely beautiful gothic portals of the two chapels near the Petit Pont, which, together with the elegant renaissance gable belonging to the Salle du Légit, were the particular artistic features of the building until its destruction by fire in December, 1772, when many of the sick inmates perished and the rest were hastily received by the archbishop in Notre Dame. Henry IV. added two wings and greatly increased the revenue of the hospital. Were it not for the frightful loss of life and the burning of the charming chapels, the destruction of the old hospital was a blessing rather than otherwise. It was small, badly arranged, and anything but architecturally beautiful. Victor Hugo describes its front as "furrowed and rugged" and

PARIS, LOOKING NORTHWEST FROM THE TOWERS OF NOTRE DAME CATHEDRAL. HOTEL DIEU IN THE FOREGROUND.

ter of 829. The Maison Dieu was not the direct offshoot of a monastery, as many other hospitals were. In accordance with the decree of Charlemagne, promulgated in 816, that at each See one of the canons should govern the hospital, and that the latter should always be near the cathedral, the Maison Dieu was erected within the shadow of the Notre Dame cathedral and was, until quite recent times, under the control of its chapter. At first it was more than a mere harborage for the sick. It was a charitable organization, embracing every form of aid to the poor and outcast. The first building to bear the name of Hotel Dieu, on the south side of the Place du Parvis Notre Dame, was commenced by Philippe Auguste, who named its first ward the Salle St. Denis. Queen Blanche of Castille added the Salle St. Thomas. It was then almost entirely rebuilt by St. Louis, who added especially the Salle Jaune and two associated

says its roof from the tower of the cathedral looked as though it were "covered with pimples and warts."

The next building that was erected to take the place of the old Hotel Dieu was devoid of all special features in the way of art and architecture. What little effect it did produce upon the artistic eye was completely lost by its juxtaposition to the great cathedral. It consisted of several irregular masses of buildings, and its portal, erected in 1801 after designs made by Clavereau, was severely plain and Doric in style. Beneath its peristyle stood the statue of the philanthropist Montyon, who was buried (1838) here, according to his desire, in the midst of the poor and sick. It was in this building also that the famous poet Gilbert died in 1780. In the reign of Louis XVI. the over-crowded condition of the hospital was a disgrace to the city of Paris and to the science of medicine. The monarch attempted some relief by erecting

four auxiliary establishments in the suburbs, namely, the St. Louis Hospital, the St. Anne Hospital, the Hospital for Incurables and the Hospital for Convalescents. A horrible picture of the wards at this time was given by Tenon, the president of a committee of investigation appointed by the Academy of Sciences. Convalescents were seen by the local commissioners in the same room with the sick, the dying and the dead. The insane were confined in neighboring rooms and apartments and kept the other wards in a continual state of excitement with their ravings. Operations were performed in the same room or ward in which there were beds containing other patients. In the days before the use of anesthetics we can well imagine that the cries and contortions of those undergoing operations would have anything but a favorable effect upon the other patients. During the French Revolution the name of the hospital was changed to L'Humanité. Finally the whole conglomeration of inadequate and unsightly buildings was demolished, an increased area was secured and the present vast, homogeneous and elegant edifice was inaugurated in August, 1877, under the direction of the architect Diet. It is an immense oblong stone building surrounding a courtyard of ample dimensions. The arrangement of the wings, grid-iron-like, is the happiest imaginable for the introduction of air and sunlight into the interiors. Overlooking the courtyard is a peristyle or open porch all round the building where convalescents may sit in the open air. The work of the hospital comprises a service of about 810 beds. Of these 430 are for men and 380 for women. Medical cases take up 555 beds while 255 are given over to surgical cases. The history of the government of the hospital is interesting. Until 1505 it was under the management of the chapter of Notre Dame. After that year it was looked after by a committee of lay governors, eight in number, selected from the citizens of Paris. The selection was made by the mayor and aldermen and the appointments confirmed by the parliament. In 1654 the number of directors was raised to twelve. In 1690 Louis XIV. made some alterations in the government and formed the Grand Committee, including in that committee the archbishop of Paris, the former presidents of parliament, of the taxation court, of the court of alms, the commissioner of police and the mayor. To-day it is under the control of the Assistance Publique, one of the departments of the Prefecture of the Seine, as I explained in my last sketch. The oldest paper in its rich collection of archives is dated 1157, and from 1531 to the present there is a complete unbroken history of its work. Such is the story in brief of God's Hostelery, Paris, the oldest hospital in Europe, and one of the greatest in the world. Within its walls medicine has had one of its firmest strongholds and from its wards have issued many discoveries in science. Did I say the poet Gilbert died here? Many another poet has died here too; yea, and statesman and artist and soldier and king, whose names have never been emblazoned on the escutcheon of fame. Sickness is a great leveler of the human race; births and deaths emphasize the equality of man. A hospital is a place for thought, a great hospital awakens reflections that only eternity can answer.

As a frequent visitor to the Hotel Dieu I was intensely interested in some of the differences between French and American hospital methods. One day I

accompanied a group of students, who were being instructed by the surgeon Kermisson, a spare, active, wiry sort of a man, who always wore a skull cap, through the wards. The operator hastened from one bed to another, examining this patient, performing a slight operation upon that one, prescribing for another, while the class arranged themselves as best they could about the foot of the bed, to see and hear what was being done. This walking through the wards has clearly its advantages for the student but disadvantages for the patient. The latter is excited and made nervous and it seemed to me was unnecessarily exposed to the contamination and germs of disease brought in by the students from the street. When an operation was to be performed a screen was placed by the attendants around a table at one end of the ward and the patient carried from the bed to the table. The patient, especially if it were a child, would scream and kick and thus disturb the entire ward. The morning visits of the staff were therefore always a time of excitement and turmoil, and in many respects the manner of them seemed to me to be unfortunate and primitive in the light of the scientific knowledge of the present day. Among the group of students, men and women, about twelve or fifteen in all, elbowed one another for a closer view or rattled their tongues in chatter like flying shuttlecocks. Modesty appeared to be an unknown quantity in such a group; science and knowledge alone were the guiding spirits. The exposure of the patients was at first something quite shocking to an American's sense of delicacy.

Upon another occasion at the end of a long ward I found a tall Japanese screen, behind which stood an operating table with a woman on it undergoing electric treatment for a fibroid tumor. Apostoli, to whom I had just been presented, was managing the operation himself, while the students pushed and crowded against each other, jammed their way in and out or stood tip-toe, craning their necks unmercifully to get a glimpse of what was in progress. My sympathy went out for the poor woman, for she was of enormous dimensions, and that with a goodly sized tumor thrown into the bargain must have made the journey of life for her a matter of no mean affair. And then to think after carrying all that flesh and blood along the rugged *via vite*, to fetch up at last upon an operating table at the end of a long and crowded hospital ward, with half a dozen men performing a private examination upon her and a dozen or more idle, curious French students (plus one American) looking on! Strange, indeed, are the destinies of some folks! For the happiness of her fleshly mortality I hope the tumor was reduced, but I have my doubts about it, never having yet seen so fortunate a termination in the electric treatment of fibromata. Apostoli, whom I afterward had the pleasure of meeting at a banquet and reunion of *Des Trente*, a non-professional society of congenial ladies and gentlemen, given by way of novelty upon the first stage of the Eiffel Tower, I found to be most enthusiastic, yet sufficiently conservative in regard to the possibilities of electricity. His ideas have been so extensively published that it is unnecessary for me to dwell upon them here.

Of the staff of the Hotel Dieu, the acquaintance of none afforded me more pleasure than that of the late Professor Germain-Sée and of the distinguished surgeon Tillaux. The first time I met the former, he was

seated at a small table surrounded by several students in one of the medical wards. He bore his years remarkably well and his kindly old face lighted up with a pleasant smile as he chatted about America and some of the good that was being accomplished by us. He was not a large man nor imposing in manner. His countenance was round and friendly, his head was bald and he wore close-cut side whiskers, leaving only the front and under part of the chin clean shaven. In accordance with the law of the hospital, Germain-Sée should have been retired many years, as he was past the age at which the government allows a man to hold a hospital position. So great, however, had been his services to medicine and so distinguished was his name, that an exception was made in his case and an extension of his time gladly granted. His didactic lectures were always well attended. In a small and poorly lighted room his class usually assembled, while he himself with one or two assistants would be seated behind a long, green baize-covered table. He always remained seated while lecturing, making use occasionally of brief notes. His style was ideal for a scientific discourse. It was decisive and clear-cut, and as the speaker leaned over the table toward his hearers and emphatically voiced his dogmatic opinions one could not help admiring the preciseness, the optimism and the fertility of resources evidently acquired by long years of valuable experience in contest with disease. At times sparks of gentle humor would flash out of the discourse. It was always a quiet, incisive sort of wit, rather than a broad rollicking humor. Instead of a peal of laughter, it would merely produce a lively titter among the students, which would subside as quickly as it had arisen.

In physique, disposition and manner, Tillaux is the very type of the old-time surgeon; large, portly, full of inspiring confidence, moving about with a heavy tread and always speaking in an assertive, commanding tone of voice. To "assist" (a word used by the ever-polite Frenchman for one who is merely a visitor) him in one of his morning visits to the wards of the hospital is good surgically and psychologically. I was more than once inclined to wish that some of our younger surgeons had somewhat of the old-time dignity and courtliness about them. It would not add one whit, of course, to their skill, but it certainly would lend a grace and pleasing manner to their noble art, and it would have somewhat of a beneficial effect upon the unstable, nervous condition of many of their patients. Appearances count for something sometimes. I would that I had space to relate more of what I saw at the famous Hotel Dieu, but I would then have to omit another great hospital, probably better known than the Hotel Dieu and that without doubt through the association of the world-renowned Charcot.

From his residence, a typical elegant French apartment on the Boulevard St. Germain, not far from the artistic Pont de Solferino, the late Professor Charcot was wont to drive in his handsome brougham and pair every morning between 9 and 10 o'clock to the Salpêtrière Hospital at the other end of the city. A pleasant way to reach the hospital, however, is to take one of the flying little propellers on the river and after a delightful sail past many ancient and modern landmarks, to land at the Pont d'Austerlitz. A few steps along the broad but not particularly elegant Boulevard de l'Hôpital will bring one in front of an old-fashioned building, over the doorway of

which will be seen engraved the words, *Hospice de la Vieillesse. Femmes*. Not far away rises the vast Halle aux Vins, which would presumably charm into ecstasies our bibulous friends; near by are the famous Jardin des Plantes, especially interesting to medical men as having been founded by Richelieu at the suggestion and solicitation of Labrosse, physician to Louis XIII. How much more influential medical men have been and are to-day in the history and government of France than they are in America. Why?

The Salpêtrière, named after a large saltpetre manufactory that was once in the vicinity, is said to be the largest almshouse in the world. It consists of an irregular assemblage of buildings with surrounding gardens, courts and promenades, all covering an area of about seventy-four acres. A brick wall surrounds the whole. Altogether the various buildings comprise forty-five large blocks. These are lighted by more than five thousand five hundred windows. Louis XIII began building the institution as an arsenal, afterward using it to relieve Paris of the numerous beggars produced by his wars. It was also used as a kind of general hospital. Additional constructions were added to it at various times. Louis XIV conferred upon it a large grant of lands and under this monarch its main building was erected after the designs of Liberal Bruant, the architect of the "Invalides." The most interesting architectural feature is the church built in the form of a Greek cross in the center of the grounds, and containing a fine altar, dating from 1670, beneath the center of the large octagonal dome. Many of the main buildings are arranged in parallel lines with an archway beneath connecting the intervening courtyards. The first of these buildings that one comes to after entering the gateway is the *Bâtiment Mazarin* built by the cardinal of that name for the aged and infirm women, who during their youth were servants in the establishment. Their lodging was given to them gratuitously; they were allowed the same food they had been accustomed to as servants and which was better than that given to the paupers; but they were paid no wages. In one of the yards with graveled walks and shady trees stood about a dozen brick buildings with overhanging roofs after the style of the Swiss chalets. Each interior was a single apartment about fourteen feet square and was for the accommodation of a special class of insane. The Salpêtrière is devoted to the care of the aged infirm, the insane, the epileptics, the idiots and the defective children. The hospital proper was a detached building of three stories and an attic, and contained twenty-four "*salles des malades*." The "*salle aux bains*" is arranged in the "*rotunde*" with sixteen baths, each being surrounded with a white curtain and abundantly heated. In 1850 a central workshop was organized for manufacturing and repairing, for destroying old linen and bedclothes and for preparing lint for dressings, etc. There are shops for carpenters, joiners and carriage makers. The wash-house built on an immense scale bleaches every year, it is said, 1,500,000 pieces of linen, not only for the hospital but also for the Hotel Dieu, the Charity and the Hôpital des Cliniques. All except the insane department is open daily for visitors. The inmates have special days upon which they may receive their friends. On Sundays and fête days they may wear whatever clothing their fancy dictates but on other days the costume of the hospital, blue in summer and gray in winter, must be donned. There

are entertainments, including music and dancing, arranged for the inmates. The cooking for the whole establishment is done in one immense kitchen. The insane of course eat in their own special dining room. The individual allowance consists of 10 decagrams of bread, 13 decagrams of meat, 45 centilitres of bouillon, a dish of vegetables, some dessert and 12 centilitres of wine. As for the insane department, the asylum is of course a very old one but its management is quite in accord with the most modern requirements. It will always be interesting on account of its association with the great reformer Pinel, a large and magnificent painting of whom striking off the chains of the grateful patients, hangs over the platform in the room in which Charcot held his public clinics.

In 1662 the institution contained nearly 10,000 people. During the Revolution the number of indigent females, the males being always sent to the companion institution the Bicêtre hospice out on the road toward Fontainebleau, was 7,000 or 8,000. Since that time the population has been steadily reduced and the management correspondingly improved. Statistics in regard to the number of inmates are obviously subject to much variation. In 1889 the total population consisted of about 6,311 souls; of these 590 were of unsound mind.

In passing it may be of interest to state that the Hospice de Bicêtre, named from John, Bishop of Winchester, Bichestre, Bicestre or Bicêtre, was founded by Richelieu in 1632 for retired soldiers. It is a most ungainly looking structure and resembles more an impregnable fortress than a hospital. It is for men what the Salpêtrière is for women, and with its rich clinic material Dejerine and others are doing some splendid work. The guillotine was first started in its deadly career here and within its walls Victor Hugo has placed the scene of his powerful story *Le Dernier Jour d'un Condamné*.

Much to my regret so much space has been already occupied that I can do but little more than mention the clinics of Professor Charcot. Having been the fortunate recipient of an autograph invitation to the home and public and private clinics of this great man, I had somewhat in my sketchbook that might have proved of interest. His uniform courtesy and kindness, his warm feeling for America and Americans, his enthusiasm and sincerity, his immense learning and clearness in imparting knowledge, his marvelous tact, gentility and preciseness could have elicited only praise from anyone who happened to know him, let alone from one who was his warm admirer. It is no wonder that, when he was gone, his great scientific attainments and his charming personality made it difficult for the authorities to fill his place. The story of his life, which has been often told, is a standing encouragement to every ambitious young doctor of slender means. Work, hard conscientious work, seems to have been its guiding motto.

Professor Charcot held his public clinics in a special hall at the Salpêtrière every Tuesday and Friday morning from 9 to 12 o'clock. Occasionally he would be delayed until near 10 o'clock. The hall was a long narrow room, lighted by small, square old-fashioned windows, with a large platform at one end and an ascending row of benches for the students. Over the platform hung the large painting of Pinel. On the platform were a long table for the use of his private pupils and assistants, and a series of high back benches for invited guests and the patients to be pre-

sent to the class. Aside from a loud-ticking clock over one of the doors, the walls were devoid of every sort of ornament. From a small door leading out from an anteroom, we would follow the professor on to the platform, making a goodly sized procession of assistants, secretaries, students, guests, visitors and patients. The class upon the audience benches consisted of about one hundred and fifty men and women, intent, studious and ready with note books to take down the first words uttered by the lecturer. The professor always wore a small, tight-fitting scull-cap and remained sitting during the entire discourse. His style was smooth, regular and systematic, resembling a memorized sermon, and showing a calm, complete mastery of the subject in hand. Rarely, he would get up to make some examination himself upon a patient or indicate some point he was impressing upon a diagram. Usually his assistant, Gilles de la Tourette, would do that for him. He used very few gestures and generally would keep his gaze fixed upon the back of the room over the heads of the students, as though he were in a sort of reverie. He rarely attempted any humor, and when it did arise it usually had its origin in the patients or something apart from the speaker himself. Whenever he was lecturing upon any one special disease, he would line up a number of patients, as many as twelve or fifteen sometimes, upon the platform. If it were necessary he would insist upon their divesting themselves of every stitch of clothing, so that as some one said, they looked like a row of innocent Fiji Islanders. Rarely, if ever, did he put the women to this wholesome exposure. When the hour of noon arrived, a large gong would sound, the last sentence would be completed and in a quiet, methodic way the professor would suddenly rise and vanish through the side door.

In his daily private clinics, in a small room before half a dozen or more pupils, he would appear less methodic and showed more of his natural disposition toward friendship and personal intimacy. Here all kinds of cases would be examined, discussed and minutely studied. To observe him make a differential diagnosis, as for instance, between hysteria and syringomyelia in a man without a clear history, was a treat in close logic and correct inference. The French nation are reputed to be a neurotic people. At all events they present to the science of medicine a goodly amount of psychosis and neurosis for study. Happy was it that so calm, industrious, logical and dispassionate an observer as Charcot arose and studied amongst them. The debt which not only neurology but the whole of medicine owes to this master can never be repaid and will probably scarcely ever be equaled by another.

4544 Lake Avenue.

## THE EVIDENCE OF INSANITY; AN OUTLINE.

BY J. SANDERSON CHRISTISON, M.D.

CHICAGO, ILL.

GENERAL CONSIDERATIONS.

The whole question of insanity hinges on the *origin*, the *support* and the *display* of ideas. Its pathology has nothing distinctly characteristic, being merely a measure of functional incompetence whatever the coexistent facts. But as all motion is potential in ideas, ideation has its equivalent in molecular change and thus mental aberration has its physiologic concomitants.

No mortal can be said to be free from errors of fact or opinion of one kind or another, but comparatively few resist demonstration—logical, or objective refutation. An idea that does not fit with popular belief is not necessarily a delusion. Indeed, if it does not clash with any demonstrable principle or particular fact, it can not be regarded as a delusion, for we have no other means of proving it false than by such evidence. It may be an intuitive prophecy or the product of a genius. The grand steps of civilization were often due to conceptions which at their birth were commonly regarded as "off" or insane, and it is quite in keeping with the order of things that exceptionally profound minds should discover truths beyond the ken of contemporaneous comprehension. The common mind, the non-meditative, is so much a product of our political, educational and social machinery that comparatively few think deep enough to think much differently, and the machine-made creature or social puppet is regarded as quite sane though he may hold all the delusions agoing, which by and by are exploded by what he may call a "crank."

The higher walks of life are hardly freer from delusions than are the lower, to-wit: Only a few years ago, the so-called Darwinian theory of evolution became epidemic in certain learned circles although based on absolutely nothing but circumstantial evidence. Since then many of its votaries have so qualified the theory that it has lost its original peculiarity of something from nothing, and now it stands for little more than the progress of a plan as yet too feebly perceived to reveal much of origin and purpose, but disclosing the immutability of entities (characteristic or essential powers) by which chaos is precluded and progress assured. What is potential in plan must be specific and definite in form, and can never intrinsically be less or more in essential characteristics. One word more on this point: Laws of nature are said to be immutable; they must be, or chaos would result. But laws are not separable from things (entities), they are identical with their properties; therefore specific entities are immutable. Again, specific entities must be created, not evolved (form and activity are conditioned by environment and have reference to growth and chemic union). They can not lose their intrinsic (specific) qualities unless we say it is a law that laws are not necessarily immutable, which is a *reductio ad absurdum*. Evolution is extension not addition. I am not writing to prove the delusional nature of Darwin's hypothesis, which by some has been accepted as an established fact. But the logical results of a truth are not acts of insanity. Some twenty years ago when the theory was dominant, and while its sister delusion "spontaneous generation" also had a spurt, a young Englishman, while out of employment and discouraged, suicided by jumping from a river bridge. He left a note stating "man is but a monkey, so I didn't care to live." This was not an accurate statement of Darwin's idea, but it contained the popular notion having a fatalistic principle. What is the criterion for this suicide's act? Was the act that of insanity, or was it a logical result of prospects, both immediate and remote, in the light of the existing conditions?

But the history of civilization is full of popular delusions varying and vacillating, and sometimes violently active. They were originated as they also now are, by circumstantial evidence, a form of suggestion, and prevailing by virtue of a common fitness,

a common degeneracy. The familiar biblical expression, "my sheep" implies both the idea of enfeeblement and the need of a leadership to overcome the prevailing delusions and conditions therefrom. It applies now as then, for just as water can not rise above its own level, so the individual mind can not transcend its own powers of comprehension without extrinsic aid. He needs the stimulus of a reinforcement, coördinate with cosmic plan. It is a curious fact that in spite of the self-evident truth of our absolute dependence, we almost totally ignore it, and by our acts imply that the world was made wrong. This is the root of criminality, which is the remote or immediate background of all insanities, and moral pascies—their last analysis.

*Definition of Insanity.*—A delusional state of mind fixed against reason. By this I mean that a delusion exists either manifest, subconscious or latent, just as any idea may be, and that neither the logic of facts nor objective evidence are effectual to dissolve. It applies equally to fleeting and fixed delusions. Reason is futile for dissolution, although it may sometimes have a subduing or eclipsing effect for a time more or less brief. This state is due to such a degree of brain inefficiency, that the energy production is inadequate for the attention required for a complete conception of the situation. By a manifest delusion I mean a delusion so dominant that most of the subject's conduct is regulated by it; by a subconscious delusion I mean a delusion which is not manifest unless elicited by inquiry; by a latent delusion I mean a delusion which practically does not exist in definite form, but has existed, and although inquiry may only elicit a denial, certain circumstances may evolve it and in a violent manner, as in some forms of epilepsy and recurrent mania. Such cases are both the most dangerous and most difficult to pass upon.

*Character of Delusions.*—A delusion is an idea which is incorrect in time or in place, or is non-existent in fact. It becomes an insane delusion by virtue of its fixity against reason—the futility of argument.

*Origin.*—Insane delusions have three origins: 1, delusions due to more or less remotely acquired errors of perception and with present mental incompetency—centric delusions; 2, delusions due to perceptive perversions of sensation arising within the nervous system, and with present mental incompetency—hallucinations; 3, delusions due to perceptive perversions of sensation arising at the periphery or end organs, and with present mental incompetency—illusions. All three forms involve perception, reason and will.

*Support.*—1. An insane delusion may be more or less plausible by virtue of circumstantial evidence, as when some of the factors are truths, as is sometimes the case in delusions of conspiracy to deprive of property or personal liberty. 2. An insane delusion may be monstrous, by containing a claim against all evidence or possibility, such as a claim to be the "mother of God" or a "horse." In my opinion many such delusions are not real, but sportive, as their subjects' conduct is commonly very inconsistent with the delusions.

*Display.*—1. An insane delusion may be; *a*, active or directly manifest and unreserved; *b*, subconscious or indirectly manifest and reserved; *c*, latent, as in lucid intervals, when it has no formal existence. 2. They may be: *a*, persistent, *b*, changeable, *c*, recurrent. 3. They may be of: *a*, grandeur, as of wealth, power,

rank, form, etc.; *b*, persecution, as of poisoning, torture, defamation, etc.; *c*, debasement, as of personal vileness or incompetence, etc.; 4. They may exist with: *a*, excitement, *b*, depression, *c*, composure.

The more centric physiologic concomitants of insanity are indicated by the degree of promptness, pertinence, distinctness, fluency and coherence of speech.

The other physiologic concomitants, which may or may not be present, are tremors, palsies, incoördinate muscular movements, sensory defects, nutritional changes and emunctory irregularities in addition to the purely psychic phenomena.

It may be stated as a rule that the less the physiologic concomitants are manifested the more obstinate the insanity, because the more insidious and subtle is the centric (cortical) defect. It also may be said that as a rule hallucinations with insanity indicate the worst prognosis owing to their being due to a more gross physiologic disturbance of centric areas than are purely centric delusions, and which when they do not speedily recover, generally result in a more serious and permanent damage to the brain. Illusions being due to peripheral perversions are as a rule the least serious indications.

Whatever of abnormal mind is not included in my definition of insanity will come under the headings of moral palsy and criminality.

*Definition of moral Paresis.*—A defective power of inhibition (will) to such an extent that although the subject may know a particular act is wrong, he is unable to refrain from doing it under special exciting circumstances or provocation. It is due to a defective action of the brain which may be caused by cranial injury, shock, fever, poisoning, inherited fault, habits of dissipation of one kind or another, etc. It includes some cases of inebriety, neurasthenias (hysteria, hypochondria, etc.), fad manias (fanaticism), violent temper, vagrancies, prostitution, etc.

*Definition of Criminality.*—A disposition of conduct in which selfness is the ruling principle existing with the power of discernment and the power of choice. It is due to a denial or eclipse of first principles. The incentives are position, wealth and pleasure to be obtained at the expense of truth, justice and economy when in conflict with purpose. There is a total absence of fraternal love in the humanitarian sense.

In criminality there is a delusional origin in reference to First Principles, and is therefore constitutional. Education is the remedy. In insanity the delusional state is incidental to a pathologic cerebration, and can only be remedied by physiologic means. The remedy for moral palsy is chiefly discipline.

#### THE STATISTIC EVIDENCES OF THE VALUE OF VACCINATION TO THE HUMAN RACE, PAST, PRESENT AND FUTURE.

Read before the American Medical Association at the Jenner Centennial Celebration, held at Atlanta, Ga., May, 1896.

BY EUGENE FOSTER, M.D.

PROFESSOR OF PRINCIPLES AND PRACTICE OF MEDICINE AND STATE MEDICINE AND DEAN OF THE FACULTY OF THE MEDICAL DEPARTMENT UNIVERSITY OF GEORGIA, AUGUSTA, GA.

(Continued from page 677.)

##### PROPOSITION 5.

Notwithstanding a marked decrease has occurred in the total smallpox death rate, a still greater decrease has taken place in the smallpox death rate among children.

From the mass of statistics at hand to demonstrate this proposition I select the evidence relative to the value of vac-

ination as shown by the enforcement of the compulsory laws of Great Britain.

In reckoning the success or failure of compulsory vaccination in Great Britain, we must remember that the law was enacted to protect helpless children from the fatal consequences to themselves of obduracy or carelessness of the parent in failing to protect them from smallpox by having them vaccinated. Let us take this epidemic of 1870-73, which has afforded vaccinophobists such an arsenal of facts to prove the worthlessness of vaccination, and see if in enacting compulsory vaccination laws the State exercised a wise and prudent care of its infantile population. Prior to the enactment of compulsory vaccination laws, 70 to 80 per cent. of the annual smallpox mortality of Great Britain was among children under 5 years old. What has been the average annual mortality in this class since compulsory vaccination? Take England first. The law requires vaccination of children at three months of age. The compulsory vaccination law of 1853 was very defective in that the machinery provided for registration of births, and vaccinations thereafter, was not such as to enable the authorities to know and secure the vaccination of all the children falling within the provisions of the law. Defective as it was in this respect, it yet had a salutary effect, for the vaccinations among this class were more than doubled over the same period anterior to the enactment of the law. It must be admitted that this result was largely due to the knowledge of parents that if they failed to comply they laid themselves liable to a penalty for such neglect. In a few years we see the annual smallpox death rate reduced to 55 per cent. of the total mortality from this disease. Fifty-five per cent. remained the average annual mortality in this class until the laws of 1867 and 1871 were enacted. By the law of 1867 a full and proper system for registering compliances with the compulsory law was inaugurated. Boards of Guardians throughout the kingdom were authorized by law to compel such compliances, and were given full authority to appoint officers whose duty should be to rigidly inquire into all failures to comply with the law. When such persons were found, these officers should warn the delinquents to comply with the law within a specified time, and if such persons failed to heed the warning the officers were to institute legal proceedings to require compliance. By the act of 1871 Boards of Guardians were required to appoint such officers. The epidemic of smallpox commenced in the latter part of 1870, and we are told that "only a portion of the population in England under 5 years of age was within the operation of the act of 1867. During the continuance of the epidemic a larger proportion came under its provisions, and some came also under the provisions of the act of 1871. The result was manifested in a reduction of the proportionate smallpox mortality under 5 years of age from 55 per cent. of the entire mortality from that cause to 33.5 per cent. in 1871, and to 30 per cent. in 1872. The act of 1867, being in some of its most important requirements permissive only, had been carried out with various degrees of efficiency by different local authorities. In those places in which the action taken under it had been tardy and ineffective, the mortality in young children amounted to or approached its old proportions; in those places in which such action had been commenced immediately on the act coming into operation, and been steadily continued, a remarkable diminution in that proportion was observed."<sup>24</sup>

LONDON.

Anti-vaccinists gleefully ask: How about the smallpox death rate of London in 1870-73? Let us examine into the matter. For twenty years prior to 1871, when the authorities provided gratuitous vaccination, but when compulsion was really nominal, the smallpox death rate of children under 5 years of age was more than 50 per cent. of the total smallpox death rate. From 1851-60 it was 59.5 per cent., and from 1861-70 it was 54.3. In 1871 and 1872, notwithstanding the negligence of the authorities of some of the unions in relation to enforcing vaccination, the average annual smallpox death rate of children under 5 years of age to the total of smallpox mortality was 36.7. In the epidemic of 1881 children under 5 years of age contributed only 27.8 per cent. of the total smallpox mortality of London.<sup>25</sup> In 1872, in Great Britain, only 85 per cent. of the births were certified as successfully vaccinated. Deducting the percentage of children having died before being vaccinated, the percentage vaccinated to the total births living was 94 per cent. certified as successfully vaccinated.

SCOTLAND.

How about Scotland? Mr. P. A. Taylor makes himself happy

<sup>24</sup> Dr. Seaton's Report in Report of Medical Officer of Privy Council, 1874.

<sup>25</sup> Eleventh Annual Report of Medical Officer of the Local Government Board.

over the failures of compulsory vaccination in Scotland. Upon what is his opinion based? Let us see. Here is a fair test, for the compulsory vaccination law of Scotland was enacted Jan. 1, 1864, and from that date to Dec. 31, 1871, the report of the registrar general for Scotland states, that after a deduction had been made of all children who had died before they could be vaccinated, 96.5 per cent. of all children alive were certified as having been successfully vaccinated. One per cent. was certified as being in such health as to prevent vaccination, or having been repeatedly tried and found insusceptible, and 2.5 per cent. unaccounted for on the registers. From this it appears that the children in Scotland under 7 years of age were protected by vaccination to a remarkable degree. But, as has been well said, "it is equally obvious that the whole infantile population can not be universally vaccinated, nor constitute a class among whom if smallpox prevail in the country there could be any reasonable expectation of meeting with complete exemption from that disease, for it includes, 1. all who are under the age by which vaccination is enforceable, of whom, of course, a very large proportion would remain unvaccinated; 2, not a few somewhat above that age are still remaining unvaccinated from the carelessness of their parents in neglecting to have vaccination done till they had received legal notice of warning and risking it probably for some time after that; 3, children in whom there was postponement of vaccination on account of their state of health; and 4, many doubtless still unprotected among the cases which had appeared in each year's return as 'postponed,' 'insusceptible,' or 'unaccounted for.' Now, as there are nearly 120,000 children born in Scotland each year who until they are 6 months old do not come under the operation of the law; as there are about 1,000 of each year's births carried on as 'postponed' or 'insusceptible'; and as there are about 2,500 annually respecting whom nothing is known, it is quite certain that there must always at any given time be among the young population of Scotland, extremely well protected as it is on the whole, a considerable actual number of unvaccinated children."

Now for the results of this unprecedented vaccination in a community of civilians. From year to year, prior to compulsory vaccination, the average annual smallpox mortality in children under 5 years of age amounted to 74 per cent. of the total smallpox mortality in Scotland. To fairly test the prophylaxis afforded by compulsory vaccination, we must take the children under 7 years of age, the epidemic having begun in 1871. The returns of the registrar general are only divided as follows: Those under 5 years of age, 5 to 20, 20 to 60, and those above 60 years of age. We therefore take those under 5 years of age, they being only those which can be used to test the value of compulsory vaccination. From the enactments of the compulsory law in 1864, the mortality of this class steadily declined from 74 per cent. of the total smallpox mortality, until in the epidemic of 1871 it was for the whole of Scotland just 21.4 of the total smallpox mortality. The mortality for the whole of Scotland had not been ascertained when Dr. Seaton (from whose reports these data are extracted) rendered his report in 1874. But let us take the eight principal towns of Scotland, from which to derive further information on the subject.

SMALLPOX DEATHS IN THE PRINCIPAL TOWNS OF SCOTLAND.

Year.	At all ages.	Under 5 years of age.	Deaths under 5 years of age; per cent. of total deaths.
1871. . . . .	886	195	22.0
1872. . . . .	1,537	362	23.5
1873. . . . .	467	124	26.5
1874, to June inclusive.	302	60	22.8
Total, 3½ years . .	3,192	750	23.5

Well may the registrar general, in his report for 1872, say, in his comments on that year—"If the same relative mortality had taken place in children at that age (under 5 years) as occurred during the previous epidemics, when they were less efficiently protected by vaccination, instead of only 362 children under 5 years of age having died from smallpox in the eight towns during 1872, 3,370 would have died. The enforcement of the vaccination act, therefore, during the seven previous years, appears to have had the effect, in those eight towns alone, of saving the lives of upward of 3,000 children." So much for the direct proof from the history of Scotland as to the beneficent effect of compulsory vaccination. Now let us compare the relative mortality of children under 5 years of age in Scotland with other countries. A glance at the following table will show the superior effects of the law of Scotland:

SEATON'S REPORT, 1874.

Towns, or groups of towns, compared.	Actual smallpox deaths under 5 years of age during the whole period of the epidemic in each town, or group of towns.	Smallpox deaths under 5 years of age during the whole period of the epidemic for equivalent population of 1,000,000 of all ages.
Eight principal towns of Scotland (population 1,083,750), 1871-74. . . . .	750	602
Berlin (population 882,589), 1871-72 . . . . .	2,837	3,448
Hamburg (population 338,974), 1871-72. . . . .	1,938	5,717
Leipsic (population 106,925), 1871. . . . .	659	6,200
Eight principal towns of Holland (population 693,080), 1870-72. . . . .	4,474.	6,445

Compare next the smallpox mortality under 5 years of age with the population living under that age, respectively, in the various towns or groups of towns.<sup>26</sup>

Towns, or groups of towns, compared.	Population living under 5 years of age.	Smallpox deaths under 5 years of age during entire period of epidemic in each place.	Smallpox deaths under 5 years of age during whole time of epidemic for equivalent of population of 100,000 children under that age.
Chief towns of Scotland (3½ yrs.)	147,433	750	508
Berlin (2 years.) . . . . .	88,093	2,837	3,200
Leipsic (1 year.) . . . . .	8,515	65	7,712

These are the only towns in which the data for this last table were at hand for comparison when the table was formed in 1874. Assuredly there must be some patent reason for this variable death rate of infantile populations in the countries having compulsory vaccination laws. Let us try and find it. A brief review of the law, together with the manner of its enforcement in the respective places, will perhaps enable us to solve the problem.

1. *Scotland.*—We have just seen the wonderful utility of compulsory vaccination in Scotland in comparison with the other countries specified in the tables just given. The law is stringently enforced, and the machinery therefor is complete, as evidenced by a vaccinated population under 5 years of age of 96½ per cent.

2. *Berlin.*—In Berlin the law required that all children should be vaccinated at one year of age. No penalty, however, was attached to neglect to comply with the law, unless smallpox follows such neglect. The delinquents were rarely prosecuted, and a good proportion failed to have their children vaccinated until they attained school age. All children seeking admittance to the public schools had to present a certificate of successful vaccination before being received therein. Dr. Guttstadt, in 1873, attributed the high mortality in Berlin in the epidemic (1871-1872) to a large accumulated number of children, whose parents had failed to have them vaccinated at 1 year of age, as required by law.

3. *Hamburg.*—There was not at the time of the outbreak of the epidemic any compulsory law, and no means to prevent parents from neglecting to have their children vaccinated, except a law which required all children applying for places in the public schools to produce a certificate of successful vaccination. Therefore it was common to find children who had attained 2 years of age, and often 7 or 8 years, before vaccination was attempted. This large residuum of unvaccinated children is sufficient to account for the greater prevalence of smallpox in Hamburg than in those of Scotland.

4. *Leipsic.* } The same was substantially true of these as in  
5. *Holland.* } Hamburg.

IRELAND.

What of compulsory vaccination in this country? triumphantly ask the anti-vaccinists. Let us test it first upon the children under 5 years of age, the class whom primarily the law was intended to protect. The compulsory vaccination act of Ireland came of force Jan. 1, 1864. The machinery for registration of compliances with the law, as well as the lack of officers to warn delinquent parents whose children remained unvaccinated beyond the prescribed age (six months), and to take the necessary steps to enforce compliance with the law, shows the act to be more defective than that of Scotland.

By the report of the public vaccinators to the local govern-

<sup>26</sup> Seaton's report 1884.

ment board of Ireland, compared with the register of births from 1865 to 1872 inclusive, it is shown that 81 per cent. of the births were vaccinated by the public vaccinators. (The public vaccinators do almost the entire vaccinations in Ireland, except in the large towns.) In Scotland the percentage of these vaccinations has been shown to be 96½ of every 100 births. We therefore see that in Ireland there is always a very large residuum of unvaccinated children, there being in 1872, 33,440 children who were not vaccinated until they had attained one year of age. In 1873 there were 19,258 such cases. Let us now compare the smallpox death rate of this class with the total smallpox mortality of the periods anterior and subsequent to the compulsory act. Seventy-nine per cent. of the total smallpox mortality of Ireland was in children under 5 years of age, as shown in the report of the epidemiological society in 1853. Under the medical charities act, and the act of 1858, the public vaccinators had been enabled to reduce this percentage to 75. By the operation of the compulsory vaccination act, in 1865 and 1866, the percentage of this class of deaths was reduced to 50. From 1866 to 1871 smallpox was almost wholly absent from Ireland. When the epidemic of smallpox began in 1871, it found the children under 7 years of old remarkably well vaccinated, and as a consequence we find the percentage of deaths in this class as follows: 1871, 20.5, and in 1872, 25 per cent. of the total smallpox mortality.

Now let us take Dublin, one of the cities especially pointed out by anti-vaccinists as an illustration of the utter failure of compulsory vaccination. In Dublin, in the two years in which the epidemic prevailed, there were 1,557 deaths from smallpox. Of this number 362, or 23 per cent., were in children under 5 years old. Dr. Seaton was unable to give the proportion which these 362 deaths bear to the total population living under 5 years of age. But he shows the comparative mortality to the whole population of Dublin, and contrasts these with the following places. The deaths under 5 years of age per million of living population in each place were as follows:

Dublin, . . . . .	1,150
Eight principal towns of Scotland, . . . . .	692
Dundee, . . . . .	1,594
Berlin, . . . . .	3,448
Hamburg, . . . . .	5,717
Lelpste, . . . . .	6,200
Chief towns of Holland, . . . . .	6,455

Let us see what has been the result of compulsory vaccination upon the whole population of Ireland. From the census taken in 1841 it was shown that for the previous ten years smallpox was the second most fatal disease in Ireland. The deaths in that period of time were 58,000. When the census was taken in 1851 it was found to be the third most fatal disease. For nineteen years previous to the act of 1863, the average annual mortality from smallpox was, as shown in the twenty-first annual report of the poor law commissioners for Ireland, 2,640. The compulsory vaccination act of 1863 came of force at the time of decline of a considerable epidemic. During the first year, which, it must be admitted, was too soon to be fairly claimed as wholly consequent upon the operation of the act, the deaths from smallpox were 854. From 1865 to 1870 inclusive, the smallpox mortality had fallen to such an extent as to be without precedent in the history of Ireland, being for the six years respectively 347, 180, 20, 19, 20 and 32. In the epidemic of 1871-1872, the deaths from smallpox were 665 in 1871, and 3,248 in 1872. Now let us compare the smallpox mortality of Ireland previous and subsequent to compulsory vaccination, and see what will be the result of the investigation. For nineteen years previous to the compulsory vaccination the average annual deaths from smallpox were 2,624; for ten years subsequent to compulsory vaccination the annual smallpox deaths were 583.<sup>27</sup> Therefore we see that under compulsory vaccination for the ten years of its operation, as compared with the nineteen years anterior to it, the deaths were not a fourth of those in the non-compulsory period.

PROPOSITION 6.

In every epidemic of smallpox, the unvaccinated portion of the population has, without a single exception, shown a vastly greater proportional attack rate as well as death rate from smallpox relative to their numbers than the vaccinated.

STATISTICS PROVING THIS PROPOSITION.

In a severe epidemic of smallpox which prevailed at Norwich in 1819, Mr. Cross minutely observed 112 families, in all of which there were cases of the disease; and the annexed table shows the result. Among 215 persons unprotected by vaccination there were 200 cases of smallpox, and of these forty-six proved fatal; while among ninety-one vaccinated persons the

only effects of this terrible infection were: 1, that one girl, who had been vaccinated nine years, "had a mild disease, limited to twenty pocks, and lasted only six days before it began to decline," and 2, that another, who had been vaccinated five years, went through "the disease in half the time (of her unvaccinated sister) without danger or detriment, a few very minute pits upon the tip of the nose being the only permanent traces."

	Number.	Cases of Smallpox.	Deaths by Smallpox.
Total number of persons in the 112 infected households. . . . .	603	202	46
1. Protected by previous smallpox <sup>28</sup> . . . . .	297	2	0
2. Protected by vaccination. . . . .	91	2	0
3. Unprotected. . . . .	215	200	46

By reference to the following table, it will be seen that, in a number of places observed, the death rate varies among the vaccinated from an inappreciably small mortality to 12¼ per cent., that amongst the unprotected, it ranges from 14½ to 53.8 per cent.

Death rate per 100 cases.<sup>29</sup>

Places and times of observation.	Total No. of cases observed.	Among the unprotected.	Among the vaccinated.

Compare the relative death rates from smallpox in London in the epidemic of smallpox for the year ending May 29, 1881, between the vaccinated and unvaccinated. Here is the table taken from the Eleventh Annual Report of the Local Government Board, 1881-82:

Death rate of people of subjoined ages.	Per 1,000,000 of each age of the vaccinated class.	Per 1,000,000 of each age of the unvaccinated class.
All ages. . . . .	90	3,350
Under 20 years. . . . .	61	4,520
Under 5 years. . . . .	40.5	5,950

TABLE D.—Number of deaths, and vaccination condition, of those being over 3 months and under 10 years of age who died from smallpox in England and Wales, 1881-87.

Vaccination condition.	Deaths, 1881-87
Vaccinated. . . . .	145
Unvaccinated. . . . .	1,427
No statement. . . . .	1,402
Total. . . . .	2,974

NOTE.—The unvaccinated are 90.8 per cent. of those as to whose vaccination condition there was information, and 48 per cent. of the whole.

<sup>28</sup> Mr. Cross mentions that he met with several who were supposed to have had smallpox formerly, yet (p. 15) notwithstanding took it on this occasion; but he does not state whether such cases are included in the above summary. In this epidemic the vaccinated slept in the same rooms, and in some instances, in the same beds, with those having smallpox. So also (as quoted by Steinbrenner) in Copenhagen—of 659 vaccinated persons who suffered in the variolous epidemics, 1823-27, only 5 died, being at the rate of 1 in 132; while of 176 unvaccinated persons who contracted the disease, more than a fourth seems to have died, and of 153 others, who professed previously to have had smallpox, there died 31. And similarly in the epidemic of 1828-30, and part of that of 1832-37, it seems that out of 228 unprotected patients 63 had died; but of 1,373 cases of post-vaccinal smallpox only 14 were fatal.

<sup>29</sup> Brit. and For. Med. Chir. Rev., October, 1857.

<sup>27</sup> See Seaton's Report, 1874.

TABLE E.—Proportion of deaths under and over 15 years of age, per 1,000 deaths from smallpox in vaccinated and unvaccinated persons respectively, 1881-87 (excluding deaths under 3 months).

Age.	Unvaccinated.	Vaccinated.
Three months and under 15 years. . . . .	597	126
Fifteen years and upward. . . . .	403	874
Total . . . . .	1,000	1,000

TABLE E.—Statistics of the smallpox epidemic in Chemnitz in 1870-71. (See 2d Report Royal Vaccination Commission of Great Britain, 1890, page 236. *Zeitschrift des Königl. Preuss. Stat. Bureau*, Jahrgang 12, 1872, Art. "Die Pocken-Epidemie in Berlin, 1870-72." by D. Gutstadt.)

NOTE.—Dr. Max Schultz, writing of Filzner's statistics, calls attention to the fact that they show there was 1 case of smallpox to every 255 households containing none but vaccinated persons, but 1 to every 26 households containing both vaccinated and unvaccinated persons. The figures prove the danger which unvaccinated persons are to the vaccinated, and thereby establish the value of compulsory vaccination. *Vide Impfung Impfgeschaft*, etc. Berlin, 1888.

Deaths.—Of 3,596 cases, 249 or 6.92 died. Among the deaths are those of 17 boys, 17 male adults, 111 girls and 11 female adults. All the children who died were unvaccinated, and of the adults, 3 males and 4 females were vaccinated, the remainder unvaccinated.

Of the 249 deaths, 242 were thus unvaccinated and only 7 of those vaccinated, the former category contributing 97.19 and the latter 2.81 per cent. of the deaths. Separating the cases of smallpox among the vaccinated from those among the unvaccinated persons, we find that of the former, only 0.73 per cent. died, but that of the latter class 9.16 per cent. died.

Of the 224 cases in the town hospital 184 had been vaccinated, 37 were unvaccinated, and 3 were doubtful. None of the vaccinated died, but 11 of the unvaccinated succumbed to the disease (15 cases of unvaccinated children under 10).

Hence the accuracy of the following table given by Lotz on p. 56 of his "Pocken und Vaccination."

Age.	Vaccinated.			Unvaccinated.		
	Cases.	Deaths.	Mortality Per cent.	Cases.	Deaths.	Mortality Per cent.
For the 1st year. . . . .	8	0	0	373	102	27.3
For the 2d year. . . . .	15	0	0	528	51	9.6
For the 3d year. . . . .	30	0	0	444	26	5.9
For the 4th year. . . . .	31	0	0	331	29	8.8
For the 5th year. . . . .	43	0	0	222	9	4.0
For the 6th year. . . . .	35	0	0	197	7	3.6
For the 7th year. . . . .	46	0	0	105	1	0.9
For the 8th year. . . . .	28	0	0	98	2	2.0
For the 9th year. . . . .	18	0	0	71	1	1.4
For the 10th year. . . . .	71	0	0	71	0	0.0
Total under 10 years of age . . . . .	265	0	0	2,440	220	9.0

(To be continued.)

## SOCIETY PROCEEDINGS.

### The American Public Health Association.

[Special Correspondence of the JOURNAL.]

*The Twenty-fourth Annual Meeting of the American Public Health Association held at Buffalo, N. Y., Sept. 15-18, 1896.*

The Executive Committee, in which all the business, other than reports of committees and presentation of papers, is practically done, and which is composed of the five officers, six elected members and the thirteen surviving ex-presidents, nine of whom were actually in attendance, met at 10 A.M., September 14, and was in continuous session the greater part of the day, and during the intervals of the regular sessions throughout the week.

Ellicott Square, in which the meeting of the Association was held, is a marvel of modern construction, occupying the entire block of ground, the value of the site alone being rated at \$1,000,000, and the cost of the building, complete in all its appointments, having amounted to \$2,350,000 more. The dimensions of the edifice are 240 x 200 feet, with an interior court 110 x 70 feet in size, glass roofed and giving abundant light to the 600 offices, 16 large counting rooms and 40 stores, besides the quarters of the Ellicott Club, which occupies nearly the whole uppermost (tenth) floor, and the assembly rooms on the second, in which the Association held its meetings. The principal room was gracefully and appropriately draped with the national flags of the United States of America, Dominion of Canada and Republic of Mexico, which countries

are represented in the membership, but the abominable acoustics of the hall, due to the numerous intervening columns, and the medley of noises from the streets, make it a trying ordeal for the speakers to reach their distant auditors. The extensive daily program for morning, afternoon and evening sessions were carried out without failure, and the interest of the members in their work was shown by their persistent attention and regular attendance to the adjournment on Friday afternoon.

The appointed hour found about two hundred and fifty persons on the floor, the adjoining offices of the Treasurer and Local Committee being crowded with members awaiting their turns to register. The Mexican contingent numbered thirty-four persons and that from the neighboring Dominion almost as many more. A number of women were present, and as a daily paper later commented: "The language of some of the papers opened their eyes to the brusque directness with which scientific sanitarians deal with rather intimately personal problems."

The Association was called to order by the President, Dr. EDUARDO LICEAGA of the City of Mexico, promptly at 10 o'clock, and the session opened with prayer by the Rev. Dr. Thomas R. Slicer of Buffalo, after which the President called to the platform and introduced to the members the distinguished founder of the Association, Prof. STEPHEN SMITH of the city of New York, and its first President during the years 1872, 1873 and 1874, after which time he declined reelection. Dr. Smith, after responding to the enthusiastic welcome which greeted him, disclaimed any special merit in the creation of the Association, which he declared to have been the logical outcome of the times, and paid generous tribute to his associates in the work, especially Dr. ELISHA HARRIS of New York, who with himself bore the entire expense of the early meetings. He also instanced Dr. Joseph M. Toner of Washington, D. C., Dr. Edwin M. Snow of Providence, R. I., Dr. John H. Rauch of Chicago, Ill., Dr. Ezra M. Hunt of Trenton, N. J., and Dr. Charles B. White of New Orleans, La., the latter the first of the Presidents to die, although all the others mentioned, who successively occupied the presidential office, and were his earnest co-workers from the beginning, have subsequently died. He extolled the wisdom of the Association in having adhered to the practice of placing its mere working business in the hands of the Executive Committee, and thus removing disputes and time-consuming contentions from the floor of the general meeting, to the interference with its legitimate and more important labors. While it has included some of the best men in the profession among its members, there were many others who were not medical, among them the Rev. Dr. Osgood, Dorman B. Eaton, Commissioner of Education, and others. This Association does not limit its influence to those in actual attendance at its meetings. The larger audience outside of the Association give it its distinctive character. He was especially gratified at the interesting feature of its development, which has made it eminently all-American, through the extension of its membership to Canada and Mexico, and hoped that Cuba and the Central American republics might also become part of it. This international association is all the more gratifying since experts in sanitary science are aware that no single country can protect itself, except so far as the English system obtains of making localities clean, instead of remaining apart and trying to fight epidemics. A clean country is primarily a healthy one. The Transactions of this Association, he was proud to say, have become an invaluable compendium of sanitary science, and Florence Nightingale wrote, years ago, that she could gather nowhere in Europe such information as was to be obtained in the reports and papers published by this body. Perhaps the grandest work accomplished by the Association has been in the development and extension of State boards of health all over this Union—and it is very gratifying to see by the programs the prominent part taken by officers and members of State and provincial and municipal boards of health in its work.

On the conclusion of ex-President Smith's remarks, the Chairman of the Local Committee of Arrangements, Dr. ERNEST WENDE of Buffalo, Commissioner of Health of that city, made the customary announcements of entertainments tendered the members and their families, which in accordance with the traditional practice of this Association, were only such as would not interfere with the purposes of its assembly. The Local Committee had prepared a very attractive, both in typography and contents, souvenir brochure, edited by Dr. WILLIAM WARREN POTTER, Chairman of the Committee on Printing, containing well executed portraits and biographic sketches of the officers, lists of committees and other necessary

information especially valuable for new members; and a novelty in the way of a membership badge, having a gilt buffalo surmounting and suspending by a tri-colored riband a gilt emblematic pendant. Each member was further supplied with a little book of detachable coupons, entitling those duly accredited to daily afternoon drives in tally-ho coaches, intended especially for wives and families during the attendance of their husbands and fathers at the sessions, and admitting to excursions and receptions—a most admirable provision against the intrusion, common to such occasions, of persons in no way interested in the Association as entertainers or participants.

The report of the Executive Committee was presented by the Secretary of the Association, Dr. IRVING A. WATSON, Secretary of the State Board of Health of New Hampshire, who performed this duty for the fourteenth successive annual occasion, making the usual announcement of the prospective business of the session, and reporting a communication from the Association of Master Plumbers of Canada, signed by their Secretary, J. C. Hughes, of Montreal, recommending the constitution of a committee on sanitation with special reference to drainage, plumbing and ventilation of public and private buildings, and such a special committee of five members was thereupon authorized. The Executive Committee further recommended the passage of a resolution, introduced by Dr. SAMUEL H. DURGIN, Health Officer of the city of Boston, reviving the committee on disinfectants and disinfection, whose former report has been so many years the standard authority on these subjects, but which in view of recent experimental research and discoveries ought to be given the opportunity of including this later knowledge. The Secretary then reported the names of fifty-three new members, recommended by the Executive Committee for election, which was accordingly done by vote of the Association.

The eminently practical and expeditious manner in which this Association dispatches its routine and administrative business through its Executive Committee, permitted the legitimate work of the session to begin promptly at 10:45 A. M., with the "Report of the Committee on Car Sanitation," by Dr. GRANVILLE P. CONN, President of the State Board of Health of New Hampshire, Chairman. This report attributed much of the opposition of railway corporations to their disinclination to submit to the interference with their business and the expenses which the necessary charges required for their improved sanitation would involve. It spoke of bad ventilation of passenger coaches as worse than their overheating, denounced the objectionable practice of closing windows and locking doors after a trip, instead of throwing them wide open for thorough airing, and advocated the abrogation of the existing system of urinals. It backed the American railway employe against the world for disregard of passengers' comfort, and for habitual insolence nothing could equal the negro porter. It commended the *train de luxe* from Paris to Marseilles as an instance of what can be done to promote the health and comfort of travelers and wondered that any one who has had the opportunity of contrasting this service with the American system could hesitate to give credit where it belonged.

Two papers on the same subject followed: "Observations on the Cleaning of Railroad Passenger Cars," by Dr. DOMINGO ORVANANOS, of the City of Mexico, Secretary of the Superior Board of Health of the Republic of Mexico; "Possibilities of Contagion of Venereal Diseases in Railway Cars," by Dr. TOMAS NORIEGA, delegate from the State of Chiapas, Mexico. The former advocated instead of the customary slipshod method of washing coaches, that they should be carefully gone over with sponges saturated with a solution of mercuric bichlorid, that the coverings of seats and backs should be frequently changed and washed at every terminal station. Dr. Noriega narrated instances in his experience of purulent ophthalmias, unmistakably one to infection in Pullman car lavatories, resulting in total loss of vision of one or both eyes. He said that reform was necessary especially in beds, lavatories and water-closets, and that in the latter, impermeable paper covers, to be removed after each visit, should replace the present permanent wooden seats. In the discussion which followed, Dr. Valentine of New York quoted the case of a bride, referred to him by another physician, who had contracted a specific ulcer on her lip by drinking from a public ice-water cup, and said that in Antwerp he had seen fresh wooden covers supplied to each new occupant of a water-closet. Dr. Kinyoun of the U. S. Marine Hospital Service, said that the hygiene laboratory of that service under his direction had been long engaged in investigating railway sanitation, and said that experiments were being made as to the proper disinfection of cars by subjecting all the several materials used in furnishing coaches to various processes. He suggested the inquiry as to the greater prevalence

of cases of tuberculosis and diphtheria at the railway terminals and at the resorts for invalids affected with these diseases. He said the impure water supply in the railway service was responsible for many cases of diarrheal and enteric diseases, and declared that it was significant that the presidents and high officials of these companies do not drink the water they furnish to passengers.

The "Report of the Committee on Steamship and Steamboat Sanitation," by Dr. FREDERICK MONTIZAMBERT of Toronto, General Superintendent of Quarantines of the Dominion of Canada, Chairman, was then read. Dr. Montizambert said he had little to add to the reports made by the former Chairmen of the Committee, Dr. Durgin of Massachusetts, in 1891, and Dr. Gihon, U. S. Navy, in 1893, except to call attention to the proposed disinfection of ships by the electrolysis of sea water, a process actually in use by the French companies of the *Messageries Maritimes*. At the exhibition at Boulogne-sur-Mer, there was an automatic apparatus no larger than a coal scuttle, which could be connected with the ordinary electric plant by a couple of wires and was capable of producing three hundred liters of electrolyzed sea water per hour. The usual methods of disinfection, involving the employment of costly materials, were malodorous and left much to be desired.

Dr. HORLBECK of Charleston, S. C., declared that enough had not been said about the wretched sanitary condition of our coastwise passenger steamships, and Dr. GIHON, U. S. N., described his present knowledge of the deplorable condition of the saloons of these vessels during their late autumn passages when crowded with consumptive invalids on their way to health resorts in Florida.

#### AFTERNOON SESSION.

The afternoon session began 3 P. M. with a paper on "The Composition and Infectiousness of Milk," by Dr. JAMES F. KENNEDY of Des Moines, Iowa, Secretary of the State Board of Health of Iowa, and was an exhaustive inquiry into the relative mortality of breast-fed children and those fed on milk, the latter being greatly in excess. He attributed a large proportion of the deaths to inanition from dilution with water, which is not only a fraud against the buyer but a crime against the children, who are literally starved to death. He narrated epidemics due to infected milk, which was a greater source of danger than dilution, and described the many ways by which morbid germs are introduced into milk—by washing pails with impure water, by the settling in pails and cans of dried germs floating in the polluted air of stable-yards, by the unclean hands of milkers, and after reaching consumers by the filthy habits of occupants of insanitary houses. He declared the remedies to be inspection, cleanliness and sterilization.

The next paper on the program was "On Pure Milk," by Dr. GARDNER T. SWARTS of Providence, R. I., Secretary of the State Board of Health of Rhode Island, who deplored the neglect of milk inspectors and physicians in his own State to ascertain the actual condition of the milk supply. He said that most of the enteritis of children was certainly due to filthy milk. He urged the establishment everywhere of milk farms similar to those near Buffalo, where the modus operandi of milking and delivering milk is carried out under the most healthful conditions and the purity of the milk certified by reputable physicians. The price of such milk must necessarily be higher, and it is only by educating the public that they can be made to pay the difference and to secure immunity from disease, which is more surely done in this way than by sterilization. There are people to day who prefer dirty milk at four cents to good milk at eight.

The "Report of the Committee on Animal Diseases and Animal Food" was then read by Dr. D. E. SALMON, D. V. M. of Washington, D. C., Chief of the Bureau of Animal Industry, Department of Agriculture, Chairman, who, while describing how much had been done in the matter of animal diseases, said that the public still needed to be educated respecting them. Outbreaks of anthrax were undoubtedly becoming more frequent. While common in Europe, this disease had been rare here. The spores of the bacillus survive for years and are distributed through carelessness in the disposal of dead animals. The carcasses should be saturated with coal oil and burned to ashes. Hides and wool are dangerous and even the hay from infected meadows used for packing crockery and glass. Tuberculosis is the subject of much attention on the part of the government, which, however, can only prevent the shipment of diseased cattle to other States, but has no control over its local sale. Tuberculous cows and swine are often found in the abattoirs, but there is necessity for coöperation between Federal and local inspectors. Some local firms insist on selling condemned carcasses. The committee testifies to the amicable relations between the Bureau of Animal Industry and the

State Boards of Health, due largely to the influence of this Association. An interesting part of the report dealt with rabies, which declared that while there was no need of alarming people, it was a duty to inform the public that such a disease does exist and is a menace to health and safety. The Chairman had sometime ago to combat the theory that there was no such disease as Texas fever. Is it reasonable to believe that a disease that has been described for two thousand years is a myth because a few physicians have never seen a case. The committee has sufficient positive evidence to establish its existence and characteristics, and recommends the measures for reducing the number of worthless dogs be rigidly enforced, and that all others allowed to run at large be muzzled.

This group of papers attracted great attention and provoked a very lively discussion. Dr. BAILLACHE while approving of the thorough supervision and inspection of dairies and dairy products recommended by Dr. GARDNER T. SWARTS, doubted its practicability. Dr. LEE of Philadelphia took issue with Dr. KENNEDY respecting the sterilization of milk, in which he did not believe we had arrived at a sanitary ultimatum. Since the practice two diseases have become prominent—infantile scurvy and rickets—which were not recognized when he studied medicine. Fresh pure milk is better than sterilized, but he agreed if we are to cook milk at all we had better do it thoroughly. Boiled milk is better than sterilized. Dr. HIBBERD of Indiana, ex-President of the AMERICAN MEDICAL ASSOCIATION, questioned whether it had been established that any child had been diseased by milk from tuberculous cows, taken into its stomach. He had never had a positive, indisputable reply to the question: Can tubercle bacilli pass the digestive organs? He believed that sterilized milk starved children to death. Dr. LYMAN of Massachusetts said as it was possible for a child to be exposed to cold and not take cold, it was equally possible for it to live in a family where tuberculosis and similar diseases exist and not contract them. He believed that the development of the general health by proper sanitary environments will be a better protection against disease than any special method of asepsis. Dr. CARTER of Des Moines, Iowa, said it was a frightful fact that dairies are, as a rule, filthy, that the cows are filthy and kept in filthy places and milked by men who are both filthy and diseased. He had employed a man who had been previously employed for two years and when he saw that he did not wash his hands nor the cow's udder and remonstrated with him, he declared that he had never done so; and a second milker, who had also been working a year in a dairy, made the same admission. He was opposed to muzzling dogs and thought a shot gun was a better protection against rabies. Dr. HOLTON of Brattleboro, Vt., agreed with Dr. HIBBERD and said he had tried to find an undoubted case where tuberculosis had been communicated by the milk or flesh of the bovine race and had not found one. He believed heredity, etc., accounted for the development of certain diseases. He had for a year and a half, without knowing it, drank milk from a tuberculous cow, subsequently discovered to be the worst in the herd. He called attention to the danger from substituting patented food for milk.

Dr. KINYOON and Dr. SALMON controverted the statements of Drs. HIBBERD and HOLTON that the infection of human beings by diseased animals had not been established. When we consider that tuberculosis may be produced in animals by feeding them upon tuberculous tissues and find children die from tuberculous disease and know that the tubercle bacillus does penetrate the intestine, we are justified in inferring this as the source of their disease. As to making children strong rather than destroy disease germs, it is the fact that the robust often die and the sickly do not. Immunity does not depend on the strength of the individual. We do not know how frequent this infection was twenty-five years ago, and we would not know to-day but for the tests that have been established. How does Dr. HOLTON know that the milk he drank was infected?

The next paper, "Contributions to the Study of the Pathogeny, Etiology and Prophylaxis of Typhus," by Dr. FRANCISCO DE P. BERNALDEZ, delegate from the State of Oaxaca, Mexico, was a very able presentation of the subject based on personal observations in many epidemics, and Dr. Bernaldez's conclusions as to the limited contagiousness of this disease were accepted without discussion.

The "Report of the Committee on Nomenclature and Forms of Statistics," by Dr. SAMUEL W. ABBOTT of Wakefield, Mass., Secretary of the State Board of Health of Massachusetts, Chairman, was read by Dr. Walter Suiter of New York, particularized the latest changes in nomenclature by the College of Physicians of London, and was supplemented by a paper "On the Nomenclature of Diseases and Forms of Statistics," by Dr. EDUARD LICÉAGA of the City of Mexico, President of the

Association, and one "On Need of Uniformity in the Meaning of the term Stillborn," by Dr. JESUS E. MONARÁS of the City of San Luis Potosi, Mexico, Director of Hygiene of the State of San Luis Potosi.

Dr. LINDSLEY of New Haven, Conn., expressed his appreciation of the great importance of this series of papers. There were a number of States which do not yet take sufficient interest in vital statistics, and as uniformity in nomenclature is the essential basis of an exact system of statistics, he hoped the Committee would be continued.

The paper "On Dengue," by Dr. HENRY D. HORLBECK of Charleston, S. C., Health Officer of Charleston, was an interesting account of the great epidemic of that disease at Charleston.

A paper "On Municipal Responsibility for Healthy School-houses," by Mrs. ELLEN H. RICHARDS, of the Institute of Technology, Boston, Mass., was read by Dr. Durgin, Health Officer of Boston, and one "On Woman in Preventive Medicine," by Mrs. HARIETTA M. PLUNKETT, President of House of Mercy Hospital, Pittsfield, Mass., was read by title.

#### EVENING SESSION.

The evening session, to which the public was especially invited, was promptly called to order at 8 p. m. by the First Vice-President, Lieutenant Colonel ALFRED A. WOODHULL, of the Medical Department of the United States Army, who most efficiently assisted President Liceaga throughout the entire meeting of the Association. The session was opened with an address by His Honor EDGAR B. JEWETT, Mayor of the city of Buffalo, who very gracefully welcomed the Association to Buffalo, and invited the members to inspect the administration of the city's affairs in their bearing upon the public health. Mayor Jewett was followed by the Reverend Dr. THOMAS R. SLICER. He said in part: "I address you to-night simply as a citizen of the city of the lowest death rate in the United States, who is interested in conserving the public health of that city to a still greater extent. The word city is the watchword at once of your opportunity and your peril. You all have seen the dwellers in the country violating all of the rules of health and seemingly being themselves healthier than those who live in cities. In the grouping of so many together there is a sense of power that is not found in the country. It is because of this sense of power that lies in the binding of lives together that we at once should have a sense of insecurity and a hope of power. But, more than this, there is that civic consciousness which belongs to every city. Buffalo, as an example, has no civic consciousness. It has not the civic consciousness which marks Birmingham, Glasgow or even Chicago. It is, so far as we have gone, a group of contiguous tribes. I do not now refer to their nationality, though that is also true, but to their diverse interests, to their alien training, to their want of common purposes in this city. Chicago would not be where it is to-day were it not for its civic consciousness, and if it had not had the opportunity of the Columbian Exposition. Until civic consciousness arrives in municipal life it is almost a continuous upgrade for the guardians of the public health. There is a constant warfare with ignorance and avarice. Some of us do not know enough to protect ourselves against contagion. Let me add in conclusion that the Health Department of any city has no business at that trough from which the politician feeds. How many of you have not come in contact with that parsimony that will deny \$1,000 for a bacteriologist and spends \$2,000 on a junketing trip for a Board of Aldermen?"

The program had provided for an address on the part of the members from the Dominion of Canada, by the Honorable RICHARD HARCOURT, Provincial Treasurer of Ontario and Minister of Health, but having been unavoidably detained, Dr. PETER H. BRYCE of Toronto, Secretary of the Provincial Board of Health of Ontario, acceptably supplied his place in a brief extemporaneous address.

This was followed by the annual address of the President of the American Public Health Association, Dr. EDUARDO LICEAGA, of the City of Mexico, President of the Superior Board of Health of the Republic of Mexico. The President's address from the standpoint of a sanitarian in a body of advanced and experienced sanitarians, was an able and forceful paper. It was written in English by the President, but was read at his request by his friend, Medical Director ALBERT L. GIBON, U. S. Navy, a former president of the Association. It related principally to the business of the Association and went into a history of the growth and development of the study of public hygiene in Mexico, which Dr. Liceaga said had been fostered and encouraged under the administration of President Diaz during the last twenty years. Some of the suggestions made by Dr. Liceaga were of great value and interest. He laid before the Association the proposition that it should devote special attention to the study of contagious diseases, with a

view not only to their cure and the prevention of epidemics, but to the means of preventing the development of individual cases. The several phases of the subject of epidemics were taken up separately and treated in an exhaustive manner. One proposition put forth by Dr. Licéaga was that isolation in infectious diseases is not so essential in some diseases as in others, and that the study of the extent to which it should be practiced would repay investigation. Another proposition was that more attention should be paid to the study of the technique of disinfection. These and many other phases of the broad subject of contagion could be studied by uniform methods over a vast extent of territory by the members of the Association, with great results. Another question which Dr. Licéaga thinks merits investigation is the ascertainment of the period within which any disease is contagious and the person affected dangerous to his neighbors. This is something in regard to which much uncertainty still exists, and definite knowledge in this regard would be of incalculable value. Dr. Licéaga recommends also that a special committee for the investigation of the subject of the prevention of disease, particularly by vaccination and inoculation, should be appointed, and made reference to the newly developed sero-therapy, which he declared was already falling into disrepute through the use of imperfect or contaminated serum. A committee to devise a means for the use and sale of only absolutely pure and perfect serum, should be appointed. In conclusion Dr. Licéaga said: "Gentlemen of the American Public Health Association, I beg to offer you my sincere congratulations on our coming again together in the twenty-fourth meeting of this Association, and on having selected for the place of our meeting this beautiful and interesting city, which is so splendidly placed at the Eastern end of this delicious lake, a lake that supplies the water for this powerful river that farther on precipitates itself into a grand cataract, a stupendous marvel of nature that thousands of pilgrims from all parts of the world come to contemplate and admire; in this city which offers to us its hospitality and affords us an opportunity of again meeting to render our homage to science and to work together for the physical well-being of our fellow-creatures."

(To be continued.)

### Mississippi Valley Medical Association.

*Twenty-second Annual Meeting, held at St. Paul, Minn., Sept. 15-18, 1896.*

The meeting opened with a very satisfactory attendance, Dr. H. O. WALKER, of Detroit, presiding.

Dr. CHARLES A. WHEATON, of St. Paul, Chairman of the Committee of Arrangements, called the meeting to order, and introduced Archbishop IRELAND, who delivered the invocation.

Governor CLOUGH of Minnesota delivered the address of welcome on behalf of the State. He said he was obliged to admit that he was no orator, and that he had always been more or less timid in the presence of a physician, but of his hearty welcome to the State all members of the Mississippi Valley Medical Association might be assured.

Hon. F. B. DORAN, Mayor of St. Paul, delivered an eloquent address of welcome on behalf of the city. He referred to the reputation of St. Paul for hospitality won by the recent encampment of the G. A. R., and he said that upon that occasion the city had welcomed the men who had preserved the nation, while now she welcomed the men who preserved the bodies of the nation's defenders.

Dr. A. J. STONE delivered the address of welcome on the part of the profession. He paid a glowing tribute to the profession of St. Paul, the absence of professional jealousy, disagreement and ill-feeling, while he begged to assure the visiting profession that they were most heartily welcome. He also took occasion to speak of the great help the ladies of St. Paul had been to the committee in making the arrangements. In speaking of Minnesota as a health resort, he said it had proved a Mecca for consumptives, and notwithstanding the fact that many cases of tuberculosis came to St. Paul when in the last stage and when beyond all hope, die there, are included in the mortality, and notwithstanding this fact the mortality of this city is the lowest of any in the world.

Dr. H. O. WALKER took the chair and thanked the speakers for the welcome they had extended. In casting about for a subject upon which to deliver the annual address, he had decided to relate some experiences he had had rather than thresh over the various subjects which are dealt with at length in the various medical journals. He took for his title "Some Experience of Surgery of the Kidney." (To be published in full in the JOURNAL.)

The report of the Treasurer was not read, by reason of Dr. H. N. Moyer's absence on account of sickness.

The program opened in the afternoon session with a paper by Dr. TRUMAN W. BROPHY, of Chicago, who presented a

#### NEW OPERATION FOR CLEFT PALATE.

He took the ground that the operation should be performed much earlier than had been done heretofore by surgeons, and that the idea that the operation should be postponed until the child reached the age of three to seven years was an erroneous one for the reason that the changes in the voice would by that time have become permanent and the correction becomes almost an impossibility. The operation suggested by the author was the cutting of the edges of the cleft and then suturing them by wire sutures secured through a lead plate on each side of the palate, and made to conform to the same. In the hands of the author the operation had been uniformly successful.

Dr. W. H. DALY, Pittsburg, in discussion said: I think the essayist has made a marked advance in the operation for cleft-palate, the most important point being its adaptability to very young children, as I think it does away with all former objections to operating on the young infant. The greatest disappointment I have had in these cases is the poor articulation which follows the operation, and which is always a source of great disappointment to the patient and family, who always expect to hear perfect speech immediately after an operation, and I think this result will be attained in Dr. Brophy's operation.

Dr. G. FÜTTERER, of Chicago, read a paper entitled

#### PLEURITIC EFFUSIONS AND THEIR TREATMENT.

The author took the ground that a bacteriologic examination should be made in all cases. The diathesis in cases of pleurisy should also be most carefully looked into, as cases of uric acid are frequently found in connection with pleurisy; these yield readily to the administration of salicylates, and but about 15 per cent. of the cases of pleurisy are believed to be pneumonic. The pleurisy of typhoid fever was also considered by the author, who did not believe it was a mixed infection, but that it was a distinct condition. As to the presence of tubercle bacilli in pleuritic effusions, Dr. Fütterer believed that they may enter through the alveolar septa and enter the pleura without producing serious effect in the lungs. The author has washed out the cavity in fourteen cases with an antiseptic solution, with success in twelve. The agar culture should be used to differentiate between tuberculosis and pleurisy. The advantages to be gained by this treatment is that many patients will submit to it when they will not submit to the excision of a rib.

Dr. GUSTAVUS M. BLECH of Detroit, read a paper on the

#### TREATMENT OF INFLAMMATORY DISEASE OF THE STOMACH.

The author criticised the old routine methods of treating acute inflammatory disease of the stomach with menthol, ice, cocaine, opium, purgations, cathartics, pepsin, etc., for the reason that they did not cure the patient and the physician was too liable to delude himself into the belief that he had cured his patient because he did not return, which the author claimed was in nearly every instance due to the fact that the treatment did him no good. The reason that was given for the failure to cure the catarrhal condition of the stomach was that we are too prone to attempt to prescribe remedies for the relief of symptoms only and not sufficient attention being given to relieving the pathologic condition which prevent the digestive process from being normal. The use of strong antiseptics, which seem to be indicated, are more likely to do more harm than good by reason of the destructive action of strong antiseptics have on animal and vegetable cells. The treatment may be summarized into:

- 1, destroy the morbid element which is present in the stomach so as to thoroughly cleanse the mucous membrane; 2, heal the diseased surface after it has been made aseptic. For the cleansing the author has found hydrozone the most satisfactory. He uses a tumblerful of lukewarm water containing a 2 per cent. of hydrozone, half an hour before meals. The naseant oxygen which is set free in the stomach by the oxidizing agent destroys the morbid element and cleanses the mucous membrane. As a healing agent glycozone in one to two dram doses immediately after meals, is recommended. This treatment is strongly urged in gastric ulcer.

Dr. F. HUNT STUCKY, Louisville, Ky.—I desire to emphasize the value of perfect lavage in cases of gastritis. I would also urge the careful attention to dietetics as well as any intestinal disorder that may exist in connection with the gastritis. There must also be something in addition to the antiseptics; the nervous system should be built up and attention paid to any cir-

culatory disturbance. I believe massage would be valuable in many of these cases.

Dr. I. N. LOVE, St. Louis—I do not believe in limiting the treatment to any one agent, the entire tract must always be kept in mind and the application or administration is but one of many things to be done. We can not separate one set of secretory glands from another but must give attention to them all and in these cases I believe especial attention should be paid to diaphoresis; massage is also to be recommended in a certain proportion of cases. I believe there are many persons suffering to-day from an auto-toxemia due to a disordered stomach and that 90 per cent. of these cases can be laid at the door of constipation. Lavage of plain water as well as drinking large quantities of water just before eating I think a great help toward starting the current downward and outward. The habits of lavage has done much harm and I do not believe it should be intrusted to the patient to carry out.

Dr. W. H. DALY, Pittsburg—I have had anything but satisfactory results from lavage, the treatment suggested, and do not favor it. I heartily agree with the speaker regarding the toxemia for I heartily believe that a very large proportion of these stomachic diseases are due to toxemia and the most important thing to do is to consider every one of these cases as a rule unto itself and treat them individually. A good idea is to give a lavage of a gallon of water and then empty the stomach by irritating the throat with the finger when a cleansing result is desired.

Dr. C. H. HUGHES, St. Louis—The most important factor in the handling of this class of cases is to treat your patient all over. Medical men of the present day in treating dyspepsia have been forced to the conclusion that the individual is possessed of a pneumo-gastric nerve and that it plays a most important part in this disease, which has so long been considered as a local one. You take for example a case of nasal catarrh which goes the round of treatment at the hands of the rhinologists, who apply the spray, cautery, remove spurs from the septum, etc., and what is the result? Are the cases cured? No; because the attendant is too prone to treat the disease as a purely local one and not through the nervous system as should be done.

Dr. F. F. LAWRENCE, Columbus—The frequent occurrence of dyspepsia in connection with gallstones has suggested the possibility of its being secondary to this condition. We have all known of cases when the patient has consulted the physician for the relief of the usual train of symptoms which would indicate gastro-intestinal disorders and without relief until an abdominal surgeon, looking for ovaries he may remove, opens the abdomen and finds gallstones, after the removal of which the gastro intestinal symptoms disappear.

Dr. J. M. MATHEWS, Louisville—I would like to suggest that the author of the paper did not attempt to treat nasal catarrh, hysteria, or some of the other diseases the gentlemen have referred to. The paper dealt with a certain class of gastric disease and the treatment is precisely what you would adopt should you have an ulcer or acute inflammation located in any other region and I think we should bear in mind that if we want to have successful results we must get at the local conditions in these cases.

Dr. H. T. PATRICK, Chicago—I think there is some value in the suggestion of the essayist but I am opposed to the presentation of a cure for a condition as complex in its nature as gastritis without stating more specifically what form it is. I think the important thing to do first is to decide upon what particular form of the disease we have to deal with, then the cause and we can then apply our cleansing and antiseptic treatment.

Dr. I. A. ABT, St. Louis—We should not for a moment lose sight of the fact that we have a pathology for all these forms of gastritis, whether it be from alcohol, tobacco or any other cause. In making this differential diagnosis lavage will be of particular value. I am firmly of the belief that many of these cases are due to toxins.

Dr. J. A. LARRABEE, Louisville—I am convinced that the portal circulation is more often at fault in these cases than is generally supposed and its correction too often neglected. Exercise is above all things the most important and should be insisted upon in order to direct the blood to other and healthier channels. While I do not propose to discard the use of antiseptics I will place more reliance on treating the portal circulation.

Dr. W. S. CALDWELL, Freeport, Ohio—I use the stomach tube for diagnosis purposes principally and when I find that there is neither fluid or debris forming in the stomach I keep the tube out, although where I find much fluid accumulated in the stomach in the morning I wash it out with the tube.

Dr. PAUL PAQUIN, of St. Louis, read a paper entitled:

THE TREATMENT OF EXPERIMENTAL TUBERCULOSIS IN ANIMALS BY THE USE OF BLOOD SERUM.

(It will be published in full in the JOURNAL.)

Dr. H. LONGSTREET TAYLOR, St. Paul—I desire to say just one word on tuberculin and its modifications. Although the essayist says that it acts by producing an antitoxin, yet this has not and can not be proved. It may be the true explanation although the observed fact of an active leucocytosis in tubercular areas during its use is a more plausible explanation. Tuberculosis in its various manifestations presents such a complicated future and such a complex one that the very existence of an antitoxin is problematic and even if found it could not be a specific in the sense that the antitoxins of the acute diseases, as diphtheria, are specifics. Tuberculin is very much in disrepute here and everywhere, but it has a few constant friends yet, among whom I stand, and with good reason, for in careful hands undoubted results are obtained with it. I have, for instance, only recently seen the glands, in three cases of undoubted glandular tuberculosis, disappear under its use; what more convincing experiment could one desire?

In a long series of cases my results with tuberculin have been eminently satisfactory. With the St. Louis serum, however, I have not been able to obtain results. All the cases upon which I have used it grew worse. Still from a short series no results can properly be claimed, for more than in any other disease probably are statistics difficult of comparison in tuberculosis.

Dr. JOS. MUIR, New York—My experience has been large and varied in the therapeutics of tuberculous disease and for years I have used tuberculin and all its modifications, especially those of Hunter, Maclean, Klebs, Kitasato; aside from these, modifications of my own consisting of different percentages of toxic albumoses, the logic being that the maximum of irritation was gradually reached within and around that impenetrable wall, which surrounds all anatomic tubercles. Dr. Paquin is scarcely satisfactory in his theories regarding the physiologic action of his serum in tuberculous areas but his paper is teeming with statistics; some one has said, Beaconsfield I believe, that statistics consist of three classes, lies, damn lies and statistics. The curability of consumption can not be judged by statistics. Its curability has been known from time immemorial since the days of the early Greeks. Milk was the great agent in the treatment and continues to be so to the present time—so from the fullness of statistics I may cite the case of Professor Emmerick in an article written by him somewhat over a year ago and in which he gave the history of ten cases of sarcoma and carcinoma cured by serum obtained of the erysipelas and prodigious toxins. It was afterward proven that one of the cases referred to had been dead two months prior to the reading of the report.

Dr. BARCLAY, Pittsburg, Pa., complimented Dr. Paquin and congratulated the profession on the earnest and honest investigations made. He felt that the absolute candor of the reports should command the attention of the profession.

Dr. H. W. LOEB, St. Louis, Mo.—I have known several cases of laryngeal tuberculosis treated with serum and knew of one case in which Paquin's serum had given remarkably good results. In others it had been less successful. I consider serotherapy more promising in the treatment of other forms of tuberculosis than that of the throat. I will report a case of a man who, six years ago was examined by six competent physicians who pronounced the case one of tuberculosis with a fatal prognosis. The serum was used and to-day the man feels perfectly well and all physical signs of the disease have disappeared except a slight thickening of the arytenoids. I have confidence in the treatments in laryngeal tuberculosis, and one fact I have noted is that when first administered the larynx improves wonderfully even though it again resume its downward course.

Dr. W. H. DALY, Pittsburg—There is one thing to be remembered in our enthusiasm over any new remedy for tuberculosis and that is a very frequent occurrence to have patients claim that they are much better whenever a new line of treatment is adopted. It was so with Koch, Bergeon and Edson. I have tried the latter for a period of three months only to abandon it and while using it among some 150 cases of complications I had developed four marked cases of acute insanity. I regret that I am forced to admit that I feel that medical science has done very little toward checking the downward career or in the diagnosis of this disease.

Dr. A. J. GREEN, St. Paul—The full ability of medicine is best demonstrated in the treatment of tuberculosis. The statistics of some of the newer remedies are very encouraging at first, but they are somewhat altered when we stop to consider how many cases of enlarged glands and tubercular laryngitis get well without any treatment. I am still inclined to the

belief that we must depend more upon climate and high altitude than any thing else.

Dr. JOSEPH MUIR, New York—The treatment of tuberculosis is a very vague thing. We should be somewhat guarded in pronouncing a cure for the reason that many cases for a time manifest a quiescent stage which simulates cure. As for the beneficial results of climate, I think more is due to the change of surroundings than to the climate.

Dr. CHAS. H. HUGHES, St. Louis, said that one should not depend on any one remedy in the treatment of consumption.

Dr. LOVE said he knew of the work and results of Dr. Paquin in his laboratory, and knew that his results in the treatment of tuberculosis were as stated.

Dr. PAQUIN, in his closing remarks, stated that serotherapy was founded on natural law. It was nature's own remedy he tried to produce when he prepared tubercle antitoxin. He believed that serotherapy in tubercle had passed the experimental stage, although by no means perfect. He said that in the earlier stages pulmonary tuberculosis could be arrested in at least 80 per cent. of the cases by the use of serum and proper adjunct treatments.

#### SECOND DAY.

Dr. HORACE H. GRANT, of Louisville, Ky., delivered the address on surgery:

#### THE RELATIONSHIP OF DIAGNOSIS TO THE FUTURE SURGICAL PROGRESS.

He said that we must find some common ground for the settlement of our differences; many of the recent operations are passing away, owing to the effect of our modern scrutinizing investigation. We forget there are men in the quiet of their laboratories doing a work which makes all our wonderful progress possible. We can not progress much further in technique of operative skill. Any great amount of paraphernalia suggests a lack of personal resource in the operator. Almost every part and organ of the human body has been removed recently with more or less good to the patient. If we would make earlier and more careful diagnosis many of the possible failures would be precluded. No surgeon dare say to the patient, "If I had known yesterday, or before, so and so, the result would have been different." Rarely will we fail to secure an operation if the operator be sure of his diagnosis and demands an operation. No term in all surgery is so often misapplied as conservatism. No aim is dearer to the surgeon than the ways and means of relieving his patient. We must not fall into the error of making one man great and another man insignificant. Experience is and should be one of the greatest aids in diagnosis. The skiagraph has lately come into importance in surgical work, and may be made a valuable adjunct in many instances. Its recent successes are noteworthy. It is yet, however, in its infancy, and is doubtless capable of still more development. No one doorway can open to success in surgery. The skillful and intelligent application of prompt relief added to a careful diagnosis will give us the most wonderful and satisfactory results. What each one finds to do let him do it with his might.

Dr. E. M. HOUGHTON demonstrated the action of the antitoxin on guinea pigs before the Association. He called attention to the conservative view the profession had taken of the antitoxins which would have a tendency to avoid the unfortunate experience the profession had had with tuberculin. The value of laboratory experiments in connection with clinic observation was emphasized by reason of our being thus enabled to obtain the exact dynamics of the flesh and blood of our patients and the advantage to be gained in varying our experiments at will. In the case of diphtheria antitoxin the physiologic effect can be foretold with almost the same certainty that we can predict the formation of hydrogen when platinized zinc and hydrochloric acid are brought together. The world's verdict in reference to the clinic value of the diphtheria antitoxin is expressed in the report of 615 physicians reporting to the American Pediatric Society on the use of the serum, of whom 600 are in favor of its use. A similar commission appointed by the German government, came to a like conclusion, while Behring claims that after a careful estimate he thinks that 20,000 lives were saved in Germany alone by the use of the heil-serum. In England the results are expressed in the report of the *Lancet* Special Commission, which report: That the influence exerted by the exhibition of antitoxin on diphtheria is at any rate quite as marked as that exerted by quinin in malaria. Our ignorance of the true action and power of the toxins and antitoxins was emphasized. The author claimed that the results obtained by Pfeiffer and his co-workers, in which he showed that if the serum obtained from the blood of an immune animal be injected into an animal infected with virulent cholera cultures the animal survives while the

control animals die. This result is not due to the antitoxic action of the serum but to the bactericidal substances developed when the serum is brought in contact with the living cells of the animal body. If an animal be treated with large and increasing quantities of living cultures of the bacillus pyocyaneus for several months, the resulting serum will possess strong bactericidal properties but weak antitoxic properties. If on the other hand the toxin is used, the resulting antitoxin will have a strong germicidal and antitoxic action. This may explain why we get a more potent diphtheria antitoxin when the horse has been immunized with a diphtheria toxin than when he has been immunized.

Eight guinea pigs were inoculated before the Association with diphtheritic toxin, five were then inoculated with the antitoxin and the second day saw the five in excellent condition while the other three died.

The Committee on Nominations, consisting of Dr. J. M. Mathews, Louisville, Dr. I. N. Love, St. Louis, X. C. Scott, Cleveland, W. N. Wishard, Indianapolis, J. M. Coulter, Chicago, W. F. Barclay, Pittsburg, W. J. Mayo, Rochester, Minn., J. P. Collins, Hot Springs, G. Blech, Detroit, T. H. Manly, New York, and E. W. Lee, Omaha, reconsidered the nomination of secretary, and selected Dr. H. W. Loeb.

Dr. ROBERT H. BABCOCK, Chicago, read a paper on:

#### A REPORT ILLUSTRATING THE VALUE OF SECONDARY PHYSICAL SIGNS IN THE DIAGNOSIS OF CARDIAC DISEASE.

The author claimed that the murmurs are the least reliable signs of valvular disease and an accurate diagnosis can not be made unless the secondary signs are recognized. If the heart be too weak it may be that the murmur can not be detected, or a grave defect may not be noted. Secondary symptoms are a modified pulse rate, character and rhythm, leading to a congestion of the veins and internal organs. In some instances there is systolic venous pulsations of the liver. This is diagnostic of insufficiency even if the murmur is not audible.

Dr. JOSEPH MUIR, of New York, read a paper on

#### REINFECTION IN CONSUMPTION.

(It will be published in the *JOURNAL*.)

Dr. J. A. LARRABEE, Louisville—The paper of Dr. Muir is unusually attractive, and reflects to us our individual experience with consumption. The doctrine of re-infection affords the only reasonable explanation of the recurrence of arrested tuberculosis, with which every general practitioner must be familiar. The principle element in our failure to secure to the patient the advantage gained by our treatment in cases of pulmonary consumption consists in our inability to remove the patient from the surroundings in which his disease commenced. The air of workshops, the carpets and drapery of the apartments, together with the illy ventilated tenements of even the well-to-do working people, contain abundant seed for the now more congenial soil. I have always believed that if the consumptive could have in the inception of his disease the comforts and care which are drawn around him in the late stages recoveries would be far more frequent. In regard to climate, I do not think that altitude or latitude are of so much importance as a sterile atmosphere to the bacilli tuberculosis. Some of the saddest sights which I have witnessed in my travels both at home and abroad have been doctors' mistakes coming home in pine boxes. I believe that the best place for a consumptive in the second stage of his disease, when the lung tissue is beginning to break down, is at home, no matter what or where that home may be. It is a sad sight to see the suffering putting up with inconveniences and deprivations, which home alone can remove, for the questionable advantage of climate. To this must be added the mental depression consequent upon absent friends and the tender touch of a loving hand. Yesterday I had something to say upon lavage when the subject of gastritis was under discussion. To-day I simply want to change the "l" into a "g" and speak of gavage, by which I mean a systematic course of forced feeding with most nutritious food, or in a word, forced nutrition. It has been sufficiently demonstrated that nutrition may be successfully forced even where there is no inclination to eat. Every farmer who has stuffed turkeys in a dark cellar for thanksgiving market knows this. If you can make your consumptive patient gain steadily in weight he will as certainly improve in all other respects. I have sent very many consumptives to New Mexico with invariably good results, but I believe that if the United States government, as proposed, were to build a sanitarium at Las Animas or Santa Fe and fill it with consumptives, it would soon become a Lazar house of disease, notwithstanding the altitude and latitude. Among many of my cases sent to this place was a young man who was fast succumbing to consumption. He was a blythe and accomplished fellow, and the sole support of a widowed mother. He had night sweats and copi-

ous expectoration and plenty of bacilli. I sent him to Las Animas to "fence ride," herding on a ranch; he rapidly improved. His clerical abilities attracted the attention of his employer, who had built a hotel, and he assumed the duties of clerk. In three weeks his symptoms returned; he wrote me and I told him to get out and go "fence riding"; he is still well, but would have died had he remained indoors. No point is better established than that consumption is a disease of aggregation of individuals. It was unknown to the nomadic tribes, and no point is more important than segregation of tuberculous subjects. If I have spoken at greater length than the limit my apology is that such a paper as Dr. Muir has presented should not go unnoticed, and without the compliment which it deserves.

Dr. HUGH T. PATRICK of Chicago, read a paper with elaborate illustrations on

#### TRUNK ANESTHESIA IN LOCOMOTOR ATAXIA.

In nearly all cases of tabes dorsalis there is a band of anesthesia about the trunk of about the level of the nipple. It is early in the disease very narrow or even incomplete, or may be represented by a zone in which the localization of touch is not normally accurate. The sensory blunting on the legs so frequent in tabes is generally an analgesia; the trunk anesthesia is ascending, tactile, and the pain sense may be quite normal. The band of anesthesia does not correspond to the cutaneous distribution of the intercostal nerves, but to the nerve fibers arising from adjoining segments of the spinal cord. In some cases there are two distinct zones of anesthesia indicating simultaneous involvement of spinal segments at some distance from each other. The borders are inconstant, ordinarily retract on continued testing, and vary in position with the method of examination. The same band of anesthesia may occur in syphilitic pseudo-tabes as shown by an illustrative case, as far as known the only one on record. The patient presented nearly all the principal symptoms of locomotor ataxia, including a wide band of trunk anesthesia, but a diagnosis of syphilis of the cord was made, and on active specific treatment he made an almost perfect recovery. A zone of anesthesia much narrower than this one still exists.

Dr. J. FRANK of Chicago, presented a paper on "A New Method of Fastening the Round Ligament in Alexander's Operation."

Dr. J. A. ART of Chicago, read on "The Clinic Significance of the Child's Fontanelle."

Dr. W. J. Mayo of Rochester, Minn., read on "The Surgical Treatment of Pyloric Obstructions."

Dr. THOS. H. MANLEY of New York read a paper on  
CONDITIONS WHICH MAY SIMULATE ORGANIC OBSTRUCTION OF THE RECTUM.

The obstructions in the large intestine are of two kinds, viz.: 1, the passive; 2, the chronic or incomplete. The former are the most rare and dangerous, with few exceptions depending on hernia, paresis, or occlusion by a new growth. The latter derange the general health though they seldom immediately imperil life. They are essentially dependent on habit, occupation or senile changes, or occur secondarily in consequence of extrinsic influences. They are more common in the female sex in consequence of difference in the anatomy and functions of neighboring organs; and may give rise to such symptoms as may lead the unwary into suspecting uterine disorders.

By a methodic systematic examination of cases of intestinal obstruction we may generally be enabled to determine whether the large or small intestine is the seat of stenosis or occlusion by certain well defined symptoms and when the large intestine is the seat of the trouble, we may determine not only the area involved but likewise whether such obstruction proceeds from causes of an intrinsic origin or from pressure conveyed through the other sources.

Dr. I. N. LOVE, St. Louis—The paper of the essayist is a most practical one on obstruction in the rectum, which is a most serious condition. It is serious if present in the male and doubly serious if present in a woman. There can be no question on the part of those who have been engaged in the practice of medicine for any length of time that 90 per cent. of the diseases of women are dependent on constipation. These patients suffer not only from general poisoning from accumulated ptomaines and auto-infection, as it were, but in addition there are encroachments and misplacements of the bowels, on the pelvic organs depending upon the regular accumulation of the fecal matter which produces mechanical obstruction. The average woman, be she mother or daughter, has not been sufficiently impressed of the danger of constipation. We all know that the old saying, the standard of comparison as it were, regarding constipation which was explained in the words "as constipated as a school marm or an owl," was correct. We

have all met with women young and old, moving in respectable society, whose bowels have not moved for ten days, two or even three weeks, yet these people are surprised if dangerous diseases overcome them. Fatal inflammation of the peritoneum and many other similar diseases in women are superinduced by constipation. We should impress women young and old that it is not only unesthetic and unartistic, but not healthful for their bowels not to move every day. Let us impress them of the fact that to overcome this condition cathartics and purgatives are objectionable; they will have removed the immediate disturbances but they produce weakness and are agents in the establishment of the constipation habit. Proper diet and eating of large quantities of fruit, together with an abundance of pure water, and especially exercise, will in nearly every case relieve the trouble. Let me emphasize the importance of the use of a great volume of water morning, noon and night; let us teach our patients not to drink water because they are thirsty, but for the purpose of washing out their alimentary system of sewerage. The fact that the essayist has cited a case where he with difficulty removed a fecal mass with the obstetric forceps from the rectum must be accepted by us. We have all had experience along that line calling for the scooping out of accumulated masses menacing the health of the individual. Women are very lax of exercise, an every day necessity: let us teach them that a proper open condition of the rectal canal is necessary to cleanliness, to the system, and cleanliness is next to godliness.

Dr. N. H. PIERCE of Chicago, presented a new "Submucous Linear Cauterization; a New Method for the Reduction of Hypertrophies of the Conchæ."

Dr. HUGH T. PATRICK of Chicago, read a paper on  
ELECTRO-THERAPEUTICS AND ELECTRO-DIAGNOSIS SIMPLIFIED.

Electro-diagnosis is limited to the affirmation or denial of a lesion of the lowest neuron, that is, of a lesion of the motor cells in the spinal cord or of the nerve fibers, the peripheral nerves springing from these cells. A lesion of this neuron causes reaction of degeneration and this stripped of all unnecessary technicalities may be recognized by two variations from the normal, namely: A loss or very considerable diminution of faradic contraction and the slow worm-like contraction of the muscles to interruptions of the galvanic current. In the electro-therapeutics of organic disease of the nervous system applications of electricity to the brain may be entirely discarded as useless. Electricity through the spinal cord is little better. In diseases of the peripheral nerve it probably hastens recovery and that current is to be chosen which the better causes muscular contractions. In functional nervous disease electricity is of more practical value than in organic affections, but it is almost impossible to determine what proportion of this good effect is due to mental impression and suggestion. The galvanic current is to be chosen for facial and intercostal neuralgia, and sciatica; the faradic for lumbago, for hysterical and anesthetic paralysis and pain. The galvanic for exophthalmic goitre and sometimes for neurasthenic headache and backache. For facial spasm, tic douloureux, spasmodic torticollis, tremor and chorea, electricity is useless aside from the mental effect.

Dr. J. A. LARRABEE, Louisville—I arise, Mr. President, to tender my personal thanks to Dr. Patrick for his plain, succinct and truthful elucidation of the application to bodies of which we know little, of a subtle fluid of which we know less. I thank him because he has made the subject of electro-diagnosis and therapeutics plain to my mind, which is a difficult task. Hitherto papers presented upon this subject have been chiefly interesting to their authors. Dr. Patrick has plainly shown us what lines are to be expected from electricity. It is not surprising that electro-therapeutics should afford a fruitful field for quackery and then it should be surrounded with all the mysteries of his ingenuity. I will say in conclusion that I have not found any benefit from electricity in chorea, nor should I expect that any benefit should accrue if the accepted pathology of that disease obtains.

Dr. A. J. OCHSNER of Chicago, in a paper on  
NERVE SUTURES AND OTHER OPERATIONS FOR INJURIES TO THE NERVES OF THE UPPER EXTREMITY.

It presented the following conclusions:

1. Suture every severed nerve.
2. The earlier the operation the better.
3. If neither sensation or motion is established within a year, the nerve should be again exposed, the cicatricial tissue removed and the ends again sutured.
4. The ends should be clean cut, should contain neither crushed tissue nor cicatricial tissue.
5. Tension must be avoided.
6. The wound must heal without suppuration to secure the best results.
7. Hemorrhage should be controlled perfectly to prevent intervening clot.
8. Carefully prepared catgut is the best suture material.
9. After suturing the ends either direct or "a distance" it is

well to stitch a fold of fascia over the united nerve-ends. 10. The extremity should be placed at rest. 11. The external incision should be ample.

Dr. H. P. NEWMAN of Chicago read a paper on

WOMAN AND HER DISEASES VERSUS GYNECOLOGY.

The author emphasized the following points: 1. As specialists we must recognize and exercise the rising interest in a medical science which shall be preventive rather than curative. 2. Our affiliation should be with the general practitioner and obstetrician rather than with the specialist in surgery, who often lacks the special training necessary to an appreciation of the many disease manifestations in woman, their etiology and prophylaxis. 3. As we have long made a study of the pathology and etiology of woman's diseases and as we know that whatever may be acquired can be prevented, our specialists are best qualified to lead in the movement for the reform of all conditions detrimental to the health of modern women.

Dr. J. H. COULTER of Chicago read a paper on

TONSILLOTOMY BY CAUTERY.

He gave the following conclusions: 1. Do only a small amount at each heating of the electrode—work five seconds and allow the patient to rest twenty seconds. 2. Burn only where you can see what you are doing. 3. Use an electrode bent at right angles and having a fine point. 4. Do not attempt too much at one sitting. 5. A strong solution of silver nitrate is an excellent hemostatic in cases where there is slight hemorrhage. 6. Be sure the electrode is thoroughly heated when you attempt to burn. 7. Cut off the portion loosened at each séance; it prevents healing by its friction, and is often an annoyance to the patient. 8. Do not operate if the gland be acutely inflamed. 9. Always remember the normal shape of the tonsil, and that one must dissect much more deeply at its superior portion in order to get all of the pathologic tissue. 10. It is sometimes best to cut from below upward while taking out the inferior portion; in this convenience should be the guide. 11. By care the operation may be rendered almost if not entirely bloodless. 12. The indication in all cases is *eventual* total ablation. 13. Succeeding steps on the same tonsil should not be more than ten days apart. 14. When hemorrhage is met with, stop the bleeding at once with the heated electrode, and apply a solution of silver nitrate 90 grains to the ounce solution or stronger. 15. Try the method in suitable cases and I feel confident you will concur with me in the opinion that it possesses some advantages not found in any other.

Dr. G. BLECH of Detroit read a paper on "Kola."

Dr. F. F. LAWRENCE of Columbus, Ohio, read a paper on

THE PATHOLOGY AND TREATMENT OF SUPPURATIVE SALPINGITIS.

He called particular attention to the following points: 1. The tubal mucosa is a true mucous membrane possessed of all the histologic elements of mucous membrane. 2. The fimbriae are prolongations of the folds of mucous membrane with a few muscular fibers beyond the end of the tube proper. 3. The closure of the fimbriated extremity of the tube is effected by first, the unfolding of these plicae and the elongation of the muscular fibers with coincident inflammatory exudate and not by adhesion of peritoneal surfaces. 4. The closure of the tubal ostium results in the formation of a circumscribed abscess. 5. The pathology of this circumscribed abscess is the same as that of suppuration with abscess formation in mucous membranes in other parts of the body except in the effect upon important contiguous tissues. 6. Occasionally the uterine end of the tube remains patent when we have the abscess of tube communicating with uterine cavity through which it may impart, discharge its contents. The treatment of the tube can not be fixed by any ironclad rule, each case must be treated as best it can by first, incision and drainage in rare cases; second, the vaginal section in a few carefully selected cases; third, abdominal section in a great majority of cases; hysterectomy in those cases where we find abscess of uterine wall, tubercular deposits, fibroids or malignant disease of fundus; as hysterectomy destroys the pelvic floor, it should never be performed except when there is some tangible lesion of the uterus.

Dr. F. B. TURCK, Chicago—I wish to take objection to the manner in which the speaker handled the bacteriology and pathology, in his paper, of the uterus and tubes. In the first place microorganisms do not peptonize living cells. It is only necrosed tissues that undergo peptonization. The manner in which infection takes place is, first a soil is found upon the surface of the mucosa—the microorganisms may develop in a mucous bed of cellular lining upon the mucous wall. As the germs grow in this rich nutrient media toxins are found

which are partly taken up by the underlying gland cells. A necrosis then occurs and the cells exfoliate and add to the nutrient media. It is then that peptonization of the necrosed cells may occur. The thinning of a tube is not due to the peptonization of its wall. When inflammation of the mucous membrane of the tube occurs, the membrane first may be thickened, then fluids are formed which distend the tube or tubes, and the pressure in this manner produces a thinning of the walls.

Dr. H. H. GRANT, Louisville—While I believe the position taken by the essayist is practically the one we must accept, it is not the ideal one. We are often forced to accept what our judgment indicates to be a second choice. There are two arguments not mentioned which, while they are in the minds of the essayist and the surgeon, are not in the minds of the general practitioner and the family, and do not assist in securing consent to operate. These are: First, there exists always, practically, a septic condition and often a gangrenous foreign material of a highly dangerous character. Secondly, there is a large proportion of apparent recovery which are in fact but partial recovery. When we can so instruct the general practitioner that he will understand the patient who lies before him has within his abdomen a virulent foreign body or pus sac, he will not hesitate to consent to and advise operation. Beside this when there is impressed on the patient the danger of recurrence, even after apparent recovery, he will more likely accept the operation. With respect to septic peritonitis a serious question arises. Whether to operate or not is still unsettled. It is humiliating to decline and often hopeless to proceed.

Dr. I. N. LOVE, St. Louis, read a paper entitled "Water."

(To be published in full in the JOURNAL.)

Dr. T. H. STUCKY, Louisville—I want to say a good word for hydrotherapy, but I would take issue with the essayist that a large quantity of water is always to be taken with meals, for example, in cases of dilated stomach I do not think it at all advisable; it also prevents thorough mastication when taken with food and thereby prevents complete salivation which would result in fermentation. I also think that too little attention is paid to the subject of water in our medical colleges.

Fifty-seven members of the Association left in a special train for Yellowstone Park Friday evening and arrived at the Park Sunday noon. They expect to return in a week.

Second International Congress of Gynecology and Obstetrics.

This Congress opened at Geneva September 1, with a notable gathering of specialists from every civilized country. The first address was made by Bouilly of Paris, with Kelly of Baltimore and Sängér of Leipsic as "co-rapporteurs," and discussion by Henrotin of Chicago, Péan, Hartmann, Richelot, Tait, Doyen, Delagenière, Laroyenne, Jacobs, Deletréz, Rouffert, Tournay, etc. Bouilly defined as follows the indications for simple incision with drainage, through the abdominal or vaginal wall:

1. An acute pelvic abscess of cellular origin, the point for the incision indicated by the projection of the collection in the abdominal wall or in the vagina. 2. Primary peritoneal collections consecutive to puerperal, abortion or gonorrhoeal lesions, acute or subacute, or to post-operative peritoneal infection. 3. Suppurated hematoceles. 4. Encysted pelvic abscess in the adnexa, unilateral, with not very thick walls, easily fluctuating, and located low down on the uterus so that it can be pushed down by pressure in the hypogastric region into contact with or near, the wall of the vagina. Simple incision is also especially indicated in acute suppurations of the ovaries or tubes accompanied by general serious conditions in which the extreme virulence of the pus contraindicates laparotomy or hysterectomy. This method of treating pelvic suppurations gives better results and ensures recovery in far more cases than is generally realized, while if a fistula persists or the suppuration returns, it does not preclude a later vaginal hysterectomy.

Laparotomy is indicated whenever there is any doubt as to the character of the lesion or whether it is uni- or bi-lateral. The latter consideration is less important in the case of suppurations, as it rarely happens that suppuration of one side is not followed by the same condition in the other. Laparotomy is also the better method for pockets located high up, when they are near the horns of the uterus and yet far enough away from it and from the vaginal cul-de-sac for the uterus to retain a certain independence and mobility; also when the pockets are rather abdominal than pelvic, not surrounded by thickened and indurated tissues, and when they have not produced repeated pelvi-peritoneal disturbances. The opening of such

a pocket in the course of a vaginal hysterectomy might produce an acute peritoneal infection by infecting the surrounding intestines unprotected by any old barriers of organized adhesions. Aside from these two restrictions; uncertainty as to the nature of the lesion and an elevated location, vaginal hysterectomy accomplishes all that can be accomplished by laparotomy in the removal of suppurated tubes and ovaries or a small pyo-salpinx. It also reaches and cures lesions for which laparotomy is useless or too dangerous. It is the only method which reaches purulent collections enclosed in the appendages, circumscribed by adhesions or merged in the neighboring parts, and separated from the great peritoneal cavity by solid and organized tracts, actual fibrous processes which render laparotomy useless and any attempt at enucleation dangerous. Hysterectomy is also the preferred method in cases of large, adherent pockets, impossible or difficult to enucleate, with or without fistulas. It is also the best method to cure chronic suppurations of the peri-uterine cellular tissue that have opened spontaneously and formed communications with neighboring organs. In these operations the purpose is simply to evacuate; the ablation of the uterus forming an ideal means of draining, through which the collections discharge and dry up. To extirpate the pocket itself under these circumstances deprives the operation of all the advantages of its simplicity and benignity, and shows a misapprehension of its chief advantages. In conclusion he stated that ablation of the uterus is a factor not to be neglected in the treatment of pelvic suppurations. Some of the laparotomists now remove the uterus along with the adnexa as this ensures perfect drainage of such marvelous efficiency that it is probably the cause of the superior results after vaginal hysterectomy. Ablation of the uterus also prevents future trouble from that organ. The immediate recovery is more rapid and the after effects are better, while the genital disturbance subsequent to suppression of the menstrual function seems to be less after ablation of the uterus with the appendages, than after ablation of the latter alone. Vaginal hysterectomy therefore, is the method *par excellence* for treating pelvic suppurations, and laparotomy only exists on its contra-indications.

Sänger, on the other hand, stated that the tendency in Germany is to favor laparotomy and ligatures, and a more conservative treatment. The Germans consider that it is far better to retain as much as possible of the genital organs than to extirpate them and resort later to the ingestion of ovarian tissue, etc., as a substitute for them. He rejects absolutely the idea of vaginal removal of a sound uterus as a preliminary to operating upon the adnexa, and states that the radical operation is not justifiable when the abdominal end of the tube is still open, nor in light cases of purulent salpingitis, abscesses of the ovaries, chronic, non-purulent affections of the adnexa, nor in simple, chronic inflammations of the uterus.

It is better to have a menstruating uterus, even if it is slightly diseased, rather than none at all. On the other hand, the radical operation is completely justified in serious suppurations of the adnexa, pelvic peritoneum, or connective cellular tissue, when these affections coincide with a serious affection of the uterus, which alone would justify its removal, and also when the purulent affection of the adnexa has spread to the uterus; also in cases of tuberculous affections. Proximity to the menopause is an additional indication for radical treatment. The objections to vaginal operations are the necessity of commencing the operation at the uterus instead of at the diseased ovaries, also the impossibility of arresting the operation; the incompleteness of the investigation of the field of operation as other purulent collections, appendicitis, etc., might exist and pass unobserved; the impossibility in certain cases of a truly radical operation, and the dangers of hemorrhages and of injury to the neighboring organs. In the case of slight suppurations of the appendages, when the pockets were not opened in the course of the operation, the peritoneal cavity can be closed without danger. The Germans prize highly the method of closing introduced by Kaltenbach and Olshausen, except in serious cases of radical vaginal operations. Whenever removal of the uterus is indicated, he considers celio-salpingo-oophoro-subvaginal-hysterectomy as the least dangerous radical operation. A part of the ovaries can even be retained with it. Drainage is indispensable in all cases of contamination of the hand of the operator or of an intact region with virulent pus; also when the hemostasis is not perfect or there is a discharge of virulent pus; also where there is a pre-existing fistula, or perforation of the intestine during the operation. He prefers Mikulicz's method of drainage, and adds that, thanks to this, the life of the patient can always be guaranteed, with complete recovery in time. Tamponing also relieves the anxiety of those who venture to close the abdomen. He classified some of the various methods in vogue as follows:

Vaginal methods: 1, anterior colpo-celiotomy (Dührssen, A. Martin, etc.); 2, posterior colpo-celiotomy (Steel, Hegar, Battey, Byford, Laroyenne, Landau, Mackenrodt, etc.); 3, anterior and posterior colpo-celiotomy (Bode, Von Erlach, Gottschalk), in combination with uni-lateral and bi-lateral salpingo-oophorectomy; 4, colpo-hysterectomy (Péan's uterine castration); colpo-hystero-salpingo-oophorectomy or radical vaginal operation (Péan, Segond, Doyen, Landau). Abdominal methods: 1, celio-salpingectomy and uni- or bi-lateral celio-salpingo-oophorectomy; 2, total celio-salpingo-oophoro-hysterectomy (Krug, Polk, Delagenière, Schauta, Bardenheuer, etc.); 3, bi-lateral celio-salpingo-oophorectomy combined with supra-vaginal hysterectomy (Zweifel, Kelly, Sünger). Mixed methods: Abdomino-vaginal hystero-salpingo-oophorectomy, commencing usually with the vagina and ending with the abdomen (Landau), and finally, in a group apart, sacral or parasacral celiotomy (Hegar, Von Hochenegg, Czerny, Schede, etc.), which has only been performed by a few surgeons and with strict limitations.

Kelly's able presentation of his methods was read by the Secretary-General. Henrotin (Chicago) insisted on the benefits of immediate vaginal incision with digital exploration, and if necessary a second opening in the anterior cul-de-sac.

Richelot (Paris) remarked that extirpation of the adnexa through the abdomen was not always followed by recovery; and the surgeon was sometimes baffled by encountering extremely virulent pus. In every second one of the laparotomies he has performed since 1894 for suppurated adnexa he has been compelled to finish with double castration. Laparotomy triumphs where there are organs to be respected, which is, he considers, its true indication. He added that the tubes and ovaries are not heard from after the removal of the uterus, as often as the uterus after the removal of the appendages; concluding with the statement that vaginal hysterectomy should be accepted as the preferred method of treating pelvic suppurations, principally because it avoids the two dangers of laparotomy: infection of the peritoneum and injury to the small intestine. Hartmann (Paris) urged more general resort to repose in bed and vaginal antiseptics as the first, and sometimes, the only treatment needed for pelvic suppurations. He has also derived great benefit at times from dilatation and curettement, which may prove useless, but in certain cases seem to be all that is necessary. Péan lauded total vaginal castration as applicable to all pelvic suppurations of genital origin and sure to produce better results than any other method of treatment. Recovery is more rapid the earlier the operation is performed, and the mortality, in skilled hands, is only from 1 to 4 per cent. He concluded by mentioning the beneficial results he has observed occur in from two months to three years after the operation; disappearance of hysteria in 6 patients, of nervousness in 2, insanity 5, melancholia 1, morphinomania 2, ileo-lumbar neuralgia 4, mammary and intracostal neuralgia 3, nausea and rebellious gastralgia 2, anemia from inanition 2, headaches and sweats 4, inability to walk 1, gravel and nephritic colic 1, rheumatic endocarditis 1, bronzed pigmentation 1, and albuminuria 2. Péan now has a record of 350 operations and repeats his previous announcement, that total vaginal castration requires a special set of instruments, such as he has been using since 1883.

The other subjects discussed at the Congress were: "Surgical Treatment of Retro-deviations of the Uterus," presented by Küstner, Polk and Pozzi, and the discussion led by Martin, Bouilly, Lawson Tait, Doyen, Jacobs, Edebohls (N. Y.), Gill Wylie, Deletréz, Stapfer and Petit; "Best Method of Closing the Abdomen," presented by Granville, Bantock and La Torre; discussion led by Martin, Tait, Richelot, Laroyenne, Doyen, Jacobs, Edebohls, Gill Wylie, Byford (Chicago) and Deletréz; and "Relative Frequency and Shape of Abnormally Small Pelvis in Different Countries," etc., which were represented by Fancourt Barnes, Dohrn, Fochier, Kufferath, Lusk, Rein, Pawlick, Pestalozzi, Treub and Barry Hart.

#### Fourth International Congress of Criminal Anthropology.

This interesting assemblage of the specialists who are fostering this infant science opened at Geneva August 24. Lombroso said in the course of his address, in regard to our prisons, that as at present conducted, the expenses have to be borne by the law-abiding citizens, and they fail to reform the criminal. The probation system, with work in mines, penal farms, etc., should take the place of our present prisons, and criminals from passion and political criminals should not be imprisoned at all, as exile alone is more than sufficient punishment. Confirmed criminals, epileptics, alcoholics, should receive special medical treatment, but the efforts of society should be espe-

cially directed to bringing up in a moral atmosphere the born "criminaloids" from the earliest months of their lives, with absolutely no intercourse with depraved associates and no opportunity for them to corrupt decent young people. With this should be combined every possible means to combat alcoholism, social, religious, with journals, pamphlets, etc., and constant medical supervision of the "criminaloids." Françotte spoke of a condition induced by alcohol which he calls alcoholic somnambulism. The individual acts in an apparently normal manner, but has no consciousness of his actions, or at least retains no remembrance of them. He considers it a legally irresponsible condition, except in cases of premeditated intoxication: Legrain's address was an appeal that the importance of alcoholism as an evil and peril to the nation should be inculcated in every way, taught in the schools and impressed upon legislators as their guiding principle. Habitual drunkards should be incarcerated, so that they could not propagate their kind, and compulsory cures legally enforced. Their children should be taken from them and societies formed for this purpose. Garofalo suggested that criminals should be classified as follows: 1, assassins; 2, violent; 3, dishonest; 4, cynics. Homicidal mania, pyromania and epilepsy would be included in the first category; hysteria and kleptomania in the third and sadism in the fourth. If penal science were relieved of some of the conventionalities which now encumber it, and the actual criminals separated from the mere revolts and disobediences, each type of criminal could then receive appropriate treatment and the science be established on a firm basis. Malarewski stated that the establishment of medico-pedagogic institutions and agricultural training colonies is the only means to reclaim children with a predisposition to degenerate, and that an international medico-pedagogic congress is the only means to accomplish the organization of such colonies. Other subjects presented were the influence of the press on criminality, anarchism from the point of view of criminal anthropology, or as Zakrewski prefers to call it, legal psychopathology, digital imprints and Bertillon's discussion of the gaps still to be filled in anthropometry. The members from Russia, Italy and Belgium were especially prominent in the Congress.—*Gaz. Méd. de Liège*, September 3.

## SELECTIONS.

**The Progress of Scientific Medicine and Pharmacy in China; A Conversation with the Physicians of Li Hung Chang.**—With the great Chinese warrior and statesman who has just honored our country with a brief visit, there came two attachés of the Chinese Imperial Medical Service, Drs. Irwin and Mark, for the purpose of insuring his health and physical comfort during his journey around the world. It has been the pleasant privilege of the writer to call upon these custodians of the bodily welfare of the Viceroy, and to talk with them in regard to the recent progress of western medical methods in the Celestial Empire.

Dr. George Mark's manner is most cordial and in every way pleasing; his English is so thoroughly excellent, that only his physiognomy and dress betray his nationality. He is in the foremost rank of the Chinese students of scientific medicine.

Dr. Andrew Irwin, an examiner and director of the Imperial Hospital at Tien-Tsin, is a genial Briton, who has come to favor and position among scientific men who are struggling to supplant the barbarous myths and superstitious practices of the Chinese physicians by the more human and more scientific methods of our western civilization. He appreciates the need of a change of this sort and the value of the progress already made, and finds pleasure in making known the condition of his favorite science in the country that has become the scene of his life work.

When the first medical missionary arrived in China in 1834, he found the medical methods of the country in a most deplorable condition. There was a scanty medical literature, of which one of the most important works was the *Materia Medica* of Li Shi Chan, which is known as the *Pun Ts'o Kong Muk*. Its first edition of forty volumes appeared near the close of the sixteenth century; the last of the four reprints was issued in 1826. This *materia medica* was a most inclusive one and it necessarily included many useful substances, as is

shown by the following quotation: "Whatsoever things are produced in the world—birds, beasts, creeping things and fishes, which are generated and have blood and breath; likewise flowers and trees, which are generated, but are without blood and breath; and also inanimate objects, such as rocks and hard iron—all of these can be used as healing medicines." There had been a so-called Imperial Medical College in Peking since the thirteenth century, but it imparted no regular courses of instruction, rarely conferred degrees, and the skill and learning of the members of its faculty were reserved for the requirements of the royal family and the members of the court.

The native practitioners were divided into three great classes: 1, the class of specialists, of which there was a subclass for nearly every division of the human body; 2, a class whose attention was given solely to diseases of the internal organs; 3, a class that treated only external diseases. A case is often cited to illustrate this condition of affairs of which it is related that a man wounded by an arrow was first visited by a physician for surface maladies. He broke off the shaft of the arrow at the surface of the body and told the patient that further treatment must be had at the hands of a physician skilled in the diseases of the internal organs.

Acupuncture and cautery by the moxa were much in vogue; counter irritation was practiced by vigorously pinching the skin with the fingers, or by harshly scraping it with a stick dipped in water or oil, and by use of various plasters. The Chinese were pioneers in the art of massage, a rude form of it forming a part of the regular operations of the native barber shops. Surgery was almost unknown and its advance has been very greatly hindered by the belief that for well-being in a future state, the body must be kept intact; hence, we hear of the pulverizing and swallowing of extracted teeth, of the eating of an excised part, or of its preservation for burial with the body after death. The medicines used were notoriously inert in many cases, and were often most disgusting in the method of their preparation or in their origin. The right to professional rank had been passed from father to son as property is inherited. In the case of a break in the line of succession, the professional privileges were sold along with the estate. Almost no study was necessary to inspire the patients with awe and faith, if the right to practice had been obtained by either purchase or inheritance from a family having a reputable ancestry of noted physicians. It has been said that "Were all of the native practitioners in the empire at once swept away, the Chinese people, so far as their prospects of health and longevity are concerned, would sustain no very serious loss."

During the last half century, the labors of the medical missionaries and other physicians from America and Europe, have done much to relieve the immediate sufferings of the people and have worked a very marked change in the practice of the native physicians in the more accessible parts of the empire. Between fifty and one hundred hospitals have been established by the efforts of various denominational organizations, and more than two hundred medical missionaries have taken part in the work, including more than a score of women. Many Chinese men and women have been trained for physicians and nurses in the hospitals, or in private study with the physicians. An association was formed in 1887, called the Medical Missionary Association of China, of which the official organ is the *China Medical Missionary Journal*, at present edited by S. R. Hodge, of Hankow, and published quarterly at Shanghai by the American Presbyterian Mission Press. Many medical works and treatises on the allied sciences have been translated into the Chinese language. Dr. John G. Kerr, an American medical missionary who went to Canton in 1851, has been especially active in this work, having issued more than twenty-five medical text-books in the Chinese language. Fryer has translated the chemic treatises of Bloxam and Roscoe, and also several books on physics, botany, *materia medica*, etc.

The late Dr. Osgood, an American medical missionary, issued a Chinese edition of Gray's "Anatomy"; Hunter has translated Squire's "Companion to the British Pharmacopœia." Martin, Smith, Allen and the Chinese physician Suvoong, are to be included among the names of those who have made contributions to the literature available for Chinese medical students who read only their native language.

More than one hundred American and European physicians not connected with the missions, have taken up their residence in China, and are engaged in private practice. A Hong-Kong Medical Society has been formed by the physicians of that city: a volume of their transactions was published in 1889. Dr. Irwin mentioned Drs. Manson and Cantlie, since retired, as among the most prominent of the founders of this society. Each of the ports open to foreign commerce has a "Surgeon to the Customs." In 1870 the Inspector General of Customs issued a request for a semi-annual report from these medical officers of the different ports in regard to the condition of the health of foreigners and citizens in their respective provinces, together with the results of studies of new diseases or of diseases rarely met outside of China. These reports are published annually under the title "China Imperial Maritime Customs; Medical Reports."

Dr. Irwin described the founding and success of the Imperial Medical College of Tien-Tsin, in connection with the Yang Ping Yuen (Imperial Hospital of the North), with great pride and feeling. The first class was examined for graduation in 1883. Of the eighteen candidates for diplomas, twelve passed. Dr. George Mark, of the Viceroy's party, was at the head of his class, of which another member is now in America for the completion of his medical education. The school was not reopened until November, 1893. There are now twenty-six students enrolled, eleven in the second year class and fifteen just beginning. The course of study requires four years for its completion. There is no separate school of pharmacy, but the students of the medical school are given instruction in the preparation of medicines. The school and hospital are both in charge of Dr. Houston, an European. There are four regular lecturers, one European and three Chinese. The medical officers of the Navy often lecture also, when their vessels are stationed conveniently. The hospital has sixty-five beds and is taxed to its utmost capacity. There is also a hospital for women, having thirty-one beds, which is in the charge of Mrs. Dr. Howard King, formerly of Philadelphia.

Dr. Kin Ta Chin, a member of the class of 1883 of the Imperial Medical College, has been decorated for his services as commander of the field corps of the Imperial Medical Service during the recent war with Japan, and is now in charge of the field hospital of the army of North China at Kin Chou.

Dr. Irwin spoke in most complimentary terms of the assistance rendered by the surgeons of our navy during the Japanese war. Especial mention was made of the work of Dr. Philip Leech at the Isabella Fisher Hospital, which is superintended by an American woman, Dr. Rachel Benn: and also, of the valuable services of Dr. Ames, who has been consulted by the Viceroy, and who ably assisted at Che Foo in caring for the wounded from Port Arthur and from the naval engagement of Yaloo.

"We place no reliance on the medicines of local manufacture," said the doctor in reply to a query, "but use only those imported from Europe and America. Many of the large manufacturers and dealers have branches or agencies in the Empire. The government contracts for drugs and medicines are a small matter in time of peace; five hundred gold dollars would cover the whole bill for one year."

There are drug stores kept by foreigners of different nationalities, and quinin and some other foreign drug staples are found on the shelves of the natives shopkeepers.

A number of American and English dentists have established

offices in the larger cities, but very little advance has been made among the native workers. Chinese dentistry is crude and a fakir's art. Mercurial preparations are used for loosening the diseased tooth, when it is extracted by means of a string or rude forceps—often with a sleight-of-hand accompaniment to prove to the patient that the trouble in the aching tooth is due to a worm. A worm is smuggled into the patient's mouth during the operation, again removed and exultingly exhibited. Artificial teeth are made from bone and fastened in the mouth by attaching them to the sound teeth with a wire or a string.

Now that the government has evidenced its appreciation of modern scientific medical methods by establishing and maintaining a school in which they may be taught to the youth of the land, and men from all parts of the empire have had occasion to either experience or witness their success and benefits during the recent war, we may safely regard this as the era of the triumph of science in China—we may hope that the day is not far distant when plasters of powdered tiger's teeth have lost their repute as remedies for the healing of external injuries; when jelly prepared from bear's paws has lost its alterative power; when potions made from the horn of the hart are no longer used for the renewal of wasted vitality; when Chinese mothers can eat chickens, ducks or turtles without fear of destroying the hearing or eye-sight to their unborn babes, or can look upon a hare or rabbit with no qualm over a possible harelip for the unborn one.—E. E. EWELL in *Pharmaceutical Era*, September 10.

**A Case of "Sadism," or Sexual Perversion with Violent Tendency.**—Dr. Morton Prince, in *Boston Medical and Surgical Journal*, reports a case of this nature in a male aged 22 years. By "Sadism" is meant the association of cruelty or violence with lust, the name being derived from the notorious Marquis de Sade, whose obscene novels treated of lust and cruelty.

Dr. Prince's patient before coming under his observation had been regarded as being the subject of neurasthenia or hysteria. His relatives made a diagnosis of general laziness, while others described him as being not quite right. His mental state was unknown to others until, after great difficulty, Dr. Prince obtained a full confession. It was his custom to lie upon the bed in the daytime and fall into a sort of trance or day-dream state, in which he was apparently between waking and sleeping. He said he thought he was awake, because if anyone should knock on the door or come into the room he would know it. While in this state he used to imagine that he killed and mutilated women. It was not possible to learn from him the exact mode in which this habit began, or what was the original exciting occasion, but his imagination began in a moderate way and afterward extended. At first, it was only a single woman whom he imagined he thus mutilated, but afterward in each "séance" he destroyed great numbers. His imagination seems to have created actual hallucinations, for he said that at these times he actually saw his victims with great vividness as objective realities and had the sensations of actually killing them; for the time being his acts were absolutely real to him, and soon a belief in them persisted.

At first it was a single girl whom he mutilated; he killed her, tore her to pieces and ate her; later he imagined that he lived in towns where it was the custom for the men to destroy all the women in this way. Then, as the habit grew, the towns became cities and the cities countries. These countries were completely depopulated of the women by the men, all of whom together held these Sadistic feasts.

While indulging in these dreams or hallucinations, he had most intense sexual excitement with emissions. His habit was thus a form of masturbation, the peculiarity being the association of sexual feeling with hallucinations of cruelty. When in the waking state he seemed to be at times confused as to whether he actually committed these imaginary murders or

not; for while at one time he said he had not, at other times there was sufficient confusion in his mind to make him think that he had committed these unpardonable sins and to be in great misery in consequence; he would then be in a state of great penitence, which was not understood by his mother until this confession was obtained. He also admitted to me that at times he thought he had actually committed these acts. He had practiced this habit from the time he was 10 years old until about 20, that, is up to about two or three years ago. During the last two years this habit had largely died out, but there has been (September, 1895) a tendency to recurrence. It was apparent that such a person was dangerous to the community and that at any time there was a possibility, under favorable conditions, that he might put what had hitherto been pure imagination into actual practice; we therefore sent him to an asylum without delay. He denied that in mutilating the bodies of his victims that he selected any particular parts of the body, as is the case with many Sadists.

His general condition was one of neurasthenia. He had much depression and suffered from great anguish of mind from which he broke down and cried at times, saying that he "suffered intensely," but could not describe very definitely from what particular feeling; it seemed to be more an anguish of mind.

His heredity is bad, and throws light upon the distinctively degenerate character of his mental condition. His mother was excessively neurasthenic. One maternal aunt was described as nervous, with abnormally fixed ideas on certain social subjects, and two maternal aunts suffered from hysteria. A maternal brother was delicate and always on the point of breaking down. His maternal grandfather was a very able and physically strong man, with decided elements of genius. He is well known to the public and recognized to be very brilliant mentally, but a man of very extreme opinions. Up to the age of 40 he had a tendency to melancholia. The maternal grandmother was neuralgic, ailing, neurasthenic. The patient's father was eccentric and a dipsomaniac. One paternal aunt was well; a second was described as having a bad temper and at one time as having had delirium (about this my notes are confused). A third had hysteria. Two cousins, sons of the second paternal aunt, both drank to excess. The first paternal aunt had four children; of these, one had a sort of puerperal insanity, from which she recovered. Two paternal uncles are said to have died of dissipation.

The early history of this patient is interesting, as showing the progressive physical descent (*facilis descensus averni*) of such a case. Since 2 years of age always more or less out of order; 5 years of age, attacks of nausea, vomiting and headache with fever, delirium alternating with coma; these attacks were followed by excessive weakness; slow recovery from weakness which persisted until the next attack, which occurred at the end of about one month; he lost flesh and his temper became irritable, so that he became violently excited and enraged over little things.

Several eminent physicians of New York were consulted. One said that he was unable to make a diagnosis. A second said it was brain disease, and a third said it was lithemia from the liver. Accordingly he was treated for this last with calomel, with the apparent results that after this he had no more attacks but only premonitory signs, which were always stopped by calomel.

This perversion of the sexual instinct is the exciting motive of many notorious murders. The Whitechapel murderer was undoubtedly the subject of Sadism. Similar instances are well known and may be found described in the literature. The subject is an important one from a medico-legal point of view, as well as of psychologic interest; and it is desirable that the motives leading to crimes of this kind should be thoroughly recognized. Lust murders, not murders for the purpose of

concealing or committing rape, but violence and murder for the purpose of inducing sexual excitement in the murderer, are probably more common than is generally supposed. The sexually exciting element in such cases is the sight or smell of blood, or the cutting, tearing, or mutilation of the victim's flesh. Verzeni found, as he confessed, unspeakable delight in strangling women, experiencing during the act erections and real sexual pleasure. Some find delight in actually eating the flesh or drinking the blood (Leger, Verzeni). Sometimes special pleasure is found in cutting or tearing out the uterus, ovaries and genitalia, which are carried away (Whitechapel murderer), but this is not always the case, and the victims are not mutilated in this respect.

A similar perversion is found in the excitement which some have in harmlessly cutting, beating or whipping women and boys. A case has been brought to my attention of a man who was in the habit of visiting a prostitute whom he used to strike over the nates with a shingle. No coitus was indulged in.

## PRACTICAL NOTES.

**Early Symptoms of Diabetes.**—Unschuld calls attention to an early symptom of diabetes which is seldom mentioned by writers on the subject, but which is yet frequently found, and may assist in an early diagnosis of the affection. This symptom consists in cramps in the calves of the legs, and is found in about 26 per cent. of all cases. The pains occur with especial frequency in the morning upon waking, and occasionally also during the night. They are rarely troublesome in the daytime, unless after a nap or a bath. Cramps of this nature, occurring in a person in feeble health, should always suggest the necessity of an examination for sugar.—*Health*, September 11.

**Changes in Urine from Medicine.**—Oleoresins and balsams (copaiba, sandal oil, turpentine and its derivatives) taken as medicines often give a yellowish zone at the circle of contact between the nitric acid and the urine in the cold test for albumin. From a ring of albumin, however, this cloud can be easily distinguished by its solubility in alcohol. Concerning the test for glucose, many organic medicaments (chloral, chloroform, turpentine, glycerin, salicylic acid, etc.) give rise to urinary ingredients which reduce copper solutions to a less or greater degree on prolonged boiling. The phenylhydrazin hydrochlorate test will differentiate all these reagents from dextrose. Sulphur (or albumin which contains it) gives a black precipitate with Boettger's bismuth test for glucose, and hence must be excluded as a factor if this method be used.—*Ed. Denver Med. Times*, September.

**Hemol Bromid.**—The *Medical News*, August 29, quoting Dr. Kobert in the *Therapeutische Wochenschrift*, states that that observer has been seeking to obviate the unpleasant after-effects of the inorganic bromids and to that end has "been making trial of an organic bromid which has no injurious effect upon either the blood or digestion. It contains only 2.7 per cent. of bromin, as against 67 per cent. which bromid of potassium contains. But only a small portion of the bromin contained in the latter salt exerts any action in the body. Holst used bromid of hemol in fifty cases of nervous disease. If a rapid effect was looked for, two grams (thirty grains) were given three times a day. One-half or one-third of this dose was employed for a calming effect. In epilepsy and hysteria, he obtained no good results where the inorganic bromids have shown themselves efficacious. In insomnia, the results were equal to sodium bromid, without any unpleasant sequelæ. The conclusion is that bromid of hemol is not capable of replacing inorganic bromids where a rapid effect is desired. It is indicated, however, in cases where the sedative and long-continued action of bromin is sought for."

**Diagnostic Value of Percussion of the Vertebral Column.**—Bechterew calls attention to the importance of the results attained by percussion of the sacral region of the spinal cord. He has derived great benefit from it in obscure cases, and urges its general adoption. He describes one traumatic case with symptoms of compression of the cauda equina, plantar, genital and perineal anaesthesia, spontaneous pains in the joints, pain on percussion of the sacral region, disturbances in the sphincters, etc., with fever. Percussion of the triangle, whose base corresponds to the upper part of the sacrum and the point to the coccyx, produces in normal conditions a slightly tympanitic resonance. In this case there was a distinctly limited dullness and an operation confirmed exactly the diagnosis as to the seat of the lesion. Caries was disclosed in the serum with a fungus mass compressing the cauda equina.—*Gaz. degli Osp. e delle Clin.*, August 4.

**Mechanical Treatment of Sciatic Neuralgia.**—Negro of Turin, has cured or materially improved 100 out of 113 severe cases of sciatic neuralgia that had resisted all other treatment, by compressing the nerve. The patient lies flat on his face, the lower limbs touching and stretching to their fullest extent, and the point is found by palpation where the sciatic nerve emerges from the ischiatic notch, which is usually the most painful spot. The right thumb is then pressed on the nerve, reinforced by the left thumb, and the strongest pressure possible exerted for fifteen to twenty seconds, turning the thumb so as to distribute the pressure laterally over as much surface as possible without removing the thumbs. This process is repeated after a minute's rest several times, the pain growing less each time. Five or six of these treatments on successive days produce good results.—*Memorabilien*, August 5.

**Formic Aldehyde as a Disinfectant, and Method of Application.**—At a meeting of the Maine State Board of Health, Professor Robinson reported that the tests of formic aldehyde which had been made had given very encouraging results. He exhibited to the board the workings of a lamp which he had constructed for its application. The lamp consists of a cylinder into which wood alcohol is continuously fed from a tank similar to that of a German student's lamp. In the top of the cylinder is fitted a diaphragm of copper gauze consisting of two layers, between which is a layer of especial material. Upon the application of gentle heat to the gauze the alcohol below begins to vaporize and change into formic aldehyde, a gas having the germicidal properties of sulphurous acid gas, but in a greater degree. The vaporization progresses as long as alcohol is supplied. Professor Robinson detailed experiments which had been made at the Bowdoin laboratories upon pure cultures of disease germs and upon infected bedding and clothing, by which the germs were quickly killed. Subsequent cultures made from infected articles were found, after exposure of the fabrics to the fumes from the lamp, to have been absolutely sterilized. About a pint of the alcohol, vaporized, would supplant the atmosphere in a room of 3,000 cubic feet.—*Sanitarian*, September.

**The Hypnotic Potency of Trional.**—In an article which appeared in the *Wiener Medicinische Presse* for April 1 and 8, 1896, and is summarized in the *Wiener Klinische Rundschau* for June 21, Dr. Richard Drews, of Hamburg, remarks upon the frequency with which the physician finds it his chief task to secure for the patient a few hours of quiet sleep, so that he may not only be freed from distress for the time being, but supplied with fresh endurance to battle with the disease. For this purpose a hypnotic is required that is easily taken, that promptly induces restful, dreamless, normal sleep, from which the patient awakes refreshed and strengthened, that is harmless and as free as possible from unpleasant collateral and remote effects, that does not beget a habit, and that can be taken for a long time.

Judging of trional from its action in thirty cases, Dr. Drews

thinks it such an ideal hypnotic. Nineteen of the patients were adults and eleven were children. The causes of sleeplessness in the adults were neurasthenia once, hysteria twice, a phlegmon of the hand once, articular rheumatism twice, muscular rheumatism once, sciatica three times, prurigo once, trigeminal neuralgia once, a scald of the foot once, intercostal neuralgia twice, cancer of the uterus once, and pulmonary and laryngeal tuberculosis with severe paroxysms of coughing and profuse sweating at night three times. In the children there were otitis media three times, meningitis with convulsions once, chorea once, night terrors twice, epilepsy once, pneumonia with severe agitation once, and furuncle of the ear once. For the adults, the dose ranged from fifteen to twenty-two grains; for the children, from three to twelve grains, according to the age. It was administered in strict accordance with Goldmann's directions. The adults took it in bed in a cup of hot milk and then drank another cup of milk; the children took it in their evening broth or in a cup of hot tea. In cases accompanied by severe pain twenty-two grains were always given to the adults instead of fifteen grains. In twenty-eight of the cases the result was invariably a restful, calm, natural sleep, coming on in the course of fifteen or twenty minutes, and on the following morning the patients felt refreshed and as well as the nature of the disease admitted of. In two of the cases, that of phlegmon of the hand and that of cancer of the uterus, the hypnotic action was delayed for an hour or an hour and a half, and did not last for from six to eight hours, as in the others, but only for three or four hours. Both these patients were sleepy the next morning and complained of oppression in the head, of headache, and of weakness, and the one with uterine cancer suffered also with ringing in the ears and with nausea. These phenomena occurred for several days after each administration of trional, but strict questioning brought out the fact that it had not been taken in the precise manner prescribed.

**Treatment of Ozena with the Antidiphtherial Serum.**—Drs. Bellfanti and Della Vedova are quoted in the *Medical Week*, May 1, as follows: Bacteriologic examinations made by the authors led to the conclusion that ozena is caused by a microorganism identical in form and cultural peculiarities with Löffler diphtheria bacillus, though differing from it in diminished virulence. The organism was not only found upon the surface but also in the depth of the nasal mucous membrane. According to the authors, it causes the chemic alterations of the secretion, the fetid odor, and the atrophy of the mucous membrane and of the bones. These results led them to undertake the treatment of ozena with diphtheria antitoxin. The results obtained were most remarkable, for of thirty-two patients sixteen were wholly cured, seven almost healed, five rapidly improved, and in only four was improvement slow. Ten c.c. of diphtheria antitoxin was injected every second day or, when possible, every day. The number of injections varied according to the age of the individual, the length of time the disease had existed, and the degree of local and general reaction. On an average 30 c.c. were required to effect a cure. At first the injections caused congestion of the nasal mucous membrane. Soon thereafter the fetid odor disappears, the secretions become liquid, and the formation of crusts ceases permanently. The accidents which compel suspension of the treatment are the same as those observed in the treatment of diphtheria and are without danger.

**Report of the Employment of the Toxins of Erysipelas upon Malignant Tumors.**—In the *Annals of Surgery* for July is given the minutes of a recent meeting of the New York Surgical Society, a part of which refers to the above subject. At that meeting Dr. L. A. Stimson, Dr. A. G. Gerster and Dr. B. F. Curtis submitted the following report upon the use of toxins in the treatment of malignant disease: "Both before and since our

appointment as a committee we have been able to observe, individually and together, a considerable number of cases treated by this means, and in no case have we found any amelioration which held out a prospect of ultimate cure. We have, on the contrary, observed in some cases that the rate of growth of the disease was much more rapid during the treatment. The treatment also imposes a very severe tax upon the strength of the patient, and apparently hastens the cachexia in most cases. We believe that in the instances of apparent cure or marked improvement the correctness of diagnosis is open to doubt. We therefore submit: 1. That the danger to the patient from this treatment is great. 2. Moreover, that the alleged successes are so few and doubtful in character that the most that can be fairly alleged for the present treatment by toxins is that it may offer a very slight chance of amelioration. 3. That valuable time has often been lost in operable cases by postponing operation for the sake of giving the method of treatment a trial. 4. Finally, and most important, that if the method is to be resorted to at all, it should be confined to the absolutely inoperable cases."

**Echinococcus in the Liver Cured by Bacelli's Method.**—The *Annali di Med. Navale*, No. 7, describes the case of a sailor brought to the hospital with severe pains in the right flank, fever, dyspnea, insomnia, greatly hypertrophied liver and evidences of a hepatic tumor. An exploratory puncture confirmed the diagnosis of echinococcus, as hooks were discovered in the limpid liquid withdrawn, which contained no albumin and very little glucose, but chlorid of sodium in abundance. The only question then was whether it was a unilocular or multilocular cyst. In the latter case the tumor is usually solid, painful on pressure and knobby, with hypertrophied spleen and a purulent or serous effusion in the peritoneal cavity, with pronounced icterus and intestinal hemorrhages. These symptoms were absent in this case and the diagnosis of a unilocular cyst was confirmed by the recovery of the patient. Thirty grams of Van Swieten's solution were injected with a Kurschmann syringe and 700 grams of liquid withdrawn. The fever ceased the fourth day after this injection. Two liters were afterward withdrawn with a Potain needle, which completely emptied the cyst. Appetite and sleep returned and the general health slowly improved, the liver subsided to its normal size and the heart and spleen returned to their normal position, but six months passed before the recovery could be considered complete.—*Gaz. d. O. e. d. C.*, August 23.

**Straightening the Spine by Wiring the Spinous Processes Together.**—Chipault's new method of treating caries of the spine is described in the *Therap. Woeh.*, No. 35. The spine is straightened and held in this position by wires that fasten the spinous processes together, so that the orthopedic appliances do not have to contend with the constant tendency to curvature. After chloroform the patient is placed on his belly, three-quarters pronation, the back turned to the operator. A longitudinal opening is then made along the spinous processes, two to three vertebræ above and below the limits of the curvature. Without touching the interspinous ligaments both sides of the processes are exposed, and the soft parts drawn aside, the assistant at each end then pulls the spine to straighten it as much as possible, and a silver wire is passed through the interspinous ligament above the highest process to be ligated at the bottom near the root. The wire is then cut, leaving on each side a piece twice as long as the wound. The ligating is done with these two ends, crossing them back and forth and passing them through each interspinous ligament from the highest process downward until the lowest is reached, when the two crossed ends are twisted together. The wires must be passed through the ligaments close to the lower edge of the process above to afford as firm a support as possible. Each crossing must be tested to see if it is strong and taut before proceeding

to the next. The soft parts are then sutured without drainage, bandaged and the patient is placed in bed. The two difficulties, lateral curvature of the spine and ankylosis of adjoining processes, are met by boring a hole in the processes in the latter case, and in the former by extending the end of the wire on the convex side up to the loop at the top and stretching it tight, which straightens also the lateral curve. In cases of lumbar or dorsal caries, the bandage can be changed in five to six days and in cervical caries in ten, and the stitches removed from the soft parts. This ligature of the spinous processes is undoubtedly an advance in the treatment of Pott's disease, but it only applies to moderate curvatures of recent origin, that have commenced suddenly and developed rapidly and are capable of reduction in anesthesia, and to weak spines. It is not adapted to old curvatures or those involving too many of the vertebræ. The presence of an unopened cold abscess or of paralysis is no obstacle. Absolute immobilization should follow the operation.

**Arsenic in Scarlet Fever.**—A Russian physician, Speransky, announces that he treated a large family of children with arsenic as a preventive measure, when one was attacked with fatal scarlet fever and isolation was impossible. Although they slept with the sick one, none of the rest took the disease except the oldest, 18 years, to whom the arsenic had not been administered and the youngest, who had been neglected and had only received occasional doses, with none at all for several days before the disease appeared. The arsenic was administered in Fowler's solution, half a drop at each of the two principal meals (8 and 9 years) with half this amount at 3 years. When the 3-year-old child was taken with the disease he received half a drop three times a day, with powders of phenacetin and terpin hydrate; the 18-year-old four drops with the powders. The arsenic attenuated the disease in a remarkable manner after it had developed, with no fever after the first day and the child so well that it was impossible to keep it in bed. The other cases treated outside showed the same results, a striking improvement in the course of the disease after the first day, with complete recovery in a week. The preventive doses were continued for six weeks.—*Semaine Médicale*, August 26.

**Hydatid Cysts of the Liver.**—Bobroff injects salt solution into the cyst pocket after he has emptied it, to prevent the liquids from the neighboring organs finding their way into it and recommends this process to others. In a recent case, after removal of the hydatid and cleansing of the pocket with gauze, he excised a piece 12 centimeters long and injected 250 grams of the salt solution. The inverse edges of the pocket were then closed with a double row of sutures and the abdomen closed completely. The wounds healed by first intention with only a slight rise in the temperature one day, and the patient left the hospital entirely cured in a month.—*Union Méd.*, August 15.

**Hot Water Vaginal Injections.**—In the treatment of female pelvic diseases by hot water injections Dr. J. H. Burtenshaw gives the following rules for method of application: 1. Use a large-sized fountain syringe, preferably one holding four quarts, attached to a support three or four feet above the body. 2. Always lie upon the back with the hips slightly elevated and the shoulders depressed. 3. Use at least three gallons of water as hot as can be borne—at a temperature of from 110 to 115 degrees Fahrenheit. 4. Take the injection twice daily, morning and evening, except on the two days preceding and the two days following the menstrual flow. In cases of chronic leucorrhœal discharge in which additional astringent elements, to the douche, are indicated, he adds a tablespoonful of the following mixture to the last quart of water: Pulv. alum, zinci sulphatis, sodii bichloratis, ac. carbolicæ, aa ʒj; aquæ, ʒvj.—*N. Y. Polyclinic*, September.

THE  
Journal of the American Medical Association  
PUBLISHED WEEKLY.

SUBSCRIPTION PRICE, INCLUDING POSTAGE:

Per Annum, in Advance . . . . . \$5.00  
Single Copies . . . . . 10 Cents.

Subscriptions may begin at any time and be sent to

THE JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION,  
No. 61 Market Street (Occidental Buildings), Chicago, Illinois.

MEMBERSHIP IN THE AMERICAN MEDICAL ASSOCIATION.

This is obtainable, at any time, by a member of any State or local Medical Society which is entitled to send delegates to the Association. All that is necessary is for the applicant to write to the Treasurer of the Association, Dr. Henry P. Newman, Venetian Building, Chicago, Ill., sending him a certificate or statement that the applicant is in good standing in his own Society, signed by the President and Secretary of said Society. Attendance as a delegate at an annual meeting of the Association is not necessary to obtain membership.

On receipt of the subscription the weekly JOURNAL of the Association will be forwarded regularly.

Gentlemen already members of the Association should send their annual subscription to the Treasurer, or direct to the JOURNAL office.

All communications and manuscript of whatever character, intended for publication in the JOURNAL, should be addressed to the Editor, and all communications relative to the business of the JOURNAL, proof sheets returned, or in regard to subscriptions, should be addressed to THE JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION, 61 Market Street (Occidental Buildings), Chicago.

Original communications are only received with the understanding that they are exclusively contributed to this JOURNAL.

INFORMATION WANTED.

It would greatly facilitate the prompt delivery of the JOURNAL to those members of the ASSOCIATION living in large cities, if they would kindly furnish this office with their street address in those cases where it is omitted from the wrapper of their JOURNAL, as we have been notified by the postmasters of the larger cities that second-class mail matter not having street address, would be placed in the general delivery to await call.

SATURDAY, OCTOBER 3, 1896.

THE MURDER OF THE INNOCENTS.

The incidence of mortality in the first years of life is a well-known showing of all tables of vital statistics, but its preventable factors are not so clearly recognized, while far behind lags the resolution to make theoretic knowledge a realized fact. Talk as we may about the disadvantages of "grandmotherly government" and "socialistic legislation," no one can affirm that in matters of preventive medicine and hygiene there can be too much governmental oversight. The wisdom and morality of the few must become that of the many, and it can only become so by stringently penal legislation and executive control. Human nature is at least not yet sufficiently ethical to be allowed indiscriminate and unscrutinized control over the young life that comes to it.

Take the matter of child life-insurance as an example. Is it not evident that parents too poor to bury a child should be held too poor to pay premiums on the insurance of the child's life? And yet this is the excuse constantly made by parents, either sincerely or deceitfully, to justify the custom. What a clear temptation to murder!

The English medical journals, especially the *Lancet*, have in late years been active in showing up the prevalence of this abuse in England, where it is undoubtedly of greater extent than with us. From

1 In the *Lancet* of April 20, 1895, a member of the Massachusetts Society for the Prevention of Cruelty to Children said she found families in which children were deprived of the most ordinary necessities of life while money for the insurance of the dying child was put aside. Several other similar instances equally pitiful are given. The cost of infant burial is within the reach of thrifty people, and for the rest, in all countries the community is bound to bury when others can not.

an editorial in the *Lancet* in 1895 (i. p. 428) we learn that of 4,629 children recently subjected to cruel treatment, 1,237 were insured. Another editorial in the *Lancet* (1895, i, p. 166) on infant neglect, insurance and mortality, among other things says: An unfortunate infant, whose death was recently investigated by the coronor for the West Middlesex district, might have been saved by medical aid (which might have been had for a mere pittance), but the parents claimed they were unable to pay a physician anything, yet the insurance premium on the child had been promptly paid up to its death. Facts like these sicken the public conscience. The *Lancet* calls for drastic reforms, and says the insurance should only be for an amount of the bare cost of the funeral arrangements (which is very cheap in England compared to our funeral rates, we believe). The same editorial urges that evidence of criminal neglect or mismanagement should disqualify parents even for the small sum insured. This seems to us very clever, as it shifts the burden and expense of proof on the interested corporation, who would likely be more rigorous in their search for evidence exempting them from payment of the policy than the municipal authorities, ordinarily interested parties.

In May, 1895, Sir RICHARD WEBSTER read in the House of Commons a bill providing for the maintenance and encouragement of the mutual benefit principle in such insurance, limiting the sum insured to an average almost as low as that of the friendly societies, £2 (\$10) up to 10 years of age. This bill also entails upon physicians the duty of inquiring as to the fact of insurance before granting a certificate of death, and a like service is required of the register. It allows a child to remain under the protection of this act until 16 years of age. The *Lancet* says: "We are aware of no present limitation except the inability to pay the premium, and the average of £4 (\$20) and a maximum of more than twice this sum is not uncommon, while payment in some clubs may be made partly in spirits. It is significant also that wilful neglect of infants, according to a recent return, has been shown to be much more common under the non-mutual system" (that is, those clubs not organized by workmen for their mutual benefit). We know nothing relative to the ultimate disposition of this act, and are not aware of any legislation in Great Britain limiting infant insurance. According to the *British Medical Journal* (1895, i, p. 291), the reports of the Select Committees on Friendly Societies, 1875 and 1888, contain a large amount of information upon this subject.

FRANCIS VACHER (*Lancet*, 1895 i, p. 254) suggests that legislation should prohibit all private corporations or individuals from insuring infants' lives, and that the government be empowered to enter into an agreement to inter any child free of cost, on payment of a small

premium at the nearest post office, thus reducing cost of insurance and bringing it directly under the law. Such a measure we do not think necessary or wise, and for us it is, of course, out of the question.

As to our own country, affairs are in a chaotic state. In 1895 a bill was reported to the Massachusetts legislature providing that no life insurance company shall issue a policy upon the life of any child under 10 years of age, living in that State. The penalty was fixed at \$100 for each offence, the law to come into force September 1, 1895. Whether the law ever came to vote or not (probably not in these days of "politics") we do not know, nor whether other States have attempted similar regulation. Medical men in charge of the medical departments of life insurance companies should bestir themselves, both as officers and members of society, to bring about judicious and needed legislative reform.

Another cause of infant mortality is overlying. It will doubtless surprise even physicians to learn that one thousand children are each year killed in London alone by this careless (or perhaps often intended and criminal) custom. Yet such is the estimate of a London coroner. From an editorial in the *British Medical Journal* (1895, i, 36), we excerpt:

There are sad sides to a Merry Christmas, and not the least sad of these this year has been the sacrifice of infant life from overlying. On December 27, 1894, Mr. BRAXTON HICKS held five inquests on the bodies of children who had died while sleeping with their parents, the cause of death in the majority of cases being suffocation. The coroner said he could not persuade parents to get cots for their children, and that a thousand infants were overlain in London alone every year. The matter is extremely serious. Perfectly healthy children are sacrificed to the bad habit of making them sleep with their parents. It is perhaps difficult to draw the line and to separate thoughtlessness from carelessness so gross as to be criminal, but Liverpool statistics showing the enormous frequency of deaths from overlying on Saturday night points to the fact that the carelessness is gross, and that unless drink be accepted as a general excuse for crime, the action is in a large proportion of cases criminal. Mr. BRAXTON HICKS announced that he would make it a rule in all future inquests of this character to disallow the expenses of the parents, a course which he adopted in each of the five cases before him. The fight against preventable diseases is hard enough, but it seems harder still to prevent the effects of carelessness and folly.

Of infanticide, every physician is well aware that neither the ancients nor present-day savages have a monopoly of the practice. In every city there are men either with or without a medical degree who make a profitable business by murder, through abortion. There are many reasons why these criminals can not be brought within the reach of the law, the principal of course being the inability to secure evidence against them. Their "patients" will not tell, but the evidences of their work are well known to every gynecologist. One thing is, above all things, certain: There should be compulsory inspection and registration of all "stillborn" infants. BRAXTON HICKS (*British Medical Journal*, 1895, ii, p. 1540) relates an instance

illustrative of the ease in which a child may be killed and falsely registered stillborn. The child, plainly a viable one, after being smothered was boldly thrown out into the middle of the road to rot. We would urge upon our general medical associations and societies the duty of promoting such badly needed legislation. They might also profitably institute investigation and control of the disgustingly much-advertised lying-in institutions where "for a consideration," infants after delivery are "supplied with homes."

Undoubtedly it is a difficult matter to educate the community in the care of children and in the value of child-life. The law and a sensitive conscience are agreed that murder of an unborn fetus is as much murder as of one born, and that infant murder is as much murder as is adult murder; but ordinarily the lower classes make an unconscious sliding-scale of criminality increasing in approximation to real murder of the adult, and beginning with conception, when and shortly after, "getting rid of it" is by no means sinful. Against such a tendency in the interest of civilization and ethics we must all protest with what power we may. But the efficacy of our protest will depend upon the numbers that speak, the publicity of the protest, and the effectualizing of it in legislative enactment.

#### CELEBRATION OF THE INTRODUCTION OF ANESTHETICS.

October 17, 1846, a venous tumor of the jaw was removed by Dr. WARREN without pain, the patient being placed under ether by WM. T. G. MORTON, a Boston dentist, and the next day a fatty tumor was removed, and in a few days, after the performance of some minor operations, Dr. HAYWARD, in the presence of Dr. H. J. BIGELOW and others, amputated the thigh of one ALICE MOHAN, MORTON, as before, administering the ether.<sup>1</sup> "From this date," says LYMAN, "the success of anesthesia was placed beyond all doubt. The great discovery was immediately heralded throughout the civilized world, and was everywhere adopted with the utmost enthusiasm."

To properly celebrate the semi-centennial of this great discovery, the Massachusetts General Hospital have issued an invitation to a limited number of guests to participate in the ceremonies. We print elsewhere a reduced fac-simile of the card of invitation. It will be noted that nothing in the invitation can be construed into an assertion of priority of use; for the medical public are now well aware that sulphuric ether had been used by inhalation for dentistry and minor surgery by W. E. CLARKE and CRAWFORD W. LONG, but it was reserved for the Massachusetts General Hospital to have the first capital operation, and to make the world hear. She can then with all propriety and conscious pride celebrate the semi-centennial of

an event that connects her name indissolubly with the greatest boon that has yet been vouchsafed to man.

The notable gathering that will be present October 16 in that now famous amphitheater, may be warm in their praises and oratory will no doubt be all that the occasion demands; but the larger amphitheater of the world, so far as inhabited by civilized man, will contain thousands of sympathizers with this movement whose sympathy, unwritten and unspoken though it be, will be as sincere and earnest as any. May prosperity continue to attend the Massachusetts General Hospital and its staff.

---

#### PROPOSED LEGISLATION IN REGARD TO EXPERT TESTIMONY.

The unsatisfactory conditions that exist in regard to medical expert testimony, have been the subject of a vast amount of earnest thought and their discussion has occupied no inconsiderable space in medical literature, but as yet the questions that have been raised seem very far from a satisfactory settlement. That they are living questions of the day is sufficiently demonstrated by the contents of the last issue of the *JOURNAL*, which contained three valuable communications by leading men in our profession together with the equally able discussion that they incited. The views there enunciated are certainly worthy of respect and careful consideration, but as the discussion shows, the solutions offered of the actual difficulties are not in all ways acceptable. Reform of abuses in medical expert testimony as they exist in our present methods of judicial inquiry is most desirable, but no one seems to have yet discovered the universally applicable cure for these evils.

The favorite remedy just now appears to be that embodied in the different legislative proposals that have been put before the law-makers of the three States of New York, Illinois and Minnesota, viz., the appointment of a commission of experts by the judge or judges, either in each particular case or for a given period for all cases. This would undoubtedly improve matters, but is open to some very obvious objections. One of these is stated by Dr. *SUITER*; the law could not deprive the defendant of his right to call in additional evidence outside of the appointed experts and, if he had accepted these, it might put him in the position of combatting his own witnesses. Besides this objection which would occur to a lawyer, there are others equally apparent to a layman or a physician. The mere fact stated above that the defendant, say in a criminal case, can not be bound to confine his expert witnesses to the list approved by the judges, leaves open the possibility of nearly or quite all the abuses now complained of. His witnesses may be qualified or not, they may be pretentious quacks or they may outweigh as experts all the official appointees. There is no assurance that judge-appointed experts will

always be really such; judges are fallible, and, as regards medical matters, often ignorant men; they may be influenced by prejudice, friendship, or partisanship, and in the present state of medical practice with the numerous schools not discriminatingly estimated by the laity, the very desire to avoid partisanship might cause a non-medical man or a body of such, to make injudicious or improper selections. An official position also, involving public consideration and compensation will be sought after by the unworthy, and too often, it may be, with success.

Allowing, however, for these imperfections, such an enactment as that pending in New York State would still do away with many of the objectionable conditions that now exist, and might well be welcomed. It creates no real standard, however, for an expert, and in this is its failure. The importance of this defect may be variously estimated, but in some respects it is a vital one, and how to avoid it is still a problem for consideration. Some provision in the law that no one shall be considered an expert and have his testimony received as such unless he can show that he has had actual experience in and has devoted a certain number of years to the study of the subjects in which he claims to be specially skilled, would perhaps best meet the requirements, and this could be brought in as a part of a bill fixing the minimum compensation for expert testimony by the State. This last, in view of some recent judicial utterances, would be an eminently desirable measure as making the State recognize the difference between the giving of opinions which are the expert's stock in trade and ordinary testimony. With such a provision in the law, also, we would not have the scandal of specialists in one department testifying as experts in another, a practice which has been unfortunately, to say the least, sometimes indulged in by men of reputation and ability, and otherwise unexceptionable medical practices. A jury of laymen is not likely to make distinctions between one man of reputation and another, and the law should not allow them to be misled in this regard by a lawyer's trick, even if men can be found willing to be his instruments. At present experts are allowed to estimate themselves and the result is often disastrous to them and to the general standing of expert testimony.

Medical expert testimony has probably suffered more from the present defects in the court practice than any other kind, and it is full time for the profession to exert itself in behalf of reform if only for the sake of its own reputation, which continually suffers under the present order of things.

---

**"The Atlanta Clinic"; Change of Management.**—With the September issue of that journal, the editor, Dr. Edward C. Davis, and business manager, Dr. W. L. Champion, retire from control. This step has been taken on account of the increased professional business preventing the proper attention to the details of the journalistic work. They will be succeeded by Dr. Lucien Lofton as editor and Mr. Ephraim Smith business manager.

## CORRESPONDENCE.

**The Spanish Language and the P.-A.M. Congress.**

NEW YORK, Sept. 23, 1896.

To the Editor:—Several physicians who think of attending the Second Pan-American Medical Congress, to be held in the city of Mexico, if they could secure the services of a well known Spanish speaking physician to act as their guide and general translator, have asked me whether I am willing to go with them in that capacity. I replied that I have no objections, but in order that the number of physicians composing the party be still larger will you be so kind as to say a few words about this matter in the JOURNAL?

There are, no doubt a large number of professional gentlemen who would willingly go to Mexico, taking advantage of the reduction of the price of the trip for that occasion, if they could find some confrère thoroughly qualified to act as their *cicerone*. I remain sincerely yours,

DR. A. M. FERNANDEZ-YBARRA.

235 Thompson Street.

**Straw Charcoal with Boric Acid as an Antiseptic.**

VALLEY CITY, N. D., Sept. 23, 1896.

To the Editor:—It may interest some of the JOURNAL readers to know that a mixture composed of one part, by weight, of muslin-sifted straw charcoal to two parts of powdered boric acid will heal old ulcers or wounds very rapidly; fresh cut or torn surfaces are healed as if by magic. This may be old to many of the profession, but I never heard of it until I used it. But even if old it may do no harm to remind all that it is a very valuable combination.

Fraternally

F. H. DEVAUX, M.D.

## SOCIETY NEWS.

**The Central Medical Society of New York.**—This Society will meet at Rochester, N. Y., October 20. Sixteen central counties of the State are represented in the membership of this society, which meets annually, alternating between Buffalo, Syracuse and Rochester.

**The American Academy of Railway Surgeons.**—This society, after a very interesting and instructive meeting at Chicago, closed its third annual session September 25. Chicago was chosen as the meeting place for next year. The following officers were elected: President, L. E. Lemen, Denver; vice-presidents, M. C. M. Gardner of San Francisco, R. Ortega of Diaz, Mexico; secretary, D. C. Bryant, Omaha; treasurer, C. B. Kibler, Corry, Pa.; editor, R. Harvey Reed, Columbus, Ohio.

**Canadian Medical Association.**—This association has elected the following officers for 1896-97: President, V. H. Moore, Brockville, Ont.; vice-presidents: For Prince Edward Island, Peter Conroy, Charlottetown; Nova Scotia, J. F. Black, Halifax; New Brunswick, Thos. Walker, St. John; Quebec, J. M. Beausoleil, Montreal; Ontario, W. W. Dickson, Pembroke; Manitoba, R. S. Thornton, Deloraine; North-West Territory, E. H. C. Rouleau, Calgary; British Columbia, E. B. C. Hannington, Victoria; general secretary, F. N. G. Starr, Toronto; treasurer, H. B. Small, Ottawa. The place of meeting in 1897 will be Montreal, in conjunction with meeting of the British Medical Association.

**The Autopsical Society of Paris.**—This twenty-year old Society, known as La Société d'Autopsie Mutuelle, has grown so rapidly in membership that it now numbers about one hundred Fellows. They are nearly all, says the *Medico-Surgical Bulletin*, scientists of note, several of whom are women. It has for its purpose the placing of the brains of its members at the disposal of surviving members for examination and dissection.

Fourteen brains, neatly catalogued, are now contained in a glass case at the end of the meeting room, and the fifteenth, which was during life the property of M. Abel Havelacque, rector of the Anthropologic Society, now rests immersed in alcohol on the table of the dissecting room, where the man's former associates will meet to weigh, probe, cut and discuss it.

**Association of Erie Railway Surgeons.**—The annual meeting was held at Lakewood, September 21. An accident occurred at the opening of the session which interfered with the pleasure of the gathering. Dr. John L. Eddy, of Olean, the president of the association, a well-known surgeon, stepped into an open elevator shaft and fell to the bottom, a distance of eight feet. He was at once removed to his room, where it was found that he had sustained a deep cut across the forehead, a badly sprained ankle and a severely bruised hip. On account of this accident to the president, the vice-president, Dr. Webb J. Kelly of Galion, Ohio, presided. Dr. S. Birdsall of Susquehanna, Pa., presented a paper on "Synes ankle-joint amputations;" Dr. F. W. Thomas of Marion, Ohio, "Injuries of the throat"; Dr. C. C. Kinnaman of Ashland, Ohio, "Symmetrical gangrene"; Dr. C. M. Daniels of Buffalo, chief surgeon of the Erie Railway, told about his relief and hospital organization scheme, as intended to be adopted by the company. Other papers were: "Traumatic spinal neurosis," by Dr. N. R. Harnden of Waverly, N. Y.; "Painful stumps after amputation," by Dr. C. B. Kibler of Corry, Pa.; "Railway shock," by Floyd S. Crego, of Buffalo; "Clinic review of cases the past year" by Dr. Thomas Manley of New York. The annual election of officers resulted as follows: President, Dr. Webb J. Kelly, Galion, Ohio; vice-president, Dr. F. W. Thomas, Marion, Ohio; secretary and treasurer, Dr. W. W. Appley of Cohocton, N. Y.

**Tri-State Medical Society of Alabama, Georgia and Tennessee.**

The eighth annual meeting will be held in Chattanooga, Oct. 13-15, 1896. The following partial list of papers indicates that the session will be of more than usual interest:

Convulsions in children treated with large doses of morphin. Y. L. Abernathy, Hill City, Tenn.

The therapy of antipyretics. P. L. Brouillette, Huntsville, Ala.

Cystitis; report of cases. D. S. Middleton, Rising Fawn, Ga. A new splint for fractures below the surgical neck. G. A. Baxter, Chattanooga.

Humphrey's operation (amputation of the penis) with presentation of patient. Cooper Holtzelav, Chattanooga.

Diseases of the veru montanum (caput gallinaginis). W. Frank Glenn, Nashville.

Acute pelvic congestion. Valentine Taliaferro, Atlanta. Operations for abscess of the liver. W. C. Townes, Chattanooga.

Treatment of pus in the pelvis. W. E. B. Davis, Birmingham. Some remarks on syphilis. W. F. Westmoreland, Atlanta.

Observations on the treatment of specific and non-specific venereal ulcers. Wm. S. Goldsmith, Atlanta.

Bacteriologic data in the drainage of the peritoneal cavity. George S. Brown, Birmingham.

A statistical report of some of the more recent remedies used in the treatment of tuberculosis, and summary of recent preventive methods of value. R. H. Hayes, Union Springs, Ala.

The Turkish bath; its therapeutic indications. Louise Eleanor Smith, Chattanooga.

Microscopic and chemic aids to diagnosis. Katherine R. Collins, Atlanta.

Vaginal hysterectomy for bilateral suppurative processes of the uterine adnexa. W. D. Haggard, Jr., Nashville.

Some obstetric complications with report of cases. R. R. Kime, Atlanta.

Puerperal eclampsia. Searle Harris, Union Springs, Ala. Puerperal eclampsia. J. E. George, Rockwood, Tenn.

Medicine; Hippocratic and operative. John P. Stewart, Attalla, Ala.

Diseases and treatment of the accessory sinuses of the nose. B. F. Travis, Chattanooga.

Report of a case of bradycardia. W. C. Bilbro, Murfreesboro.

Paper on diseases of the eye. J. M. Crawford, Atlanta.

Paper on diseases of the eye. Alec Sterling, Atlanta.  
The Woodbridge treatment of typhoid fever. J. W. Duncan, Atlanta.

Treatment of cancer of the skin. C. R. Achison, Nashville.  
President's address; the Doctor of Medicine. J. B. Murfree, Murfreesboro, Tenn.

**College of Physicians of Philadelphia**—SECTION ON OPHTHALMOLOGY.—A meeting of the section was held March 17, 1896, Dr. Wm. F. Norris, chairman, presiding.

Dr. George C. Harlan exhibited a case of traumatic encephalnia in a boy 5 years old, who five months previously was wounded by the horn of a bull. The right cheek and temple and the lower eyelid were lacerated, and the inferior margin of the orbit was chipped. There was complete ptosis. At the time of examination the tendo oculi was found to have been torn away and the lower lid was dragged downward and outward by the action of the orbicularis and the contraction of the cicatrix. The surgeon who attended the patient at the time of the accident reported that there was considerable orbital cellulitis with abundant discharge of pus from between the lids, but there never was exophthalmia. He thought that the cellulitis was confined to the lower part of the orbit. At present the eyeball is retracted and has the appearance of being very much smaller than its fellow. The cornea is situated five millimeters behind the plane of that of the other eye. There is scarcely more ptosis than would result from the depression and loss of support of the lid. When the patient looks directly forward the palpebral fissure is five or six millimeters wide. He insists that he sees well with the eye. Though the movements of the eyeball are much restricted no diplopia can be detected. There is complete inability to look upward beyond the horizontal line either directly or to the right or left. Horizontal movements are normal and the downward excursion is much exaggerated.

Dr. Charles A. Oliver gave the clinical history of a case of ciliary staphyloma and excavation of the optic disc following traumatic cataract in a boy 4 years old. The clinical picture of this case of complicated secondary glaucoma was complete. Unlike similar cases of sudden obstruction to proper lymph-stream circulation, there remained from the very first, as shown by the fields of vision, and as afterward proven ophthalmoscopically, an element that may possibly complicate many more cases of the traumatic type of this disease than is at present imagined, and that is retinal detachment. Again, the condition of the vitreous and its peculiarity of opacities, taken in connection with the history of the case, would tend to show that there was a hemorrhage into that humor which probably might have been recognized ophthalmoscopically had the patient been seen a week earlier. These, with a few certain evidences of a low grade iridocyclitis, made the case still more atypical. On the other hand, the progressive diminution of the field of vision; the gradual distension of the globe and the localized tissue-bulgings in the upper ciliary regions; the deep and characteristic cupping of the nerve-head; the reapproximation of the remaining areas of retinal detachment; and the late, fixedly increased intraocular tension all show the certainty of degeneration even in a young and yielding eyeball when such tissues are subjected to a persisting increased intraocular pressure. The case illustrates the results of two conflicting contemporaneous conditions produced by traumatism: localized inflammatory reaction and obstruction of lymph-stream circulation.

Dr. George E. de Schweinitz presented a "Further note on an unusual form of macular lesion following iritis." The patient, a woman 50 years old, recovered with a nearly normal sharpness of vision, but with some vitreous opacities from a violent attack of serous iritis. The eye remained comfortable for eight months, when she appeared with a positive scotoma and the ability to see to count fingers only when situated in the periphery of the visual field. In addition to the positive

scotoma which the patient described as appearing "like a dinner plate with a green edge," there was a small absolute scotoma about the horizontal level. Ophthalmoscopic examination revealed an oval reddish area, giving the impression of a disintegrating hemorrhage and containing in the center several white dots situated exactly in the center of the macular region. Dr. de Schweinitz referred to the unusually distinct macular ring which seemed to indicate that there must be some thickening in the periphery of the hemorrhagic area.

Dr. Oliver exhibited a water-color sketch of a case of unusual submacular hemorrhage forming a part of some very curious lymph extravasations in the retina without any vitreous disturbances, found in the left eye of a healthy woman 65 years old, from whose eye he had successfully removed a black cataract by simple extraction about two months previously.

Dr. de Schweinitz gave the clinic history of a patient suffering from convergent strabismus of the left eye and a very high myopia 16 D. Ophthalmoscopically, the following lesions were presented. A small posterior polar cataract, numerous fine vitreous opacities, and a horizontally oval optic disc, of a greenish-gray color. The nerve-head was imbedded in the center of a huge mass of opaque fibers which followed the course of the principal vessels almost to the periphery of the eye-ground, in all directions, but less markedly downward and to the nasal side. A small patch in the macular region was not covered by the opaque fibers, but was disturbed by superficial choroidal changes. There was almost complete loss of nasal field, and of the entire center of the visual field, with exception of a small area to the nasal side of fixation, about 10 degrees in diameter, within which the white test object was dimly seen. Colors were correctly appreciated when held in the temporal field.

In the discussion, Dr. B. Alexander Randall showed a card-specimen of a case of retained nerve-sheaths in a case that had been sent to him for supposed intracranial disturbances. In this case there was an isolated patch situated in the macular region. Dr. Oliver exhibited the drawing of a case in which the medullation began at the edge of the disc and divided into two comet-like processes extending along the lines of the larger retinal vessels.

Dr. James Thorington, by invitation, exhibited an asbestos cover chimney with disc attachment for ophthalmoscopic purposes. The original form with the disc attachment he had made two years previously. The present arrangement showed that five changes could be made in the disc. 1. The one centimeter opening fulfilled all the purposes of the original chimney. 2. The two centimeter opening permitted greater freedom of movement on the part of the observer, without moving the light. 3. The three centimeter opening may be used as a source of light for the concave skiascope, or for the ophthalmoscope, otoscope, etc. 4. A round section of cobalt blue glass for the chromatic aberration test of ametropia had been added, as likewise: 5. The perforated disc with perforations and spaces each 1.45 millimeter to test for astigmatism at one meter's distance.

Dr. Thorington showed a new form of perimetric lenses which received its name from the fact that their optical center corresponds to the points of fixation in the fields of vision. The reasons given for the recommendation of the lens, were, that it gives to the eye that form of lens which is consistent with a normal form of the visual field; it removes the edge of the lens to a sufficient distance so that the edge can not be seen to any great degree while the eye is fixed straight ahead; and that bifocal segments can be made much larger. He stated that the increase in weight need rarely exceed the ordinary form, twenty-five to thirty grains; the large size does not attract much attention; and the cost will remain the same as in the ordinary styles used. Upon account of necessary greater weight and thickness, he believed that this form of lens can not be used.

for cases of aphakia and high myopia, but showed that as this class of cases constitutes much less than one-half of all refraction cases (37 per cent.), the lens will be accepted in the majority of instances.

Dr. Oliver exhibited and demonstrated a series of microscopic specimens showing the various forms of eyes seen in fish, reptiles, birds, quadrupeds, and man. He showed the marked differences in the conditions of the dioptric media; the varying shapes of the eye-ball; the relative positions of the eye in the head of the animal; the adaptations for near- and for far-focusing; the arrangements for increase of the interior illumination; the positions and peculiarities of the nerve structure; and the relationship existing intra-cranially between the two organs, in the aquatic, the terrestrial and the aerial forms of animal life.

## PUBLIC HEALTH.

**California's Mortality Report for August.**—Reports from fifty cities, towns, villages and sanitary districts, aggregating a population of 739,132, show a mortality of 865—a death rate of 1.17 per thousand for August, 1896, or 14.04 per 1,000 per annum.

**Isolation of Lepers in Russia.**—A "leprosorium" has just been completed at Wenden, and Virchow congratulating the Society for the Prevention of Leprosy during his recent visit to Russia, remarked that they had accomplished in this isolation of the lepers more than the most powerful of the popes had been able to effect in the days of their greatest supremacy.

**Horse-meat Consumption in Paris.**—There are at least two hundred horse butcher shops in Paris. The first one dates from July 1, 1866, since when the consumption has grown continuously. In 1872, 5,034 horses were eaten in Paris; in 1878, 10,000; in 1894, 21,227; in 1895, more than 30,000.

**Mortality Report of Connecticut for August.**—There were 1,644 deaths reported during the month of August. This was 33 more than in July, and 293 more than the average number of deaths in August for the five years preceding the present. The death rate was 23.6 for the large towns; for the small towns 21.6 and for the whole State 23.

**Typhoid Fever in the Navy.**—Surgeon C. A. Siegfried, of the battleship *Massachusetts*, reports that on August 31 he was compelled to transfer from the vessel to the Brooklyn Naval Hospital the fifth case of typhoid fever that had occurred aboard since she was commissioned at League Island in June last. The surgeon is reported as saying that he attributes the disease to the bad drainage of Philadelphia, and the condition of that part of the city nearest League Island.

**Quarantine Station for Northern New Jersey.**—Dr. A. H. Doty, Health Officer of the Port of New York, has applied, through Dr. H. C. Herold, the Health Officer of Newark, to Governor Griggs of New Jersey, for the establishment of a quarantine station at Perth Amboy. While all vessels that come to New York are obliged to stop at the boarding station of the quarantine office on Staten Island, they can land at Perth Amboy without interference, and there is therefore danger of contagious disease being spread from that point. Governor Griggs, it is reported, will recommend such a health station in his next annual message to the Legislature. In the meanwhile he has promised to use a \$10,000 emergency fund which is at his disposal for the suppression of any outbreak of disease, should the occasion arise.

**A Society for the Prevention of Noise.**—The formation of such a society is suggested in the *North American Review* by Dr. J. H. Girdner. He contends that there is as rightful need for such a society as for the Society for the Prevention of Cruelty to Children. It is, indeed, for the prevention of cruelty to grown people. The continued concussion of noise on the audi-

tory nerve is injurious to the whole nervous system, and is a great contributing element to the nervous prostration so common among city dwellers. It is a well-known fact that one coming from the country is almost stupefied by the multitude of sounds in a great city. The city man is used to it, but it is at the expense of vital force, and he undergoes, unconsciously, a strain that is great and wearing. Dr. Girdner's view is that a man has as much right to legal protection against an assault on his auditory nerves by useless noises as he has against an assault on his nerves of touch, by being whipped or beaten in any way.

**Improvements at the New York Quarantine.**—Dr. A. H. Doty, health officer of the port of New York, is commended by the *Medical News*, August 29, for the great degree of efficiency that has signalized his tenure of office. One of his innovations is the wearing of a uniform by himself and his deputies when they are "on duty." The uniform is a badge of authority especially impressive, normally so we might say upon the foreign element that visit these shores for the first time. New headquarters are in course of construction, a part of which will be devoted to a bacteriologic laboratory. This laboratory is already fully equipped and ready at a moment's notice to undertake the diagnostic confirmation of suspicious cases, so that a few hours of delay, while the investigation is being made, enables the health officer to determine on a scientific basis, whether a ship must be detained at quarantine or be allowed to proceed. "This fact is not usually appreciated by the general public, and the solution of this question of delay by the present health officer certainly reflects the greatest credit upon him. If a ship arrives after sundown, instead of being obliged to lie at anchor for the night in the lower bay, she is inspected at once and allowed, if in a suitable condition, to proceed to her berth. If there are immigrants or others requiring individual inspection, an electric search-light is set up upon the deck, and under its powerful beams the inspection is satisfactorily accomplished. If the passengers or cargo require disinfection, the boat, which the health officer has just had constructed, will accomplish it *tuto, cito et jucunde*. A row of bathrooms on either side of the boat will quickly disinfect eight persons by spray or vapor, or both. Clothing, bedding, etc., is all disinfected by steam, *in vacuo*, in a great car, such as is in use by the city Board of Health. The cargo itself is disinfected by sulphur gas, which is carried from the disinfecting boat in pipes under pressure, and distributed where needed, as water is distributed with hose. Thus, a ship, her cargo and her crew, coming from an infected port could, in a few hours, be sent into the harbor with a clean bill of health, the safety of the public being assured and the rights of the shipping-master protected as well. Surely this is a prodigious advance over old methods. Should a ship come to our shores, containing many cases of infectious disease—cholera, for example—there would be no long and vexatious detention of the well and clean, together with the sick. The former, after disinfection, would go on their way, and for the latter the health officer has provided large and commodious barges anchored near the quarantine islands, isolation being thus complete and the conditions as favorable as possible for recovery. It is to be hoped that this system may not require the severe test of experience, but if it should, we see no reason to doubt its efficiency. If successful, it would redound primarily to the great credit and praise of the present health officer; it would also be a demonstration to the public that its safety in sanitary matters depends largely upon the endorsement and support of the medical profession."

**Typhoid Fever at Albany, N. Y.**—The *Bulletin* of the North Carolina Board of Health, August, gives a résumé of some recent studies on the subject, "Does Good Water Pay?" The writer takes for an object lesson the state of affairs that exist at

Albany, N. Y., a city whose water supply is taken from the contaminated Hudson River. He quotes the statements of Professor Mason of the neighboring city, Troy, to show the economy that might be exercised by officials in curtailing the expense account inevitably incident by that water-borne zymotic disease, typhoid fever. What is the tax levied annually by that fever upon a city of 100,000, for instance Albany, N. Y. From statistics given in the five last annual reports of the State Board of Health, the deaths due to typhoid fever in Albany average 75 for the year. Rating the money value of each life at \$2,000, this death rate would mean an annual pecuniary loss to the city of \$150,000. Funeral expenses are variously estimated at from \$20 to \$30. Should we accept the intermediate value of \$25, this item would cause \$1,875 to be added to the above sum, thus raising the total direct loss through death to \$151,875. But typhoid fever does not always kill, its mortality rate is commonly quoted at about 10 per cent. For the present purposes should we assume nine recoveries for each death from the disease, and place forty-three days as the period of convalescence (the average of 500 cases at the Pennsylvania Hospital), we should have a term of 29,025 days as representing the time lost, per year, by the 675 persons who have the fever and recover. Thus an annual loss of over seventy-nine years has to be borne by the city's capital of productive labor. This great amount of enforced idleness, when translated into money value, should very properly be added to the death loss above estimated. Fixing the rate of wages at \$1 per individual per day, a very low figure, considering that the bulk of typhoid patients are in the very prime of life, there is a loss of \$43 for wages for each recovery, or a total yearly loss for the city from this item of \$29,025. The cost of nursing and doctors' bills equals at least \$25 per case, which is a very low estimate, thus adding the further amount of \$16,875 to the gross sum. Expressed in tabular form, this yearly tax imposed by typhoid fever in Albany is given, and, upon a most conservative estimate, it is practically \$200,000, which is \$2 a year for each man, woman and child in the city, or a yearly tax of \$10 for every family of five persons: 75 deaths at \$2,000 each, \$150,000; 75 funerals at \$25 each, \$1,875; wages of 675 convalescents, during 43 days, at \$1 per day, \$29,025; nursing and doctors' bills for 675 convalescents, at \$25 each case, \$16,875; total tax levied annually by typhoid fever upon the city of Albany, \$197,775. It can readily be seen that public works which could eliminate a reasonable fraction of this great tax would pay for themselves in the course of a few years, even though they were originally expensive. Finally, it is right to inquire what fraction of the present typhoid loss it would be reasonable to hope to save if pure water should be served in the city in place of its present polluted supply. To answer this question, recourse must be had to statistics obtained from other cities, covering periods before and after better water systems had been introduced. Such data have been already given for a number of cities and communities, and it only remains to anticipate what will be later said of Munich, and state that improved water and sewerage have reduced the annual typhoid mortality from an average of 25.4 per 100,000 to 2.7. Surely pure water pays in a city with such a record, and likewise it would pay in the newer but growing cities on this side of the Atlantic. Americans insist upon being supplied with much more water per capita than is usually furnished for Europe, but they are singularly indifferent as to its quality. It would be a reform of great moment if they could be induced to curtail the present enormous waste of public water, such as that of Buffalo, for instance, which is stated to be 70 per cent. of the entire pumpage, and to spend the money thus permitted to leak away in a vigorous effort to improve the quality of the water. No such lowering of the typhoid death rate as occurred in Munich, San Remo and sundry other places, could be looked for, perhaps, but a large percentage of the present rate could

be cut off, and we think, from a consideration of the above figures, that such a reduction would pay. No weight should be attached to the argument, so often advanced by the individual householder, that he and his family have used the water without evil results for the past fifty years. A single family is too small a collection of units upon which to base any estimate touching the question at issue. Placing the typhoid death rate for Albany, as above, at 75 annually, it would call for one death in a family of five persons every 261 years, a period much beyond the limit of ordinary family record."

**Vaccination in London Neglected; the Gloucester Epidemic Stamped Out.**—From the parliamentary intelligence reported in the *London Lancet* of August 22, we learn that in Gloucester, during the thirty weeks ending July 25, there were notified 2,008 cases of smallpox. That journal further states that "Gloucester seems to have got rid of the disease and to be able to chronicle a clean sheet so far as smallpox is concerned, after suffering 2,000 attacks within a period of about ten months. The bitter lesson taught by this epidemic is not likely apparently to stem the tide of opposition to vaccination wherever antivaccinationists congregate. Proof of this has been seen quite recently in the parish of Islington, in the different attitude of the vestry, who, as a health body, are desirous of seeing the vaccination acts enforced, and of the so-called vaccination authority, to wit, the poor-law guardians, who are wilfully ignoring the voice of the vestry; not only so, but the guardians also decline to hear what the public sanitary officers of the parish have to say on the health side of the question. The only consolation to be derived is to suppose that the reign of the poor-law administrators is probably short-lived now, and the sooner the bodies charged with safeguarding the public health have a voice in the matter the better will it be for all concerned." In another paragraph the same journal makes the following reference to the closing up of the epidemic at Gloucester, and to the expenses borne by its citizens on account of that epidemic: "The Gloucester sanitary committee have, it appears, discontinued the issue of weekly statements as to smallpox occurrences, the health of the city being deemed to approximate now to its normal condition. It would seem that the expenses connected with the recent epidemic, so far as the guardians are concerned, have been about \$10,280, and that it has been decided to ask the local government board to sanction the raising of a loan to meet the case. It will be interesting to know what is the sum total to which the citizens will have to subscribe in respect of the epidemic in all its bearings. The expenses appearing on the books of the town council will, however, we imagine, go but a very little way toward the whole, as the amount of money which must of necessity have been expended in one way and another by the public in matters of a personal character but having direct relation with the prevalence of smallpox in the town, must have been excessive. We know that charitable contributions were made with a liberal hand."

**A Less Stringent Quarantine for Diphtheria.**—The *Archives of Pediatrics*, in an editorial paragraph, commends the considerate courage of the New York City Board of Health in adopting a change, not of the highest moment but of importance as indicating a spirit of concession. The regulations have been by some considered unduly harsh and arbitrary and as trenching upon the patient's personal liberty. It further says:

"There was a growing tendency to postpone the sending of cultures through the fear that patients who might suffer from very mild attacks of diphtheria might be made prisoners for days or weeks after every symptom of disease had disappeared. That experience is not a pleasant one to the family physician. It was questioned whether the board of health was warranted in depriving citizens of their liberty unless they were able to say that the bacilli discovered in the throat, weeks after an attack of diphtheria, were virulent. It seemed doubtful to

many men of large experience whether the scientific evidence yet available warranted such rigid measures. The present regulations will certainly commend themselves to the practitioner. They prohibit any person known to have Löffler bacilli on their mucous membranes from attending school or mingling in other public assemblies where innocent and unsuspecting persons may become infected. Provision is made for informing every family in which diphtheria occurs regarding the method of its propagation and the dangers which may follow from contact with those who are known to carry the germs in their throats. This knowledge having been furnished the patient and the attending physician are privileged, under certain limitations, to assume any responsibility and risk which may arise from the violation of quarantine. This action is unquestionably wise. It removes the chief objection which has been raised against sending cultures to the board of health. It will undoubtedly encourage the earlier sending of cultures, and hence the earlier and more accurate diagnosis of diphtheria, and would seem to sufficiently guard the public interest. The endeavor made during recent years by the Board of Health of New York to aid the physicians of the city in their battle against disease can not be too highly commended. The willingness also exhibited to correct errors and to render necessary regulations as little irksome as possible, is worthy of equal commendation."

**Sanitary Rules for Schools in Indiana.**—The Indiana State Board of Health has issued the following letter of explanation in relation to the opening of the public schools for the fall term:

"Simultaneously with the annual opening of the public school, diphtheria, measles, mumps, scarlet fever and many other diseases usually increase. This is caused by the congregating of the pupils. They mass together and contact spreads infection. Some few pupils may have just recovered from a communicable disease, or they may be from families that have been smitten and, being infected, they transmit disease to those who are susceptible. It is reasonable to assume that the suddenly imposed confinement in the school after a period of freedom frets the children for a few days, causing more or less nervousness and so resistance is temporarily lowered. In this way susceptibility may be increased, and sickness may more readily follow. To do all that is possible to prevent the usual school-opening increase in illness is the object of these rules.

"It is ordered in the rules that desk tops and banisters be washed with soap and water and afterward treated with a disinfectant. This is required because it is more probable that disease germs are planted upon exposed desk tops and banisters by infected persons, and being transferred by the children's hands to their mouths, disease results. The washing and disinfecting will do much to prevent infection from this source.

"Open water buckets and large tin cups are condemned because the dipping of water with cups, which are used by many, introduce spittle into the supply; and beside, open buckets catch dust and dirt. Diphtheria, diarrhea, sore mouth and other complaints have been transmitted in this way. This source of disease may be avoided to a considerable degree by supplying a covered tank with a large, free-flowing faucet and a small cup. The opening of a large faucet will furnish a strong stream, which will suddenly fill the cup and wash the saliva from the edge. Ample drainage must be provided for carrying away the waste water.

"Slates are condemned because of their uncleanness. Writing and figures being obliterated, as they frequently are, with spittle, and as the damp slates readily collect dust, the danger of transmission of disease in this way is very great. Small children generally place pencils and pens in their mouths, and if these articles are promiscuously distributed without being sterilized, as the rules direct, infection may result. The collection of pencils seems necessary to always insure one to each pupil.

"Spitting is prohibited because it is a possible source of disease, is filthy and is unnecessary.

"These rules may seem trifling and unnecessary to those who have not given consideration to modern sanitation, but the teachers more than any other public officer may secure the physical well-being of the pupils as well as the intellectual advancement.

"It is hoped that all the school authorities of the State will promptly enforce these rules.

"DOUGLAS C. RAMSEY, M.D., President.

"J. N. HURTY, M.D., Secretary."

COPY OF RULES ISSUED.

**RULE 1.** All teachers of public, private and parochial schools, all county, city and town health officers and all school

authorities shall refuse admittance to the schools under their jurisdiction of any person from any household where contagious disease exists, or any person affected with any evident or apparent communicable disease, or any person who may recently have been affected with diphtheria, membranous croup, scarlet fever, whooping cough, contagious skin disease, measles or other communicable disease, until first presenting a certificate signed by a reputable physician stating that danger of communicating such disease is past, and said certificate is approved and indorsed by the health officer in whose jurisdiction the person may reside.

**RULE 2.** All teachers of public, private or parochial schools shall refuse admittance to their schools of filthy or unclean persons.

**RULE 3.** All school commissioners, school trustees in cities and towns and township trustees shall have the school houses under their control put in sanitary condition before school is opened and kept so throughout the year. Floors shall be scrubbed, windows cleaned, desks and all woodwork washed with soap and water and treated with a disinfectant. Windows shall be in repair, so that ventilation may be made perfect. Heating apparatus shall be efficient and in good order and dirty walls and banisters made clean. Banisters and tops of desks shall be washed with soap and water and treated with a disinfectant once each week.

**NOTE.** The disinfectant for treating desk tops, banisters, etc., and for use in urinals and closets may be cheaply made by the following formula and kept on hand in any quantity desired. To make ten gallons: Chlorinated lime, 40 ounces; soft water, 10 gallons. Thoroughly stir together and let stand until clear. The undissolved lime will fall to the bottom and the clear supernatant liquid may be used on the desks, banisters, baseboards, etc. The fresh milky mixture, as well as the creamy sediment may be used in urinals, closets and sinks. This disinfectant is not poisonous or dangerous. Chlorid of lime of the best quality may be purchased in quantity for 5 cents per pound. The cost of the disinfectant is, therefore, less than 2 cents per gallon. The use of all patent or secret disinfectants is discouraged by the State board of health.

**RULE 4.** School commissioners, school trustees in cities and towns and township trustees shall provide small drinking cups not to hold over a gill. Buckets or pails to dip from are condemned, and reservoirs or tanks of ample size having large, easy acting, free flowing faucets shall be provided. When water is drawn direct from public water pipes or pumps, reservoirs or tanks are not required. Ample drainage facilities for waste water shall be provided and the pupils directed to allow the cups to flow over when water is drawn. Drinking cups shall be cleaned and sterilized daily.

**RULE 5.** Slates are condemned. Paper tablets or pads shall be used instead. Riveted metal boxes of tin or galvanized iron with hinged covers and of proper size shall be provided for each school room. These are to receive pens or pencils, which must be collected from the children each day, and shall not again be distributed until box and all have been sterilized by heating in an oven at or above boiling heat for one-half hour. School commissioners and school trustees in cities and towns and township trustees are directed to enforce this rule.

**RULE 6.** Heating and ventilating shall be looked after with great care. Every school room shall be provided with a thermometer and a temperature not exceeding 75 degrees Fahrenheit nor less than 65 degrees be maintained during school hours. School commissioners, school trustees in cities and towns and township trustees are directed to enforce this rule.

**RULE 7.** Janitors when sweeping shall use damp sawdust or slightly sprinkle in order to prevent dust. Dusting shall be done with damp cloths. School commissioners, school trustees in cities and towns and township trustees are directed to enforce this rule.

**RULE 8.** The water supply shall be pure and wholesome, and closet or privy facilities shall be unobjectionable. School commissioners, school trustees in cities and towns and township trustees are directed to enforce this rule.

**RULE 9.** Spitting on the floor of any school building is absolutely forbidden. Teachers and all school authorities are directed to enforce this rule.

DOUGLAS C. RAMSEY, M.D., President.

J. N. HURTY, M.D., Secretary.

## NECROLOGY.

WILLIAM TURNER WOOTON, M.D. (Department of Medicine, University of Pennsylvania, Philadelphia, 1846), at Frederick, Md., September 14, aged 74 years. He was a member of an

old and distinguished Maryland family, was born in Montgomery County, but had practiced medicine in Frederick nearly all his life. Dr. Wooton was a frequent contributor to leading medical journals.

JOHN LAWRENCE DAWSON, M.D., at Charleston, S. C., September 17. He was born at the celebrated Mitkin plantation, near Monck's Corner, in 1815. Was the son of Lawrence Monck Dawson and grandson of a daughter of Lord Proprietor Monck. He graduated from the Medical College of the State of South Carolina, Charleston, in 1836.

After leaving the Medical College Dr. Dawson went to Paris with Dr. Chazal and spent some time studying and visiting the hospitals. Returning to South Carolina he located in Summerville. After a year or two, however, Dr. Dawson returned to Charleston. For some years he was United States physician to the Arsenal garrison, city registrar and health officer, holding the offices simultaneously. It was during his occupancy of these positions, in about 1840, when with the late Dr. Henry W. DeSaussure, he brought out the census of Charleston, which has been used as a standard authority since. Dr. Dawson joined the State Medical Society in 1837 and was prominent in its deliberations. He was a member of the standing committee, and also treasurer of the Society for the relief of the Families of the Diseased and Disabled Indigent Members of the Medical Profession of the State of South Carolina, an organization of which he was one of the founders.

P. F. BEVERLY, M.D., at one time President of the Ohio State Medical Society, at Columbus, Ohio, September 18, from a stroke of paralysis, the third one in a year. Dr. Beverly was 69 years of age, and a graduate of Starling Medical College, Columbus, Ohio.

CHARLES BERNACKI, M.D., of New York City, at Schandau, a Saxon watering place, September 17, aged 84 years. He was born at Starascol, Galicia, studied medicine in the University of Vienna and, after some practice in military hospitals in Australian Poland, opened an office in Vienna. After the political disturbances of 1848 he fled to America. From 1846 he was medical director of the Germania Life Insurance Co.

J. C. SACKVILLE, M.D., of Washington, Pa., aged 82. He was struck by a Baltimore and Ohio train September 23, and instantly killed. Dr. Sackville was a cousin of Lord Sackville West, formerly English ambassador at Washington, D. C., and a brother-in-law of the English poet, Robert Carr Foster. He graduated from the Royal College of Surgeons, London, England, in 1838.

EDWARD BENKENDORFF, M.D. (Medical Department, Washington University, St. Louis, Mo., 1847.) He was a native of Prussia. A relative of the same name is lord chamberlain to the czar.

H. H. HUNT, M.D., at Independence, Iowa, September 25, aged 72 years. He was county coroner for thirty years and was also a surgeon in the late war.

WILLIAM H. PERKINS, M.D., Long Island College Hospital, Brooklyn, N. Y., at Hancock, Md., September 11.—P. S. McArthur, M.D., Geneva Medical College, Geneva, N. Y., 1847, at La Crosse, Wis., September 19, aged 74 years.

## MISCELLANY.

**Treasurer's Notice.**—The Treasurer has received \$5.00 in currency from Buffalo, N. Y., which he will properly credit if the remitter will send in his name with date of remittance.

**Dartmouth Medical College.**—William Thayer Smith, M.D., of Hanover, N. H., has been appointed dean of Dartmouth Medical College, to fill the place of the late Dr. Carleton P. Frost. Dr. Smith has been professor of physiology for a number of years. Prof. Gilman Frost has been appointed secretary and treasurer.

**Professor Virchow's Birthday.**—A cablegram states that great preparations are being made for the birthday of Professor Virchow, which occurs October 13. Scientists from all parts of the world, including the United States, will be present with gifts and congratulations.

**Mutilation of Prisoners in Abyssinia.**—The Italian government recently sent an artificial-limb maker to Africa to supply hands and feet to about two hundred and fifty native soldiers who had been captured by the Abyssinians and, after having each a foot and a hand cut off, were set free again, but the unfortunates who have been evirated can find no instrument maker to come to their relief. Eviration is a cruelty much practiced by the Abyssinians on their Italian prisoners.

**International Scientific Language.**—In letter written before his death by Prof. Billroth to Dr. Jankau he remarks: I recommend the simplest of the Latin languages, Spanish, for an international scientific language; after this would come Italian and French, and among the Germanic tongues, English alone. English might even be preferable to all others, as it is one of the simplest. But as the Latin races have no aptitude for acquiring foreign tongues, it is necessary on account of their great talents in scientific matters, to make this concession to them, and select one of the Latin tongues for the international language.—*Gaz. Méd. de Paris*, August 29.

**Toxicity of Gastric Juice in Epileptics.**—Agostini has found that the gastric juice from an epileptic injected into the abdomen of a rabbit proves fatal with general toxic and clonic convulsions, especially if withdrawn immediately before or after an attack. Gastric juice from a normal person injected in the same way does not produce any evil effects. He considers these facts a valuable indication for the successful therapeutic treatment of epilepsy, with systematic rinsing of the stomach, disinfection of the intestines, etc. He found that the toxicity was diminished by the administration of bromids.—*Cbl. f. Phys.*, August 22.

**An Ancient Russian Superstition.**—A fatal case arising out of the widespread superstition that a candle made from human fat bestows invisibility upon its possessor, is reported from Ostrogzhsk. Two Russian thieves of the district were so firmly persuaded of the truth of this that they murdered a youth of their village in order to procure the candles in question. Having cut open the body, they removed the fat surrounding the kidneys, and, placing it in a tin box, took it home. There they proceeded to melt the fat over the fire. Unluckily for them an old woman, their housekeeper, became suspicious and informed the authorities. Her statement, coupled with the mysterious disappearance of the youth, who was a handsome and a popular young fellow of 18, led to the prompt arrest of the ruffians and their ultimate trial for the murder. The body was discovered, and the portions lacking therefrom lent further confirmation to the crime.

**Can Commit to Insane Asylum.**—The supreme court of Louisiana holds, in the case of State v. Uniake, decided June 30, 1896, that where a party has been indicted, and his counsel suggests his insanity, before trial, and a commission is appointed to inquire into his mental condition, and reports him to be insane, and the jury returns a verdict accordingly, and the judge of the criminal district court remands him to the parish prison, without a commitment to the insane asylum, the judge of the civil district court has authority, under section 1768, Revised Statutes, to inquire into the facts and circumstances of the case, and if, in his opinion, he is dangerous to the citizens and the peace of the State, to commit him to the insane asylum of the State.

**Right to Have Examination made by Female Physician.**—Under the provision of the New York Code that if a female plaintiff be subjected to a physical examination she shall have the right to have such examination made by a female physician, a decision

was called attention to in the *JOURNAL* of June 20, page 1245, to the effect that the fact that the order compels her to submit to an examination by a physician not of her own sex, is not a ground for the vacation of the order, she not having made any effort to have the order modified. But the appellate term of the supreme court of New York, first department, takes a different view of it, as its decision of July 27, 1896, in *Lawrence v. Samuels*, shows. It holds that the provision in question is for the protection of female suitors, and that the plaintiff in this case was entitled, as of right, to have inserted in the order the provision that a female physician make the examination, without making any special application for it as a favor or privilege, and that, in so far as the order appealed from a male physician named, it must be reversed, with liberty to the defendant to apply to the court below for the naming of such a physician as the Code authorizes.

**Effect of the X Ray on the Skin.**—We have seen it clearly demonstrated that the ray has an effect upon the skin, but only after frequent and long exposure to its influence. The appearance of the skin strongly resembles severe sunburn, with the accompanying pain, swelling, blistering and discoloration. The congestion in the hand is very marked, and the hand hanging in the usual dependent position occasions great pain. We have under observation at present a case in which the long exposure to the X ray has produced these symptoms, other exciting causes being positively excluded. The face showed the same series of changes as the hands.—*Canadian Pract.*, September.

**Woman's Inferior Sensitiveness to Pain.**—Ottolenghi reports in the *Cbl. f. Nerv. u. Psych.*, No. 7, that he has been testing with Edelmann's faradimeter the sensitiveness to pain and the endurance of pain in 682 women. He finds that women are less sensitive to pain than men, and that this sensitiveness is less in early life, increases to the twenty-fourth year, and decreases after that. The higher classes are most sensitive, and degenerates the least. He found the latter very obtuse to the sensation of pain. Endurance of pain varies between much broader limits in women than in men, reaching a maximum far beyond the masculine limit, possibly due to great "suggestibility" of the female sex. "General sensibility" reaches the highest point in the nineteenth year. He concludes from his investigations that sensitiveness to pain stands in close relation to the "psyche," while "general sensibility" depends upon the peripheral nerves. He considers woman's comparative insensibility to pain as a sign of her inferiority to man, as the uncivilized and degenerates are the least sensitive. He also attempts to prove a connection between this characteristic and her longevity.—*Cbl. f. Phys.*, August 8.

**Might be Entitled to Accident Insurance.**—A physician was insured "against bodily injuries sustained through external, violent and accidental means." While he was in his carriage on the highway, he attempted to administer to himself in his leg, for extreme exhaustion, medicine with a hypodermic needle. His carriage suddenly started, causing him to accidentally insert the needle deeply into his leg. This, he alleged and testified, produced blood poisoning and suppuration. The physician who attended him recognized it as a case of cellulitis, with which the morphia used had nothing whatever to do, and which resulted from the introduction of the needle, together with some condition of the skin or needle. Five judges of the appellate division of the supreme court of New York heard arguments on appeal from a judgment dismissing on the merits the complaint in an action against the company which issued the policy of accident insurance, with two of the five dissenting that judgment is reversed and a new trial ordered. The court holds, *Bailey v. Interstate Casualty Company*, decided July 7, 1896, that the question whether the

injuries complained of were sustained through external, violent and accidental means, within the meaning of the policy should have been submitted to the jury. If, in the use of the needle, an agency that otherwise would not have been in force, and which was the efficient cause of the injuries, was accidentally set in motion, it says that it sees no good reason why it might not be found that the injuries were attributable to the accident as the sole and proximate cause. As to the contention that the diseased condition of the leg arose from the use of morphia, and therefore within one of the conditions of the policy that upon the evidence it also holds was a question of fact for the jury to determine.

**Regents Control.**—The supreme court of Michigan holds that the constitution of that State gives the control of the University of Michigan to the board of regents, and that the legislature has no control over the university or the board of regents. On this ground it holds unconstitutional Act No. 257, Laws 1895, wherein the legislature provided that the board of regents should establish a homeopathic medical college as a branch or department of the University at Detroit and should discontinue the homeopathic college now maintained at Ann Arbor as a branch of the university, and transfer the same to Detroit. In consequence, it denies a writ of mandamus, which was asked in *Sterling v. Regents of the University of Michigan*, decided July 28, 1896, to compel action on the part of the board in accordance with the legislative will. It also suggests that the attorney general is the proper party to move in such a case, and a private citizen does not possess the right, without permission of the court, to apply for this writ to compel a public board to perform an omitted duty.

**The Use of Oxygen After Ether in Surgical Operations.**—Dr. William A. Morrison, of East Boston, Mass., relates several cases in the *Boston Medical and Surgical Journal* in which inhalations of oxygen most effectually and rapidly remove the unpleasant after effects of ether. From these cases he concludes: 1. That some cases receive much more benefit from its use than others. 2. That in the most favorable cases astonishing results follow; the nausea is apparently relieved or prevented, consciousness is quickly recovered, the breath is entirely deprived of the odor of ether in a very short time, and the feeling of malaise, so frequently complained of, is absent. 3. That some cases are not benefited (or are positively harmed) by its use. In another case of his, a man with a gangrenous foot, convulsions appeared soon after inhaling the gas, and he was therefore obliged to discontinue its use. He is unable to state why the man did not tolerate it. 4. That the best method of administering oxygen after etherization is by the use of a soft-rubber catheter gently introduced into the nares until the eye of the catheter is approximately opposite the opening in the trachea. It seems to him desirable that all cases in which oxygen has been used after etherization should be reported, so that the profession should be assisted in determining what cases are likely to be benefited by the inhalation, and in what cases its use is contraindicated. This was recommended by Professor Jackson when ether was first administered.

**Liability for Harshness in Examination.**—In the personal injury case of *Goodhart v. Pennsylvania Railway Company*, which was decided by the supreme court of Pennsylvania, July 15, 1896, it says that the evidence in regard to the examination made by a physician on behalf of the defendant was not directed to the extent of the plaintiff's injuries, but to the severity of the examination. Its evident object was to persuade the jury that the character of the examination and the conduct of the physician in question and his assistants was unnecessarily harsh and annoying, and was a proper subject to be considered in assessing the plaintiff's damages. But the supreme court holds otherwise. It says that it must be borne in mind that a

claim was being made against the railroad company for damages based upon an alleged injury received in consequence of an accident on its line. In order to determine intelligently the extent of its liability, it was important for the defendant company to know the nature of the injury, and the extent to which the plaintiff was affected by it. This could only be known as the result of a medical examination made by competent and experienced physicians. The physician above referred to and his assistants were selected as proper persons to make the examination, and advise the company of their estimate of the plaintiff's condition, and its consequent liability. If, in the discharge of their professional duty to their employer, they went beyond what was reasonably necessary and employed methods and tests that were cruel, and such as the judgment of the medical profession does not approve, and thereby inflicted injury on the plaintiff, the supreme court holds that they were liable for their own trespass, whether committed with malice or through ignorance. But rudeness and incivility in the manner in which the examination was conducted, if rudeness or incivility can be affirmed of anything that was said or done in that connection, the court insists could throw no light on the extent of the injury actually suffered by the plaintiff, and the evidence referred to should have been rejected. Damages for a personal injury, it says, consist of three principal items: 1. The expenses to which the injured person is subjected by reason of the injury complained of. 2. The inconvenience and suffering naturally resulting from it. 3. The loss of earning power, if any, whether temporary or permanent, consequent upon the character of the injury—each of which elements it further discusses.

**Specific Immunity Versus Transient Protection in Cholera and other Infection Processes.**—Dr. Pfeiffer in a *Deutsche Medicinische Wochenschrift*, April 11, having been employed in an inquiry concerning the different kinds of immunity that can be effected in the laboratory, offers the following as a part of the results of his investigations upon the subject of immunity: The cholera poison is contained in the body substance of the cholera vibrio, so that dead, as well as living cholera bacilli show marked toxic properties. The cholera poison becomes capable of absorption by the disintegration of the cholera bacteria; analogous conditions have been established as regards typhoid fever, anthrax, chicken cholera, staphylococcus infection, and apparently influenza. Animals may be rendered immune to toxic doses of living cholera spirilla, and typhoid bacilli by previous treatment with various substances of bacterial and non-bacterial origin. This protection is transient, and does not depend upon specific changes in the fluids of the body, and is designated as resistance, in contradistinction to specific immunity. In the blood serum of human beings and animals that have been exposed to the action of the living or dead cholera spirilla or typhoid bacilli, there occur specific protective bodies, which are thus capable of rendering aid in differential diagnosis in cases in which ordinary methods have failed; and these substances may be made to accumulate in the blood in concentrated degree by properly conducted immunization. In their relation to chemic and physical agencies, they bear a close analogy with the antitoxins, from which, however, they are differentiated by their action. While the antitoxins occupy a specific relation to certain poisons, and are capable of destroying these in the animal body, the anti-bodies of cholera and typhoid fever are incapable of thus acting upon the poison of typhoid bacilli and cholera spirilla. Their activity consists in the destruction of the bacteria, but this property makes itself manifest, as a rule, only in the body, and is capable of demonstration outside the body only under special circumstances. These anti-bodies are also found, though in small quantities, in the normal blood of animals and human beings. They are neither bacterial products deprived of virulence, nor combinations of these with components of the immunized organism,

but they are probably entirely new substances resulting from the specific reaction of the body to a specific irritant. The evidence points to the view that the anti-bodies are specific ferments. It is possible that the antitoxins also are specific enzymes. As fermentative activity plays an important part in the production of natural immunity, it is possible to relate natural and acquired immunity, antitoxic and bactericidal functions to a common general principle. This report as will be seen, fully sustains the position assumed by this JOURNAL in an editorial entitled the "Failure of the Antitoxine."

**A Question of Implied Contract.**—The defense to an action brought to recover for medical services rendered the daughter of the party sued was that the plaintiff was not in active practice at the time such services were rendered; that plaintiff was closely related to the family of the defendant by consanguinity and affinity, and the families were upon the most intimate terms; that for thirty or forty years plaintiff and defendant extended hospitalities, courtesies and favors to each other in the way of kindnesses and substantial benefits, without charges or any kind of legal obligation from one to the other, and that a greater part of the time defendant made plaintiff's home a general stopping place for rest, recreation and refreshments, and it was at these times and on these occasions and under these circumstances that the plaintiff, as the defendant then thought and believed, acting as much or more in the capacity of a friend than as a physician, examined and prescribed for the family of the defendant when indisposed. The evidence both showed that the services of the plaintiff were rendered as stated in his account and that the relations existing between the parties was as stated in the defendant's answer, and that their conduct and transactions with each other were the same as alleged. On the trial the court gave a charge to the jury to the effect that, if the plaintiff's demand was just and due he would be entitled to recover, and, further, that if they did not believe such account was just and due, and was contrary to law and equity, then they should find for the defendant. The plaintiff asked a special charge upon the question of implied contract, which the court refused to give. Under the circumstances the court of civil appeals of Texas holds, *Bonner, v. Bradley*, decided June 13, 1896, the trial judge failed to properly charge the jury, and reversed the judgment which was rendered in favor of the defendant. It says that when services are performed at the request of a party, the law will imply a promise to pay the reasonable value thereof, unless such request be made and acceded to as a gratuitous favor, and that if, at the time the services were performed by the plaintiff, it was not the intention of the parties that charges should be made for such services, then the defendant would not be liable therefor.

**Twins Extra-uterine Pregnancy; One Fully Developed Fetus of Fifteen Years' Retention.**—The *British Medical Journal* quotes Dr. Folet, in *Annales de Gynécologie et d'Obstétrique*, regarding a case of the above nature. The patient, a Flemish woman, aged 49 years, had an abdominal tumor, dull, uniformly hard, devoid of all tenderness, movable in its lower part and extending three inches above the umbilicus, which was diagnosed as a fibroma, partially calcified, and abdominal hysterectomy decided upon. As soon as the abdomen was opened an edge of bone (one parietal overriding another) was felt through a moderately thick sac of supple tissue, and the diagnosis at once amended to one of extra-uterine pregnancy. The sac did not appear to contain any fluid; it was partially adherent to the abdominal wall, from which it had to be detached with caution; it had many adhesions to the intestines, which were easily separated by the fingers. Only one ligature was required and the tumor was only retained by its base, when with a circular rent it burst, and five-sixths of the sac came away with the contents, leaving a funnel

formed by the remaining sixth attached by its outer surface to the pelvic organs. In the interest of the patient no endeavor was made to determine the exact relation of the sac to its surroundings; the edge of the funnel was fastened by eight silk sutures in the lower part of the abdominal wound, a large drain wrapped in iodoform gauze inserted in the peritoneum and the remainder of the incision closed. Recovery was perfect. The temperature never rose above 37.5 degrees C. and in six weeks the cavity of the cyst was obliterated and the healing complete. The structure of the cyst seemed to show it to be a tubal one. It contained two fetuses, one (female) 46 cm. in length, with well formed nails, had lived to term; it was not, properly speaking, a lithopedion; the tissues, though dense, were supple and nowhere calcified, and on sections of thigh and arm the skin and muscles were recognized by the naked eye and microscope. The other fetus had died about the third month; the thorax and head were much compressed, but could be made out and the members were distinct. The cords of both ended at the lower end of the sac in a single placenta, the degenerated tissue of which was represented by reddish-brown matter like touchwood, and broke into flakes on the slightest traction. Some days after the operation it was ascertained through an interpreter, that sixteen years previous the woman had become pregnant, having before that had four children at term. She duly quickened but at nine or ten months had a false labor: blood and membranes came away and she had hemorrhage for six weeks. As she ceased to feel the movements of the child and nothing further happened, she persuaded herself that she had been mistaken, and that she had not been pregnant, the more easily because her abdomen diminished a little in size and her catamenia returned and continued until she was 46. A doctor whom she consulted two or three years afterward, while giving no definite diagnosis, deprecated any treatment. She was led to apply to Folet on account of repeated attacks of pain during the last year, probably due to the peritonitis which caused the intestinal adhesions.

**Medico-Literary Notes.**—A book by E. Bonavia, M.D., has just been issued by the Longmans, on studies in the evolution of animals, taking into account the markings of animals as well as their coloration.

Cruden labored nineteen years on his "Concordance to the Bible," and immediately after its publication was sent to an asylum. He never entirely recovered from the mental disease induced by this gigantic undertaking.

Dr. Conan Doyle lately confessed to the London Authors' Club that he first began to write to get a little money to pay some bills. For nearly ten years most of his manuscript came back to him by return of post. His first profitable article was for a trade paper. Dr. Doyle says the choicest moment of his life was when Thackeray patted him, a boy of five, on the head and praised him. His last book, called "Rodney Stone," has a good deal in it about the fistic science, which was in its prime about a century ago.

Messrs. Thacker, Spink & Co., Calcutta, publish a new edition of "The Indigenous Drugs of India," which has been produced by the Rai Bahadur, Dr. Kanny Lall Dey, in association with Mr. William Mair. Fifty copies of the book have already been purchased by the government of India. The work is dedicated with permission to the Pharmaceutical Society of Great Britain, of which Dr. Dey is an honorary member, and extends to over 400 octavo pages. It will be published in London within the current month.

Among the various devices now being tried to relieve Guy's Hospital, London, of its financial difficulties, is that of raising a sufficient sum to permanently endow a bed in memory of the poet Keats, who served a short time there as a medical student.

In Huxley's "Autobiography" he stands up for truth as

greater than facts, and life than information. He says, "Life seems terribly foreshortened as they look back, and the mountains they set themselves to climb in youth turns out to be a mere spur of immeasurably higher ranges, when, with failing breath, they reach the top. But if I might speak of the objects I have had more or less definitely in view since I began the ascent of my hillock, they are briefly these: To promote the increase of natural knowledge and to forward the application of scientific methods of investigation to all problems of life to the best of my ability, in the conviction, which has grown with my growth and strengthened with my strength, that there is no alleviation for the sufferings of mankind excepting veracity of thought and of action, and the resolute facing of the world as it is when the garment of make-believe by which pious hands have hidden its uglier features is stripped off."

*The Medical Chronicle* is the title of the medical journal conducted by the faculty of the Owens College, Manchester. This college will open its winter session on October 2, and Mr. Jonathan Hutchinson has consented to deliver the introductory address, in the physiological theater of the new medical buildings.

Mr. C. C. Bell, in *Chemist and Druggist*, writes of the medieval names of drug plants. He says many of the English names occur also in Lyte, Gerard, Parkinson and the other old herbalists, and a considerable number are still in use, but these are not now in every case applied to the same plants as formerly. Gerard gives others of them in his list of obsolete names, but when these are deducted a good many still remain which had gone out of use before he wrote. Among these are some of especial interest. Donnhooft (spelt "donnhove") is one. It is the same as coltsfoot, "donn" or "dun" being an old name for horse, whence comes "donkey" or little horse. "Wowel" and "feldhove" are names given to the same plant. "Cetewale," which the glossaries give as English for "zodoar" (zodoary, a species of tumeric), appears in Lyte and Gerard as "setwall" a name for valerian; Chaucer, in "The Millere's Tale," names it along with licorice. Wermode in these glossaries means "wormwood" and is the correct form. Skeat explains it as "waremood" (preserver of the mind); Mr. Mowat, with greater apparent likelihood, says it is "waremoth" (preservative against moths). This certainly accords with the French *garde robe*, and with our old rhyme:

"Where chamber is sweeped, and wormwood is thrown,  
No flea for his life dare abide to be known,"

which, however, Mr. Mowat does not quote. Wilde keyn, again (which appears in the glossaries under vicus quercinus, and is evidently an echo of the French *qui de chene*), is not in Gerard. Other names calling for particular mention, some of which appear in Gerard and some not, are "groundswile" (ground-swallow), an appropriate name for so prolific a weed as groundsel; "wymalve" (French *guimauve*), for mallow; "hepebrede" (hip-bread, for dog-rose; "horse heal," for elecampane; marygold is called "yellebotel," or yellow-bottle. Shepherd's needle, which Gerard calls "ladies' combe," is glossed less flatteringly as "pouclesnedele," which, on the authority of a quotation in Halliwell, may be taken as equal to devil's needle; dandelion (*dens leonis*) as "doleronue;" hollyhock as St. Cuthbertscole; bryony as "wildnep;" burdock has given to it the name *filantropos*, because its seeds stick to men's clothes; duckmeat appears in a particularly interesting form as "cibus anatis, ang. enedechede" (a clerical error for "enedmete," "ened" being an old name for duck). Similarly "paddockstol" recalls the old name for frog or toad. "Cold as paddocks though they be, Here I lift them up to Thee," says Herrick's child of her hands in her "Grace before meat." "Aleon" are distinguished as of three kinds, *cyotrium*, *epaticum* and *caballinum*. Opium appears as "opium Thebaicum" (indicative of its geographic source), glossed "succus papaveris albi" and "opium miconis, succus papaveris nigri."

The entry immediately following this is a sad muddle, being "Opium quirrinacium, lesera, quilleya, succus iusquiami, idem." This is in "Alphita." In the "Sinonoma" "opium quirrinacium" is glossed "assfoetida idem;" what "quilleya" is, it is impossible to say; "iusquiamus" is henbane. This is only one instance of many hopelessly confused glosses. White, black and red poppies appear under their respective Latin names, and of the second we are told that diacodion is made. Nothing more is said of their use. Cowslip appears under "paralialis herba" as "cousloppe," meaning cowdung, a not very poetical name; "endyve" is under lactuca. The glosses on dracunculus are interesting as specimens of the fancifulness of our forefathers: "Dracuncia, asclepias, viperina, pentaria, serpentilla, colubrina, basilica (basilisk), cocodrilla (cockatrice), idem gallice et anglice, dragaunce" ("in English, dragons," says Gerard, who gives an equally long, but different, set of synonyms from Epuleius Barbarus). "Mandragora" as described at length are of two kinds, male and female; no other name is given to it. "Sene" (senna), again, has as yet no English form; and it is interesting to note that both these plants are mentioned by Shakespeare in the form here given. "Zinziber" also appears only in this form, and rhubarb only as reubarbarum.

### Hospitals.

**New Post Hospital for Fortress Monroe, Va.**—The Government will build a new hospital to cost about \$20,000. Plans for the hospital have been received, and the work will be let by contract after thirty days' advertisement.

**Pennsylvania Hospital Annual Report.**—The managers of the Pennsylvania Hospital have issued their annual report, showing that in the Pine Street Hospital the patients remaining in May, 1895, numbered 210. New patients received in the year to May, 1896, were 2,408; remaining at latter date, 186; beds occupied, 2,618. A large amount of work was done by the out-patient department, the visits aggregating 46,197. In the department for the insane the figures for the year were: Women, new cases, 88; discharged, 82; remaining, 233; men, new cases, 77; discharged, 91; remaining, 181; total treated, 537; remaining, 414.

**A Cottage Hospital at Proctor, Vt.**—A new hospital at Proctor, Vt., was formally opened on August 8. It is a modern building, a short distance from the center of the town, and arranged to accommodate ten patients. The first story has an accident and operating room thoroughly equipped with modern surgical furnishings. One of the wards is also on this floor. The domestic and executive arrangements are all in the second story. The hospital has been built and equipped by the Proctor Marble Company; and while primarily intended for such of the employes as may need its services, it is to be open to any person in the village. The management has been placed in the hands of a committee of townspeople. The district nursing in the town, which is already completely established, is now to be done from the hospital by its training school. The attending physicians thus far appointed are Drs. J. M. Hamilton of Proctor and H. H. Swift of Pittsford.—*Boston Medical and Surgical Journal*.

### Philadelphia.

DR. B. MEADE BOLTON, Director of the Bacteriological Laboratory, wishes it to be distinctly understood that he is not responsible for the recent establishment of the plant in the City Hall for the manufacture of disinfectant solution, known commercially as electrozone. The tests which have been alleged to have been made in the city laboratory he states were not made by him or under his direction and that he has not had anything to do with testing, reporting or publishing anything in regard to the matter, which is understood to be under the supervision of the City Board of Health or some of its officials.

THE REPORT of the unsanitary condition of the League Island

Navy Yard, arising from the fact that cases of typhoid fever have occurred recently in several vessels which had been fitted out at this place, has led to an investigation which is now in progress by the authorities at Washington. The Board of Health has not been able to find any case of typhoid fever at the station or within several miles of it. The water supply is not derived from the city pipes, but from cisterns filled with rain water so that the infection is not due to the use of water from the Schuylkill, and there is no great prevalence of typhoid in the city at present.

## THE PUBLIC SERVICES.

**Army Changes.** Official List of changes in the stations and duties of officers serving in the Medical Department, U. S. Army, from Sept. 19 to Sept. 25, 1896.

A board of officers is appointed to meet at the Headquarters Department of the Missouri, Chicago, Ill., on Monday, Oct. 5, 1896, at 10 o'clock, A.M., for the examination of such officers of the Medical Department as may be ordered before it to determine their fitness for promotion. Detail for the Board:

Lieutenant-Colonel Albert Hartsuff, Deputy Surgeon-General.

Major Henry Lippincott, Surgeon.

Captain Norton Stroug, Assistant Surgeon.

The following named officers will report in person to the president of the examining board appointed to meet at Chicago, Ill., on Monday, Oct. 5, 1896, for examination for promotion:

First Lieutenant Henry C. Fisher, Assistant Surgeon.

First Lieutenant Henry A. Shaw, Assistant Surgeon.

First Lieutenant Charles F. Kieffer, Assistant Surgeon.

Major John V. Lauderdale, Surgeon, will upon the arrival of Major Egon A. Koerper, Surgeon, at Fort Crook, Neb., repair to his home and await retirement.

Major James P. Kimball, Surgeon, is relieved from duty at Fort Wingate, New Mexico, and ordered to Fort Columbus, N. Y., for duty, relieving Major John Van R. Hoff, Surgeon. Major Hoff, on being thus relieved, is ordered to Vancouver Barracks, Washington, for duty, relieving Captain Rudolph G. Ebert, Assistant Surgeon. Captain Ebert, on being thus relieved, is ordered to Philadelphia, Pa., for duty as attending surgeon and examiner of recruits, relieving Captain William W. Gray, Assistant Surgeon. Captain Gray, on being thus relieved, is ordered to Fort Apache, Ariz., for duty relieving First Lieutenant Irving W. Rand, Assistant Surgeon. Lieutenant Rand, on being thus relieved, is ordered to Fort Clark, Texas, for duty.

**Navy Changes.** Changes in the Medical Corps of the U. S. Navy for the week ending Sept. 25, 1896.

September 23.—Passed Assistant Surgeon G. A. Lung, detached from the "Vermont" and ordered to the naval hospital, Chelsea, Mass.

Passed Assistant Surgeon H. D. Wilson, detached from the Chelsea, Mass., hospital and ordered to the "Bache."

Passed Assistant Surgeon G. H. Barber, ordered to the Naval Academy, Assistant Surgeon M. K. Johnson, detached from the "Bache" and ordered to the "New York."

Assistant Surgeon F. C. Cook, ordered to the "Vermont."

### Change of Address.

Butler, T. J., from Chicago to Lockport, Ill.

Case, C. E., from Tacoma to Everett, Wash.

Johnson, C. W., from 625 Locust St., to 2309 Locust St., St. Louis, Mo.

Todd, F. Walton, from Coronado to Camp Capitola, Santa Cruz, Cal.

Taylor, P. K., from Kington, R. I., to 211 W. 139th St., New York, N. Y.

Walsh, T. G., from 330 Grove St. to 369 Greenbush St., Milwaukee, Wis.

Wiggin, F. H., from Littlefield, Conn., to 55 W. 36th St., New York, N. Y.

### LETTERS RECEIVED.

Alta Pharmacal Co., St. Louis, Mo.; Allport, Frank, Minneapolis, Minn.; Adams, A. L., Jacksonville, Ill.

Bernd, Henry & Co., St. Louis, Mo.; Bourns, F. S., Atlanta, Ga.; Benjamin, D., Camden, N. J.; Bumstead, J. E., Dundee, Ill.

Dewey, Richard, Wawatosa, Wis.; Drevet Mfg Co., The, New York, N. Y.; Douglas, Richard, Nashville, Tenn.; DeCourcy, J. O., St. Libory, Ill.

Epley, F. W., New Richmond, Wis.

Feiel, A., Columbus, Ohio.

Galloway, D. H., Chicago, Ill.; Gradle, H., Chicago, Ill.

Hammond, J. C., Denison, Iowa; Hot Springs League, Hot Springs, Ark.; Hahn, H. H., Youngstown, Ohio; Haddock, W. J., Iowa City, Iowa; Hummel, A. L., Adv. Agency, New York, N. Y.; Higgins, F. W., Cortland, N. Y.; Hoffman, J. R., Ottawa, Ill.

Imperial Granum Co., Youngstown, Ohio.

Jegl, H. A., Arcadia, Wis.

Krebs, Paul H., Cleveland, Ohio; Kibler, C. B., Corry, Pa.; Kransse, Wm. C., Buffalo, N. Y.

Laughlin Pen Co., (2) New Haven, Ind.; Lautenbach, L. J., Philadelphia, Pa.

McBride, R. E., Gibson City, La.; Merrill, Wm. Stetson, Chicago, Ill.; Marchand, Chas., New York, N. Y.; Mizell, A. G., Chicago, Ill.; Mettler, L. Harrison, (2) Chicago, Ill.; Merrick, M. B., (2) Passaic, N. J.

Nelson, C. D., Greeley, Colo.

Ozone Company, Chicago, Ill.

Parmele, Chas. Roome, New York, N. Y.; Pettit, J. W., Ottawa, Ill.

Rockey, A. E., Portland, Ore.; Reed, R. Harvey, Columbus, Ohio;

Rosenberry, A. J., Wausau, Wis.

Schneider, August, Buffalo, N. Y.; Stowell, Chas. H., Washington, D. C.; Savage, G. C., Nashville, Tenn.; Spencer, John C., San Francisco, Cal.; Schaffelin, W. H. & Co., New York, N. Y.; Steele, D. A. K., Chicago, Ill.; Starr, G. L., Hudson, Ohio; Simmons, Geo. H., Lincoln, Neb.

Tyree, J. S., Washington, D. C.; Tukey, Henry E., Louisville, Ky.

Wilson, Cunningham, Birmingham, Ala.; Wilson, A. J., (2) Chicago, Ill.; Walton Oxygen Works, New York, N. Y.

## LECTURE.

### MEDICAL EDUCATION.

Opening lecture delivered at Rush Medical College, Chicago,  
September 29, 1896.

BY EDWIN KLEBS, M.D.  
PROFESSOR OF PATHOLOGY.

Ladies and Gentlemen: The wish expressed by my new colleagues that I open the lectures of this new year of medical instruction by some considerations of our work, laid upon me the somewhat difficult task of explaining my opinion, in a foreign language, on the organization of schools in this country, with which, also, I am not yet perfectly acquainted.

You must not think that this will be a confession of my ignorance of American history and institutions. On the contrary, I have always, from the time of my youth, inspired by the treatises of Ralph Waldo Emerson, loved this land. At the time of the great civil war I eagerly studied the work done by your fathers, who, destitute of everything necessary to carry on a successful war, decided to live or die for liberty and humanity.

I was astonished at this time to acknowledge the origin of a new war hygiene, later further developed in the great wars of the old country. Comparing the great losses in the Crimean war, which preceded the American civil war, with those of the Franco-German war of 1870, you will not fail to see the great progress in this new field, principally, as I think, effected by the distribution of the wounded and sick over vast areas, by means of the mighty streams.

It seems to me that the American people, impelled by urgent necessity, became more and more inventive, and learned more in a few years than it would have learned in centuries without that impulse.

The wonderful development in this land that you all know, from your own experience, now followed during the short period of twenty to thirty years. All facilities were enhanced by the confidence in the restored Union; enormous wealth and prosperity, such as were never known before in history, were arising from the soil of the new land.

Naturally, then came depression. In the restless strife for improvement many things, without which a people can not be happy, were not taken into account. I only mention the devastation of woods, threatening a change of climate, unless replanted systematically, an injury not otherwise to be remedied.

Political and financial influences have more and more increased the internal difficulties, so that now will come a time when the labor of the whole land will be required to sustain this prosperity.

But how will the people endure this change of conditions, the irreparable loss of so many facilities? I think that they will accept the new position, the harder strife for life, the conditions of life impaired

and narrowed also by the competition of the whole world. This confidence is based in the first place, on historical facts. A people who have surmounted the hardships of a civil war will find a method also in this harder time, but in another way.

Not the pioneer and the digger, but the teacher and educator will be the leaders in the new course. Science will be the aim and purpose.

The educational question now moves the whole world. European civilization based wholly on the old classic traditions of Rome and Greece, has reached, especially in Germany, a standard in classic education which seems to be incompatible with the claims of modern life. Natural science will more and more supplant the ancient literature and the modern philologist finds that the modern languages have attained a higher certainty and clearness by which to express the modern thoughts than the dead languages now occupying nearly the whole time of the scholar.

The reform of higher school education now commencing in Germany, will save our country from imitating the so-called classic studies. Let us fill the mind of the child and the youth with a broad knowledge of earth and heaven, of living beings and dead material, of human life and thought, history and philosophy, so that they may understand the coming life and be able to distinguish the good and the evil, the just and the unjust; religion and morals must have a prominent part in this system of education. What I wish to say is this, that for the young man or woman willing to devote themselves to medical science, a non-classic education is quite sufficient. But the requirements of preliminary education necessary for admission to our colleges, seem to be totally insufficient. Unless certain literary colleges have been attended, an examination in writing, in the branches of a good English education, including algebra as far as equations of the second degree, the first book of geometry, English composition, elementary physics and the elements of the Latin language should be substituted; chemistry and physics will be taught in the freshman year.

I do not find in the program the descriptive natural sciences, the natural history of plants and animals, the geology and mineralogy, which contain the elements of so many parts of the medical science, not to speak of knowledge of human history, art and thought. I am quite sure that a great number of our pupils have completed their education in these directions, but I doubt if that is the case with everyone.

I do not pretend to propose reformations, but I do hope to find the young men better educated than the scanty requirements for admission to the leading medical colleges lead me to believe.

For comparison, I will give a short outline of the requirements in German universities, in natural history only. The young men entering the university have learned a great deal of natural history at the

gymnasiums, but before commencing the medical studies they must spend a whole year's course in natural sciences, such as botany, zoology, chemistry and physics, including practical work in microscopy and the chemic laboratory.

If we look at the schedule of Rush Medical College we will perceive that in the freshman year no more than 745 hours are devoted to study, in the following three years from 870 to 1,036. I think that one could very well dedicate 150 to 200 hours to the study of botany and zoology in the first year. But this, as other practical questions, must be considered at another time. Furthermore, I would wish for a certain knowledge of the German and French languages, already required by the Johns Hopkins University, also some ability in drawing. Without knowledge of these modern languages the medical student can only make use of the English literature and translations from the German and French, but as the greatest part of medical literature and the most valuable is published in periodicals, the student can not fully understand the medical literature of his time without this knowledge of modern languages. As the development of science is a very rapid one, scientific work is not possible without personal literary study.

But we have given enough detail on medical teaching. Let us now look at the American students and their qualifications for this science. As I have had many opportunities to teach Americans in European laboratories, I am prepared to speak upon that point with due reservation. First I will say something about the ladies studying medicine abroad. The greatest number I had in Zurich were Russian or other Slavs, German, Swiss and American. The best prepared for study were Swiss, American and German. In diligence they surpassed nearly every male student and as far as memory is concerned, it was very difficult for our male students to attain better marks than the female in the examinations. In the anatomic and microscopic work, over which I made personal observations, I found American ladies among my best workers; in the composition of publications there were some differences, however, depending more upon the personal character than upon mental faculties. One lady whom I highly esteemed for her assiduity and very clever work, labored somewhat under a too much developed pride, declining every help in the composition of her paper, which, based upon delicate microscopic researches, would have made more impression if the points and the deductions had been more thoroughly discussed. I do not know if that was a personal propriety, but I can understand that a woman prides herself on independent work; this pride can be a very good support in the hard work awaiting the doctress. I shall ever remember another American whom I had the pleasure to aid in her original work, as the best example of a medical student, fitted to do any scientific work. In this direction I must give the American ladies the first place and I hope to see here the same attainment in practical medicine.

As to the qualification of American men for scientific medical work, there can be no doubt. From my youth to the present time I have had many opportunities to come in contact with them as a teacher, and can openly express my opinion, that they would not, in any way, remain behind any other people, only being handicapped by their preliminary education and imperfect knowledge of foreign languages. But

these slight defects were compensated for by a burning zeal for learning. My first experience dates back to the early sixties, when I was assistant of Professor Virchow. My first pupil, a man as old as I, was a Californian and showed, perhaps, more enthusiasm than your Eastern people, but I will never forget his open-hearted joy, when he understood a difficult matter, explained by the inexperienced teacher, in pretty bad English. And I have made the same observation, repeatedly, through a quarter of a century. All young Americans that came to me for study, were brave, joyful, enthusiastic people, but sometimes a little deficient in school education. They have all been my friends.

You, probably, all know the cause of these characteristics. The American life is a practical one, and the arts and sciences, here, come in second place. But I am sure this state of things will change before long. Deficiency in education is more and more improved and there are many men of the highest and most refined education in liberal arts and sciences. One of my friends in Germany, a learned man of high standing, a deep critic of Göthe, stated that he was astonished by American visitors, oftentimes finding that they had the most profound understanding of German literature and philosophy. That is a good indication of what can be done by your people in medical science also.

In medical practice we can certainly meet any competition, but not in medical science. The reason for this is to be found in the organization of our medical schools, which I have already touched upon. I understand very well that these organizations resulted from compromises and that under given circumstances, for the moment, higher attainments could not be demanded without driving a large number of students into the hands of so-called medical colleges, which one of my friends designated as "paper mills," a shameless scattering of diplomas for money.

Regarding these facts I can not find a better remedy than to place the higher education in the hands of the Federal Government. This would present many difficulties, as I know from my experience in Switzerland, and I would not like to interfere in practical questions. But we can take these matters out of the hands of the government and regulate them. By "we" I mean all good citizens who find that the prosperity of the country depends upon the education of the people. Very much is done in this direction. For our prominent scientific institutions are founded by private individuals, by donations, often rich men restoring a part of their earnings to the people, the well-conducted work of whom has procured these means. A political economist in Germany has named that the "inheritance of the people." "To give is more blessed than to receive," said Jesus, the greatest socialist. Yes, we will bless these rich men who will help in the education of the people and perhaps prevent the day of wrath. But not alone to the rich people should the appeal be made to assist in the educational question. Every physician, every patient is interested in this work and can afford to promote the higher medical education. I am sure the generous American people will favor progress in higher scientific education.

Here arises a very important question: Is the efficiency of such institutions for higher learning assured by money alone? Can money buy such institutions, as it can buy railroads or steamships?

The success in original scientific work depends more upon the worker than upon the external conditions of work. In my youth I have seen Helmholtz, the great physicist, work out his great discoveries in optics with the simplest means, and calculating with a child on his lap. The great mathematician, Gauss, when asked how he had found his new methods enormously enlarging mathematic conception, replied: "By repeated thought over the same matter." So we see that the personal conditions for scientific work are given everywhere, if there is a quiet place for thinking and men apt for this work. An exceptional mental faculty is not necessary for this, as not every learned man needs to be a genius. Continuous work is sufficient if the right way is laid open. Such indicators (Wegweiser) guiding the seekers after knowledge will arise in every country where learning is esteemed and supported.

I have experienced a striking example in my own life. I came to a university, in a land where science was not much developed, but proud of its great political power in a past time. This aristocratic people, with high self-consciousness, resented bitterly that so many strangers were called by an intelligent government to fill the chairs at the university. Some wished to injure the intruders, not personally, but by diminishing the number for instruction. A politician of high standing was induced to promote the attack, which would be adverse to the development of the university, when one of the professors opened the eyes of this political leader, showing the true aim of his associates, by saying: "You, as a liberal and reformer can not support an action against natural development. Give good seed to the soil and you will see good fruit ripen. Learned men can not be found everywhere. Take what you have and you will see, that in some generation, you will have enough support from your own countrymen." Thereupon the good man ceased to support his tempters and the chairs of the university are now, after nearly thirty years, occupied by a great number of native teachers, universally acknowledged to be of the highest rank.

What I wish to show by this experience is that higher study needs a thorough cultivation, continued for a long time. It is the same as with the cultivation of plants. If King Probus had not planted the grapes on the borders of the Rhine, the Rhine wine would not have won its world-wide celebrity. I tasted the California wines some forty years ago and I was not pleased with it, but now it is quite a different thing.

As we can not reform the whole system of higher education at once, we must commence slowly, warming and protecting the delicate plant sown in a soil in which, as yet, other plants, industry, farming, business of all kinds have grown so luxuriantly. If the soil commences to be exhausted by the one fruit, the good farmer will plant another. Science is a plant that has borne very good fruit in old Europe, why should it not develop here, when a young, fresh people, free from many prejudices of the old world, will strive to win the first rank in the great problems of the human mind?

But how shall we promote strong scientific work in our department, the medical science? In the first place you must change your opinion on the tendencies of the college or university. It does not suffice to have excellent instructors and well educated pupils, but we must have the will to give or receive more than

medical instruction, sufficient for medical practice, or only for the examination. That would be the office of a high school or a university, in the sense of German universities. More than in other countries, you will find that these institutions are founded not only for education, but also for observation.

The difference between a school and a university is not always comprehended as it should be here, nor in Europe. As a young professor, I often spoke with business men about the difficult task of a university professor, but they did not understand me. "Oh," one said, "I think, in the first year, that it may be very difficult to lecture so much, but later one learns that." This is only too true, many professors learn to repeat the same lectures, and very amusing anecdotes are told in Germany about teachers accustomed to do this. One of these learned professors, reading his lecture absent-mindedly, also read the foot-note: "Here I like to make a joke." But I can assure you that this sort of professors died out, and from that time the acknowledged glory of German and other universities commenced to fill the world and attract people from every country. By these remarks I do not mean to say that German universities are perfect. As the devil always sows weeds among the wheat, so there the high position of professorship has attracted many inferior people who rely more upon protection than personal worth, and the egotism of many professors goes a little too far. Where there is much light there will also be shadow; but at all events we can look to German universities as the best examples of our scientific schools.

The first object of these schools is, and must be to educate the pupils to scientific and practical work. We must educate them to be independent observers, for a physician must have this quality, and without it he will not enjoy his task. He may fill his position very well, operate and prescribe, but if he does not look at his patient with the eyes of an observer he will fail to see many features of the highest importance. To the superficial physician not trained to careful observation, one case looks like another and he will be astonished if the expected effect of a certain remedy does not appear. It is, as with a savage people or a flock of cattle to the unexercised eye, they seem to be all alike; the observer, however, if he be an experienced traveler or a cattle grower, will see the differences. Certainly the good physician will learn, in the office and at the bedside, what he has not learned at school; but it would be better if he would go out into the world wholly instructed and experienced. Scientific work, done while a student, will aid the practitioner.

Hoping that you are convinced of the great importance of this truly dominant question, I will add some suggestions as to what should be done in this direction. First, every laboratory should be so arranged that a certain number of students and also of younger graduates could work, not in learning the elements, those must be understood, but for original scientific work. The smallest problem which we attempt to solve brings with it more elucidation than the reading and memorizing of a whole text-book. I fear that in our method of teaching learning, memory is too much relied upon, recitations prevail and not discussions. With young people, working on problems, there must be more discussion than recitation. I prefer a student who does not know so many facts, numbers or figures, but who understands the connection of facts

and how to make conclusions from the known to the unknown.

In the laboratory opened for the work of students, it is not necessary to give long lectures but to discuss the matters in a conversational manner.

Whoever is farther advanced in his work, will come and expound his results to the teacher and his colleagues. From the discussion new thoughts will arise not before given by the teacher. The scholars can learn without feeling that they are being instructed. I hear that such a system has been commenced here in private primary schools; if it is practicable with children, why should it not be with thinking men?

But in this matter another side is to be taken into consideration. If we have such laboratories who will work in them? The student is busy the whole day and the young physician must oftentimes attend to making his living. I do not think that people are poorer here than in Germany, where all this is done, but if so, the means for such work must be found and I do not doubt but it will be. In German universities we have so-called stipendia, which enable the poorer student to continue his studies, and beside that, we do not want to have medical proletarians (a very good word of Billroth). Whoever undertakes this noble study should first find the necessary means. The poor should not be excluded, but they must show the true qualifications.

For the young graduates, working to perfect their education, I would recommend the two appointments which, in my opinion, have made German universities great; first, the doctorate, obtained by scientific work; second, the private university teachers (Privat-Docenten).

The title of doctor, historically, means more than that of physician; it expresses a scientific qualification, shown by original scientific work. For that degree the publication of a dissertation is required, that is, a scientific treatise and theses, scientific questions which the applicant will defend in free debate against every one.

This venerable practice has been, as all human things, liable to deterioration, but it has influenced, in a very ostensible manner, the high standing of the profession. Innumerable students of medicine have been compelled, by this custom, to do original work, or treat clinic observations in a historic and critical way. Certainly the dissertations have awakened many literary talents which would have slumbered without this incitement.

Graduation or examination is necessary for the *Doctorat*; the latter is intended to show the qualification for scientific work and teaching. It is therefore indispensable for every physician teaching in a medical faculty.

The private lecturer, privat-docent, is a position quite unknown in English and American colleges; in France the professeur agrégé occupies nearly the same position. The title privat-docent is conferred by the faculty, on application, for a certain branch of science. He lectures in the same manner as the professors, mostly supplying gaps in the regular lectures or giving lectures on special parts of the science, elaborated by his own work. Many of the private lecturers are assistants, and are given the opportunity by their chief to deliver special courses. Without going into particulars, one will see that this institution is highly adapted to the education of professors.

I wish to submit this institution of private lectures to the earnest consideration of leading men in this country. Having so far only touched upon the student epoch of medical men, we can not make the whole importance of this discussion quite clear if we do not explain the standing of our profession and science in public and private life.

The profound change which our science has undergone in the last century will be made clear by some historic references. In the earliest times medicine was in the hands of the priests and based only upon occasional observations such as were made by the people. Hippocrates destroyed the secret and put these ideas into systematic order. The observation of facts became controlled and the work of physicians subjected to general rules, governed always by moral laws, highly appreciated at all times by the true physician. Since that time the work of the physician possesses a sacred feature. The patient needs to rely, with full confidence, on the knowledge and the truthfulness of his physician. He must know that he can not be deceived, although errors can not be entirely excluded. If the physician has any doubts consultation may be sought.

The medical profession must be so organized that it will be the best for the public. Quackery and evil conduct are more contemptible than in any other occupation. Where the government does not protect the medical profession it must protect itself, as is done here by the code of ethics, accepted by the AMERICAN MEDICAL ASSOCIATION.

This organization, securing the interests of the public as well as of the physicians, has sometimes roused distrust rather than confidence, but a thinking man will congratulate himself for having a medical profession caring for its honor. This position of the profession seems to be one of the principal features which attracts the young men to our lecture rooms. The practice is not so lucrative as in the old times, when one would say "*dat Galenus opes.*" The sense of humanity forms another attraction to the medical science; if the physician can help, he is loved as a god, and to the incurable he can always bring comfort and diminish their suffering.

In our time, in which the strife for gain seems to reign, the people have double interest that our profession preserve these feelings, and I hope that the public will support them. It will be to the interest of the patient that he follows obediently the prescriptions of his physician. I have seen so many patients ruined by their feeble, distrustful character, changing from one physician to another, thus losing the best time in which they could have been saved. But, on the whole, I have found the American to be an excellent patient, not excited, not nervous, but quietly doing and sustaining whatever was necessary. I have never elsewhere seen so much courage in enduring pain.

But the position of the physician in our time must be looked upon from another side. The change in the medical principles, effected in the last thirty years, is so enormous that weaker minds could not follow. On the whole, one can say that the younger generation has fully adopted the new theory of the bacterial causes of disease, though not always willing to make the necessary deductions.

How great this change was may be shown by an example. The two pathologic conditions, which alone nearly governed the old pathology, were "fever"

and "inflammation." The seething of bad humors or juices in humoral pathology, the struggle of the soul, the Archaus of Stahl, through many centuries formed personifications of disease, very apt to be attacked by the zealous physician, who mistook the signs or symptoms of the disease for the disease itself. Under this delusion such things as "essential fever," or fever in itself were spoken of. Later, under the auspices of a more developed physiology, one tried to explain these phenomena by the doctrine of irritation. Albrecht von Haller has shown that irritability is the general property of all living substance, a property consisting in the outbreak of the genuine activity of the organ, after an external influence has acted as an irritant. So the muscle will contract, if it is acted upon by mechanical, electric or chemic influences in the same manner as it does when irritated by its nerves through the action of the brain or by an electric current. The action producing the irritation can be of very different nature, the effect produced upon the body is always the same. You will understand this if you think of the works of a clock moving in the same manner, whether its spring or pendulum be put in action by the hand, by an earthquake, or by removing a hindrance.

This theory seems to best explain the two symptoms governing, or of disease itself. From Broussais to Virchow this explanation prevailed, giving very good indications for therapeutics. If the irritability of an organ or the whole body is increased, one has recourse to remedies of a soothing, mitigating action; if the irritability is deficient, one must irritate; if the two processes do not help, according to the doctrine there only remained the counter-irritation (contrastimulus). If, for example, an inflammation of a knee-joint was treated without good result first with cold later with warm poultices, there remained only a counter-irritant, the burning. The consequence was that old country women, shepherds, etc., sometimes had greater success than learned physicians.

This inadequate doctrine was destroyed by pathologic anatomy, which, from the end of the last century, was more and more developed in Europe, first in France and England then in Germany. After many great predecessors, Rudolph Virchow developed a new doctrine which seemed, at first, to cover every logical desire, namely, the cellular pathology.

This doctrine showed the composition of the body to consist of a great many living organisms, the so-called cells, bound together by the common action of vessels and nerves. This theory disclosed manifold processes in disease, in their minutest details; it enriched our knowledge, but it did not advance our therapeutics; to the action of cells was confined the regulation of irritation. So the cellular pathology was thought to have found in the action of the cells, the whole essence of disease, and the question, Why do the cells act in an abnormal manner? was asked no more.

For Virchow and for many of his pupils and followers, the question of cause did not exist. He declined to go farther, with the oracular answer of a sovereign, "We can not know all things."

I admire R. Virchow very much, having been for a long time his pupil and assistant, having learned from him the finer distinctions of pathologic processes. I acknowledge that he has enriched pathology more than any one else before him, but he did not have the right to command a stop to all other progress in our

science. The word "why" must always be used, if the knowledge does not cover the whole truth and does not explain the cause of action.

Already a new dawn announced the bright day of our present knowledge. Medical historians and geographers remembering the spread of the great plagues, and enlightened thinkers, as Henle, had, contemporaneously with Virchow's cellular pathology, proclaimed the theory of the external origin of contagious diseases, from living matter, the germ theory hinted at in oldest popular medicine. The microcosmos were opposed by the macrocosmos in pathology.

In our time the investigations in this direction had commenced, first without regard to pathology. Pasteur had detected the origin of fermentation due to microbes, destroying the physical contact-theory of Justus von Liebig. But Pasteur declared, fearing to oppose the dominating school of pathology, that these discoveries had nothing to do with pathology. When later, in the seventies, he transferred the germ theory to pathologic questions, he had to suffer many persecutions, as I know from his own mouth.

Already, many years before Pasteur recognized his error, the parasite of anthrax was found by two German observers (Pollender and Brauell), but were, by all leading men, declared as inorganized, or if bacterial nature was conceded, as consequent to the disease or organisms developed in the dying animal.

A sort of madness seemed to have controlled the defenders of the old doctrine, so that even the excellent experiments of Davaine did not change the minds of stubborn *doctrinaires*. Davaine isolated these organisms and showed that a single one was sufficient to infect and kill an animal. The development being first local, at the place of implantation, and the general infection could be prevented by destroying or extirpating the infected part.

Lister developed the same idea, the external infection in wounds, and commenced a reform in surgery, which was more and more refined and perfected later.

At the same time I demonstrated the propagation of certain bacteria in the internal organs of the body after they had found entrance through natural openings or through wounds. The abundant material of the Franco-German war of 1870 gave me the opportunity to show that these organisms, while spreading in the organs, always precede the cellular derangements. Cultures and infection of animals in these and other cases of infectious diseases showed the causal nature of, probably, all contagious diseases. By separating the bacteria from fluids, in the cultures, by filtration, we could demonstrate that only the bacteria produced the disease. It was shown by Tiegel, my assistant, and later in Tokio, that the fluid had only toxic influences (1871 to 1873).

I also was very vigorously attacked from all points, especially from the medical side, whereas other learned people, such as Tyndall, were convinced of the importance of the new development in pathology. Certainly many imperfections, unavoidable in a new research, may have given some reason for criticism. The later researches of Robert Koch and others decided the battle on the fundamental principle in pathology. This can be pronounced in the following thesis: *Disease is the struggle of two organisms, the one invading the other.*

If I have explained my opinion clearly enough you will see what can be done for scientific medical education. By my lectures, which I will give in this

college, I will attempt to inspire the student to do original work, which is the only way to promote the scientific standard.

## ORIGINAL ARTICLES.

### A MEDICAL ASPECT OF CRIME.

Read in the Section on Neurology and Medical Jurisprudence, at the Forty-seventh Annual Meeting of the American Medical Association, held at Atlanta, Ga., May 5-8, 1896.

BY A. C. CORR, M.D.

CARLINVILLE, ILL.

Aside from the uncivilized barbarism that would induce a barbarous or half civilized person to commit outrages on the individuals of a neighboring tribe or state while practicing obedience to his own tribal laws, there are exceptions in which the individual is not true to his own tribal or state laws. These he continually violates, through some unknown impelling force that makes him act in utter disregard of the good, safety and comfort or all. This latter violation is usually called crime.

Now in all the mutations of the silent revolution that has wrought so wonderfully since the debut of an organized Christian civilization, we have room for so many different phases of a variation of progress that we have amid a high Christian civilization, great irregularities in which individuals are untrue to their assumed, acquired and inherited responsibilities and obligations, and tend frequently or constantly to violate those laws, written and unwritten, which are for the good of all, both living and unborn. Besides this variation as between civilization and barbarism as to the highest types of that which we may call tragic crimes as between nations, there is quite as much variation or want of consistency in our civilized Christian and free country between communities and states. What is a crime in one state or city is not necessarily such in another. What is a crime in one section is not in another, and some things that are a violation of law on one day in the year or week is not on another. Amid this almost inconceivable and inscrutable maze of varying conditions, individual and collective, local and general, we are called on in this ASSOCIATION, established for the well-being of society, to discuss the Medical Aspect of Crime.

As far as the discussion in this paper is concerned it shall be based on the fact, that the brain and the nervous system are the physiologic organ of the mind and intellectuality, and that every grouping of ideational activity, or well defined mental faculty has its origin in the functional activity of brain or nerve cells and fibers, either local as in areas, or disseminated throughout the nervous system, or both local and disseminated, and that *morality*, the ethical sense, the sense of moral uprightness, of justice, of right between men, people and things, has such an origin; that it is a faculty of the mind just the same as the will of the reason, and that as such it is subject to the same laws as the functional activities of other organs; that it is susceptible of being cultivated, of being repressed, of becoming increased by education and activity, of being diminished by neglect and occupation, of being perverted as in diseased conditions manifested in a class of criminals; that it is deficient in many persons to a greater or less degree. In other words there are children, youth, adults and mature persons who are moral imbeciles from congenital deficiency of the moral sense.

This faculty of moral sense or morality is the inhibitory faculty of the mind, the let or hindrance to the human expressions, activity and conduct, modified by the will, the reason, the judgment, the understanding and the impulses and intellectual delusions.

This faculty of morality is the latest and best results of man's long continued culture and its exercise is the highest function of his very complicated cerebral and nervous mechanism.

With this physiologic source and condition of crime before us its treatment is greatly simplified. When amid the mutations in progress of development from barbarism to civilization and advanced christianization, influenced by atavism and connation, the impulse to commit an act is felt that belongs to the criminal calendar, that is, to do that which is in disregard of the rights of others and is hurtful to the well-being of the civil social compact, and is in violation of law written or unwritten, the individual sense of justice and moral uprightness intervenes and inhibits or sanctions the act, just in proportion to the development of the moral faculty of the individual.

Now, would you have crime lessened? Then you should cultivate and develop the moral sense and repress the emotions. I can not give here a tithe of all the details this cultivation would embrace, but certain it is that some code approximately correct should be formulated and put in practice expressly for this purpose. Something that would teach children as definitely to exercise the moral and ethical faculties as there is to teach the exercise and development of the reasoning and intellectual or mathematical. Children should be taught as early as possible *that there is a principle of right and justice in the abstract, irrespective of any mere religious sentiment or superstition.* Each child ought to be impressed, if in no other way, by mere precept in a round of words, that he who has not an average moral perception is a moral idiot and is to be held in apprehension as one unsafe to trust. Lessons in morals ought to be formulated and a spirit of emulation engendered that would cause them to strive with each other to learn the most of them. These lessons should be elementary and advanced and graded in adaptation to the ability of each child to grasp and comprehend them. *And every school of whatever character, should be required to rigidly teach them; for the exercise of morality, to the extent of being just and upright in conduct and character, is the best and highest function of the human brain.* In this course each crime should be designated and its heinousness expatiated on and a thorough understanding of its turpitude required, and that its commission and practice would lead to still further immoral practices in the individual, propagate the same or similar practices by inheritance to others. *And over all this ought to be held the terror of lawful punishment.* For he who can not or will not learn, let him be deterred by fear of pain and penalty and let the seal of disapprobation be placed on every act that violates the least of the moral code.

This much should be done for the individual from childhood up, and should not be neglected, and whatever religious influence that may be deemed proper should be added. If anyone can be deterred from criminal or immoral practices through fear of impaired future happiness, by all means give him enough to answer the purpose. It is the practicing that cultivates more than the mere tendency inactive.

At present the public schools in our country, through which most of this grade of work in moral culture must be done, is incompetent for the task. There is among school teachers as well as among the laity in general, no definite idea as to the difference between morality and religion, between moral uprightness and the mere ritualistic processes of a beatific worship.

I once had occasion to investigate this subject among public school teachers in my own State, and I dare say they average with those in other States. Some said morals is a theological question, and if we attempted to teach it in schools it would give rise to religious sectarian wranglings that would impair the harmony and usefulness of the school, and if this or that teacher inculcated his or her moral ideas (religious views) it would create dissension and independence among the patrons of the school because of their varied religious beliefs. One who was in high esteem as principal of public schools said in substance "that the question of how to promote the morals of my pupils has given me a great deal of anxiety, and is a matter I never felt satisfied how to manage, owing to the varied religious views entertained by my teachers and pupils. I have in one school a class of six or seven studying natural sciences, two members of which are believers in the theory of evolution, and it gives me a great deal of annoyance and anxiety for fear they will ruin the morals of the remainder of the class and in fact infect the whole school." Other teachers replied to my queries that they would leave the question of morals or religion to the Sabbath schools, the churches, the sectarian schools and the colleges. There were still others who frankly admitted that the question of teaching morals was not well understood and criminally neglected.

Now, I do not think I misrepresent the great body of divines and religious instructors, including all denominations from pope, priest, bishop, theologic professor and clergyman to pastor, when I say that they are not more systematic and definite in their conception of in what moral uprightness consists and how crime is to be prevented.

Nor has the legal profession elucidated and proposed a better plan than the hurling of statutes and sentences of punishment. Now, what shall I say of the medical profession? Have we elucidated any better or well devised method of defining morals and cultivating the moral sense? In fact I doubt not that when this point is discussed that it will reveal quite as wide a range of different ideas as to the moral sense and faculty of the brain and mind as the classes to which I have referred.

But having to do with the brain as an anatomic organ and its physiologic phenomena, the mind in the abstract, it is our incumbent duty to determine whence the source of criminality in the individual as far as his mental composition is concerned and what additional plans shall be formulated for its prevention. The conclusions arrived at on this point shall constitute a basis for the consideration of the medical aspect of crime.

The moral defect with its criminal tendencies is always congenital, many times hereditary and always modified in a greater or less degree by *environment* and *synergistic influences*.

By *congenital* I mean the inborn tendency, which mental condition is a derivative complex, much

like a double decomposition in chemistry, and by which a mental composition is transmitted congenitally that is unlike either parent in moral perception, yet like one or the other, or both in many other respects. This is *congenital* moral imbecility, while an *hereditary* moral imbecility must be like one or the other or both parents.

The congenital variety of mental complex is that in which criminal children are born of amiable parents, or amiable children of criminal parents. Many instances of both varieties I have observed.

Having established in a fairly plausible way that the tendency to crime is inborn and consists in a defective mental composition in which the moral perceptions are weak or deficient and that it may be cultivated like any other mental faculty, it may be well to consider some one or two conditions of environment or synergistic influences that cooperate with a slight or marked criminal tendency to make the criminal. To a large extent all men are creatures of association or environment. Many with only slight tendencies are schooled out of or away from crime. While many are schooled into it who but for such synergistic influences would have always remained guiltless.

Beyond these suggestions I would be recreant to my trust were I not to arraign the liquor traffic as being the greatest despoiler of human morals and well being. While we do in our associated capacity much to school children and youths out of and away from crime, yet we tolerate and perpetuate a traffic that unschools and dissipates much that our well designed efforts have wrought. The use of alcoholic beverages is always to degrade and debase the moral sense in the individual and disorganize society. It never elevates or cultivates a moral sense, but degrades and tends to make criminals just in proportion as it is used. It never sent a child to Sabbath school but has sent many to the penitentiary and the gallows. If a man uses a thousand barrels of it, it does not do him as much good, based on his necessities, as the eating of a teaspoonful of meal.

Its tendency to produce crime and make criminals can be proven by the history of any county in the United States where the sale and use of it has been prohibited for only one year, for just in proportion to the efficiency of the restricted sale and use of the beverage among the citizens will crime and criminality have been diminished.

I do not think that the destruction of the liquor traffic would by any means prove a panacea for all crime, but its synergistic influence amid a degree of moral imbecility is at the present time greater than all other influences combined.

Some eminent medical gentlemen have argued that some one or more organic instincts are responsible for most all the crime, and that a surgical procedure or operation would prevent crime and reform the criminals. The most remarkable contribution to the discussion of this character that I have seen is a paper by Dr. Robert Boal to the Illinois State Medical Association in 1894, entitled "Emasculation and Ovariectomy as a Penalty for Crime and the Reformation of Criminals."

The discussion was made under nine considerations which were practically these:

1. "We are taught by both physiology and psychology that all human beings are controlled in their conduct and actions, and appetencies are expressed

through their organic instincts. Of these, two are of paramount importance. They are love of life and sexual love. The first is the strongest and outlasts all others. Next is love of sex, which dominates human conduct and desires. Its bestowal was wise, but when uncontrolled it is potent for evil."

2. "The greater proportion of the crimes characteristic of the criminal and vicious classes may be traced directly and indirectly to the influence of this uncontrollable and dominating sexual love. The rapes, homicides, suicides, defalcations and embezzlements may be ascribed either directly to sexual love, or to influences associated with it. So well is this understood that when we hear of the cashier of a bank absconding with its funds, or a trusted clerk robbing his employer and betraying his confidence, almost the first comment heard is, 'Oh, there is a woman in the case.' With scarce an exception, there are few vices in the calendar of crime, licentiousness, prostitution, intemperance, gambling and others that are nameless, that are not designated, associated with and maintained by sexual love."

3. "The physical or structural characteristics of the criminal and defective classes are produced, reproduced and multiplied, and perpetuated by intermarriage or sexual commerce of persons of like defects, and we have accordingly the results of living activities of matter or what is called heredity."

4. "By the imposition of the penalty of emasculation and ovariectomy we destroy the capabilities of these defective criminal classes, to inflict injury upon society, thus depriving them of the power of reproduction."

5. "For the purpose of intimidating others from the commission of crime, while neither cruel nor vindictive it is more terrifying and repulsive, next to death, than any or all modes of punishment. The loss of sexuality as a mark of manhood is so utterly abhorrent to all men that it would be avoided if possible by all individuals not hopelessly insane."

6. Practically, "By unsexing all constitutionally depraved convicts we would curtail such production and aid nature in natural selection and the survival of the fittest."

Seventh and eighth considerations are conclusions based on the acceptance of the six preceding referring to the results and effects of emasculation and ovariectomy on the disposition of the individual, and that as a punishment would not excite revenge, etc.

Ninth consideration is a general statement as to range of application of the punishment, to the effect that it might be safely applied to insane persons, cranks and paranoiacs.

To this ninth consideration I have only to ask, Would emasculation and ovariectomy change the delusions of the insane and make them safe citizens at large in society? I have quoted these "Considerations" because they embody an idea that is held by many both in the medical and legal professions. I think the idea is untenable as a whole. I discussed them in a paper before the same society a year later, when I replied to the "Considerations" seriatim. In the discussion of this paper Dr. N. S. Davis of Chicago, said, "I have seen nothing in my observations in human society to make me believe that human depravity is greatly ruled by simply the sexual organs in either sex. That they are capable of exerting a predominating influence in individual cases, as much and probably a great deal more owing to bad training,

bad education, bad surroundings than to any inherent vice in these organs, is undoubtedly true, but whether they have any more tendency to produce crime than a man's stomach I very much doubt. I think it has been shown that a well developed dyspeptic is about as likely to go wrong as almost any other class we might enumerate. It is not, in my estimation, the fault of the organs that we propose to excise as much as it is a fault in the brain that accompanies them, and if you want to get rid of the tendency to crime you will have to excise some of the cells of the brain, if you can find the proper ones, instead of the sexual organs."

## THE PHYSICIAN AND THE CRIMINAL.

Read in the Section on Neurology and Medical Jurisprudence at the Forty-seventh Annual Meeting of the American Medical Association, held at Atlanta, Ga., May 5-8, 1896.

BY J. B. RANSOM, M.D.

PHYSICIAN TO THE NEW YORK CLINTON STATE PRISON,  
DANNEMORA, N. Y.

The axiom that the proper study of mankind is man has evidently not long been applied to criminal man, for careful search reveals a striking dearth of records in this regard. Until 1841 nothing worth recording had been done in the special observation of criminals, and the science of criminal anthropology, strictly speaking, was only begun in 1854, and not until Lombroso's work "The Criminal," was published in 1876 did criminal anthropology assert itself as an independent science.

There are several instances where observations have been published as to the characteristics of criminals, but no connected and definite work was done. (Immediately after the publication of "The Criminal," however, numerous works on criminal anthropology were published, especially in Italy.) All the valuable work done in this line is of recent date; good literature in this field is therefore limited, and carries with it the conclusion that the whole subject has been surprisingly neglected, and he who would enter this field of work must find himself somewhat lonely. On every hand, however, there are evidences of an arising interest in this feature of social life. In France, Germany, England and Italy more especially, criminology is fast assuming the dignity that rightly belongs to this important and essential science. In our own country, however, no such concentrated results have obtained, and the study of criminal man is a slighted one and the subject little understood. More striking is this when we consider that such study is not without necessity, for a glance at the census figures of the United States will show a proportionate increase of incarcerated criminals of nearly five times from 1850 to 1890 inclusive.

Year.	Prisoners.	Ratio of population.
1850 . . . . .	6,737	1 in 3,442
1860 . . . . .	19,086	1 in 1,647
1870 . . . . .	32,901	1 in 1,171
1880 . . . . .	58,609	1 in 855
1890 . . . . .	82,329	1 in 757

The number of homicides in 1889 were 3,567 in the United States, in 1895, 10,500. This, too, in the face of the fact that society and the courts and general public sentiment has constantly grown more lenient, and the number of unpunished criminals has largely increased; as for instance, according to Andrew D. White, if the whole number of murderers for the six years last past were in prison there would be 40,000; as a matter of fact there are only 7,300. Neither is

it because we are unaware of the existence of crime, for it is everywhere present; the newspapers of the day flaunt it in our faces, and our own observations make known to us the existence of a large criminal class, which is surely and rapidly invading every department and function of our social and political life. It is not necessary to enlarge upon this unpleasant feature; it is apparent to every one. The condition confronts us; it remains to determine the causes and apply the remedy, and that without delay. These causes are many and various, but it will only be within my province to speak of those which relate to us as a profession more particularly, and seek to determine just what our responsibilities are in this whole field of scientific and sociologic work.

It would seem that a common interest in the study of man in a biologic sense would have elicited the very best efforts of the medical profession, inasmuch as man has always been the humble recipient of all the experimental work of an aggressive profession since its conception, but that such has not been the case is apparent by the very few medical men who have been engaged in this important branch of science. It may be assumed that this was chiefly due to the fact that in the early history of medicine, the profession of that day were so intent upon the problem of cure, as—to them—much more important consideration than man himself. In a less remote period medical men were engaged in the elucidation of theories, and still more recently earnestly in pursuit of man's common enemy, the microbe; not that this work has not been necessary, and of inestimable value to a common progress, but it does seem paradoxical that its prosecution should have so completely obscured its object, man!

Only occasionally had the physician devoted himself to this work up to the time of Sampson, Lombroso, Forbes Winslow, Camper and Lallemand. It is, however, in our own country that the least attention has been paid to this subject, excepting in isolated cases where men like Drs. Arthur McDonald, Jacobi and Flint, and physicians connected with penal institutions have urged the necessity of criminal anthropology as a branch of medical work. This has been, however, so fragmentary and unclassified that it has not assumed at any time an organized effort in this direction, and therefore has elicited little interest and accomplished less; but the rapid advance in this work recently made in Italy, France, England and Germany, and the alarming ascendancy of crime, so diametrically opposed to the progress of our time, the inability of our present administration of the law, and of the penal system to cope with the necessities and conditions of the hour, have forced into consideration of society and government a problem which should have had its solution, or at least intelligent recognition, as paramount to their safety and well being long ago. As it is in the closing years of the nineteenth century with all its marvelous achievements, with all its progress in culture and refinement, society finds itself confronted by a condition which threatens its very existence. Society is finding out that it has nursed or tolerated within its own bosom the upas which may poison it to death. Aroused to a recognition of the fact that such a condition exists, it finds itself in possession of only the crude elements of an embryonic science, which to be adequate to these demands must be rapidly developed into one, comprehensive and efficient. Crime and the criminal must receive more

weighty consideration by all concerned, or the integrity and strength of our social and political institutions will be subjected (they are already threatened) with serious disaster therefrom. Society has heretofore been content to relegate this whole feature to the courts and the penal code.

It needs no demonstration to show that the modern trial, sentence and punishment of the criminal, so largely based upon assumption and in ignorance of the criminal himself, has measurably failed to protect society from the rising tide of crime. In spite of the exercise of their powers crime has continually and markedly increased. This is in the largest sense due to the fact that the procedures of the courts and administration of law, have based their action upon the theory that its function was first to detect crime, and then to punish it, losing sight of the fact that all men are not alike, and that punitive measures could only be efficient when they take into consideration the individual characteristics and apply the treatment to the criminal's special needs. Intelligent trial and sentence can only be secured when we have a scientific knowledge of the criminal, the nature of his crimes and the natural and social phenomena connected therewith. Such an administration of criminal law can only be obtained by the thorough classification of the criminal into distinct and characteristic types. In the words of Flint: "Before a disease can be treated intelligently it must be diagnosed."

More especially is this true when those types represent physical and psychic anomalies.

I think, in the light which recent investigation has shed upon this subject, that it may be indisputably asserted that crime is often the natural outcome of disease, and that into such causation enter many forms of deviation from the normal standard in both the physical and mental organization represented by arrests of growth, deformities, asymmetries, intercurrent diseases, as well as psychic aberrations and disorders.

This whole subject is at present in a state of chaos, and it is impossible to draw definite conclusions from the data at our disposal; naturally enough as the possibilities of this field have opened up to view, there has dawned upon the consciousness of some the idea that there is such a thing as a natural criminal, and that the commission of crime is not always the result of a long process of evil doing, instituted by telling the first white lie, which precedes the going through of the story book stages of moral decline which go to make up the average romantic criminal. This conception leads them to come hastily to conclusions based upon a few meagre details and incidents, and with many learned phrases rush into print seeking to establish the theory that society has made an awful mistake, and assert that crime is and always has been a disease. A great deal is said upon the subject which clearly shows an utter lack of knowledge and a misconception of the whole subject.

All this grandiloquent flourishing of pamphlets and inclination to rush in where wise men fear to tread might well be expected with reference to a science of less than half a century's growth; neither is this limited to the over-enthusiastic, for even our most careful students and painstaking observers in the enthusiasm of first discovery have made many erroneous statements and drawn conclusions altogether too arbitrary; but when all this cyclonic agitation of high sounding terms has ceased to confuse our senses,

we shall see that these conditions are but the natural accompaniment of the birth of a new science, and that soon from out all this incoherent mass of nebulistic data will be crystallized constructive elements, which when assembled by the skillful and competent men of our time, will constitute a perfected science of criminal anthropology, applicable to the needs of society, and protective of the general welfare. In the study of the criminal there has been a tendency to base all conclusions upon anthropologic data; even Benedict and Lombroso have gone so far as to assert the existence of a criminal brain as a distinct type, which I think is unwarranted by what has been derived from still later investigation. To these extreme views I certainly do not assent, for in the words of Jacobi, "The criminal can not be considered an entity, but as a being possessed of characteristics as various as those of other types of men;" neither would I go so far as Rondeau when he states that "all assassins are patients as are all other criminals." I do not believe that all criminals are diseased in the common acceptation of the term, nor is all crime the result of such disease.

Many criminals are diseased and present anomalies of structure as the cause of crime; there are however criminals who are so from environment, and from the inhumanity heaped upon them by men. There are also criminals of circumstance or accident. Neither do I believe that the rogue can be told from the honest man by the shape of his head alone, or by his physiognomy, or the deformity of his jaws, ears, nose, or lips, or by any other one of the numerous anomalies we find in all types of mankind, and especially in the types representing the lower strata of society, neither have we as yet the data representing the normal type of man, with which to compare the abnormal.<sup>1</sup> When we have we can make more positive statements. It is only by the sum total that an exact estimate can be made that is by a careful consideration of all the anomalous conditions which are grouped in and about the criminal, physically, psychically and socially, and a balance struck between abnormal tendency and inhibitory power that a correct conclusion can be reached. It is the preponderance of tendency which must determine the character of the individual. There is however abundant evidence and well established data to show that crime is largely the natural outcome of disease in the perpetrator, and that by comparison with other men, the criminal class shows a preponderance of anomalous conditions, as for instance, in one of Lombroso's tables of the measurements of the skull we find "that men with normal skulls were three times as numerous among soldiers as among criminals. Of men with a noteworthy number of anomalies occurring together, out of 711 soldiers there are only three or four, there were three times as many amongst criminals as amongst soldiers, and there was not one soldier of the 711 who showed an extraordinary number, say five or more," and the same is true of physiognomic, psychologic, and physiologic anomalies amongst criminals.

As a rule special anomalies do not necessarily indicate special tendencies to certain crimes, but as stated in my paper, "Shall Insane Criminals be Imprisoned or Put to Death?"<sup>2</sup> in the examination of several thousand criminals, I have been lead to believe that, as a rule, when in the inherent criminal the right

side of the cranium, that is, indicating the right hemisphere of the brain in excessive development over the left, especially where there is a marked fullness over the paracentral lobe, the possessor's impulses lead toward homicide. I have repeatedly been able to place my hand upon this part of the head of criminals, and designate their crimes to be either assault or homicide without any previous knowledge of their history or themselves.

More recent observations have substantiated the above, especially the last criminal executed at Clinton Prison for an unusually unprovoked and brutal murder, the right side of the brain weighing more than the left.

"To the student of criminal anthropology, however, every characteristic in the criminal's natural history has an anthropologic, physiologic and psychologic value in itself, and must be a technical study," that he may arrive at a correct conclusion as a whole; therefore it is not altogether from apparent anomalous conditions alone that he would assume that the man presented a criminal type, or was criminally diseased, for crime is often due to intercurrent disease; especially to chronic diseases of the heart, meningitis, tuberculous disease, and syphilis; criminals are especially prone to diseases of the heart. Out of 2,011 men examined by myself in a general way on admission into prison, 239 had gross heart lesions, and many more obscure and less important ones. I should estimate that 25 per cent. of all criminals would show disease of the heart or of the great blood vessels. When we consider the relation of the heart to the circulation of the blood in the brain, we shall understand how a diseased heart can produce brain disturbance. Meningitis is also a prolific cause of crime, especially those of assault and homicide; this is particularly noticeable in the latter. It is not necessary for me to refer to the maniacal tendency due to inflammation of the meninges. Any one who has conducted a patient through the several stages of a meningitis, knows well the effect of the disease upon the mental condition. The result of meningitis is often a thickened patch, a softened area, or a circumscribed adhesion, any one of which is capable of driving the unhappy possessor to the most fiendish acts of violence; as the spur to the horse, it urges on the diabolical impulse. In autopsies upon criminals who had committed assaults or homicides, it is very seldom, if ever, that some such thickened patch or atrophic area has not been discovered. In my last case the adhesions were extensive. M. Dally, from a twenty years' experience, says that "all criminals who have been subjected to autopsy after execution gave evidence of cerebral injury, often undiscovered prior to autopsy." From my own experience I believe this injury is usually the result of some form of meningeal inflammation. Syphilis is well known to cause grave neurosis, and among criminals a very large percentage are syphilitic. The effects of syphilis upon the brain, either in the deposit of gummatous tumors, or in the production of degeneracy of brain tissues, is a prolific cause for mental disorders, especially of a temporary nature. I have seen a number of criminals who were, no doubt so, from the effect of syphilis, or its injudicious treatment. Tuberculosis is also a prime factor in the problem of crime. Many a man is a criminal because of the presence of tubercular toxins circulating in his brain, or to the poverty which this inability to earn his livelihood brings him. Almost every

<sup>1</sup> It is encouraging to know that there is a decided movement in the endeavor to establish a normal structural gauge for men, by the use of instruments and technical observation.

<sup>2</sup> Referred to later on.

physician is familiar with what is called the insanity of phthisis. Several other diseases are distinct causes for crime, especially those connected with the genito-urinary organs.

A large amount of data might be offered which would go to establish the fact that a large proportion of crime is the direct and natural outcome of some form of disease. I shall not enter into detailed minutiae or technicalities; neither shall I weary you with an array of craniometric figures and anthropologic data, for such information is best found in the works of Benedict, Lombroso, Lacassagne, Ferri, Ferrero, Garofalo and Dugdale, but simply attempt in a general way to institute a discussion of the relation of the physician to the criminal problem. I shall also purposely avoid the sociologic aspect only in so far as is necessary to define this relation.

If it be conceded that crime is the result of disease we shall have a conception of the criminal, which at once changes the whole application of the principle of treatment, revolutionizes sociology and annihilates many of the more primitive methods of the administration of so-called justice. Surely all efforts should be directed not toward inflicting upon an already unfortunate individual still greater misfortune, but in assisting him to overcome his infirmity. Now if this was true of all criminals, and if the question of degree did not enter so largely into the problem, the whole matter would be simplified; there are, however, questions of degree and questions as to what proportion of crime is due to disease, recognizable and estimatable. Herein lies the opportunity for the exercise of large common sense, and in the consideration and treatment of the whole subject, let us be guided by it.

Much confusion arises from false notions as to what the criminal is. Too often the criminal is considered an abstract quantity, as if belonging to a different order of beings: such is not the case however, they are men and women, creatures of hope, of longing, and of fear. Our ideas of the criminal should not lead us to think that the mere fact of putting a man behind the bars, and habituating him in stripes, at once assigns him to a different species, for it will be found that the criminal is much like other men, amenable to treatment and improvement. The distinction which criminologists would make in the theory that the criminal is of degenerate type, does not apply to the incarcerated criminal alone, but also applies to millions who have never seen the inside of a court of justice, or felt the dampness of a prison cell. There is no distinction from a psychologic or physical standpoint between the incarcerated and the unpunished criminal, other than the results consequent upon his environment.

It is because the conditions which enter into the criminal make up that lead to the commission of crime are not better understood, and the naturally fallacious conception as to what the positive school of criminology advocates in the scientific treatment of crime, that efforts looking toward the improvement of our methods of treating the criminal are so fruitless. The positive school of criminology does not desire to divorce the criminal from his responsibility to the law, or mitigate the punishment of crime, which is its inevitable auxiliary; it proposes to punish crime, not, however, in a retaliatory or vengeful way, but, in so far as is possible, use its punishment as a means of restoring the offender to his former recti-

tude before society and the law, recognizing "that crime is not always of the free will, but rather a natural phenomenon which can only disappear when its natural factors are eliminated." It seeks rather to adapt measures to conditions rather than attempting to make conditions fit measures, and recommends a plan of treatment based upon the classification of the criminal resting upon scientific anthropologic data. Equally fallacious notions are entertained as to what is the part of criminal anthropology in the scientific treatment of the criminal. The modern criminologist does not seek to base conclusions upon anthropologic data alone, but as Ferri puts it: "All that he seeks of anthropology is this—Is the criminal, and in what respect, a normal or an abnormal man? And if he is abnormal, is it congenital or contracted, capable or incapable of rectification?" This is all, but sufficient to enable the criminologist to come to positive conclusions covering the measures that society can take to protect itself against crime. This then is the summing up of the whole matter: 1. A correct and efficient treatment must rest, as in all other departments of human affairs, upon the proper classification as a primary and essential step to proper observation. 2. That such classification to be of value must rest upon anthropologic data. 3. Inasmuch as anthropology is scientific and positively medical, the essential work of classification naturally falls within the physician's province, and can alone be performed by him.

Not only is the object of classification to admit of a more intelligent study of the criminal, but it is through such classification alone that proper treatment can be administered.

The classification of the criminal also predisposes the necessity of proper classification and grading of penal institutions, so that when the criminal has been assigned to his class by the courts, he can receive the treatment best suited to his individual requirements; the insane or weak minded criminal should be sentenced to a hospital for the care of the insane; the born or habitual to an institution specially calculated to care for confirmed and incorrigible criminals; criminals of passion and occasion, to short term institutions where they could receive treatment looking to their reform. To accomplish this, all of these institutions should be graded to facilitate their special study and treatment. The criminal having in him the possibilities of reform should have opportunity for such reform. The confirmed and hopeless criminal should be excluded from society permanently. This phase of the criminal's treatment is more explicitly treated of in my pamphlet published in November, 1895, "The State and the Criminal."

Having been properly graded, every institution devoted to the care of the criminal should be provided with a physician specially qualified not only for the proper care and treatment of the ordinary ills of the criminal, but abundantly able to conduct a proper study of the criminal based upon anthropologic data and criminologic factors. Not only will such efficiency ensure proper grading and intelligent treatment of the criminal, but it would furnish to the science of criminology valuable data upon which to base still further conclusions. The first step in the classification is the appointment to every criminal court of a competent physician to assist the court in determining expert questions relative to the criminal's physical and psychic condition at the time of trial.

The physician in this work of classification should

bring to his aid all instruments of precision necessary to the proper measuring and estimating of the criminal from this standpoint such as the sphygmograph and craniometer.<sup>3</sup> This would only apply to cases not having been previously examined and recorded.

First in the proper classification of the criminal is his division into two great classes, curable and incurable; in so far as results are concerned, this covers the whole ground, but that such a division can be correctly made, necessitates the classification of the criminal with reference to his type, especially in the application of treatment to that numerous class of curable criminals. I have therefore adopted as a most useful classification that of Ferri, which divided the criminal into five classes, to wit: 1. The insane criminal; 2. The born criminal; 3. The habitual criminal. 4. The occasional criminal; 5. The criminal of passion.

It will be found that this classification meets the largest requirements possible under our present knowledge, but unmixed types of criminals are unknown and criminals can not be precisely classed under certain categories, for they frequently exhibit mixed propensities, and merge from one type into another. And in one some of the characteristics of several types may be blended. This classification, however, is a practical one and based upon sound observation.

*The Insane Criminal.*—There can be no scientific distinction made between the criminally insane and the insane criminal. The distinction is only an associate one and refers to conviction. True criminal science knows no distinction between the incarcerated and the criminal at large. To him the abnormal condition which controls a criminal act, constitutes the criminal identity. The courts have shown their utter inability to differentiate between the insane criminal and the ordinary. If a man has within him a tendency sufficiently strong to cause him to commit offences against person or property, he is a criminal, and if such depends upon an abnormal mental condition, he is an insane criminal; the only distinction necessary to make is in a penologic sense, and that is the distinction between the insane convict and the insane criminal. The question turns upon the point of insanity related to responsibility under the law. To be able to distinguish between the born criminal with abnormalities of structure and psychic disturbances, and the insane criminal, is sometimes a difficult thing to do, and I can not agree with those who deem it an easy matter to decide, so intimately mixed are the inherent tendencies and anomalous conditions present in the two types; so frequently the same conditions are manifested in both that it is sometimes very difficult but not necessarily impossible.

Garofalo's distinction is a good one, and is applicable to a large number of cases. He makes the distinction, "with the insane criminals, that in the act itself lies the satisfaction, not the object, while with criminals the act is only a means to an end." To the former crime is a pleasure, to the latter a paying business necessitating, it may be, diagreeable acts.

Criminals of unsound mind can not all be classed in the same category if we are to study them intelligently; indeed, it is difficult to make a classification which is always distinctive.

For my own convenience I subdivide insane criminals into five classes:

1. The paranoiac, who are persons exhibiting self exaltation, systematized progressive delusions, writers of insane political documents, and with tendencies toward political homicides which are usually consistent with their delusions. Guiteau and Prendergast are good examples of this class.

2. The psychic epileptic. A class not numerous and who commit the unexplainable murders. This class of criminals commit outrageous murders during epileptic seizure, and which seems utterly inconsistent with the circumstances and the perpetrator, and can not be judged by the ordinary psychology of criminals. (Ferri.)

3. The phrenasthenic or psychopathic criminal, who is one of irresistible impulse, feebleness of will, and with morbid tendencies to private murder. This class of criminals commit atrocious crimes, apparently without motive and purely from the force of impulse, or from the satisfaction of the criminal act itself. Good examples of this class are Jack the Ripper and Mrs. Halliday.

4. The morally insane or reasoning phrenasthenic. The only difference between the morally insane or reasoning phrenasthenic is the absence of delusions, and their perversions are of the sentiments and affections. (Regis.) "They represent a small class and are the individuals who apparently with full reason and judgment commit themselves in an unconscious and frequently paroxysmal manner to indulge in errors of conduct and immoral acts which are really pathologic, and although apparently less insane they are more profoundly degenerate than the delusion cases, and have a more marked degree of mental infirmity and imbecility."

The fifth class of insane criminals "consists of a large body of persons tainted by a common and clinic form of mental alienation, all of whom are apt to become criminal. This class of insane criminal are sometimes identical, and sometimes opposed to the born and occasional criminal." (Ferri.) This class commit various crimes under insane impulses and are commonly degenerates. It is seldom that a criminal of this class commits an atrocious crime unless under an impulse of passion.

These classifications are more a matter of convenience and should not be arbitrary; practically, the whole importance of the determination of the criminal insanity or sanity devolves upon the question of responsibility, and classification is only useful in arriving at correct conclusions as to the individual's responsibility under the law.

*The Born Criminal.*—The born or instinctive criminal is one who most frequently presents anomalies of organization and psychic aberration; they are criminals the same as other men are mechanics or artizans, and look upon the penalties of crime as the natural risk incidental to the business; who do not regard a crime from its moral aspects, but simply from the risks attendant upon its execution. The born criminal as a rule is deficient in both moral and physical sensibility. This criminal insensibility is manifested in his perfect inability to see the evil side of a criminal act, and to forecast its effect upon himself as a moral entity; also in his indifference to consequences and to feelings of remorse. He plans and executes with the whole moral code left out, only as it is used to escape the penalty which may deprive him of the exercise of his craft.

The lack of physical sensibility is often marked.

<sup>3</sup> The time will no doubt shortly come when hypnotic suggestion and the use of special instruments for the measurement of brain impulses, as related to physical conditions, will be added to the physician's armamentarium.

My attention was first called to it particularly while doing operations upon this class of men, they exhibiting no evidence of pain even though the operation might be painful and to the normal person excruciating. One man attempted to castrate himself and when discovered had succeeded in exposing the testicle, having opened the scrotum throughout, and was about to cut the cord. This same man under a previous operation for ligation of the radial artery had shown almost perfect insensibility to pain. Another case was that of a man about 30 years of age, in good health, classed as an ordinary convict, quite inoffensive, but who was drawn into an altercation with a fellow workman in the repair shop, and who in a fit of rage walked deliberately across the shop to a small circular saw, threw on the belt, and without hesitancy placed his forearm upon the carriage and sawed it completely off just below the elbow joint. He seemed perfectly indifferent to the whole affair and to suffer no pain. He was discharged from prison, was again incarcerated, is now serving a second term and is still considered an ordinary convict. Numbers burn themselves in a most horrible manner to get rid of doing a moderate task, cut off their fingers and mutilate and injure themselves in different ways to carry a point, not because they could endure pain heroically, but simply because they had learned that these things did not hurt them overmuch. This insensibility to pain tends to rapid healing of their wounds. There is, however, one erotic type of born criminal who is over-sensitive to all sorts of pain and suffers exaggeratedly from the slightest injury. This moral and physical insensibility at once places the possessor in a low order of organization and one largely incapable of reformation or improvement. From this class will always come the major portion of incorrigibles.

*The Occasional Criminal.*—The occasional criminal presents rarely marked anomalies of structure such as characterize the born criminal. This type are more criminals from environment and circumstances, and do not present those anomalous conditions that bring them properly within the province of a medical study; they are therefore best left to the sociologist, only in so far as individual cases present psychic and physical diseases requiring medical treatment.

*The Criminal of Passion.*—The criminal of passion is one of irresistible impulses, who under the stress of uncontrollable passion commits crime of which there has been no premeditation, and for which he suffers the keenest remorse. "He is usually strong enough to resist ordinary temptations, but does not resist psychologic storms which are sometimes actually irresistible." They are of highly neurotic type, and their study is of interest and consequence to the physician in that they approximate criminals of unsound mind, and it is often a question to determine as to the sanity of their acts. They are not criminals in the true sense, but rather offenders, victims of their own impulses.

We come now to consider the physician's relation to the criminal as regards his treatment. The complete study and treatment of the criminal must ever be largely a sociologic one. As has been said by Lacassagne: "The criminal is a microbe inseparable from his culture broth, the social surrounding." And gradually but surely the purely anthropologic study of the criminal has given place to a plainly more sociologic one based upon it.

The treatment of acquired and intercurrent disease of the criminal falls almost entirely within the field of labor of the physician to penal institutions, and should embrace in its operations all of the medical, surgical, mechanical and therapeutic means at the disposal of the physician. In the treatment of heart lesions so numerous among criminals, both gymnastic exercise and proper medicaments should be used.

For syphilis, constant specific medicaments and operative procedures should be used, and the same in meningeal lesions. Tuberculosis: rigid isolation, with the destruction of the bacilli by every modern means, and climatic influence should be a part of the treatment. The various manifestations of psychic disorders and abnormalities should receive generous treatment by means of spray baths, surgical shock and electricity. At Clinton Prison, New York, all these therapeutic means are in active operation with beneficial and successful results. Aside from the treatment of the physical ills mentioned, it is with the insane, the born and weak-minded criminal that the physician will have the most to do in the treatment of psychic disorders and the development in him of the power to control brain impulses.

The treatment of the insane criminal falls entirely within the sphere of the State Hospital for the Insane. The chief office of the physician with reference to the insane criminal is his classification and isolation. This function as now exercised is chiefly directed toward the examination of the criminal when accused of crime, and is a medico-legal one, and one which is not to the credit of our profession, which I set forth in a paper read before the Medical Society of the State of New York in February, 1895: "Shall Insane Criminals be Imprisoned or Put to Death?"

I am pleased to be able to state that there is a good prospect of remedial legislation in my own State regarding the exhibition of medical expert testimony in all criminal trials.

It is not, however, so important to the protection of society that the insane criminal receive just and equitable treatment in courts of justice, as it is that he be apprehended before he is able to accomplish the execution of his delusional impulses. It is the apprehension and detention alone that can protect society from their depredations. Had Guiteau and Prendergast been apprehended, both Garfield and Mayor Harrison might still have been alive.

We should urge the passage of such laws as would tend to place some competent medical officer in every community as having the right of surveillance with reference to this type of mankind.

In the treatment of the born and habitual criminal, the first object should be to increase inhibitory power. The will may be said to be the gateway of the mind, and through its narrow portals pass impulses for good or evil, wise or foolish, and it is the exercise of this faculty that must control the tide of psychic impulses that seek to find passage to the outer world. Since inhibitory power is the essential factor, the cultivation and strengthening of this power should be one of the chief objects of treatment in the weak-minded and degenerate criminal, the exercise of certain brain functions over and over again constitute a habit of action which becomes routine and natural. If the will is to be strengthened and habit broken, new tracks of association fibers must be brought into play, dormant brain cells stimulated into activity and the whole current of thought and cerebration revolution-

ized. This can only be accomplished by some sudden shock, either physical or mental.

It is a well-known physiologic law that by severe mechanic shock we can suspend the function of cell groups, partially or entirely. It was to this principle of shock that were due many beneficent effects from the use of the more primitive forms of physical punishment in corrective institutions. It is a well-recognized fact by penologists that the shock attendant upon corporeal punishment has often resulted in the cure of certain psychoses. Many a man has been converted from an intractable crank on the border line of insanity into a tractable and useful one.

I find this view is substantiated by the figures relative to the commitment of insane convicts to the State Hospital for Insane convicts, which, prior to the abolition of corporeal punishment in the prisons of the State of New York showed .00874 per cent. and since its abolition up to the present year .01764 per cent., or more than double the former percentage. While these figures can not be relied on as alone affected by this change, they are sufficiently indicative of the relation existing between the two, since apparently the contributing circumstances would rather tend to lessen the number of commitments than to increase them. I am not using these figures for the advocacy of corporeal punishment, but simply to show the influence of shock in preventing mental disease. In the application of all the forms of shock the effects are produced by the pedagogic impression made upon the brain, which in the class of criminals under consideration is always weak and incompetent, and whose brain cells respond more readily to stimuli applied through physical sensation.

In a paper read before the Medical Society of the State of New York upon craniotomy in idiocy, in January, 1895, Dr. Charles L. Dana attributes the benefits derived from operations upon the skull for this condition as due chiefly to what he terms "Surgico-pedagogic influences." My own experience has substantiated this view with reference to weak-minded and degenerate criminals. My attention was first called to this in observing that in certain cases where criminals had been severely handled in fights, and where the shock was considerable, and especially when associated with extensive scalp wounds, that these men usually became more tractable afterward and evinced marked changes in many ways during the remainder of their incarceration.

In several of these cases there was an almost complete turn about in the disposition and psychic condition. This led me to investigate, and I found that by freely cutting through the scalp down to the bone, and raising the periosteum, still greater improvement followed. I have now begun a series of operations upon neurasthenics and weak-minded criminals. April 1, of this year I operated upon a young man, aged 22 years, serving a first term in State prison. Operation for relief of neurasthenia and excessive masturbation. Patient was extremely nervous, sleepless, despondent and apparently becoming demented. The hair was closely shaven, and under antiseptic precautions the operation was performed as follows: Two horse-shoe incisions were made five inches in length, one on the right and one on the left side of head, one and one-half inches from the median line at the apex of the cranial arch. The periosteum was cut cleanly through, and separated from the bone for a distance of about one inch all round the incision;

grooves were then cut in the bone, but no bone removed; the wound was packed with iodoform gauze and dressed ordinarily. The wounds were then packed loosely until they healed by granulation. No sutures were put in. The effects of this operation were like magic, the young man improved in every particular, slept well; appetite improved; figure became erect, took on flesh rapidly; circulation improved, and his whole aspect was very much more vigorous. The habit of masturbation was entirely relieved. I show you photographs of the young man before, and fifteen days after the operation. Prior to this I had circumcised him, and used all other means at my disposal to effect the cure of his habit with negative results. (This operation is also beneficial in meningeal inflammations, and also with thickened and adherent scalp areas.) This principle has for a long time been recognized in isolated and incidental ways, but never to my knowledge has it been understood thoroughly or applied in any systematic manner.

Here is a wide field for study and experiment, and I believe that much can be accomplished in the treat-

Before operation.

After operation.

J. R., AGED 22.

ment of this class of criminals by the application of some form of shock. I am contemplating the construction of an electrical apparatus, which will produce the maximum amount of shock and physical impression with a minimum risk of injury. Any means by which powerful influences can be brought to bear upon the subject will offer the best and most favorable opportunity for improving the patients.

The treatment of the occasional criminal, and the criminal of passion does not require special enumeration.

The application of scientific principles of classification and treatment of the criminal considered from a sociologic standpoint, is one fraught with difficulty and we need not flatter ourselves that apparent good results will come quickly or that the way is easy; the duty is plain however and we must walk therein. It has ceased to be a matter of choice and we must be equal to the responsibilities which this new field of action enforces. Already in the half century of its life, the science of criminal anthropology has recorded brilliant achieve-

ments in the accumulation of invaluable data and the elucidation of many valuable truths. These achievements have come largely through the labor of medical men; therefore the soundness and efficacy of this relation of physician to the scientific treatment of the criminal can not be doubted, nor that it falls properly within the medical province, for if we interpret aright the significance of the astonishing developments of our time and note correctly the movement of modern medical thought and action, we shall come quickly to the conclusion that the field of medical work and practice is rapidly widening and that its mission can no longer be so entirely restricted to the narrow limits of the treatment and cure of disease, but more to its diagnosis and prevention, and its future accomplishments must comprehend much more that appertains to the safety and welfare of the people. Through the gateway of laboratory work in our own profession, and the investigations of the correlative sciences, a great flood of light has come; old systems are breaking up, relations are changing, new adjustments are in order, the X rays alone is likely to revolutionize the whole rationale of diagnostic, prognostic and operative procedure. He who shapes his course by the experience of the past alone will soon find himself deprived of the needful appreciation of an enlightened public. The profession must take to itself larger spheres of action, must extend its powers, must put itself in harmony with new conditions; its relation to society and the community at large must be better understood. The physician is to become a mentor to the people, and his efforts like those of his time must look to the improvement of mankind, not in the concoction of monstrous formulas, or in the combination of nauseous decoctions, but in his knowledge of the causation and the exercise of his powers in the prevention of disease and the general guardianship of the home, the individual and the public. So far as this function has been exercised it has accomplished much good and has been of incalculable benefit to society at large; in the protection of our shores from pestilence, our municipalities from infectious diseases and the securing of abundant opportunities of healthful living the labors of our profession have been untiring, fruitful and reassuring.

The opening of this new field of criminal anthropology and sociology, embracing the type study of man, and the resolving of society into its respective classes offers equal opportunity for the exercise of high and noble powers.

It is only through the exercise of such a prerogative that the physician can sustain the position in which the evolutionary processes of scientific progress have allotted to him, and he will only rise equal to the dignity of this requisition when he shall have assumed the rôle of a competent student of the bio-psychic principles and elements which enter into the different types of criminal man, and society be enabled to protect itself against crime; a protection too long and entirely entrusted to the offices of the penal code.

#### DISCUSSION ON PAPERS OF DRS. CORR AND RANSOM.

Dr. D. R. BROWER—In Illinois, our State Society and our various local societies have, during the past two or three years, had this question before them on various occasions, and what is true of the State of Illinois is true of many of the other States. The question of crime is not a legal question; it was until twenty-five or thirty, or possibly forty years ago, a purely legal question, and to-day in its practical application it is a purely legal question; but in reality it is a medico-legal ques-

tion; and, as a consequence of the utter failure of the law and the church to stay this criminal procession, we have the results, the vast, marvelous, overwhelming increase of crime. The only thing that can possibly stay this great increase is for the medical profession to step to the front and teach the intelligent laity that the care of the criminal is as much a medical as a legal question. There are some things that study of this question has satisfied me as being established: 1, the increase of crime; 2, we state as the cause of this increase of crime a vicious parentage, bad environment, alcoholism, a constant increase in the urban population and last, though not least, the unreasonable manner in which the laws are administered; 3, that the habitual criminal is an abnormal man, which is shown physically by asymmetry in cranial cerebral development and in physiognomy, as well as by anomalies, in physical sensibilities and in motor activities. One of these anomalies does not make a criminal man, but in the habitual criminal these abnormalities are present in a vastly greater amount than in any other person in the community. There are psychic abnormalities manifested by a moral sensibility. This is most manifest and almost universal; not limited to the moral criminals, but prevailing throughout the whole great class, leaving out the few who are classified under the occasional and passionate criminals. There is a lack of forethought with them; they live simply in to-day. And there is a low grade of intelligence, a prodigious amount of vanity, and an emotional instability. The practical part, upon which the laity must be intelligently educated, is what to do with them—how to treat them. The question is a medico-legal one, and the doctors must come to the assistance of the church and the law. The social and biologic condition of the person, and not the accident of crime, should determine the degree and kind of punishment. As our laws are administered to-day, if the theft is a trifling one, the punishment is but slight; if the amount taken is a large sum, the punishment is accordingly great. The reference is not to the criminal, but to his crime, whereas the crime is a mere incident, as the theft was \$5 because there was not \$5,000 to steal. The measures that are to counteract crime must be, not according to the crime itself, but to the condition of the criminal.

In my studies of this question in the institutions of my own State I found a woman who had been sentenced to our Bridewell thirty times. She should have been sentenced but once, and the county of Cook would have been saved the expense of twenty-nine arrests, trials and imprisonments, while the community round about her would have been saved a great deal of perplexity and considerable destruction of property. She had upon her, as plainly marked as any habitual criminal ever had, the physical and psychic stigmata of degeneration.

It is this unreasonable administration of our laws that has probably more to do than anything else with this marked increase in crime. I would like very much, if it is practicable, to have attached to every court some person who is skilled in criminal anthropology who can aid the court in determining what the sentence shall be. The rule that has been adopted in some of the courts of Illinois so far as the reformatory institutions are concerned, has been that of indeterminate sentences, and consider this is a much better plan. If the indeterminate sentence should be applied to all criminals, and the investigation of the anthropologic condition of the criminal made in the institution to which he is consigned, vastly more beneficial results would follow than by his investigation during the trial.

It is by indeterminate sentences that I think the matter can best be settled. The only trouble in the State of Illinois, so far as the reformatories are concerned, is that the maximum limit is not enough in every instance. In the next place a very serious interference with the suppression of crime is placing the pardoning power in the hands of the governor. It should rather be placed in the hands of a commission skilled in the subject of criminal anthropology.

The plan of disposing of these criminals just before and during the trial is a mistake. These supposed criminals are sent to a common jail and the associations of that jail are vile, and the man who has not yet been declared a criminal by the law is there thrown into contact with confirmed criminals. This is very wrong. There should be established in every community detention places where there can be a separation and isolation of these criminals awaiting trials; and then, when the sentence comes, there should be three classes of institutions to which these people are consigned: A reform school for the juveniles; reformatories for the curables, and penitentiaries for the incurables.

Some of our laity think that this medical disturbance in the matter of crime is for the purpose of relieving criminals of the penalties of crime. Such is not the case. First to protect the community; first to see to it that these criminals, once arrested, should be kept in custody until they are cured; that is the most important point.

It is only through such societies as this, through medical men and women, that the laity can be educated up to a proper appreciation of this great question. We are going through now precisely what was gone through at the beginning of the century, or a little before, in the matter of insanity, when that was divorced from the custody of the church and the law.

We are to-day pupils in this work of reformation, and very soon the same results will be accomplished with reference to the care, treatment and the cure of these criminals—probably not to the same extent, but similar results will follow as have been seen in the care and the cure of insanity.

DR. JOHN PUNTON—There is no doubt that there is a great lack on the part of both the medical and the legal professions in failing to handle these cases properly. These changes which are proposed, however, would mean an entire subversion of the constitution of many of the States of the Union; in other words, the present status of the legal adjustments of crime would be undermined and that is a very large matter for the medical profession to undertake to do. I am in the main in favor of the reforms outlined, and just in proportion as we agitate this matter we are aiding not only the legal profession but also the community in which we live.

DR. CAMPBELL—That law and the church have failed to repress crime is well known; it is now proposed that we of the medical profession shall take hold of it. The alarming increase in crime is known to us. But I do not entertain any sanguine anticipations of the doctors doing much more than the church and the law have done, if so much. This great increase of crime can not be attributed to the causes that have been assigned to it, so far as I have heard here to-night. We have always had bad education, syphilis, alcohol, bad inheritance and bad environment. In my opinion this great increase of the criminal class is owing to the advance of our civilization; the increase in the species; the growing stress that has been brought to bear upon the means of gaining a livelihood. These forces are irresistible. They will continue, and crime as the result of them will continue; and if all these admirable suggestions are carried out, I doubt if 5 per cent. of the crime will be stopped.

DR. POWELL—I think the commission of experienced men would be a very desirable thing to have.

DR. QUINBY—If we study the results of imprisonment, we see the victim, instead of being benefited by punishment, made worse by it. This is due to the method and management of our criminal jurisprudence. A young man who was well disposed, whose environments were correct, whose education was proper, whose bringing up was right, but who became involved through alcoholism, was thrown among the class of hardened criminals when arrested, and from that hour, he was kept there six months for some slight offense, he has become a degenerate man. He told me that his barbarous treatment

during his confinement is what sent him downward. Now, could that man have been arrested and treated somewhere instead of being thrown into prison; if we could have institutions for treatment, not simply for imprisonment, the results would be different.

These are all abnormal cases. They are sick, and how do we treat them—as mentally and physically defective? No. Cruelly, inhumanely, putting them with criminals, into the charge oftentimes of men who are themselves brutes.

The criminal classes in this country are largely increasing, and something must be done to stop this increase. The church is not in a condition to do it, because these individuals are sick people, defective physically and mentally, the power of alcohol always having a tendency to destroy will power; hence, the physician is the proper man to give advice.

DR. BISHOP—We feel a little sensitive when the preacher and the public blame us about things, and we are in the same position exactly when we blame the church and the community. We are part of the church, or should be, we are part of the community, and as citizens we are responsible. There is a great deal of hypersensitiveness on the part of our good friends who believe that these criminals as a rule are defective. It seems to me that very often they are liars.

I think a slight change in the law would be of advantage; on the basis of sentencing to prison for a determinate period, and if at the end of that time they were not cured, and still unfit for freedom, to keep them in prison for an indefinite period until they showed that they were fit to be released.

It is an outrage to send men to prison and have them resort to all sort of crime that it is possible to do inside those walls, and then set them loose on the world at the end of the time for which they were sentenced. The mistake is that they are not made to feel that they can gain something by improving.

There is no question that men are morally deficient as they are mentally and physically lacking, and the proper place to treat them is in some school for development.

DR. CORR—The question is how to prevent crime, how to prevent the young person who starts out with a small degree of tendency from cultivating that tendency and from becoming a criminal. We must improve our society so that we do not have any of that class born. Dr. Ransom has classified crime very finely, but we want a classification which shall tell us how to prevent it. Now, if it be true that the conduct of people is guided and inhibited by the moral sense and that is a faculty of the human mind that is capable of cultivation, I ask you to formulate some plan by which this end can be accomplished.

## THE PSYCHOLOGY OF NARCOTISM.

Read in the Section on Neurology and Medical Jurisprudence at the Forty-seventh Annual Meeting of the American Medical Association, at Atlanta, Ga., May 5-8, 1896.

BY W. XAVIER SUDDUTH, A.M., M.D.

CHICAGO, ILL.

Nature intended that man should be a comfortable animal and enjoy to the full the fruits of his labor.

Man has ordered otherwise, and as a consequence in the receding days of the nineteenth century, when art and intellect have reached their highest development, we find man, born to be the favored creature of nature, laboring under self-imposed burdens of society, oftentimes heavier than he can bear. As a natural consequence of his pernicious environment he is frequently found seeking surcease from the pains of existence in self-immolation, temporary intoxication or suicide, the method adopted depending much upon his belief in a future state and his relation thereto.

What are some of the steps that have operated to bring about these deplorable conditions? They can not be laid to natural causes because there has

never been a time in the history of civilization when the actual needs of man were to be satisfied with as little expenditure of vital force as at present. The cause of the stress of the age must therefore be looked for, not in the physical, but in the psychic domain of man's nature, and it is to this phase of the question that I desire to call your attention to-day.

In that degree that man is able to perform the necessary duties of life by force of habit so does he lessen the labor of existence. The hardest work man has to do in this world is to think. Every psychosis has its neurosis. New experiences or acts are successfully mastered only by the expenditure of thought. The greater part of the absolutely necessary acts of existence are performed by rote rather than by thought. Thought labor requires nerve action, just as surely as locomotion incurs muscular activity; and while it is true that there is a marked physical difference between mental and muscular action, yet physiologically considered they both express a condition of catabolism that has to be met by metabolism. Ordinary cell wear is not necessarily painful. On the other hand, a certain degree of pleasurable exhilaration accompanies most necessary bodily functional activity. When, however, exercise is carried beyond a certain point, so as to become forced, it soon becomes painful. When weariness ensues as a consequence of functional activity, pleasure ceases and pain begins. Pain is the absence of pleasure according to our major premise laid down in the opening sentences of this paper, and if this be true, then its abolishment does not consist in self-immolation, but in a readjustment of our relation to our environment or its more or less complete reconstruction.

Pain and pleasure are not distinct physical conditions, no matter how intimately they may appear to be related, but mental states, and therefore require careful consideration to differentiate them. Pleasure and pain are often so closely connected that it is with difficulty that they can be separated. Not only this but the terminology used to express the two conditions is inextricably confused. Many people are said to "cry for joy." In fact, so narrow is the division line between the two conditions that the scale turns upon the mental state of the individual at the time of experiencing any particular sensation, as to whether he suffer pain or feel pleasure. The close relationship between them is thus shown by a case in which the one merges into other. Continuous stimulation that at first gives pleasure, in time becomes painful. This leads to the conclusion that only a certain amount of pleasure is bearable by human nature, if furnished without intermission. The system may be surfeited by pleasure as well as borne down by pain. But what is it that suffers? Surely not the physical that alone experiences wear. No! Pleasure and pain are not conditions *per se*, but mental perceptions of sensations experienced at the time or revived from some previous experience, through thought images brought before the mind by association of ideas. Then again, not only does pleasure easily merge into pain but the very absence of pain, to him who has suffered, is a pleasure. The fullest appreciation of the pleasures of existence are to be had by comparison with painful experiences happily passed. While many of our joys and sorrows are the result of purely physical sensations, yet a considerable proportion of our pleasures and pains are intimately associated with our emotions and are distinctly dependent upon the peculiar physi-

cal condition in which the experience finds us. Many of the acutest pains of existence are those of restriction. Man longs to be free, to cast off the burdens of care, for even a short space of time, to secure a respite from the pains of existence—to lose himself; hence his resort to the use of narcotics. Sad delusion! The greatest slave of all is he who seeks his freedom in these deceptive agents. Nine out of ten narcomaniaes will tell you the same story, when asked as to how the habit was formed. "I took it to relieve pain," "to drive dull care away," "to get a little rest," and thus the chains of habit were forged.

Dr. Carpenter says, "that our nervous system grows to the modes in which it has been exercised." That is only another way of putting the fact that we develop along the lines of least resistance, according to the bent of our special inclinations, limited and modified by our peculiar environment. Habits are more easily formed in youth than later in life, by reason of the fact that the organism is in the formative stage and the inhibitive feature of the will is less developed than it is later on. If a young man or woman reaches the age of twenty without having acquired any vicious habits of thought, action or appetite, ten to one they will go through life free from contamination. Nevertheless, physical states of weakness later in life seem to unman the individual and reestablish, to a greater or less extent, the conditions prevailing in adolescence. Drugs that may be given during the crisis of a disease with impunity, if continued during convalescence are apt to give rise to drug habits, hence the necessity of discontinuing the use of stimulants and narcotics during this stage of the disease and depending upon a nutritious diet and natural remedies to bridge over this critical period when the will is weakened and the moral faculties seem to be more or less clouded.

Narcomaniaes may, for convenience of study, be divided into three classes:

1. Those who have acquired the habit through hereditary tendencies, and who find in the use of narcotics a physical pleasure.
2. Those who, though physically strong, yet are led into the habit by social customs as the result of environment.
3. Those who turn to narcotics for relief of the pains of existence.

The psychologic bearing of the several classes is essentially different when laboring under the spell of the drug. Members of the first class have, in most instances, the warning example of degenerate ancestors; yet so great is the demand of the system for sedation that they brave the dangers and public opinion with a brazen effrontery that is many times astonishing. They have no desire to reform and their course is continuously, progressively downward. With them there is no shadow of turning. They are wholly given over to evil ways and the sooner they end their days the better for themselves and mankind at large.

The second class, considerably larger than the first, much larger in some countries than others, suffers mostly from the direct effect of the drug because removed from the moral stigma under which other classes labor. While its members are seriously handicapped in the battle of life, yet they manage to preserve a tolerable existence, unless the particular narcotic used happens to be hasheesh or opium, and even against the latter the natives of India seem to hold a more or less charmed existence.

It is to the third class, however, that I desire to call special attention, because they are those who dwell among us: Our fathers, mothers, brothers, sisters and friends. Brought to their condition of enslavement, many times by circumstances over which they have no control, held accountable by a highly intellectual and moral civilization, they suffer, not only from the direct effect of the drug used, but from the goadings of an outraged moral nature. The members of this class, oftentimes forge their chains through years of petty indulgence in the use of the milder sedatives and narcotics. Their case then is one of slow growth and needs to be studied from that standpoint. A diseased condition of the will is established, in which the individual finds himself unable to stand out against what he knows to be sin against the physical body. It was not always so; there were times when, in the early history of the case, had he had the right kind of treatment, he could have broken the bonds of the growing habit with comparative ease. These diseased conditions of the will form most interesting psychologic studies and promise to throw much light upon the rationale of treatment. In the main, an entirely erroneous idea of the function of the will prevails. Most persons consider it as a direct motor force only, confusing it with volition, which is the act of the will, and thus overlook entirely its inhibitive aspect. In one sense the will may be said to be dual; but in any event it represents a state of the mind, and is, according to James, "a memory of past acts." Its parents are desire and feeling and its offspring are represented in such mental states as "I wish," "I will" and "I will not," which latter is many times synonymous with "I can not."

In order that feeling and desire may become motor impulses, they must be accompanied by a knowledge of the attainability of the object desired, otherwise a futile or even no effort is made to attain the object desired. We thus observe the difference between "I wish" and "I will" and note that faith is one of the principal attributes of a strong will. The inhibitive aspect of the will which enables its possessor to say no is largely a matter of education. Uncivilized man knows no master, save want, and when opportunity for indulgence offers, gives full reign to his unhallowed passions. The tendency of civilization is to teach the control of the passions through the limitations of environment. Man thus learns to inhibit his desires and hold in check his feelings through the inhibitory action of his will. He is thereby enabled to contain himself within the bounds of decorum and decency. It is by will power that man is an abstemious animal and when given over to indulgence he is simply evidencing the atavistic principle which so often crops out during the evolutionary process. Civilization teaches man to "wish" and to "wait" for many things in this life, upheld by the hope of their fulfillment in some future existence, if not in this, and also that by restraining his passions and appetite he is serving his own best good.

Continued indulgence in the use of narcotics finally creates an appetite. Like a bad debtor, they promise much and pay little. The system continually cries out for relief that comes not. This irresistible craving is intensified by moral or physical restraint and the habitué is urged on by his vitiated appetite to greater and greater indulgence when opportunity offers. No feat is considered too dangerous to be attempted to secure the coveted dram; no human tie

too sacred to prevent the fulfillment of his unhallowed desire, even hope of future salvation is freely given up for the cup that cheereth but to damn. The intensity of the passion for narcotics when once the habit has taken hold upon its victim, points only too plainly to something essentially different from a mere physical appetite. Hunger for food, even unto starvation, shows no comparison in its suffering to the agony of the alcoholic inebriate or the opium fiend when deprived of his wanted potion. Everything points to a diseased mental state beyond the power of any drug to reach it as an *antidote*. While drugs play an important role as alteratives and tonics in the treatment of inebriety yet there is not a "cure" in existence, that has any efficacy, that does not base its permanency upon the "suggestive" methods employed in effecting the cure. While it is true that some depend almost entirely upon "drug suggestion" yet the cures that promise most in permanency of results have incorporated in them a system of psycho-physics, using the term medically, that is successful in proportion as it is scientific and comprehensive.

Inebriety, in all its forms, is beyond question a neurosis and permanency of cure depends upon establishing an absolutely altered mental state, together with the maintenance of a healthy environment until such time as the individual has fully regained possession of his will, and developed sufficient moral stamina to withstand the temptations of the open saloon and social life.

100 State Street.

### FEIGNED INSANITY; REPORT OF THREE CASES.

Read in the Section on Neurology and Medical Jurisprudence, at the Forty-seventh Annual Meeting of the American Medical Association, at Atlanta, Ga., May 5-8, 1896.

BY WILLIAM FRANCIS DREWRY, M.D.

FIRST ASSISTANT PHYSICIAN CENTRAL STATE HOSPITAL, ETC.  
PETERSBURG, VA.

The simulation of insanity is not an innovation peculiar to modern day schemers, though it is now frequently resorted to by designing criminals.

In the sacred writings is recorded that the Shepherd King of Israel "changed his behavior and feigned himself mad and scabbled on the doors of the gate, and let his spittle fall down upon his beard," because he was "sore afraid of the king of Gath."

In order to escape the Trojan war, Ulysses feigned insanity by plowing the sea-shore and sowing salt instead of corn. And Lucius Junius Brutus, it is said, played the imbecile for a purpose.

To detect simulation and to establish the requisite proof of it, have at all times been matters of more or less difficulty. Casper met with many cases of the sort and appreciated the difficulties which they presented. Says Hammond: "No one, no matter how skillful an alienist he may be, is beyond the point of being imposed upon for a short time by persons assuming to have certain forms of mental derangement." Snell remarks that if a simulator preserves a complete passiveness and an obstinate silence, it is not impossible that insanity may be so perfectly simulated that detection may not be accomplished. Conolly Norman regards the question of simulation of insanity as "one of the most difficult with which alienists have to deal, one requiring much experience, acumen and sagacity, if a satisfactory decision is to be arrived at."

In his work on "Sanity and Insanity," Mercier says: "There is no form of insanity that may not be simulated by a case of drunkenness; and when it is not known, from other sources of information, that these manifestations are due to drink, no expert in the world, however skillful, could distinguish between the insanity that is due to alcoholic poisoning, and the insanity that is due to other causes."

Tardien and others think, however, that nothing is more difficult to counterfeit than mental disease and that the attempt to deceive may be easily discovered by a careful observer. Conolly asserts that he can "hardly imagine a case which would be proof against an efficient system of observation."

When we remember that, besides the fact that scores of criminals resort to the insanity dodge to escape merited punishment, the truly insane sometimes simulate insanity, that simulation itself may be an indication of mental alienation, and that occasionally there is a tendency of feigned insanity after long duration to become real insanity, the question of accurate diagnosis may not always be unattended with uncertainty and embarrassment. To an experienced alienist there will of course seldom be any great difficulty in arriving at a correct conclusion, but to one with more or less limited knowledge of the various manifestations of mental diseases, a clever imposter, with the faculty of imitation well developed, would appear somewhat in the nature of a psychic problem.

At all events, before giving a positive answer to so delicate and important a question as whether one is insane and therefore entitled to all possible humane consideration, or sane, and consequently responsible for his illegal acts, a physician should study methodically and scientifically the suspected case, keeping his conscience pure and undefiled under all circumstances. "His opinion," says an eminent authority, "should be founded upon the conception of pure knowledge, based upon observation and induction."

The question of disease—that and nothing more—is the one for the physician to determine. Is the person whose legal or testamentary responsibility is in doubt, *insane*—is his mind affected by *disease*? That is the problem the solution of which devolves upon the physician. Says Bucknill: "The element of disease in abnormal conditions of mind is the touchstone of irresponsibility and the detection of its existence or non-existence is the peculiar and oftentimes the difficult task of the psychologist."

So, view the matter in any way you will, it can be only a question of diagnosis.

*Case 1.*—In February, 1895, Isaiah P. was indicted on the charge of house-breaking and larceny. While in jail awaiting his trial in the hustings court of a Virginia city, he suddenly began acting so strangely that doubt was entertained regarding his mental condition. Upon being arraigned in court his behavior was so utterly at variance with that of an ordinary sane man, he was remanded to jail and the trial of his case postponed, so that his mental condition might be investigated.

The writer was appointed by the judge to ascertain whether or not the prisoner was insane. Whereupon I visited him several times, dealt with him not in the rôle of a secret detective, but in that of an impartial physician, and as such proceeded systematically to inform myself as fully as possible of his history and symptoms.

*History and heredity.*—Isaiah was born in 1857, of

negro parentage. There was nothing of special interest connected with his early life. From childhood he was a bad, indolent fellow. Only two of his family were ever afflicted with any form of neurosis or of psychosis. His mother, at 65, was sent to an asylum in a state of senile dementia. A younger sister died of phthisis pulmonalis, complicated with melancholia, while in a hospital.

During a spree some ten years ago (1886, I think), Isaiah received a blow on the right side of his head which produced a depressed fracture, but under careful surgical treatment he made a complete recovery, the only visible result remaining being a slight depression in the cranium. On more than one occasion he was suspected of larceny, and finally, in 1888, was convicted and sentenced to five years in the State penitentiary.

It was claimed by his family that he had had, since the blow on the head, several epileptic fits and been at times "curious in his ways." But in the absence of corroborative evidence these statements were accepted with a degree of reserve.

*Appearance and symptoms.*—A careful physical examination revealed nothing of special pathologic import. His bodily condition was about normal.

He came into my presence with an air of exaggerated excitement, moved about restlessly, took no notice of his surroundings, looked wild and uneasy, talked incessantly and foolishly. The almost exclusive subject of his foolish, incoherent gibberish was "locusts." He talked about locusts most of the time, but when questioned he gave answers foreign to the subject of his apparent or assumed delusion, saying he did not understand what I meant. All questions were answered very slowly and hesitatingly. When I told him my business his incoherence and restlessness became intensified. When unobserved he became quiet and composed.

Odd sensations in his head were frequently complained of. He would put his hand to his head and say something was "scrambling about in here."

Memory and intelligence, to all appearances, were absolutely lost. Apparently he recalled nothing that had ever happened, nor did he remember any person or place he had ever seen. He could not or would not distinguish one piece of money from another, nor tell a man from a woman.

To every question he gave a negative or an absurd reply. For instance:

Question. Where were you born? Ans. Caught ninety-nine locusts to-day.

Ques. How do you feel to-day? Ans. Eat locusts with butter.

Ques. Let me see your tongue. Ans. Holds up his foot.

Ques. Did you sleep well last night? Ans. Tell him all right. Here they come.

Ques. Tell me about the locusts. Ans. Had bread and shucks for dinner.

Ques. But what of the locusts? Ans. I don't understand you.

Ques. How long has your mind been affected this way? Ans. Some say 49 years; I say 100.

Ques. Have you heard from home lately? Ans. Fell in river last night. The locusts are rolling down the mountains. Let them roll.

He slept well several hours every night, and frequently in day time after he had become very tired from constant exertion and excitement.

I took occasion to remark in an undertone to the jailor, that if the patient were to sing, become noisy at night, destructive to clothing, filthy in his habits, devoid of the sense of pain, my belief in his insanity would be confirmed. A few days later Isaiah had become so noisy and filthy at night that he had to be isolated. He had tried to be wakeful, but, negro-like, he soon fell asleep. His clothes were torn, shoes thrown away, coat reversed, etc. I thrust a needle into his flesh at various points, without making any perceptible impression. Said he did not feel any pain at all. A few minutes later, when a needle was suddenly stuck into his back, he forgot to be insensible to pain and consequently jumped some distance.

My notes show many and various evidences of Isaiah's clumsy effort to "play crazy," but the above is quite sufficient to prove beyond any doubt, *simulation*. I had no trouble in detecting the fraud.

For two months, in fact, until the day he was taken to the penitentiary to serve out a twenty-three years' sentence, he continued his efforts to deceive. Finally, however, he acknowledged the attempted fraud.

In my statement to the court and jury I gave, in substance, the following as the grounds of my opinion:

1. There was no prodromal stage of indisposition, malaise or depression preceding the sudden outbreak. The "attack" occurred in the midst of normal health. He had few symptoms of any form of insanity that might begin somewhat suddenly, viz.: transitory mania, epileptic mania, confusional insanity, acute hallucinatory insanity, alcoholic mania, none of which it is possible to counterfeit. Then, the fixedness of the form of delusion he tried to imitate would exclude any of the above types of insanity.

2. Sudden development of a fixed delusion regarding one particular subject is not consistent with the clinical history of any known form of insanity; for paranoia, monomania or delusional insanity, is of slow and gradual development and unattended with any special excitement, loss of intelligence, etc.

3. If he were trying to appear a paranoiac or monomaniac, he overlooked many essential points; for instance, when questioned regarding his delusion, he invariably gave an answer entirely foreign to the subject; and the peculiarity of expression which so strongly marks that class of cases, was entirely wanting; and, furthermore, there was no excitement or irritability of temper when contradicted.

4. Loss of memory, reason and intelligence would occur in dementia, but the quickness with which he carried out my suggestions regarding the "lacking symptoms" of insanity, to say nothing about his appearance and general shrewdness, would preclude any suspicion of mental decay.

5. Contrary to what is observed in acute mania and other forms of insanity, there was no sign of insomnia. The more intense his restlessness, the more profound the sleep which followed.

6. The hesitancy, extravagance and silliness with which he replied to simple questions; the absurd, disordered ideas which flowed slowly and thoughtfully would not be exhibited in the really insane, whose ideas form and flow rapidly, disconnectedly and are not devoid of sense.

7. There were no physical symptoms upon which to base a diagnosis of either functional or organic disease of the brain. The injury to the head had left no perceptible ill result, motor, sensory or mental.

8. The insanity of his mother being a psychosis of

old age, could have but little effect, if any, upon the offspring of her early life. But the fact that she was insane and that she had an insane and phthisical child might be considered, in connection with the possible effects of the blow on the head, sufficient grounds upon which a neurotic diathesis or nervous instability might be based. It is possible that in this case the head injury might have caused some moral deficiency.

9. The order of development and the assumed symptoms failed to conform to the complete clinical picture of any recognized type of mental disease.

10. The motive for feigning was not overlooked, though that was of secondary importance when compared with the history and symptoms of the case.

*Case 2.*—Another instance of a criminal trying to escape the stern edict of the law by pretending to be insane, has lately come under my personal observation. In this case, however, the ultimate purpose of the malingerer was accomplished.

Isaac H., a negro youth, had served a few months of an eighteen year sentence in the State prison, for murder. He assumed the rôle of a madman, and by taking advantage of the lax and crude method of adjudging one insane in Virginia, he succeeded in gaining admission to the insane asylum where no special arrangements are provided for the custody of insane criminals. Every possible precaution was exercised to prevent his escape; yet Isaac, after a short sojourn, very ingeniously gained his liberty and has never since been heard of. We had diagnosed the case correctly and were contemplating returning the prisoner to his legitimate abode. I have not time here to make an analysis of the case. Suffice it to say, he so far over-acted the part, and behaved so differently from any other case of acute mania—the form of insanity he was trying to counterfeit—the deception was too flagrant.

The history of the case, the clumsy, over-acted symptoms, the motive, were all carefully studied, and by a process of elimination no type of insanity was left to fit his case. In the words of the distinguished Dr. Chapin, of Philadelphia: "The method of arriving at a conclusion is, bring together all the features in the history and manifestations of the case and then decide whether the case corresponds to a type of insanity, which in all of its features could not be simulated except by a trained alienist. In this way a mistake will rarely be made."

*Case 3.*—Some years ago there was admitted into the Central Hospital a young colored girl, of intelligence above the average of her race, and with a physical formation well-nigh perfect. Her case had been diagnosed "epileptic insanity."

It was some time before I had an opportunity of seeing her "in a fit." From the post-epileptic condition I had serious doubt about the genuineness of the epilepsy. Eventually I saw her repeatedly in her "terrible attacks," as her family had designated the seizures.

She would cry out suddenly, then fall, snap her jaws together, make a noise like the bark of a dog, foam at the mouth and act most maniacally, etc. Then she would pass into a convulsive state, jerk violently, tear off all her clothes, assume the opisthotonos position, grind her teeth, strike and snap at everything in reach, and finally pass into a quiet sleep. These violent attacks would continue sometimes for an hour or two, after which the patient would become quiet and

composed, her only complaint being that she felt sore. Said she knew nothing of the attacks, when they came on or how they affected her, but expressed great mortification on account of her affliction.

I noticed that the fall was rather guarded, that she never bit her tongue or hurt herself in any way, that the sphincters were never relaxed, that the pupils were in every way normal, the iris not-insensible to light. It was evident that sensory perception existed. She became bathed in hot perspiration, and seemed to be well nigh exhausted.

The assumed tonic and clonic convulsions were by no means like those seen in real epilepsy. The post-epileptic condition she made no attempt to imitate.

The girl was carefully nursed for some time, but after watching her curious maneuvers a few times, I told her that she was feigning and that the next attack she had I should put her in a room and pay no attention to her whatever. My threat was promptly carried into execution, and the effect was all that could have been desired.

She was soon sent home, got married, though has never had any children, and has ever since remained free from that "epileptic insanity" which she palmed off so successfully on some of her friends for the sole purpose, as far as I could discern, of arousing sympathy. There was, however, doubtless some hysteria in her case.

That there is no established rule or test by which feigned insanity may be detected, but that each case must be decided upon according to the history and symptoms presented, can not be well denied. Alienists everywhere, will bear me out in these assertions. The individual whose sanity or insanity is being questioned should constitute the chief object of the investigation.

Whenever there is doubt about the mental condition of one charged with crime, it would be well, for the court to select a committee of competent alienists to investigate the case and report in writing the result of their examinations and deliberations. This need not preclude a cross-examination.

In Russia and elsewhere methods similar to this prevail. In some of the countries there is, I believe, a regular court physician who decides all doubtful medical cases. It has been advocated in some quarters of this country that there be appointed State experts in insanity to act in all cases where an element of uncertainty exists.

But the best plan, probably, would be to transfer the suspect to an insane asylum and keep him there, under proper safe-guard, for a specified time, in order that the attending physicians may determine the question of real or counterfeited insanity.

For the reason that the position often taken by lawyers is so entirely at variance with the true conception of the disease—insanity—that medical witnesses, who have no special knowledge of insanity, are often called upon to give expert testimony, that physicians are sometimes utilized by shrewd counsel for partisan or for sinister purposes, that juries composed entirely of laymen are not competent to try a case which involves a question of mental alienation—brain disease—and finally, chiefly that the ends of justice and mercy are sometimes thwarted, our system of medical jurisprudence of insanity is in need of revision.

The increase in the membership during the month of September was very satisfactory. Let the good work go on!

## THE ACTION OF STRYCHNIN IN PULMONARY CONSUMPTION IN RELATION TO THE NEUROTIC ORIGIN OF THIS DISEASE.

Read in the Section on Neurology and Medical Jurisprudence, at the Forty-seventh Annual Meeting of the American Medical Association, held at Atlanta, Ga., May 5-8, 1896.

BY THOMAS J. MAYS, A.M., M.D.

PROFESSOR OF DISEASES OF THE CHEST IN THE PHILADELPHIA POLYCLINIC, AND VISITING PHYSICIAN TO THE RUSH HOSPITAL FOR CONSUMPTION IN PHILADELPHIA.

Freedom of thought is the foundation of all progress; and while this law develops a diversity of opinion in practical therapeutics so great as to give rise to the belief that no two physicians treat the same disease in the same way, it is nevertheless true that in the struggle to relieve and cure disease we consciously or unconsciously seek and follow methods which finally lead to adoption of the same principles if not of the same details of treatment. This unanimity in practice is sometimes reached through certain etiologic and pathologic convictions which we hold of disease; or, as is more often the case, we are driven to it by the power which comes from witnessing the successful effects of well directed medication either in the hands of others or our own, and in spite of any theory we may possess in regard to the origin or mechanism of disease.

For a number of years I have said and written much in favor of the neurotic origin of pulmonary consumption, and while this theory may not be perfect in all its details, I believe that it gives us a more rational explanation of the causes and nature of this disease than any other. Not only do I feel convinced of this, but my experience assures me that the therapeutic measures which are directly addressed to the nervous system are the most effective in the relief and cure of this disease. Led by these considerations I have employed a number of neurotic agents in the treatment of this disease; the principal one is strychnin, to which I shall now devote a few remarks.

Of all the drugs in the materia medica there is none that compares favorably with the action of strychnin in the treatment of pulmonary consumption. As is well known this agent has an elective affinity for the whole nervous system, but over and above this it possesses a special influence on the nerves which preside over the function of respiration. Its action is reputed to be wholly devoted to the motor nervous system, but there is reason for believing that it also affects the peripheral sensory nerves. In small doses it stimulates, in medium doses it tetanizes, and in large doses it paralyzes the nervous system. The dose is a relative or a movable quantity however, for that which produces tetanus or paralysis at one time may act as a stimulus at another.

How, then, does strychnin act in pulmonary consumption? It is taken for granted that the lung disease is merely a superficial manifestation of disorder of the pulmonary nerve supply. Therefore the strychnin primarily raises the tone of the nervous system as a whole, and of the respiratory nerves in particular. In this way it not only increases the resistance of the lung to disease, but it aids digestion, assimilation and blood-building. Let us say that the tone of the nervous system is depressed. By employing strychnin we can do this, but must be careful to avoid the danger point, yet at the same time this point must be approached as closely as is consistent with the safety of the patient. The best way to bring

about this object is to begin with a moderately small dose of the drug, 1-30 grain four times a day, give this for one week, then increase it to 1-24 grain for another week, during the next give 1-20 grain, the following week raise the dose to about 1-16 grain, and so on, making a slight increase every week until you observe nervousness, restlessness or twitching of the muscles—the signs of the beginning of strychnin intoxication. In most cases these symptoms do not develop until 1-12 or  $\frac{1}{8}$  grain or even a larger dose is reached. It must be understood that the drug is to be given in these doses four or even five times a day. The object is to impress the nervous system with the full stimulant effect of this drug. The sooner this end is attained the better will it be for the patient. For this reason you begin with small doses and work upward as rapidly as you can with safety. After the desired point has been reached the question arises whether it is better to continue the largest dose or to resume the original. I think it best not to vary from this line during the remainder of the treatment, for you do not wish to lose what has been accomplished. Keep the strychnin treatment up to the highest level of safety, but shun the point where its stimulus extends into the region of tetanus and of paralysis. It is best, however, to reduce the dose somewhat at this point. If, for example, it is found that  $\frac{1}{8}$  grain is a maximum dose reduce to 1-16 grain, gradually increase the dose again until  $\frac{1}{8}$  grain is reached, and then return to 1-16 or 1-12 grain. After you have increased and decreased the dose several times you will probably find that  $\frac{1}{8}$  grain no longer produces any dangerous symptoms, and that you now can give as much as 1-6 grain. When administered in this way the drug may be given for an indefinite period to the majority of phthical patients.

The remedial effects of the drug show themselves in various ways. The nervousness, sleeplessness and pain in the chest will be ameliorated, and perhaps entirely disappear; the cough, expectoration and dyspnea will diminish; vomiting will abate; the appetite improves; the patient gains in flesh and color; the weak and rapid acting of the heart will become slower and stronger; the red corpuscles increase in number, and the patient becomes more hopeful and brighter.

Of all the drugs in our possession strychnin makes the most profound impression on the nervous system, and in my opinion yields a larger measure of benefit in the treatment of pulmonary consumption than can be derived from any other single agent. In connection with it I employ well regulated rest, good food, quinin, phenacetin, hypophosphites, electricity, cod liver oil, etc.

I will not weary you by relating any examples from my experience in confirmation of what I have said, but will quote in part a "case of phthisis apparently cured" which was reported by Dr. William Pepper in the December (1895) number of *The University Medical Magazine*: Female, aged 21, with a decided phthical family history, began to emaciate rapidly in March, 1893. In less than a month she was bedridden and weighed 100 pounds. She had high fever, night sweats, anorexia, vomiting, copious expectoration and all the physical signs of pulmonary disintegration. She received an egg albumin diet and the medicinal treatment consisted of 1-100 grain of

strychnin nitrate with 1-1000 grain of atropin sulphate every two hours hypodermatically; and 1-50 grain of strychnin nitrate with 1-12 grain of the double chlorid of gold and sodium and  $\frac{1}{2}$  grain of a vegetable digestive every two hours by the mouth. After a few days the amount of gold and sodium was increased to  $\frac{1}{8}$  grain every two hours. At first she showed signs of strychnin intoxication, and the amount was reduced, but she soon resumed the original dose, and after the first two weeks bore the drug well, although always just inside the border line of its toxic action. During April she improved decidedly, and during May the improvement was also very rapid. By the latter part of this month she weighed 125 pounds. The abnormal physical signs and the tubercle bacilli disappeared and in September she weighed 132 pounds, and was in perfect health. In August, 1895, she had a slight attack of pneumonia, after which all the symptoms she had two years previously, recurred, and her weight fell to 114 pounds. She was placed on her former treatment, and made a rapid recovery. On November 1 she again weighed 124 pounds, her cough and expectoration had almost disappeared. No tubercle bacilli have been found since the previous October.

Dr. Pepper, in summing up the case says, that among its noteworthy points are the absence from the treatment of all cough medication and antiseptics, and the large doses of strychnin and the double chlorid of gold and sodium with which the system was kept literally saturated.

There can be no doubt that this was an apparently hopeless case of phthisis from its very outset, and great credit attaches to the distinguished prescriber for guiding it to such a successful termination. The question arises as to which of the agents played the most prominent rôle in bringing about this issue. From my own experience with the drugs which were employed I believe that the strychnin is chiefly responsible for this, although in forming a correct estimate we must not lose sight of the value of the nutritious food and the physical rest.

When we take into consideration that insanity, idiocy, hysteria, chorea, epilepsy, asthma and all forms of nervous disorder are prone to develop into pulmonary phthisis; that the former diseases are frequently converted into the latter through heredity; that all poisons like those of alcohol, syphilis, lead, mercury, influenza, whooping cough, etc., have the power of engendering nervous disease and pulmonary consumption, and as a matter of fact the former are often followed by the latter disease; and that the markedly beneficial action of strychnin in this disease comes exclusively through the nervous system, it does not require a very great stretch of the imagination to perceive that the neurotic element plays a leading part in the etiology of pulmonary consumption.

**Perchlorid of Iron in Treatment of Ingrowing Nail.**—Reghi's method is being extensively quoted, as he has been very successful with it. After soaking the foot until the scab is loosened and the pus washed off, a piece of cotton dipped in a 50 per cent. solution of perchlorid of iron is inserted in the ungueo-phalangeal groove, and the toe lightly wrapped up. This is repeated twice a day, the blackish scab that forms removed each time. The patient remains in bed a couple of days, and the cure is complete in twenty, although a small piece of cotton should be worn between the nail and the flesh for some time.—*Bulletin Méd.*, No. 58.

## FUNCTIONAL DYSPEPSIA OF CHILDREN WITH ILLUSTRATIVE CASES.

Read in the Section on Diseases of Children, at the Forty-seventh Annual Meeting of the American Medical Association, held at Atlanta, Ga., May 5-8, 1896.

BY J. M. G. CARTER, M.D., Sc.D., Ph.D.

Professor of Preventive and Clinical Medicine in the College of Physicians and Surgeons of Chicago, Fellow of the American Academy of Medicine, etc.

WAUKEGAN, ILL.

The term *dyspepsia* is so frequently used by writers as a synonym for indigestion that one needs to explain the meaning he attaches to the word. In this paper it is to be understood as referring to the condition which permits or encourages acute attacks of deranged digestion or unnatural distress in the stomach or bowels from the presence or absence of normal food or its products. The acute attacks of interference with digestion are here termed indigestion. Frequent attacks of indigestion may occur in the course of a case of dyspepsia.

*Functional dyspepsia* includes all cases which are not due to some organic lesion of the stomach. Many cases of gastritis in children are sequelæ of indigestion and must be carefully differentiated from functional dyspepsia. But cases resulting from undeveloped stomachs properly belong in this class. From these limitations and explanations it may be seen that we include under the term functional dyspepsia cases which result from some congenital imperfection in structure, from improper food whether of quantity or quality, from variations of temperature especially increased heat, from the presence of bacteria or their products, from reflexes caused by diseases in other parts of the body, and from weakness following or accompanying general illness.

*Case 1.*—I have lately had under my care a baby born before the termination of the eighth utero-gestation month. It was small and though perfect in limb and feature, had little vitality. Its digestive powers were so feeble that its mother's milk caused it great distress. The mother's milk ceased in a few days. A wet nurse was secured but was soon dismissed because relief was not obtained and because the baby seemed to dislike the milk. Cow's milk, diluted, raw or sterilized or condensed, was borne but a short time without distress. Malted milk food (Horlick's) agreed for a short time, and then a return was made to cow's milk. These experiments occupied ten weeks. The milk was then predigested, with worse results apparently than had been experienced before. The bowels alternated between constipation and diarrhea. Vomiting was occasional; usually the dejecta consisted of the food unchanged. Fermentation and gaseous eructations were frequent. The child continued to grow and gain flesh. There was no doubt in my mind that the cause of the disturbance in this case was imperfect or under development of the stomach.

Such cases may persist through childhood and even to adult life. When they do it is difficult to differentiate them from another class of cases, which result from cicatrices following ulcers of the stomach.

*Case 2.*—I was called to see a baby seven or eight months old, at the breast. It was emaciated, yet nursed feebly. Examination of the mother's milk showed it to be poor in quality but abundant in quantity. The baby suffered pain from gaseous distension of stomach and bowels. Vomiting was frequent, and occasionally diarrhea. Treatment made no special impression. Then the infant was given cow's milk, but with no beneficial result, rather an increase of the dyspeptic symptoms. Other changes were made without relief until condensed milk (Swiss brand) was given. Very soon after this change the digestive derangement subsided and the little patient began to gain flesh. The recovery was complete. This case was undoubtedly one due to dietetic disturbance.

*Case 3.*—The influence of heat is illustrated by the following case: I was called in July to see a baby which was suffering with diarrhea. The patient vomited occasionally, suffered some distress in the stomach and bowels, took its mother's milk ravenously; diarrhea lienteric, except when charcoal, lime water or pepsin were given, then the discharges were bet-

ter for a time. The child was ten months old. The weather was very warm. At first directions were given to remove nearly all clothing, bathe the patient frequently and keep it cool. The treatment was followed by immediate improvement. The weather became warmer, the patient worse. The use of cold water and ice relieved the symptoms. The patient's temperature was not increased. There were no evidences of enteritis or colitis. On cool, cloudy days the case was better, on warm days worse. A change to cow's milk was followed by negative results, no increase or diminution in symptoms. The patient recovered when cool weather came.

*Case 4.*—That the presence of bacteria may cause dyspepsia in an infant is well illustrated by the following: Baby F. was a year old, a bottle baby. It had attacks of stomach derangement every few days or weeks, especially during the summer. At such times it had colicky pains, distension of stomach and bowels, vomiting of coagulated milk, with similar coagula passing from the bowels, causing diarrhea. No fever. When I was called the condition was such as just described, somewhat aggravated by the warm weather. Everything about the child was dirty, an innumerable host of flies trying to clean things up. The bottle nipple was not clean, having many specks of milk coagula and fermented flakes upon it. The bottle was in the same unhygienic condition. Similar specks were found in the baby's mouth. Although a microscopic examination was not made, I was satisfied that the case was one of functional dyspepsia due to the bacteria and their products engendered in what was evidently a favorable culture medium. The treatment, which consisted in cleaning up the field for operation and the use of antiseptics, confirmed the diagnosis by producing a cure.

*Case 5.*—Cases of functional dyspepsia due to some neurosis are rare in young children, but the following I think well illustrates a case due to reflex influence induced by disease in some other part of the body. I was called to see a boy 5 years old who had been suffering with poor appetite and deranged digestion for some months. Gaseous eructations were frequent, but the stomach was not permanently dilated nor very frequently distended by gas. Food of almost any variety and kind, whether nitrogenous or non-nitrogenous, caused more or less distress. Soon pyrosis and other symptoms made eating dreaded. A few weeks after the beginning he showed signs of failure of nutrition, began to be anemic, lose flesh and grow weak. The bowels were regular. No tenderness of the stomach was manifested and the temperature was not above normal. About two months from the first indications of disturbance I was called because constipation had become troublesome and a tumor was discovered in the lower part of the bowel. Examination revealed no organic disease of the stomach, but did reveal a sarcoma of considerable size in the pelvic cavity, chiefly to the right of the median line. The tumor, about 4 inches in diameter, pressed upon the rectum and interfered with the normal evacuations of the bowel. Perhaps eventually the fermentation and ptomaines occurring in the bowels caused by retained feces were prominent factors of the gastric as well as intestinal disturbances. The case passed rapidly to a fatal termination without further gastric derangements than those due to reflex influences and the poisoning caused by fecal ptomaines.

*Case 6.*—The last case I desire to mention was one who had been prostrated for several weeks with typhoid fever. He was 8 years old and had been greatly weakened by the long sickness. When the milk diet was no further insisted upon and a gradual change was made to other food, gastric disturbances in the way of eructations, distress, distension and heartburn were frequent. These continued for three weeks. They were due to the anemic and atonic condition of the stomach and should certainly be considered functional disturbances. Dietetic care and recovery of strength and health removed all dyspeptic symptoms, so that after three weeks and since there has been no evidence of gastric trouble.

Other cases of anemia and atonic conditions may be accompanied by functional dyspepsia, just as in adults.

This brief presentation of cases will help to impress the writer's views of etiology and treatment of functional dyspepsia. By far the greater number of cases are due to improper food, the improper administration of food or to reduced vitality. An extended experience with the use of hydrochloric acid and pepsin will convince one that the relative number of cases cured by these remedies is small; in fact, the number benefited will be disappointing. Still we can not rely exclusively upon dietetic and tonic treatment. An attempt to render the alimentary canal aseptic is

paramount. The following are the chief indications to be met in this condition: 1. Correct the food both as to quantity and quality. 2. Try to render the stomach and intestines aseptic. 3. Assist nature in her effort to restore the natural functions and tone up the system.

1. Too frequently the undeveloped state of the salivary glands in the first few months of infancy is forgotten and food, such as rice water and cereal preparations, is given which can not be digested in the stomach and in many cases at least is not completely digested in the intestines. A similar result may obtain if given in too large quantities later in life. Under such circumstances the undigested food becomes a nidus for the growth of bacteria, fermentations result, irritating gases and bacterial products may cause diarrhea and at times constipation. A too abundant proteid diet of eggs and meat may in a similar manner and for the same cause result in putrefactive decompositions and the gases formed likewise produce constipation or diarrhea, even in older children.

2. The rational treatment in these cases is, of course, antiseptics. An effort should be made to correct or remove the cause and give antiseptics. Antiseptics can not be given in sufficient amounts to overcome the condition unless an irritating diet be corrected, especially is this true in nursing and bottle babies. It is true also in older children. Salicylate of bismuth, salol, carbolic acid, charcoal and other antiseptics used in these conditions have given me excellent results. I have treated diarrheas due to indigestion in the same way with like results. In functional dyspepsia, however, a habit of indigestion may be established, as it were, and a tendency to certain bacterial growths may become persistent. Here it is necessary to persevere in an antiseptic course of treatment. I have lately treated bacterial diarrhea of a very aggravated type, in patients old enough to be using a mixed diet, by the administration of a milk diet and salol without other medication and with the most satisfactory results. Salol may be given in doses of one to two grains every two or three hours until improvement occurs. Infants under one year yield very readily to salicylate of bismuth. Where from idiosyncrasy or other cause the salicylate is not well borne, salol in one-half grain doses will frequently be all that is needed. In many cases minute doses of calomel act as an antiseptic and afford gratifying relief. Cases of summer complaint preceded or accompanied by functional dyspepsia frequently yield quickly to the antiseptic treatment. The same is true of those dyspeptic cases following prostrating fevers, neuroses and other forms of exhaustion in which there is fermentation or putrefaction of food due to delayed or weak digestion and the formation of irritating gases. The dilatation of the stomach which so frequently accompanies functional dyspepsia in children is nearly always due to gaseous distention and is temporary. The removal or diminution of the gas is a step toward a cure. Where much distention exists and antiseptic practice does not afford ready relief, the stomach-tube or a soft catheter may be introduced through the mouth or nose and the gas allowed to escape. The general douching of the stomach seems to me to be less valuable in children than in adults, but sometimes it is useful to remove offending matters. The douche is sometimes of value also in atonic cases where the gastric walls are relaxed by over distention

or a weakened condition of the general system, anemia, etc.

3. Finally it is necessary in many instances to give hydrochloric acid, pepsin, lactopeptin, peptenzyme, papoid, diastase and similar preparations to help correct the deranged secretions and assist in digesting the food. In addition to the administration of these internal remedies which act chemically or by catalysis, stomachics, the aromatic sulphuric acid, nitric or the nitro-muriatic acid and other preparations to stimulate the secretions may be needed. An alcohol sponge bath twice a day followed by inunction with cocoanut or olive oil to which quinin may be added in suitable cases, frequently aids materially in restoring the patient to health and vigor. The use of malt preparations and other tonics is frequently demanded. The anemia, neurasthenic or other conditions of depressed vitality will guide in their administration.

### THE TREATMENT OF CHRONIC INFLAMMATION OF THE BLADDER, WITH REPORTS OF TWO CASES OF CONGENITAL DIVERTICULA.

Read before the Colorado State Medical Society, June, 1896.

BY LEONARD FREEMAN, B.S., M.D.

PROFESSOR OF PRINCIPLES OF SURGERY AND SURGICAL PATHOLOGY GROSS MEDICAL COLLEGE, SURGEON TO THE COUNTY HOSPITAL AND ST. ANTHONY'S HOSPITAL,  
DENVER, COLO.

Chronic inflammation of the bladder is practically always due to microorganisms, the one most often encountered being the bacillus coli communis, which exists normally in such abundance in the intestinal canal. The gonococcus, the tubercle bacillus, the typhoid bacillus, the various pyogenic bacteria, etc., are also frequently found. It should never be forgotten that it is not a calculus, an enlarged prostate, a tumor, or a quantity of residual urine which is the direct cause of an inflammation, but the bacteria which have in some manner gained entrance to the bladder in presence of these conditions. Even a cancer does not produce inflammatory symptoms until infection has taken place. I had recently under my care an old gentleman with vesical carcinoma, whose urine remained free from pus for a considerable time after the growth began. It is possible for germs to enter the bladder through the kidneys, the urethra, and even through the blood, but in most cases catheterization is responsible for simple infection. A vesical calculus may exist for years without a sign of cystitis, provided no instrument has been introduced into the bladder. I have seen a man with an enlarged prostate whose bladder had been dilated, almost to the umbilicus, with residual urine for over two years, and yet the urine when removed was as clear as spring water.

From a therapeutic standpoint, chronic inflammations may conveniently be grouped under three heads: 1, inflammation in connection with the presence of a foreign substance—calculus, tumor, piece of catheter, etc.; 2, inflammation in connection with the presence of residual urine; 3, inflammation due to specific infection, such as gonorrhoea, tuberculosis, syphilis, etc. Under the last heading may be placed inflammations due to certain microorganisms other than those of the diseases mentioned.

The first two groups are closely allied. It is not so much because a foreign substance exists, or because

it injures the mucous membrane, that inflammation occurs; but because the bladder is unable to clear itself sufficiently of objectionable ingredients of the urine, which remain collected about the substance. In other words, it is to the residual urine that the trouble is due. Nevertheless, the divisions given above are retained for the sake of convenience.

1. Inflammation in connection with foreign substances.—It is self-evident that rational treatment indicates removal of the offending substance, be it stone, tumor or other material. Simple removal is usually sufficient, provided no obstacle to complete emptying of the bladder remain, such as atony, a diverticulum, etc. I have observed a case in which a stone had existed in the bladder for nearly fifteen years, where the marked inflammatory symptoms disappeared within a few days after lithotomy had been performed.

2. Inflammation in connection with residual urine.—This is found in enlarged prostate, stricture of the urethra, paralysis and paresis of the bladder, certain diverticula, etc. In case of stricture, the enlargement of the narrowed urethra is the essential feature of treatment. The management of other forms is not so simple, and often taxes the surgeon's resources to the utmost.

*General treatment.*—It should be appreciated by all that general treatment is of much less importance than is usually supposed. The various balsams, resins and other compounds, so often mentioned in books and so widely advertised, often do some good, but as curative agents they are sadly deficient. They are, nevertheless, prescribed on every hand, frequently to the exclusion of local measures. Local treatment in chronic cystitis is the only reliable treatment.

We do not speak at present of "soothing the mucous membrane" by internal remedies, but of "inhibiting bacterial growth by means of antiseptics." Good may be accomplished in this way, although much less than is often imagined. Perhaps the most satisfactory drug for the purpose is salol, given every few hours in 5 grain doses.

The patient's bowels should be kept open, not only because constipation leads to congestion of the vesical veins, but because there is no more efficient method of removing poisonous substances from the system than through the bowels. The necessity of proper foods, tonics, cleanliness of the skin, etc., will suggest itself. Plenty of milk at frequent intervals does excellent service, both as a food and as a diluent of the urine.

*Local treatment.*—The main indications are: 1, disposal of residual urine; 2, washing out the bladder.

Residual urine.—This must be removed, no matter how small the quantity. If the urethra will easily admit a catheter of sufficient size to thoroughly drain off not only all traces of urine, but stringy pus and clots of blood which may also be present, then the regular use of a catheter will often be sufficient. When the inflammation is obstinate or severe, a soft catheter may at times be tied in and continuous drainage instituted. This method, which is not extensively used in this country, gives excellent results, even in cases of enlarged prostate. But if only a very small or specially constructed instrument can be employed, or if the patient can not be entrusted to catheterize himself, or if the channel is irritable, or if there are other reasons why the use of a catheter is unsatisfactory, then more radical procedures become

necessary. At the present day the operative measures most frequently adopted are castration, resection of the vasa deferentia and suprapubic cystostomy with retention of a permanent opening. A sufficient number of cases have been reported for us to say with considerable certainty that, in general, castration furnishes the surest and safest means of combating the evil effects of an hypertrophied prostate. Some cases of inflammation, however, are so severe, and the debilitated patient so much in need of immediate relief, that suprapubic cystostomy should be done at once, and thorough drainage of the bladder secured. In all other cases castration is applicable, provided the nature and consequences of the operation are fully appreciated by the patient. Among those within the age of sexual activity there will always be some who naturally object to the removal of the testicles, no matter how strongly the operation may be indicated. For these the older operation of prostatectomy is indicated, although it should not have the preference, on account of its uncertainty and danger. For patients who, while recognizing that their term of sexual activity is past, still object to castration for various reasons, resection of the vasa deferentia may be done, although it offers at present a less certain prospect of cure than removal of the testicles.

Washing out of the bladder.—Several points should be borne in mind in this connection:

1. The bladder must not be over-distended, as this may keep up a chronic inflammation which would otherwise tend to subside. There is also reason to suppose that septic material can in this way be forced into the mouths of the ureters, thus leading to kidney complications. No more than four or five ounces of fluid should be employed, and less than this is often preferable. A good-sized syringe of hard rubber, which can be easily used with one hand, is safer and better adapted to the purpose than a fountain syringe, although the latter is in general use.

2. The prostatic urethra should be irrigated as well as the bladder, especially in gonorrhoeal affections, as it is often the seat of inflammation which may reinfect the adjacent viscus. The catheter should be slowly inserted while the fluid is being injected until the fluid no longer appears anteriorly at the meatus, but passes through the deep urethra into the bladder, the eye of the catheter being just beyond the constrictor muscle. When practicable, it is well to leave considerable fluid in the bladder, which the patient is instructed to pass after the catheter is removed, thus irrigating the channel from behind forward. If the bladder, however, is insufficient, and the solution not a mild one, it is better to withdraw it entirely. In obstinate cases of posterior urethritis it answers an excellent purpose to occasionally inject a few drops of concentrated solution of nitrate of silver ( $\frac{1}{2}$  to 5 per cent.) with an Ultzmann's capillary injector.

3. A single, not a double, catheter should always be used. The current from a double catheter selects a short, easy channel for itself, and passes directly from one eye of the instrument to the other without distending the folds of the mucosa and cleansing the bladder as it should.

4. When the organ is not too sensitive, the fluid should be injected with some force, so as to more effectively wash the mucosa.

5. The catheter should be soft rubber or linen, as large as can be used without undue discomfort, especially when thick pus and clots of blood are present,

and it should not be forgotten that a catheter is just as large as its eye and no larger.

6. Almost any antiseptic or astringent fluid will give good results if properly employed. Personally, I prefer the permanganate of potassium or the nitrate of silver. The former is both an antiseptic and an astringent, and its strength can be conveniently judged by the depth of color of the solution. The stains are quickly removed with oxalic acid. The nitrate of silver is less easily handled, but sometimes gives better results.

7. One daily irrigation is usually sufficient, although two may be required. Care should be taken not to carry the treatment too far and cause more harm than good by undue interference.

8. It is generally more satisfactory to irrigate an insufficient bladder with the patient standing, as the viscus is more easily cleansed in this position.

In this connection I desire briefly to mention two cases of congenital diverticula of the bladder. These malformations are very rare and present many puzzling features to the diagnostician. They are similar in appearance to the diverticula which occur in inflamed bladders with hypertrophied trabeculae and obstruction to the outflow of urine. In congenital diverticula, however, there is not necessarily any damming back of the urine with distension, and there is little or no tendency to progressive enlargement. At times practically a double bladder exists, with a ureter emptying into each division, but the results are clinically the same—the retention of residual urine, and a tendency to chronic inflammation and the formation of calculi.

One case came under my charge a number of years ago in the Cincinnati Hospital. He was a young man of good physique, who had experienced no marked urinary disturbance until he suffered an attack of gonorrhoeal cystitis. This proved to be extraordinarily obstinate, and yielded to none of the usual forms of treatment. There was little or no prostatic enlargement and no urethral obstruction. It seemed almost inexplicable to me at the time, that after the man had passed his urine, a catheter would draw off an additional quantity, and after some moving about of the instrument in the bladder, still more would be obtained. The patient shortly died with surgical kidney, and at the autopsy four or five diverticula were found each somewhat larger than a walnut. They diverged from the posterior and inferior walls of the bladder, were perfectly smooth within, and their openings were about the size of the little finger.

The second case is a young man of 29, who has recently been under my care. He is well built and active both physically and mentally. Up to the age of about 14 nothing abnormal was observed in connection with the urinary apparatus except that the urine appeared to be unusually strong in odor. About fifteen years ago it became necessary to pass a catheter, following an injury to the back with hematuria. Cystitis together with pyuria developed, which persisted for some years. After much and varied treatment, it was finally cured by irrigation. The patient's health remained good for several years, until, as a consequence of an injury to the back, retention of urine took place and a catheter was again passed. Cystitis once more supervened in an aggravated form, and continued for six or eight years, in spite of the most strenuous efforts toward its subjugation. During this period the gentleman was under the care of many of

the world's most eminent surgeons, including Agnew and J. William White of Philadelphia, Sir Henry Thompson of London, Czerny of Heidelberg, and Guyon of Paris. The presence of a diverticulum was not suspected even after prolonged and careful examination with the cystoscope. I mention these names in order to show that the diagnosis of a congenital diverticulum of the bladder may be exceedingly difficult, not to say well nigh impossible. When the patient came under my charge he was in a pitiable condition. He was forced to urinate, with pain and strangury, about every twenty minutes, both night and day, and it was necessary to frequently irrigate the bladder in order to make life even tolerable. The urine was loaded with blood and pus, and was offensive in the extreme; there was, however, little fever. The passage of a Thompson's "searcher" in the effort to find a stone, stirred up a quantity of decomposed urine, which called my attention to the possibility of the existence of a diverticulum, but the idea was partially dismissed because of the amount of hemorrhage, which was more consistent with the presence of a tumor or of tuberculosis. A careful examination of the urine by Dr. E. R. Axtell and myself failed to reveal tubercle bacilli, so that the idea of tuberculosis was given up. A suprapubic cystotomy was made for purposes of drainage and exploration, especially as some form of tumor was strongly suspected. An opening large enough to admit the little finger was found in the trigonum, to the left of the median line, which communicated with a diverticulum the size of a Messina orange, passing upward and backward along the side of the sacrum to the left of the rectum. The interior was smooth and nearly spherical in shape. After the pouch had once been recognized it could easily be felt by a finger in the rectum. It being manifestly impossible to remove the diverticulum through a suprapubic incision, it was decided to drain the bladder until the cystitis had subsided and then attempt to close the opening without recurrence of inflammation. If this failed an attempt could be made to remove the pouch through the ischio-rectal fossa. The cystitis rapidly and completely subsided as soon as thorough drainage was instituted, the patient improving rapidly in weight and general condition. An attempt to close the artificial urethra was soon followed however by a reappearance of the inflammatory conditions, due probably to infection from the prostatic urethra. Drainage was again procured and the entire urethra and bladder subjected to frequent irrigation with permanganate of potassium and nitrate of silver. The next proceeding was to drain the bladder through a catheter tied in the urethra while permitting the fistulous opening to close. This also failed, as the posterior urethra proved to be too sensitive to permit the catheter to remain more than a few hours, despite all preparatory treatment. It was decided to institute continuous drainage of the bladder through the supra-pubic opening, for a time at least. This was accomplished by means of a soft catheter, held by a truss-like arrangement, and emptying into a rubber urinal secured to the thigh. The apparatus, which proved to be very effective, was constructed by cutting a small, hollow rubber ball in half, and passing the catheter through a slit in the bottom of one of the hemispheres. The section of the ball fit nicely into the large dimple surrounding the orifice of the artificial urethra, and served to hold the catheter securely in place. A hard-rubber plate

secured around the waist and under the perineum by rubber bands held the ball in position. The patient has been wearing this apparatus in perfect comfort for about three months, and finds that he is inconvenienced scarcely at all by his condition, while his health and energy have been completely restored.

An examination of these two cases presents some interesting points: 1. Congenital diverticula can exist for many years without their possessors being aware of any abnormality. 2. Cystitis may not take place until infection is caused by catheterization, gonorrhoea, etc. 3. Cystitis in the presence of diverticula may sometimes be cured without opening the bladder, and remain so indefinitely, provided reinfection is not brought about. 4. Hemorrhage from chronic cystitis may be so great as to strongly simulate hemorrhage from a tumor. 5. Residual urine, without stricture of the urethra, enlargement of the prostate, or paresis of the bladder, should be suggestive of a diverticulum. 6. Even in the best hands, the opening of a diverticulum may be overlooked with the cystoscope. Perhaps a reason for this is that the mucosa during life is so congested and folded about the opening as to conceal it. 7. In obscure vesical affections, with cystitis, it is rational to open the bladder for purposes of exploration and drainage, the preferable incision being the suprapubic, as offering the better opportunity for removal of foreign bodies, if such be present.

#### DANGERS OF BICYCLING; WITH REPORT OF A CASE OF ACUTE DILATATION OF THE HEART.

BY WILLIAM C. KRAUSS, M.D.

PROFESSOR OF NERVOUS DISEASES, MEDICAL DEPARTMENT NIAOARA UNIVERSITY, BUFFALO, N. Y.

Ever since the great popularity which has attended bicycling in this country, numerous articles have appeared in the medical and lay press pointing out real and imaginary dangers liable to beset those attracted to this sport. These dangers have attended both sexes, more particularly the female bicyclists, and consisted in disturbances affecting the pelvic viscera. No doubt over-indulgence in this pastime can and will produce congestions and irritations of these organs, perhaps displacements and even inflammations, but such cases are comparatively rare.

From the moral point of view another danger has been discovered by the Woman's Rescue League of Washington: That the bicycle is nothing more or less than the devil's advance agent, and through the opportunities which it offers is causing an alarming increase of immorality among women. The writer believes this to be true only in so far as it affects those women upon whom the devil already has a mortgage, and employs the wheel only as a subterfuge to foreclose the claim. The wheel has been a great aid to physicians in the treatment of neurasthenic, hysteric and hypochondriac women, and the good it has done to them and the pleasures derived from it by others will more than counterbalance the harm which those unable to ride think it has and may create. Pleasure and health can be derived from bicycling only so long as the laws of hygiene and common sense are heeded, and their violation will be followed by disagreeable consequences.

The male sex is predisposed to that ungainly and unhuman distortion, the "camel's back," as a result of faulty posture and ambition for speed, and perhaps

fame. Not only is the spinal column strained and distorted, but the thoracic and abdominal viscera are subject to undue pressure, and hence to restricted movements and imperfect physiologic action. No sport is a healthy one which in its performance coerces the body into an unnatural position, and the great popularity attained by rowing and base ball is partly due to the comfort and pleasure which the normal position of the body insures.

Through long-continued pressure caused by long rides and faulty fitting saddles, the male genito-urinary tract is liable to damage, and this should therefore be carefully guarded against. The dangers which do, arise, however, from bicycling affect the beginners, and scorchers mostly, who have not learned the secret of the sport, namely, moderation.

After consent is obtained from the family physician to ride, a properly geared wheel should be selected, with an easy and comfortably fitting saddle, the handle bar raised so as to give the body an erect and graceful position, and this advice constantly borne in mind, that the sport should be discontinued at the first sign of fatigue. As the days go by this fatigue will grow less and less, and the rider able to take longer spins as the muscles become firmer and more accustomed to this form of exercise. The whole system undergoes a certain kind of training or physical education, the heart and respiratory muscles accustoming themselves to the necessary strain just as do the extensors of the thighs and the calf muscles. Just as over-indulgence results in tiredness and lameness of the leg muscles, so also are the heart and respiratory muscles affected. The heart through increased work put upon it by long, rapid spins is taxed to its utmost, and when persevered in, serious damage to the heart walls or heart valves may result. As Osler truthfully says: "Endurance in prolonged contests is measured by the capabilities of the heart and its essence consists in being able to meet the continuous tendency to overstep the limits of dilatation."

One form of heart trouble especially is attended upon over-exertion and over-fatigue, namely, the acute dilatation of the heart walls, due to over distension of the muscle fibers. The cause of this dilatation is an incomplete exhaustion of the ventricles, generally the right, during systole, and an excessive engorgement during diastole with possibly some defective nutritive change in the muscle fibers. The symptoms arising from this condition are subjective and objective and are well illustrated in a case which recently came under my observation.

James H. C., age 37 years; height 5 feet 6 inches; weight 138 pounds; married and has eight children. He had an attack of rheumatism when 12 years of age, and typhoid fever when 29. Has always been a hard-working man, employed on the railroad sometimes ten to fourteen hours daily. About May 1, 1896, he purchased a wheel and rode occasionally from his home to the railroad yards, perhaps a distance of half a mile. On May 8, 1896, he accompanied a few friends on a spin into the country and rode four miles in twenty-five minutes. On dismounting he noticed a severe pain over the left side of the chest extending to the neck, also that he was completely "winded," and the left side of the chest was throbbing violently. After only a few minutes rest, urged by his friends, he remounted the wheel and rode home, covering the distance in thirty minutes. On reaching home he could scarcely breathe, was in profuse perspiration, trembled all over and was obliged to go to bed. Vomited during the night; the following morning he found he was still in the same condition and was unable to go to work, and scarcely able to be on his feet. The least exertion caused his left side to "thump" vigorously, while the vessels in the neck throbbled so wildly as to make them perceptible. Patient also noticed a feeling of weakness all over the body and a

stiffness of the knee joints, accompanied always with great dyspnea.

After remaining idle for several weeks and not obtaining very much relief, he consulted me on July 20, 1896, for "weakness and trembling," thinking that he had some nervous disorder; he stated that his sickness began on May 8, 1896; that he worked the day previous and up to that day was in his usual good health.

*Status Præsens.*—Face has an anxious, apprehensive expression; eyes are glassy and facial muscles quivering. Pallor and emaciation are pronounced. There is a slight tremor to the head; is not painful on percussion and has never had headache.

The examination of the eyes was made by Dr. R. H. Satterlee, of Buffalo, N. Y. "Ophthalmoscope shows hyperopia, right eye 2 diopters, left eye 1 diopter. No astigmatism could be discovered. Both eyes have unsteady lateral movement. Left eye does not move as freely as right eye. Weakness of all eye muscles, particularly the interni. Accepts no glass at first; vision later after wearing R. + .50 D., L. + .25 D. for half an hour, 20-20. These prescribed to be worn two months constantly."

Strength of arms diminished; dynamometer test shows, right hand 60; left, 40; tremulous and with increased tendon and muscular reflex action. The legs likewise are weakened, also tremulous, and the reflexes are exaggerated. There is no anesthesia or hyperæsthesia of the face, arms or legs.

The chest offers the most important symptoms, both objective and subjective. The precordial area is largely increased and reverberates with every heart beat. The apex point is diffused and impossible to locate. On palpation a tremulous and purring sensation is experienced which is communicated to nearly the whole side of the thorax. Percussion shows increased area of cardiac dullness extending to the right of the sternum, to the left of the mammillary line and below the nipple. Auscultation does not reveal any valvular murmurs, although the sounds are indistinct and diffused. The heart beats number 130 to 150 per minute.

Urine is increased in quantity, but does not contain albumin or sugar. Bowels are regular. Sleep is fair but is often awakened by the heart's action. During the day he is aware of much fluttering of the heart while napping.

On July 27, 1896, I again had occasion to see the patient and found his heart in practically the same condition, beating 130 times per minute, and as tumultuously as on the former examination.

The history of this case leaves little doubt as to the correctness of the diagnosis—acute dilatation, and the cause of such dilatation—over bicycling. The distance covered and the time would be insignificant to a trained wheelman, but to one not accustomed to long rides it was quite an undertaking and was fraught with serious consequences. In conversation with beginners in the sport one hears so often, "I rode eight or ten miles to-day in such a time," or "I rode a mile in such a time and have only been on the wheel a few days," and yet these riders may never have taken any kind of regular physical exercise. They certainly are imprudent and should be discouraged in their ambitious tendencies until they are in condition to endure the necessary strain. To the writer this seems one of the greatest dangers of bicycling and yet one of the easiest to avoid.

THE STATISTIC EVIDENCES OF THE VALUE OF VACCINATION TO THE HUMAN RACE, PAST, PRESENT AND FUTURE.

Read before the American Medical Association at the Jenner Centennial Celebration, held at Atlanta, Ga., May, 1896.

BY EUGENE FOSTER, M.D.

PROFESSOR OF PRINCIPLES AND PRACTICE OF MEDICINE AND STATE MEDICINE AND DEAN OF THE FACULTY OF THE MEDICAL DEPARTMENT UNIVERSITY OF GEORGIA, AUGUSTA, GA.

(Continued from page 753.)

<sup>30</sup> Dr. Kinnis, formerly Superintendent of Vaccination at Colombo, in his "Report on Smallpox as it appeared at Ceylon in 1833-4," and in an appendix relating to observation made by Dr. Forbes in the epidemic of 1830, gives enumerations from

which the annexed table is compiled. It will be observed that the gradation of death rates marked in the last column, though far less detailed than in Mr. Marson's statement, is to the same general effect. And in the cases noticed by Dr. Kinnis himself the difference is further developed; for he distinguished persons pretending to have been vaccinated into such as had no marks, and such as had unsatisfactory marks of vaccination, and found that the death rate of the latter was 26<sup>1</sup>/<sub>3</sub>, that of the former 32 1-7. Cases of chickenpox are not included in the annexed table, and Dr. Kinnis gives at length (pp. 10-14) his reasons for concluding "that the febrile eruptive disease known in Ceylon by the name of chickenpox arises from an infectious matter essentially different from that which produces smallpox and modified smallpox."—Op. cit. Colombo, Govt. Press, 1835.

Occurrences and fatality of smallpox.

	Number of cases	Number of deaths.	Percentage of deaths.
In persons decidedly not vaccinated . . . . .	851	146	41.5
In persons having no marks or but unsatisfactory marks of vaccination . . . . .	199	52	26.1
In persons having satisfactory marks of vaccination . . . . .	187	3	1.6
In persons having marks of smallpox . . . . .	4	2	50.0

Comparison of the number of cases of smallpox which were treated in the General Hospital at Vienna during the 5 years, 1851-55 inclusive, as regards the ages of patients and the number of cases which terminated fatally.

Age of patients.	Vaccinated.		Not vaccinated.	
	Total number.	Number of deaths.	Total number.	Number of deaths.
To 10 years of age . . . . .	55	8	34	15
From 11 to 20 . . . . .	834	16	111	25
From 21 to 30 . . . . .	892	43	83	23
From 31 to 40 . . . . .	171	7	10	5
From 41 to 50 . . . . .	35	1	3	3
From 51 to 60 . . . . .	9	1	8	...
Total . . . . .	1,995	76	244	71

The number of cases of variola in various forms was 2,239, namely:

Who had been vaccinated . . . . . 1,995  
Who had not been vaccinated . . . . . 244

Vaccinated as well as non-vaccinated persons were seized with the smallpox; still, with this difference, that of the vaccinated cases 8<sup>1</sup>/<sub>3</sub> per cent., but of the non-vaccinated 33.3 per cent. were cases of variola vera.

Of the 1,995 vaccinated cases 76, and of the 244 non-vaccinated cases 71, terminated fatally.

<sup>31</sup> "Interesting and instructive are, moreover, the following figures which throw light upon the relation existing between unvaccinated, vaccinated and revaccinated persons becoming sick or dying of smallpox. According to the memoranda of certain hospitals, among those who died of smallpox during the years 1870 and 1871 were:

	Unvaccinated. Per cent.	Vaccinated. Per cent.	Revaccinated. Per cent.
In Muenster . . . . .	80	13	0
In Posen . . . . .	70	12	2
In 4 hospitals of Berlin . . . . .	51	13	0
	70	16	4
	66	15	4
	81	14	9

In Chemnitz in 1871, among 249 dead were only seven vaccinated persons.

According to Buchanan in 1881 in England, there was only one victim who had been vaccinated while there were 200 deaths among unvaccinated children from 1 to 2 years old.

In Bavaria in 1882, among the smallpox cases were counted 14.6 per cent. vaccinated, 5.8 per cent. revaccinated, 45.5 per cent. unvaccinated.

In the Imperial General Hospital of Prague during ten years, from 1847 to 1856, 872 persons were treated for smallpox; of these, 819 had been successfully vaccinated, and forty-three unsuccessfully or not at all. With ten the vaccination or its result, could not be ascertained in a manner to be relied upon. Here must be particularly remarked that in 1847, in the aforementioned institution, not one case of smallpox is recorded.

Out of the 872 patients, sixty-three died, and of this number

<sup>30</sup> See first report Royal Vaccination Commission, 1889, p. 75.

<sup>31</sup> U. S. Consul, Berlin, loc. cit.

forty-one were of those who were described as successfully vaccinated, twenty as vaccinated without success, and two as those concerning whose vaccination nothing certain was known.

Leaving out those concerning whose vaccination nothing could with certainty be said, it is here shown that of the successfully vaccinated the twentieth part died; of the unsuccessfully vaccinated the half, while the number of vaccinated patients was nineteen times greater than that of the non-vaccinated.

In the Hospital of the Brothers of Mercy at Prague, during the years 1847 to 1856 inclusive, 410 patients were treated for smallpox; of these, 370 were vaccinated, and only forty non-vaccinated. Of the vaccinated four died; of the non-vaccinated five died.

Of the vaccinated (the success or non-success of the vaccination not being taken into consideration) the ninety-second part died, of the non-vaccinated the eighth part died, while the number of the vaccinated was nine and one-fourth times greater than that of the non-vaccinated.

In the Elizabethan Hospital at Prague, during six years, from 1851 to 1856, 118 cases of smallpox were admitted; of these, 108 were vaccinated and ten non-vaccinated. Of the vaccinated two died, of the non-vaccinated one died; i. e., one fifty-fourth of the vaccinated, and one-tenth of the non-vaccinated, the vaccinated patients being ten and four-fifths times the number of the non-vaccinated.

In order to arrive at an idea as to the frequency of attacks of smallpox during the different periods of life, and the amount of safety secured by vaccination, we subjoin the following tables, which show the rates of mortality among the vaccinated and non-vaccinated patients of the General Hospital, Vienna, during the period above mentioned:

Ramsey on smallpox, Transactions New York Medical Society.

Ages.	Total number of cases.	Vaccinated.		Non-vaccinated.	
		Cases.	Deaths.	Cases.	Deaths.
1 to 10 years . . . . .	418	284	35	184	74
11 to 20 years . . . . .	2,634	2,228	83	406	83
21 to 31 years . . . . .	2,671	2,329	128	342	115
31 to 40 years . . . . .	406	354	21	52	24
41 and upward . . . . .	84	72	4	12	4

Deaths per 100 cases at each age, as follows:

	1-10	11-20	21-30	31-40	41 and upward.
Among 5 217 vaccinated . . . . .	14.9	3.7	5.6	5.9	5.5
Among 996 non-vaccinated . . . . .	40.	20.4	33.6	46.2	33.3

Report of the Faculty of Medicine at Prague, submitted to Minister of the Interior, November, 1856. Vaccinated and unvaccinated cases of smallpox which terminated fatally, according to the official vaccination return (21 years).

Year.	Cases of vaccination.	Smallpox.					
		Remaining non-vaccinated. <sup>32</sup>	Cases.		Deaths.		
			Vaccinated.	Non-vaccinated.	Vaccinated.	Non-vaccinated.	
1835 . . . . .	132,727	4,029	505	490	20	136	
1836 . . . . .	130,194	3,319	874	215	26	64	
1837 . . . . .	126,123	3,971	57	123	4	52	
1838 . . . . .	138,527	3,967	101	96	15	32

Average . . . . .	143,122 <sup>1/2</sup>	4,291 <sup>9/2</sup>	389 <sup>9/2</sup>	355 <sup>7/2</sup>	20 <sup>3/2</sup>	103 <sup>1/2</sup>	

REMARKS.—One case of smallpox occurs among 367<sup>2</sup>/<sub>5</sub> vaccinated;

12<sup>1</sup>/<sub>5</sub> non vaccinated. One fatal case of smallpox occurs among 7,166<sup>2</sup>/<sub>5</sub> vaccinated; 40<sup>2</sup>/<sub>5</sub> non-vaccinated. Among cases of smallpox died the nineteenth part of the vaccinated; the third part of the non-vaccinated.

"M. Bousquet,<sup>33</sup> in his detail of the epidemic which prevailed at Marsilles in 1825, states that the whole population was estimated at 40,000. Of these, 30,000 had been vaccinated, 2,000 had had smallpox, 8,000 had neither been vaccinated nor had smallpox. Of the 30,000 vaccinated 2,000 were seized with smallpox, twenty of whom, or one for every hundred affected, died. Of the 2,000 who had before had smallpox, either naturally or by inoculation, twenty were attacked, and of these four died, or one for every five who took the disease. Of the 8,000 who had not been vaccinated nor had smallpox, 4,000 contracted it and 1,000 died, or one in every four. By this it appears that one-half of the non-vaccinated, one-fifteenth of the vaccinated, and one-hundredth of the variolated took the disease. But such was the difference in the comparative mortality of the attack in the vaccinated and the variolated, that while the variolated part of the population were cut off in the proportion of one out of every 500, the vaccinated lost only one out of every 1,500; or, in other words, of an equal number of variolated and vaccinated cases, three of the variolated died from the second attack, for every one that died who had been previously vaccinated."

In Berlin in the year 1872,<sup>34</sup> the mortality of the disease was 243 per 100,000 population, and the year after it was 262. Thereupon vaccination during the first year of life and revaccination at the age of 12 years was made compulsory by law, and with the effect that in the year 1875 the death rate was lowered to 36 per 100,000 inhabitants; the next year it was lowered to 31, the next to 3 and so through later years with an average annual mortality of 1.7 per 100,000 people. During the year 1890 only fifty-eight cases occurred in the whole German Empire, or 1.18 cases to each 1,000,000 of population.

A village in Leicestershire, England, of 1,300 inhabitants was visited by the pestilence in 1872. All but two of the inhabitants were efficiently vaccinated and escaped the disease; whereas the two unvaccinated persons died of it.

The late Dr. J. H. Rauch, for many years Secretary of the State Board of Health, has shown that in the Illinois epidemic of 1881-83, the mortality rate of the vaccinated was approximately 6 per cent., and of the unvaccinated it was 49 per cent.

Corbally has demonstrated that in the Sheffield, England, epidemic of 1887-88, vaccinated children were, as compared with the unvaccinated, twenty times less liable to attack from smallpox, and twenty-four times less liable to die when attacked. That is to say, the vaccinated children had, as compared with the unvaccinated, four hundred and eighty fold security against death from smallpox.

In the Halifax, England, epidemic of 1892-93, the death rate from smallpox among vaccinated persons was 1.8 per cent., and among the unvaccinated it was nearly 41 per cent. No case occurred in a vaccinated child under 5 years of age, and in the Leicester epidemic of 1893 no case occurred in a vaccinated child under 10 years of age.

From the records of 5,000 cases treated in the Municipal Hospital of Philadelphia, according to W. M. Welch in the *New York Medical Journal*, March, 1894, it appears that the death rate in that institution in post-vaccinal cases, and all in which there had been an attempt at vaccination are included, was 16.26 per cent., and the death rate in non-vaccinal cases was 58.38 per cent.

Seventy-three per cent. of the cases in unvaccinated infants under 1 year of age ended in death, and no fatal case occurred among vaccinated infants of the same age. Between the ages of 1 and 7 years the mortality of post-vaccinal cases was 5.7 per cent., and of non-vaccinal cases it was 51.48 per cent.

In Chicago only seventeen cases of smallpox have occurred in the last fifteen years among the well vaccinated public school children of that city, whose average number exceeded 200,000.

Dr. Clendenin,<sup>35</sup> health officer of Cincinnati, Ohio, says that, in the epidemic of smallpox in that city (1868-69) 95 per cent. of those who died of smallpox were among the unvaccinated. He further says that no death occurred from smallpox in which there was unmistakable proof that the individual had been properly vaccinated.

Dr. Benj. Lee of Philadelphia, Pa., in his report to the Pennsylvania State Medical Society, 1873, shows that the mortality from smallpox in the epidemic then just ceased was 55.9 per cent. in the unvaccinated; in the vaccinated with one

<sup>32</sup> I presume that "ungeimpft verbliebene" in the third column is intended to denote (in comparison with the total births of the year) the number of infants who remain unvaccinated at the end of the legally specified time.—[J. S.]

<sup>34</sup> Vital Statistics, Indiana, 1894, p. 98-99.

<sup>35</sup> Dr. W. B. Davis, Transactions, Ohio Medical Society, 1870.

vaccinal scar it was 15.2 per cent., while the mortality among those having five or more scars was 5.5 per cent.

During 1875 the mortality among 1,866 vaccinated persons treated in the Riverside Hospital, New York City, was 375, while among the 405 patients who had never been vaccinated, 200 died.

Statistical tables demonstrating the unquestionable controlling power of vaccination over smallpox might be multiplied indefinitely, but I have already, I fear, entered too lengthily into this part of my subject. I will therefore close the statistical data under Proposition 6 by quoting the following :

1. Mortality from smallpox among the vaccinated, doubtfully vaccinated and unvaccinated.<sup>36</sup>

	Cases.			Deaths.			Mortality Per cent.		
	Vaccinated.	Doubtfully vaccinated.	Unvaccinated.	Vaccinated.	Doubtfully vaccinated.	Unvaccinated.	Vaccinated.	Doubtfully vaccinated.	Unvaccinated.
London Smallpox Hospital (1836-67) <sup>37</sup> . . . . .	10,308	268	2,920	790	106	1,013	7.59	40.3	34.9
Metropolitan Asylum Board Hospital <sup>38</sup> . . . . .	13,575	2,180	3,973	1,027	671	1,593	7.56	31.5	40.0

2. Mortality from smallpox among the vaccinated, doubtfully vaccinated and unvaccinated, under 10.

	Cases.			Deaths.			Mortality Per cent.		
	Vaccinated.	Doubtfully vaccinated.	Unvaccinated.	Vaccinated.	Doubtfully vaccinated.	Unvaccinated.	Vaccinated.	Doubtfully vaccinated.	Unvaccinated.
Metropolitan Asylum Hospitals <sup>39</sup> . . . . .	1,291	359	1,512	56	102	745	4.33	28.4	49.2

Dr. Lyon Playfair in a speech in the British House of Commons, June, 1883, said : "On this point I would refer to the case of Leipsic, which for eighteen years prior to 1870, had zealously supported the anti-vaccination movement, and during that period there had been but twenty-nine deaths from smallpox, although vaccination had been greatly neglected in the town. When the pandemic reached Leipsic in 1871 the town had a population of 107,000, and smallpox attacked 1,027 of this number, or 9,600 per million of the population, and out of 23,892 children under 15 years of age, 715 died, being 30,000 per million."

"The statistics of the London epidemic were prepared with great care, and the mortality among the vaccinated was 90 per million inhabitants, while among the unvaccinated it was 3,350 per million. In the hospitals 45 per cent. of the unvaccinated and 15 per cent of the vaccinated died."

Comparative mortality of smallpox after smallpox, and of smallpox after vaccination.

Authorities.	Smallpox after smallpox.			Smallpox after vaccination.		
	No. of cases.	Deaths.	Ratio of deaths to 100 cases.	No. of cases.	Deaths.	Ratio of deaths to 100 cases.

<sup>36</sup> In the statistics of the metropolitan smallpox asylums, the "vaccinated" are those who present marks, however imperfect, of a primary vaccination; the "unvaccinated" those who present no marks, and in whose case it is admitted by the patients themselves, or their guardians, that they have never undergone the operation; the "doubtfully vaccinated" those who present no evidence of vaccination but who profess to have undergone the operation or have no knowledge as to whether they have ever undergone the operation. It is evident that the "doubtfully vaccinated" are really "unvaccinated."

<sup>37</sup> Marson: Evidence before the Select Committee on Vaccination, 1871.

It thus appears that, while they who take smallpox a second time die in the proportion of 15.7 in the 100, they who take smallpox after vaccination die only in the proportion of 3.3 in the 100—a proportion absolutely lower than the mortality of the mildest disease.

Borough of Sheffield, England. In this Borough in an epidemic of smallpox during the years 1887 and 1888, Dr. F. W. Barry, inspector of the Local Government Board, after having a house to house inspection made throughout these two years, gives the following report as the result of his investigation :

VACCINATED.

In the borough of Sheffield there resided 268,397 persons who had been returned as vaccinated. Of these 4,131, or 1.55 per cent., had been attacked by smallpox, and 0.07 per cent. died of the disease.

Of the 68,230 vaccinated children under 10 years of age 353, or 0.5 per cent., contracted smallpox, and 6, or 0.009 per cent., died.

Of 196,905 vaccinated persons aged 10 years and upward 3,374, or 1.9, contracted smallpox and 194, or 0.10 per cent., died.

UNVACCINATED.

There were 5,715 citizens of all ages returned as unvaccinated. Of these, 552, or 9.7 per cent., had been attacked by smallpox, and 4.8 per cent. died.

Of 2,259 unvaccinated children under 10 years of age 228, or 10.1 per cent., contracted smallpox and 100, or 4.4 cent., died.

Of 3,429 unvaccinated persons aged 10 years and upward 322, or 9.4 per cent., contracted smallpox and 174, or 5.1 per cent., died.

The proportions of unvaccinated and vaccinated who were attacked and who died of smallpox among the inmates of houses that were actually invaded by smallpox, that is where people were brought in actual contact with the disease, Borough of Sheffield, England, 1887-1888. Of course in the general population of the Borough a number of citizens were never brought into actual contact with infected persons or fomites.

In the whole Borough of Sheffield 18,756 persons of all ages were enumerated as living in houses invaded by smallpox and of these 4,703 or 25.1 per cent. contracted the disease, and 474 or 2.5 per cent. died.

The proportions of the population of the vaccinated and unvaccinated classes respectively, living in invaded houses in the entire Borough, who had been attacked by smallpox and who died of the disease, were as follows :

VACCINATED.

Of the 18,020 vaccinated persons of all ages enumerated as living in invaded houses 4,151, or 23 per cent., contracted smallpox and 200, or 1.1 per cent., died.

UNVACCINATED.

Of the 736 unvaccinated persons of all ages enumerated as living in invaded houses 552, or 75 per cent., contracted smallpox and 274, or 37.3 per cent., died.

CHILDREN UNDER 10 YEARS OF AGE.

VACCINATED.

Of 4,498 children under 10 years of age 353, or 7.8 per cent., contracted smallpox and 6, or 0.1 per cent., died.

Of 13,435 vaccinated persons, aged 10 or upward 3,374, or 28.1 per cent., died.

UNVACCINATED.

Of 263 unvaccinated children under 10 years of age 228, or 86.9 per cent., had smallpox and 100, or 38.1 per cent., died.

Of 469 unvaccinated persons 10 years old and upward 322, or 68.6 per cent., contracted smallpox and 174, or 37.1 per cent., died.

On page 42 of Report of Royal Vaccination Commission the following facts are to be found giving the proportions of the population of the Borough of Sheffield of the vaccinated and unvaccinated classes respectively at these several age-periods who at the end of the census had contracted smallpox, and who had died of the disease.

IN THE TOTAL ENUMERATED POPULATION.

VACCINATED.

Of 33,393 vaccinated children under 5 years of age 121, or 0.36 per cent., had been attacked by smallpox and 1, or 0.003 per cent., had died.

Of 34,843 vaccinated children aged 5 but under 10 years 282, or 0.67 per cent., had been attacked and 5, or 0.14 per cent., had died.

Of 32,965 vaccinated persons aged 10 but under 15 years 629, or 1.9 per cent., had been attacked and 11, or 0.03 per cent., had died.

Of 27,111 vaccinated persons aged 15 but under 20 years 979, or 3.6 per cent., had been attacked and 19, or 0.07 per cent., had died.

UNVACCINATED.

Of 1,981 unvaccinated children under 5 years of age 128, or 6.5 per cent., had been attacked by smallpox and 66 (exclusive of children under one month of age), or 3.3 per cent., had died.

Of 278 unvaccinated children aged 5 but under 10 years 100, or 36 per cent., had been attacked and 34, or 12.2 per cent., had died.

Of 235 unvaccinated persons aged 10 but under 15 years 91, or 38.7 per cent., had been attacked and 32, or 13.6 per cent., had died.

Of 282 unvaccinated persons aged 15 but under 20 years 84, or 29.8 per cent., had been attacked and 53, or 18.8 per cent., had died.

The above facts are extracted from the testimony of F. W. Barry, M.D., inspector of Local Government Board, Oct. 8, 1889, pages 39 to 42 inclusive, Second Report of Royal Vaccination Commission of England, submitted to Parliament, May 29, 1890.

<sup>38</sup> These include cases admitted into the following asylums: Deptford, 1878-81; Hamstead, 1876-78; Homerton Smallpox Hospital, 1871-82; Homerton, Fever Hospital, 1876-77 and 1881-82; Stockwell, 1882. *Vide* annual reports of the several hospitals. For further figures consult report of board of health of the city of Philadelphia, 1872; papers on vaccination by Mr. Simon, etc.

<sup>39</sup> Homerton Smallpox Hospital, 1871-80; Deptford Hospital, 1878; Stockwell Smallpox Hospital, 1882.

## VACCINATED.

Of 44,788 vaccinated persons aged 20 but under 30 years 1,267, or 2.8 per cent., had been attacked and 69, or 0.15 per cent., had died.

Of 92,041 vaccinated persons aged 30 and upward 899, or 0.97 per cent., had been attacked and 95, or 0.1 per cent., had died.

On page 43 of the same report will be found the following tables as to the proportions of vaccinated and unvaccinated in the invaded houses by age-periods.

## VACCINATED.

Of 2,154 vaccinated children under 5 years of age enumerated as living in invaded houses 121, or 5.6 per cent., had been attacked by smallpox and 1, or 0.05 per cent., had died.

Of 2,339 vaccinated children aged 5 but under 10 years 232, or 9.9 per cent., had been attacked and 5, or 0.21 per cent., had died.

Of 2,496 vaccinated persons aged 10 but under 15 years 629, or 25.2 per cent., had been attacked and 11, or 0.4 per cent., had died.

Of 2,370 vaccinated persons aged 15 but under 20 years 979, or 41.3 per cent., had been attacked and 19, or 0.8 per cent., had died.

Of 3,278 vaccinated persons aged 20 but under 30 years 1,267, or 38.7 per cent., had been attacked and 69, or 2.1 per cent., had died.

Of 5,290 vaccinated persons aged 30 years and upward 899, or 17.4 per cent., had been attacked and 95, or 1.8 per cent., had died.

NOTE.—"Those classified as vaccinated include all persons successfully at any period beyond thirteen days prior to the appearance on them of the eruption of smallpox. As a matter of fact I do not think there is a recorded case in which smallpox quickly followed vaccination or re-vaccination when the interval between the operation and the appearance of smallpox exceeded six or seven days. Those classified as unvaccinated include all persons who have either never been successfully vaccinated or whose vaccination was performed for the first time within thirteen days of the appearance on them of the eruption of smallpox. In the vaccination census if a person stated that he was vaccinated that was accepted as correct; if he stated that he was unvaccinated that again was accepted as correct. A certain number were reported as vaccinated who really were unvaccinated." Barry, *loc. cit.*

Question 1988. Dr. Barry continuing (see page 45) said: I propose to read in very much the same manner as I have read with regard to the census data, the relations of vaccination and smallpox as indicated by the health office data. I first of all take page 190. The total cases of smallpox reported to the health department to have occurred in the Borough of Sheffield during the period from the commencement of the epidemic to the 31st of March, 1888, were 6,088 in number. Of these it was stated that 5,035 were of the "vaccinated" as against 1,053 of the "unvaccinated" class. In 589 cases, or 9.7 per cent., of the total of all classes attacked the disease proved fatal. Of the 5,035 persons of the "vaccinated" class attacked, 246, or 4.9 per cent., died; whilst of the 1,053 persons of the "unvaccinated" class attacked 343, or 32.6 per cent., died. In the "vaccinated" class smallpox is reported to have attacked 97 persons under 5 years of age, of whom 1, or 1 per cent., died; 243 between 5 and 10 years of age, of whom 6, or 2.5 per cent., died; 2,034 between 10 and 20 years of age, of whom 38, or 1.9 per cent., died; 1,579 between 20 and 30 years of age, of whom 87, or 5.5 per cent., died; and 1,084, aged 30 years and upward, of whom 114, or 10.5 per cent., died. In the "unvaccinated" class, smallpox is reported to have attacked 242 persons under 5 years of age, of whom 113, or 46.7 per cent., died; 184 between 5 and 10 years of age, of whom 39, or 21.2 per cent., died; 380 between 10 and 20 years of age, of whom 92, or 24.2 per cent., died; 169 between 20 and 30 years of age, of whom 65, or 38.5 per cent., died; and 78 aged 30 years and upward, of whom 34, or 43.6 per cent., died.

Dr. Barry, page 51, Second Report of Royal Vaccination Commission gives a tabular statement showing the fatality per cent. of admissions in each hospital and all hospitals in Sheffield in 1887 and 1888, and says:

From an examination of that table it will be seen that there is a general correspondence between the fatality rates which obtained in the several hospitals at the different age periods. The figures with regard to the Lodge Moor and Ecclesall Bierlow Hospitals show the chief variations, but in the case of these hospitals the figures are very small. From the summary of the figures with regard to all the hospitals, it appears that the total of 1,798 cases of smallpox, 256, or 14.2 per cent., proved fatal. Of the total number of cases, 1,351 were of the "vaccinated" as against 447 of the "unvaccinated" class. Of the 1,351 persons of the "vaccinated" class admitted, 110, or

## UNVACCINATED.

Of 884 unvaccinated persons aged 20 but under 30 years 98, or 10.8 per cent., had been attacked and 61, or 6.9 per cent., had died.

Of 2,028 unvaccinated persons aged 30 and upward 49, or 2.4 per cent., had been attacked and 28, or 1.4 per cent., had died.

## UNVACCINATED.

Of 154 unvaccinated children under 5 years of age enumerated as living in invaded houses 128, or 83 per cent., had been attacked by smallpox and 66 (exclusive of children under one month old), or 42.9 per cent., had died.

Of 109 unvaccinated children aged 5 but under 10 years 100, or 91.8 per cent., had been attacked and 34, or 31.2 per cent., had died.

Of 93 unvaccinated persons aged 10 but under 15 years 91, or 98 per cent., had been attacked and 32, or 34.4 per cent., had died.

Of 98 unvaccinated persons aged 15 but under 20 years 84, or 85.8 per cent., had been attacked and 53, or 54.1 per cent., had died.

Of 124 unvaccinated persons aged 20 but under 30 years 98, or 79.1 per cent., had been attacked and 61, or 49.2 per cent., had died.

Of 154 unvaccinated persons aged 30 years and upward 49, or 31.8 per cent., had been attacked and 28, or 18.2 per cent., had died.

8.1 per cent., died; whilst of the 447 "unvaccinated" persons admitted, 146, or 32.7 per cent., died. Of the 1,351 persons of the "vaccinated" class admitted, 67 were under 10 years of age, and of these 1, or 1.5 per cent., died; 573 were aged 10 but under 20 years, and of these 13, or 2.3 per cent., died; 426 were aged 20 but under 30 years, and of these 42, or 9.9 per cent., died; and 285 were aged 30 years and upward, and of these 54, or 19 per cent., died. The whole of the persons of the "vaccinated" class who died had been vaccinated in infancy only, with one exception, and the figures show a greater liability to fatal termination with increasing years. Of 447 persons of the "unvaccinated" class admitted, 101 were under 10 years of age, and of these 34, or 33.7 per cent., died; 205 were aged 10 but under 20 years, and of these 56, or 27.3 per cent., died; 100 were aged 20 but under 30 years, and of these 41, or 41 per cent., died; and 41 were aged 30 years and upward, and of these 15, or 36.6 per cent., died. In the hospitals of course all the patients were under the same conditions; they were not being treated in different class houses, some in good ones and some in bad ones, but they were all being treated under the same nursing and with the same general surroundings, and, as I here note in the report, "except during the first few months of the epidemic, very few of the milder cases found their way to the hospitals, and consequently the proportions of severe and fatal cases were larger there than amongst the population as a whole." Then dealing in the same way with the fatality of the cases in hospital, taking all ages. Taking children aged 0-10: "For each individual vaccinated child 0-10 years of age suffering from a fatal attack of smallpox, 22.4 unvaccinated children died of that disease." Taking persons from 10 to 20 years of age: "For each individual vaccinated person, 10 to 20 years of age suffering from a fatal attack of smallpox, 12 unvaccinated persons of similar age died of that disease." Then as to persons from 20 to 30 years: "For each individual vaccinated person aged from 20 to 30 years of age suffering from a fatal attack of smallpox, 4.1 unvaccinated persons of similar age died of that disease."

(To be continued.)

## SOCIETY PROCEEDINGS.

## American Association of Obstetricians and Gynecologists.

Ninth Annual Meeting held in Richmond, Va.,  
Sept. 22-24, 1896.

## FIRST DAY—MORNING SESSION.

The Association was called to order at 10 A.M. by the President, Dr. JOSEPH PRICE of Philadelphia.

After the usual preliminary exercises, the reading of papers was proceeded with.

Dr. JOHN M. DUFF of Pittsburg, read a paper entitled PELVIC DISEASES AND THEIR PRINCIPAL CAUSES; WHAT SHOULD THE LAITY BE TAUGHT CONCERNING THEM?

He said that notwithstanding the fact that some of the prominent members of the medical profession had, in talks to the galleries, held the gynecologists up for ridicule and criticised them severely, he did not think any apology was due either the profession or the public for the character, or results of pelvic surgeons. Those members of the profession who had been devoting themselves to the care of diseases peculiar to women, had in the face of revilings and professional and public prejudice worked patiently and persistently until they were now obtaining results of which they may well feel proud, results far beyond what the most sanguine expectations of the hardy pioneers of a quarter of a century ago led them to hope for. They were to-day charged with irrational radicalism, with an operative mania, which was gratified without a proper consideration of the ultimate benefit to the patient. Entreatingly they were urged to adopt more conservative measures, and thus stop the wholesale mutilation which was going on at present, which it is claimed is neither scientific nor humane. Sentiments such as these, endorsed by men of reputation, were eagerly taken up by the lay press as sensational news and advertised by pretenders as an endorsement of their methods of practice, and thus the laity, in the opinion of Dr. Duff, are taught false notions regarding the nature of pelvic diseases and their treatment. That there is a great amount of mutilation connected with pelvic surgery, he would not deny; but that regular pelvic surgeons were guilty of reckless despoliation was not, he thought, susceptible of proof. Pelvic surgeons could scarcely be held accountable for the work of general

practitioners; and for the work of ignorant egotists and pretenders, who with brazen effrontery undertake operations of which they are not qualified by character or education, the pelvic surgeons disclaim all responsibility.

During the period of the evolution and upbuilding of pelvic surgery no doubt much of the work was crude, and perhaps too much was done by over-zealous operators. That at this day, through mistaken diagnosis, operations are sometimes needlessly performed, no one would have the hardihood to deny; but that such cases are as frequent as some critics say they are, Dr. Duff could not believe. He said the true pelvic surgeon was governed by nobler purposes, by more elevated aims. Conservatism in its true sense, the saving of life, relief from pain and the curing of the patient, was his watchword. Dr. Duff then dwelt at length upon various pathologic conditions which demand the attention of the pelvic surgeon.

Dr. WALTER B. DORSETT of St. Louis, followed with a paper on

DECEPTIVE SIMILARITY OF SIGNS AND SYMPTOMS OF INTRA-ABDOMINAL DISEASE, WITH CASES.

In order to arrive at a conclusion and to formulate a diagnosis in a given case, be it medical or surgical, the practitioner must exercise care and judgment in the consideration of such signs and symptoms as are presented. Each should be weighed, and mental annotations taken as to their value individually and collectively.

Dr. Dorsett directed attention to the importance of the family and personal history of patients, to the pulse and temperature, the knowledge to be gained by manual examination, the use of analgesics, etc.

Regarding the exploratory incision, it should not be regarded as an evidence of ignorance, but as a legitimate means of diagnosis, and the off-hand diagnostician, or the surgeon who never makes mistakes, should be looked upon with, at least, a grain of suspicion. To illustrate his statements, three interesting cases were reported, one of which we give in full:

Mrs. M., aged 28, married eight years, no pregnancies, was seen by Dr. Dorsett about a week after having recovered from an attack of malarial fever. Temperature 99, pulse 90, tongue slightly coated and a tendency toward diarrhea. Complained of general abdominal tenderness; palpation of abdomen revealed a slightly more tender spot at McBurney's point; no swelling or tumefaction could be felt. A vaginal examination revealed a retroversion with fixation, no tubal enlargement nor tenderness could be made out. No vaginal discharge. Diagnosis: Gastro-intestinal irritation with chronic inflammation of pelvic contents; diarrheal mixture was prescribed and patient was told that further attendance would probably not be necessary. Four days subsequently the temperature was 99.8 F., pulse 100, abdominal palpation revealed a distinctly tender spot with some swelling at McBurney's point. Patient stated that she had eaten heartily of Wienerwurst the day before, and had been awakened during the night by cramps at the navel. Bimanual examination was again resorted to with negative result. Appendicitis was diagnosed at this visit, first stage. Dram doses of salts were prescribed, and the patient was urged to go to the hospital, but refused. The next day she was seen and found sitting in a rocking chair, and aside from slight tenderness over abdomen, was feeling quite comfortable. Salts acted freely. Bimanual examination again gave negative results; temperature 99, pulse 100. Patient was ordered to bed and advised to keep quiet. The case was regarded as better and thought to be out of danger. The following day the pain became more severe and the patient came to the hospital of her own accord. Upon examination the right iliac fossa was found to be exceedingly tender and fluctuating. Vaginal examination revealed nothing aside from what was found at the previous examination. Temperature 103, pulse 130. Diagnosis: Ruptured appendiceal abscess. She was anesthetized and placed upon the table and a section made in the median line. The large sac was found on the right side filled with blood and clots, and when washed out a rent of the posterior layer of the broad ligament was found which communicated with another rent in the Fallopian tube. Appendix perfectly healthy, and was not disturbed. A thorough washing out of the sac was done and ligation of the tube with a portion of the broad ligament, a glass drainage tube was introduced. Notwithstanding the utmost care, the temperature remained high, pulse became worse, the abdomen became distended, and the patient died on the third day.

Postoperative diagnosis: Ruptured tubal pregnancy without the usual symptoms. There was no history of shock; no cessation of menstruation, or nervous symptoms of pregnancy. No passage of decidua; no vaginal discharge of any kind, but in its stead a good history and train of signs and symptoms of inflammatory disease of the appendix.

Dr. RUFUS B. HALL of Cincinnati read a paper entitled,

THE MOST POTENT CAUSES OF PELVIC INFLAMMATION.

He claimed that septic infection following labor or abortion or gonorrheal infection, was the cause in almost every instance. He says there will always be some cases of septic infection following labor, which are in nowise due to infection from the attendant, injury to small pelvic tumors, etc. The retention of the products of conception in abortion is a very frequent cause. He advises completely emptying the uterus at once after abortion. The Doctor believes the most frequent cause to be gonorrheal infection conveyed to the woman from a latent gonorrhea of her husband. The more he sees of the ravages of gonorrhea, the more he is convinced of the fact that the profession is derelict in its duty to its patients in the dissemination of knowledge upon this subject. The teaching of a few years ago that gonorrhea in the male could be easily and speedily cured by a little balsam of copaiba, or oil of sandal wood, with mild astringent injections, and that the patient was well as soon as the purulent discharge ceased, is false doctrine and must be corrected. This must be done by the family physician. Dr. Hall does not stand alone when he says that he has on many occasions been compelled to remove suppurating tubes and ovaries from women who had contracted the disease from their husbands, who believed themselves well when married. He has no hesitation in saying that gonorrhea is more destructive to women than syphilis, and believes it is the duty of every physician to impress upon his male patient the fact that he is not well as soon as the urethral discharge disappears. He is a firm advocate of legislation upon this, believing that every man should have a certificate from the health officer of freedom from syphilis and gonorrhea before he is granted a marriage license.

Dr. HENRY CARSTENS of Detroit in discussing the three preceding papers, said that when prominent ministers of churches consulted physicians and asked them to produce abortion on their wives he became discouraged, and thought it was love's labor lost. Still the gynecologist should keep on preaching against the evils attending the production of abortion. Regarding Dr. Dorsett's paper, the difficulty attending diagnosis in some cases was exceedingly great. The gynecologist should exhaust his diagnostic resources before resorting to abdominal section. The too frequent opening of the abdomen stimulated incompetents to do likewise, and as a consequence results were disastrous, eventually reacting on gynecologists.

Dr. W. E. B. DAVIS of Birmingham, Ala., does not believe that gonorrhea plays so important a part in the production of pelvic inflammation as was heretofore taught. One's conception of cases of pelvic trouble depends largely upon the class of practice he has. The cases met with in dispensary practice are different from those encountered in private work. He believes that fully 50 per cent. of the cases of pelvic inflammation are due to puerperal infection, either at the time of delivery at full term or premature delivery. As to tubercular trouble, more importance is being attached to it as a cause of pelvic inflammation than it deserves. Those who did considerable operative work knew that only a small per cent. of cases have their origin in tuberculosis.

Dr. JAMES MCFADDEN GASTON of Atlanta (by invitation) called attention to the prophylactic management of cases of pregnancy prior to the period of confinement. Extreme hygienic precautions might warrant in some instances the use of antiseptic washes prior to labor, but as there was a great tendency on the part of some members of the profession to resort to measures which are regarded as precautionary in the way of preparing a woman for labor and using washes in advance of confinement, it struck him this was altogether out of place, inasmuch as there was a normal condition of things, and nature should be allowed to take its course unless there were ample reasons for interference.

Dr. ERNEST S. LEWIS of New Orleans cited a case in connection with errors that sometimes arise in the diagnosis of abdominal tumors. He operated on a patient last winter for what he supposed at the time was a small ovarian tumor, but after the abdomen was opened it turned out to be a retroverted gravid uterus.

Dr. F. D. THOMPSON of Fort Worth, Texas, would like the essayists to have gone more fully into the point as to when it was safe for men to marry and have intercourse with their wives, who had been the subjects of gonorrhea. Many cases of gonorrhea occurred in married men, and the gynecologist had before him all the ills and consequences incident to this disease. How long shall such men abstain from sexual intercourse? These points should be dealt with more fully and explicitly.

Dr. LEWIS S. McMERTRY of Louisville considered the view enunciated by Dr. Hall as to gonorrhea and its relations to

marriage impracticable. Regarding the exploratory incision for diagnostic purposes, a small opening was not always sufficient. The incision should be sufficiently large to allow the surgeon to thoroughly explore the abdominal cavity to detect such pathologic conditions as might be present.

Dr. L. H. DUNNING of Indianapolis cited cases of the impracticability of making a small incision for the detection of intra-abdominal pathologic conditions. He favors an exploratory opening sufficiently large to make a thorough search.

Dr. A. H. CORDIER of Kansas City, Mo., said, regarding the possibility of making diagnoses in intra-abdominal pathologic conditions, that in 80 per cent. of the cases this could be done by painstaking efforts.

Dr. EDWIN RICKETTS of Cincinnati agreed with the previous speakers that it was exceedingly difficult to diagnose intra-abdominal lesions previous to opening the abdomen, and sometimes the surgeon did not know the nature of the growth even after the abdomen was opened. Cases illustrating the great difficulty attending diagnosis of intra-abdominal growths were cited.

Dr. E. F. FISH of Milwaukee said that while he did not believe in promiscuous exploratory laparotomy, he could recall one case in particular in which the operation saved the patient's life.

Dr. RICHARD H. GIBBONS of New York City thought many of the cases dealt with in the papers were due to puerperal contamination, or in some instances to laceration of the cervix, as had been pointed out by Emmet. He believes that Noeggerath gave us the keynote to the class of infection produced by gonorrhoea. Relative to diagnosing intra-abdominal diseases, there was no particular symptom that was pathognomonic. Dr. Gibbons pointed out the unreliability of McBurney's point, of which so much had been said and written, and called attention to an article written by him and published in the *New York Medical Journal*.

Dr. HOWARD W. LONGYEAR of Detroit emphasized the importance of educating the laity in regard to gonorrhoea. He believes the teachers of our public schools should be empowered to impart the necessary knowledge regarding the dangers of this disease and its consequences.

Dr. GEORGE BEN JOHNSTON of Richmond presented the specimen of an ovarian tumor, the first removed under Listerism in the State of Virginia so far as he had been able to ascertain. The patient was an unmarried woman, 26 years of age. The tumor was removed March 19, 1879. The tumor with the sac and fluid contents weighed thirty-four pounds. The operation was performed under the spray and with the elaborate dressings recommended by Lister, etc. The patient died, however, from sepsis. In November of the same year he was consulted by Mrs. M., whom he presented to the Association for what turned out to be an enormous unilocular ovarian tumor. Her measurements were 6 feet, 4 inches around the abdomen at the umbilicus, and 3 feet, 2 inches from the ensiform cartilage to the pubes. The contents of the tumor and sac weighed ninety-six pounds. This operation was performed at the patient's house with the same care as that of the previous one.

#### TUBO-OVARIAN CYSTS WITH INTERESTING CASES.

Dr. ALBERT GOLDSPOHN of Chicago read a paper on this subject. By tubo-ovarian cyst is meant a non-purulent sac whose walls are composed, in variable proportion, of the walls of the Fallopian tubes and those of some cystic ovarian or parovarian formation with the coalescence of two or more cavities, at least one from each, into one, by a free communication. The fluid contents of such a sac may be serous or hemorrhagic, or may partake in variable degree of the qualities and characteristics of the fluid contained in glandular ovarian cystomas. The fimbriæ of the abdominal ostium of the tube may be distinguished or not upon the inner or on the outer side of the ovarian portion of the sac, or they may have coalesced with other structures to form some portion of the walls of the united sac. The ovarian element in this formation can have originated from a hydropic Graafian follicle, a cystic corpus luteum, from the primordial glandular ducts of Pflueger in the ovary, or from the parovarium. In order to exclude a large number of ordinary tubo-ovarian conglomerates we need to recognize the following minimum requirements in distinguishing a tubo-ovarian cyst: 1, the participation of the tube, which is easy enough from its position and connections; 2, to prove the participation of the ovary by demonstrating some ovarian tissues in the wall of the sac; 3, that their cavities are united by some opening through which the mucous membrane of the tube is continuous with the lining of the ovarian cyst or follicle. Applying this standard the author has been compelled to exclude a number of cases that have been mentioned as such

cysts, because the three points were not proven in each of the cases.

The first description of a tubo-ovarian cyst was given by Blasius in 1834, but the correct name was proposed by Richard in 1853, who spoke of "kysts tubo-ovariens" in demonstrating a number of postmortem specimens. The total number of authenticated cases that the author has been able to find in literature is thirty-eight by twenty-five different authors. Dr. Goldspohn reported three interesting cases, and called attention to some interesting features in connection with the anatomy as influencing intermittent profluent discharges and showing the inflammatory element in their causation. From a study of specimens, from the results of experience, and from the arguments of the best authors, the author deduces the following conclusions:

1. Tubo-ovarian cysts come to pass in consequence of a plastic inflammatory union between a Fallopian tube and the adjacent ovary, after either or both of these organs and the intervening peritoneum have experienced a non-purulent pathologic change of a cystic character. The septum intervening between the two lumina disappearing in consequence of pressure atrophy from the tension of liquid confined to one or both sides of it.

2. This union of a distended tube cavity may occur also with that of a parovarian cyst (v. Ott), or with that of a peritoneal pseudo-cyst (Zedel).

3. In those rarer cases in which the fimbriæ are really found floating in the interior of the main cyst cavity, we must assume either the congenital anomaly of an "ovarian tube," as was seen by Schneidmahl in a mare, as a vitium primæ formationis, or that an ovarian cyst or follicle cyst ruptured, and the abdominal end of the tube dropped into the rent and was united to its edges by inflammatory action, thus making a joint cyst and tubal cavity.

Dr. WALTER B. CHASE, of Brooklyn, followed with a paper entitled

#### MIXED TUMORS OF THE OVARY.

Mixed tumors of the ovary have a peculiar interest, for the reason that, if small, they are often difficult of diagnosis. These tumors of the ovary may be made up of a variety of cysts, or may be a combination of cysts and solid growths. The etiology of tumors as a whole is a matter of great importance, both in the relation to diagnosis and treatment.

The question of what constitutes a tumor might be considered with profit. Senn, in his recent classical work on the "Pathology and Surgical Treatment of Tumors," defines a tumor as "a localized increase of tissue proliferation of embryonic cells of congenital or post-natal origin." An important fact concerning true tumors is that they never disappear except by removal or destruction. Benign tumors always remain local, while malignant ones are disseminated by migration or transportation of their peculiar cells, and they always originate as benign or malignant growths. If the tumor matrix is made up of embryonic cells of the lowest development, there is greater liability to malignant growth, than if from tissues susceptible to the highest physiologic type of development.

Retention cysts of the ovary are not tumors in a technical sense, and they never attain large size. Large ovarian cysts are most often cystadenomas and are not developed from Graafian follicles, but arise from the embryonic structure.

It would seem from what has been said that the genesis of simple and mixed tumors is divested of much that was misleading and contradictory and reduced to a rational basis. It also demonstrates with great clearness that tumors are not only of local origin, but at their inception are congenital.

The case reported, which was operated upon by the author at St. John's Hospital, Aug. 4, 1894, as reported by Dr. H. P. De Forest, pathologist to the Methodist Episcopal Hospital, was a mixed tumor of the left ovary, consisting of a large cystadenoma, containing about two gallons of clear straw-colored fluid, a dermoid intimately united with the cystadenoma, containing less than a quart of fluid, leaving true bony plates in its wall, and numerous encysted papillomas encrusted within the walls of both cysts.

#### AFTERNOON SESSION.

Dr. A. H. CORDIER of Kansas City, Mo., read a paper on MOVABLE KIDNEY; LOCAL AND REMOTE RESULTS in which he drew the following deductions: 1. A movable kidney often produces a dilatation of the stomach with all the accompanying symptoms of a disease of that organ. 2. It is a fruitful source of gallstones, because of the pedicle producing a partial obstruction of the common duct. 3. The bending of the ureter often gives rise to a hydronephrosis. This, in turn, is sometimes converted into a pyonephrosis. 4. It may pro-

duce death by a complete strangulation by a torsion of the vessels and ureter. 5. By dragging on the abdominal aorta and kinking the vena cava, a condition simulating an aneurysm of these vessels may be produced. 6. Pain of a referred character to the region of distribution of the spinal nerves is often induced by a movable kidney's disturbance of the abdominal plexus. 7. A general nerve exhaustion (neurasthenia) is often induced by the interference of this condition with digestion, assimilation and elimination. 8. Nephrorrhaphy is a safe and effective surgical procedure. 9. All cases of movable kidney, if accompanied by symptoms pointing to the kidney as their source should be operated on. 10. In summing up the local and remote results of this now often recognized condition, the author thinks the correctness of the deductions has been frequently demonstrated by the disappearance of each and every symptom after a restoration and retention of the kidney in its normal position. 11. Symptoms are not to be relied upon in making a diagnosis of movable kidney. The physical examination is the only trustworthy guide.

#### THE LIMITS OF NEPHRORRHAPHY

was the subject of a paper by Dr. HUGH M. TAYLOR of Richmond, Va. He conceded the frequency of nephroptosis. Since he had been systematically looking for movable kidney, he has found it so frequent in its occurrence that he no longer regards the experience of Glenard, Lindner, Edebohl and Noble as unique. His opinion is equally fixed that only a small proportion of the cases met with give rise to symptoms or suffering, ill health or death, and consequently a majority of cases do not call for nephrorrhaphy. He favors the classification of nephroptosis under three clinic heads:

1. Patients who have displaced kidney do not know it and suffer no inconvenience whatever from it. This type he thinks represents by far the largest class.

2. Patients with displaced kidney, who may or may not know it, who suffer from gastro-enteric discomfort and perhaps a long train of vague neurotic disturbances. In this type he thinks we find the largest class calling for operative interference.

3. Patients with movable kidney, who are subjects of occasional or frequent mild or severe attacks of renal crises. This last mentioned is he thinks the least frequent type met with, but the urgency of the symptoms more frequently demands operative interference.

Nephrorrhaphy for the relief of gastro-enteric disorder is limited by our ability to tell to what extent the disorder is due to renal ptosis *per se* or to enteroptosis, or to some one of the many well-known etiologic factors of gastro-enteric disorder. Nephrorrhaphy for the relief of the condition of Deitl's or renal crises must be limited by one's success in differentiating between this condition and that of gall tract, appendicular and kidney colic due to nephrolithiasis. He accepted as logically sustained the conclusion that the Deitl's or renal crises is due to a kink or twist of the ureter with retained urine in the ureter and pelvis of the kidney. Apart from the violent paroxysms of pain (the renal crises) the tendency of ureteral twist and urinary obstruction to induce hydronephrosis and in exceptional instances pyonephrosis, rendered operative interference more imperative in this class of cases. His protest was not against nephrorrhaphy, but only its abuse. He conceded the value of operative interference in many selected cases but deprecated the tendency toward operative interference merely because the kidney is movable.

Dr. GEORGE BEN JOHNSTON of Richmond, Va., said that some years ago his attention was called to the subject by encountering several cases of movable kidney that had been unobserved either by him or the physician who preceded him in the treatment of these cases for obscure nervous and gastro-intestinal disturbances, and when he observed the similarity of symptoms in the first three cases which he saw, he was obliged to associate those symptoms with the presence of movable kidney. He prevailed on these women to be operated upon for movable kidney and in all three cases the results were most gratifying.

Dr. L. H. DUNNING of Indianapolis, was greatly interested in the subject, for the reason that in 1880 he resorted to operative procedures for the cure of floating kidney, and in connection with this work he sought to determine if possible some of the causes which led to movable kidney. He emphasized the importance of differentiating between floating and movable kidney, the former being always congenital, the latter acquired to a greater or less extent. He found by his investigations that the partially fixed condition of the kidney depends upon three or four causes, the two principal ones of which were its position behind the peritoneum, and second the fact that it had an envelope of cellulo-adipose tissue. A little further investigation showed that the perinephritic cellulo-adipose tissue was composed of two parts, one fixed, the other movable. The normal

kidney had a range of motion of from one-half to three-quarters of an inch in its fatty envelope.

Dr. THOS. B. EASTMAN of Indianapolis, reported the case of a woman, 25 years of age, who came to him with the symptoms of appendicitis. She also had considerable albumin in the urine. Operation showed that the appendix was firmly adherent to the kidney. It required considerable force to liberate it. As soon as liberated the kidney bounded back into place as though it were rubber. The appendix was removed, the albumin in the urine ceased, and the woman made an uneventful recovery.

Dr. JAMES MCFADDEN GASTON of Atlanta, directed attention to the possibility of movable kidney being mistaken for enlarged gall bladder. The gall bladder is capable of being pushed back into the lumbar region and carried around in front in just the same manner as a floating kidney. It behooved gynecologists to look into this phase of the matter.

Dr. W. E. B. DAVIS of Birmingham, had seen a number of cases of movable kidney, and said that at the Charleston meeting of the Southern Surgical and Gynecologic Association there was quite a difference of opinion as to the frequency of the condition. He believes that movable kidney is a condition which does not require in all cases operative interference. Of the number of cases he had seen he had only operated on a few.

Dr. I. S. STONE of Washington, D. C., related the case of a woman who, after the operation of nephrorrhaphy had been performed, gained twenty-five pounds in flesh. In many instances this procedure brought color back to the cheeks of patients and made them feel well. He had never seen such gratifying results from any other operation in surgery except perhaps from the removal of an ovarian tumor. The patients made rapid improvement after the operation.

Dr. JOSEPH PRICE of Philadelphia, said his experience was somewhat limited in operating for movable kidney. The improvement in the condition of patients so operated upon was rapid, but there was such a thing as operating too much upon cases of movable kidney.

Dr. J. HENRY CARSTENS of Detroit, said the line should be drawn between movable and floating kidney. The trouble which arose from floating kidney consisted of a twisting of the ureter and consequent obstruction.

Dr. RICHARD H. GIBBONS of New York, detailed an operation which had been devised and recommended by a foreigner for holding the kidney in place in its newly made position.

#### TREATMENT OF PERIUTERINE SEPTIC DISEASES.

Dr. W. E. B. DAVIS of Birmingham, Ala., read a paper on this subject. Only recently has the extremely radical procedure of hysterectomy been practiced in this country for septic diseases of the internal genitals. A wave which had its origin in Paris at the hands of Péan, aided by Richelet, Segond, Jacobs and others, reached our shores three years ago and has found a considerable following among our leading operators. The claim is made that there is no use in leaving the uterus behind after the removal of the appendages; in every operation for septic diseases of the female generative organs which demands the removal of the tubes and ovaries, hysterectomy should also be performed, unless there are plain contraindications forbidding it.

It should be the aim of the surgeon to preserve everything consistent with thorough surgical work, and not to sacrifice important organs because it can be done with only small mortality. We are told that the uterus has no function after the removal of the appendages, but this has not been demonstrated, and on the contrary we know that the sexual life of the woman is very much better preserved by leaving the uterus, and that the mental effect is also much better. A slow convalescence, or even a second operation is preferable to its removal unless very much diseased. It is a reflection on the correctness of the reports of complete recoveries of such a large per cent. of the cases by most excellent surgeons, when the uterus was not removed, to accept the argument now being made in favor of hysterectomy in all these cases. As stated by Dr. Davis at the last meeting of the AMERICAN MEDICAL ASSOCIATION, he could not agree with Dr. Sutton and others that pus in the tubes was due to gonorrhoea in 75 per cent. of cases. He thought that puerperal infection was rarely the cause of more than 50 per cent. Tubercular infection was rarely the cause and was not so important as he claimed. However, the importance attached to gonorrhoea was against the argument for the removal of the uterus, as the infection from this source was not deep and could be removed with the curette. Because some patients were not completely cured by the removal of the appendages was no argument for hysterectomy in every case where the bilateral operation was required; for nearly all these could be

relieved by a thorough curettage. Some large uteri would require in addition to this a high amputation of the cervix, and only a small number would need a hysterectomy.

Vaginal incision for the drainage of pus in the pelvis, not confined to the tubes, was a most valuable method of treatment in a well-recognized class of cases, and had been practiced for a long time with gratifying results. A large number of these cases require no further surgery. More recently large pus tubes and ovarian abscesses had been incised and drained through the vagina with permanent recoveries in a good proportion of cases. The uterus should always be curetted at the same time. These were the very cases where the vaginal operation and hysterectomy had been recommended so highly by the French surgeons. Yet a considerable per cent. of these cases could be relieved by vaginal incision and drainage. The object of the surgeon should be, not so much toward still further reducing the death rate from the operation, but to relieve the cases and preserve as far as possible organs which had so much to do with the woman's health and happiness.

Dr. L. H. DUNNING of Indianapolis followed with a paper entitled

SHALL HYSTERECTOMY BE PERFORMED IN INFLAMMATORY DISEASES OF THE PELVIC ORGANS.

The author discussed only that form of inflammation of the pelvic organs and tissues denominated diffuse pelvic inflammation, and drew the following conclusions:

1. We recognize the utility of hysterectomy in a small percentage of bilateral suppuration of the tubes and ovaries in which the uterus is distinctly septic, and in cases of septic uteri which can not be cured by other means after bilateral salpingo-oophorectomy.

2. We oppose hysterectomy as a rule in inflammatory diseases of the pelvic tissues upon the following grounds, viz.: (a) The uterus is the central organ of the reproductive system and should not, except upon palpable and urgent cause be extirpated. (b) It is only in rare cases that the uterus is so far diseased as to resist the curative effects of appropriate treatment. (c) The removal of the uterus profoundly affects the nervous system and emotional nature of young women deprived of this organ. (d) We oppose the removal of the uterus from anatomic reasons, to wit: As a result the vagina is shortened, the anatomic relations of the bladder, sigmoid and rectum are changed, the elasticity of the pelvic diaphragm is greatly diminished or entirely removed, the elastic tissue being largely replaced by sensitive scar tissue. (e) In married women it often disturbs the sexual relations of husband and wife and is apt to induce mental depression. (f) Vaginal hysterectomy compels the use of drainage because of the necrosis of tissue and suppuration induced.

SHALL THE UTERUS BE LEFT IN SITU IN EXCISION OF THE ADNEXA?

This paper was read by Dr. E. F. FISH of Milwaukee, Wis. The paper was a general defense of the uterus and an argument in favor of leaving it in situ, if sound, after excision of the appendages. It takes up and considers the pathologic conditions requiring hysterectomy after salpingo-oophorectomy, as well as the conditions which do not require it. The author argues against all operations which leave a degenerate uterus, such as Hegar's, Tait's, Martin's and Robinson's, except under extreme conditions, and concludes thus: 1. That whenever it becomes necessary to excise the uterine adnexa, if the uterus is sound, leave it. 2. Whenever we excise the tubes and ovaries, and the uterus, though in a pathologic condition, in our judgment will yield to treatment, leave it. 3. Whenever it is necessary to do an abdominal hystero-salpingo-oophorectomy and the cervix is healthy, do a supravaginal amputation, as this leaves the vaginal vault intact. 4. Whenever it is necessary to do a supravaginal amputation, suspend the cervix to the stumps of the broad ligaments, or anchor it to the abdominal wall to prevent prolapsus vaginae (Baldy). 5. Whenever it is necessary to do a general ablation, and the cervix uteri is unsound, take the entire organ because of the danger of carcinoma. 6. Whenever a subserous or interstitial myoma can be removed without too great damage to the uterus, do a myomectomy and leave the organ. 7. Whenever we excise the appendages and leave the uterus, ventral fixation is not an unsurgical operative conclusion.

The author's reasons for leaving the uterus were: 1. That it helps to maintain the woman's sexual integrity. 2. It relieves the patient of much mental strain and is a prophylactic measure to neurasthenia, melancholia and insanity. 3. It tends to maintain the family ties unstrained. 4. It obviates the possibility of vaginal hernia, cystocele and proctocele, and delays vaginal atrophy, and last of all, it holds up and prevents shortening of the vagina.

A spirited discussion followed the reading of the above three papers, and was participated in by Drs. L. S. McMurtry, John M. Duff, Joseph Price, J. Henry Carstens, Albert Goldspohn, George H. Rohé, James F. Baldwin, A. B. Miller, Walter P. Manton, J. W. Bovee, Rufus B. Hall, W. E. B. Davis, E. F. Fish; some favored the abdominal and some the vaginal route.

SECOND DAY—MORNING SESSION.

Dr. J. W. LONG, of Richmond, Va., contributed a paper entitled

DYNAMIC ILEUS.

Intestinal obstruction had been variously classified, but Dr. Long regarded the classification adopted by Murphy as the simplest and the most rational: 1. Adynamic ileus, always the result of intestinal paralysis, due to varying causes, may be clearly illustrated by such cases as those following injury to the spinal cord and paralysis due to peritonitis. 2. Dynamic ileus. This variety formed the subject of the paper and was discussed in detail. 3. Mechanical ileus embraced such common lesions as strangulated hernia, intussusception, fecal impaction, etc.

We report one of Dr. Long's cases herewith. Mrs. C., was brought to him on May 27, 1896. She is 21 years old, married three years, but never pregnant. She is rather below the medium size and height. In temperament she is of the spoiled child type, not hysterical but rebellious. It was with great difficulty that she could be induced to have any local treatment or even take her medicines. After admission to hospital her obstreperous disposition required all the tact and firmness of a sagacious nurse. Early in April of this year the patient had malaria followed by delayed menstruation, pelveo-abdominal pain and obstinate constipation. The malaria and menstrual disturbance yielded promptly to treatment, but the abdominal pain continued and gradually the ileus symptoms became more and more pronounced. After exhausting every other measure to move the bowels the patient was given chloroform and by means of a Rickett's tube she succeeded in washing away a quantity of fecal matter. Notwithstanding there was no improvement, the nausea and vomiting recurred oftener and were more distressing, the pain and tenderness became worse and a marked degree of tympany supervened. When she was brought to the hospital there had been no movement of the bowels for four weeks excepting what was washed away with the colon tube while the patient was anesthetized. The history justified the diagnosis of intestinal obstruction, while the urgent symptoms demanded an immediate operation. The abdomen was opened by a median incision. No mechanical obstruction could be found, although a careful search was made along the whole length of the intestine. The bowel was moderately distended with gas and congested. A singular feature, however, was that at three points, two in the ileum and one in the sigmoid flexure, the canal was constricted sufficient to constitute obstruction. In the ileum one of the constrictions was about 15 inches from its lower end and 6 inches long, the other was nearer the jejunum and about 4 inches long. The lumen was not entirely closed at either point, but was greatly reduced, being less than half the normal size, while the diameter of the remaining portions of the bowel was increased on account of the distention with gas. No peristalsis was observed, but the contracted portions could be dilated by "milking," the intestinal contents along. In the sigmoid the limitations of the contracted portion were not so sharply defined, but the lesion was just as evident. The walls were thickened and the caliber much diminished. Incidentally a small ovarian cyst on the right side was discovered and removed. As the intestine had been handled a good deal the abdomen was flushed with normal salt solution. The incision was closed with two tiers of sutures, silk for the peritoneum, and interrupted silver wire for the remaining layers. The recovery was most satisfactory in every way. The bowels responded to the usual laxatives and enemas on the second day, and from the first to last there was not a hitch in her convalescence. The patient left the hospital in four weeks, and three weeks thereafter took a trip to Alabama. There could be discovered no evidence of lead, or ptomain poisoning.

SPONTANEOUS RUPTURE OF UTERUS DURING LABOR AT TERM, WITH SPECIMEN.

A paper on this subject was read by Dr. B. M. HYPES, of St. Louis.

Mrs. O., aged 31, of German parentage, general health good, previous to birth of first child. No history of any constitutional disease. About one year after marriage, aged 26 years, was delivered of a seven and one-half months child, which lived but a few minutes. This labor was easy, lasting about six hours. The midwife in attendance failed to get the after-birth,

which was removed by the family physician twenty hours after the birth of the child by means of his hand and the curette. The woman then suffered for six weeks with a severe case of metro-peritonitis. From this time her health remained impaired, and for the next few years she was a sufferer from general debility, impaired digestion, and a "sore spot" in the hypogastrium. Four years from the birth of her first child she again became pregnant. During gestation, her general health was much improved. She exhibited no functional disturbances; her only complaint was the sore spot over the fundus of the uterus and to the right of the median line. Labor pains began Sept. 16, 1895, at 10 P.M., at full term. The family physician was called; found labor in progress, vertex presentation, with normal condition of mother and child. The pains were slight and progress slow. At 2 A.M., September 17, he gave a dose of morphia and went home. At 9 A.M., upon his return he found the patient comfortable, with occasional slight labor pains. He left the house with injunction to call him when signs of labor became pronounced. Patient remained quiet during the day. Suddenly at 3 P.M., she was seized with violent vomiting, followed by the most excruciating pains in her abdomen associated with rolling and tossing in bed, gasping for breath, faint feelings, pallid face and rapid exhaustion; in short, the usual symptoms of abdominal shock. The family physician was at once sent for and upon his arrival, at 4 P.M. found her in complete collapse, with convulsive seizures. The symptoms, with vaginal and abdominal examination, revealed to him this dreadful condition: The presenting part receded, the womb empty, and the child plainly felt in abdominal cavity. The patient had suffered spontaneous rupture of the uterus. He at once dispatched for surgical aid, but by the time the surgeon, Dr. Meisenbach, arrived, the patient was moribund. Still with the hope of saving the child, laparotomy was hastily performed, and the child, which had escaped entirely into the abdominal cavity, was extracted from a mass of blood and amniotic fluid. It had ceased to live, and continued efforts at resuscitation failed to cause it to breathe. The child was fully developed, male, weighed six pounds, and was 18 inches long. The uterus, when removed from body, presented the following condition: A rupture through fundus superiorly, extending from half an inch from the entrance of one tube to an equal distance from the entrance of the other; the walls, at place of rupture, were comparatively thin. Placenta located at middle third of uterus, anteriorly and to the right, where the walls were much thickened. Vaginal portion of the cervix almost obliterated as at term, and dilated for the ready admission of two fingers. The lower zone of the uterus exhibited no thinning or formation of Bandl's contraction ring; no disease of tubes, ovaries, or placenta. A microscopic examination was made soon after rupture and revealed fatty degeneration of tissue at point of rupture. The points of unusual interest in the case are the cause of the rupture, and its location at the fundus uteri.

Dr. EDWIN RICKETTS of Cincinnati, Ohio, read a paper entitled

**PORRO'S OPERATION AT OR NEAR THE FIFTH MONTH FOR SMALL FIBROID OF CERVIX, ACCOMPANIED BY HYDRAMNIOS AND TOTAL RETENTION OF URINE.**

The author reported the following case and briefly commented on it:

Mrs. M., white, aged 26, of short stature, mother of two children of 6 and 3 years of age, with an abortion at 8 weeks early in 1895, no specific history, and a patient of Drs. J. B. and C. M. Warwick, of Lucasville, Ohio. Drs. Warwick first saw her on Jan. 10, 1896, finding that she menstruated last in the first week of November, 1895. They also found the uterus enlarged and firmly bound down in the pelvis, especially to the left, and extremely tender to pressure. There was uterine hemorrhage in March, 1896, and again in the following month lasting for twenty-four hours. Her labors and abortion were prolonged and severe and accompanied by great suffering, while dilatation in all instances was accomplished with difficulty. From Jan. 10, 1896, she had no desire to urinate, nor could she void a drop of urine without the aid of the catheter. Feb. 23, 1896, she had severe labor pains lasting thirty-six hours and accompanied by slight hemorrhage, the right portion of the cervix being soft and the left hard, which condition was also present at the time of operation. During April and until May 22, the date of operation, she was very tender over the lower part of the abdomen, and at times had a temperature above 100, with a pulse running from 90 to 100.
