Of late years, the Mitchell's screw-piles [PILE ENGINE] have been very successfully applied for the purpose of supporting fixed lights on shoals in shallow water, and in comparatively-speaking protected positions; such as the beacon light at Fleetwood on the Wire, and the Maplin light at the mouth of the Thames. Wherever it would be possible so to do, these iron beacons should be substituted for the more unstable floating lights, for the oscillation of the latter must always impair their efficiency; and the pillar structures in the day time form more conspicuous beacons than the low hulls of the vessels can do. And here it may be as well to remark, that even lighthouse towers are of greater value for the purposes of navigation when they are constructed of materials which are of colours able to make them conspicuous objects by night as well as by day. The English lighthouses are usually painted white, or red; the lighthouse of Pondichéry, in the French East Indies, is painted in alternate vertical bands of white and black, a most efficient method of rendering it visible from a distance; the Scottish lighthouses are usually left of their natural colours, and are rarely distinguishable from the surrounding landscape in the day-time.

The buoyage of the shores of England would appear to be conducted in a very efficient manner, for there are no less than 1109 buoys in position upon those shores, without counting the wreck-buoys, or the warping-buoys at the entrances of ports, harbours, or docks. The Admiralty, as might naturally be expected, continue to use the old-fashioned nun and can buoys; but at Liverpool, and in the ports of active commerce, the Herbert's buoys are most generally used. These are made with wide circular bottoms, having a depression in the centre to which the eye for the mooring-chain is attached, so as to bring the centre of gravity as low as possible; their cost varies with their size, between 40*l.* and 90*l.* In consequence of the gradual growth of the buoyage system of England, there is great irregularity in the mode of colouring or marking them: in foreign countries the custom is, however, to paint the buoys respectively on the port and starboard sides of the channel of different colours, usually black and red; and though no doubt it would be preferable to adopt a uniformity of system in this respect, there would be a great amount of inconvenience in changing the colours of the buoys in any old-established line of navigation. It is worthy of remark that in the year 1858, not more than 4 per cent. of the buoys laid down by the public authorities of the United Kingdoms, broke from their moorings, whilst about 6 per cent. of those laid down by local authorities got adrift. In the portion of the Thames between London and the open sea, there are nearly seventy buoys, in addition to the light-ships, harbour-lights, fixed lights, and beacons; in the Mersey, the local authority connected with the port has established no less than 7 lighthouses, 3 floating-lights, 65 buoys, and 10 beacons; and indeed any one who may have had occasion to visit English and foreign ports, must be convinced that the buoyage of our shores is far more perfectly performed than that of any foreign ones.

Beacons are of every imaginable variety, from substantial stone pillars and iron structures on piles, to heaps of stones, poles with baskets at their heads, and to simple bushes or twigs; their cost varying from 10,000*l.* to a few shillings. There are above 260 structures of some importance, erected for the purpose of beacons, whose situations are indicated upon the Admiralty charts; and of course there are numerous smaller ones upon the banks of the rivers and navigable creeks of our shores. The only system which seems to prevail in the establishment and construction of these beacons, is that they should indicate, in a manner understood by the local pilots, the course of the navigable channel; and it would only be a pedantic affectation to seek to establish any general system in a service which essentially depends upon local necessities. The beacons on the respective sides of a navigable channel ought, however, to present some characteristic difference of colour or of outline.

It may be desirable to add that in England and Ireland the lamps of lighthouses are lighted from sunset to sunrise; in Scotland they are lighted at the commencement of the darkness and extinguished at dawn, in accordance with a calculated table. The regulation standard of consumption of oil in a first-class French dioptric apparatus is 785 gallons per annum; it would appear that in England the average consumption of all classes of lights is below this standard, whilst that of Scotland is above it.

As the arrangement of this article rendered it necessary to notice in the commencement the history and organisation of the Trinity House; and then, the practical details of the lighthouse system as now carried into execution; the history of lighthouses has been deferred to the conclusion. At a very early period in the history of commerce the necessity for such structures must have been felt, and the ancients paid very great attention to their construction. Originally the lights on the sea-shore were nothing but open fires on the ground; but by degrees lofty towers were substituted for these rude modes of illumination, and at last the lighthouses were treated as architectural monuments of the highest order. The recorded history of the Colossus of Rhodes would appear to be rather apocryphal; and the accounts handed to us of the Pharos of Alexandria are also of very doubtful authenticity; Josephus, however, states that its fire could be distinguished at 45 miles distance. This tower fell as recently as A.D. 1303, having been constructed by Ptolemy Philadelphus about B.C. 470. The Romans erected many lighthouses, and authentic records have come down to us of those of Ostia, Capreæ, Ravenna, Puteoli, at the mouth of the Chrysorhoas, at the Bosphorus, at Boulogne, Dover, &c., both in the writings of historians, and in medals; and Pennant gives even a plate of a tower, supposed to have been a Roman light-house, which existed at Gaireg in Wales. The mode of illumination adopted in these cases seems to have been either an open wood or coal fire; or the combustion of torches dipped in tar; and in the most ancient of these structures, the irons for suspending the fire pots, or for holding the torches, may still be seen. During the Middle Ages towers were erected for similar purposes, of which remains may still occasionally be met with, and the tower of Genoa, a monument of the Renaissance period, may be referred to as a model of taste in such structures. The tower of Cordouan, at the mouth of the Garonne, was, however, the one which marked the most distinctly the revival of this class of monuments in modern time, and even at the present day it is worthy of careful examination by the engineer and architect. It was commenced in the reign of Henri II. of France, but no light was exhibited in it until the reign of Henri IV.; the style of architecture adopted is a very ornate style of Renaissance, as practised in France about the end of the 16th century.

Perhaps the turning point, so to speak, of the history of lighthouse building is to be found in the erection of Smeaton's celebrated Eddystone lighthouse, completed in the year 1759; for the success which attended the erection of that structure in so exposed a situation has led to the subsequent operations of the same kind throughout the world. Two attempts had previously been made to establish lights on this dangerous reef of rocks in the Channel; one by Winstanley, the other by Redyard; the structure erected by the former was washed away in the night of the 26th of November, 1703; and that erected by the latter was burnt on the 2nd of December, 1755. Smeaton was then applied to by the lessee; and he resolved to construct the new lighthouse of masonry, solid up to a certain height, in order to secure a sufficient resistance to the action of the sea by the dead weight of his structure, and thence hollow, to enclose the store and living rooms; the outline of his tower Smeaton copied from the outline of the bole of an oak tree, which he considered to be the best form to resist external violence from the winds and waves. Smeaton has recorded his own operations in a folio volume, published in 1791, entitled, "A Narrative of the Building of the Eddystone Lighthouse," to which the student is earnestly referred as to a model of a technical account of a most important work. From this it appears that the first stone was laid on the 12th of June, 1757, and that the light was first exhibited on the 16th of October, 1759: the light itself was obtained in Smeaton's time by the combustion of a great number of candles placed in metallic reflectors. Smeaton also erected an important lighthouse at Spurn Point, at the mouth of the Humber; but the grand principles of construction he introduced in the Eddystone were not again conspicuously applied, until the construction of the Start Point Lighthouse, between 1802 and 1806, under the direct orders of Mr. Stevenson, the engineer to the Commissioners of the Northern lights. Since the latter period the construction of lighthouses on the Bell Rock, the Skerry Vore, the Bishop's Rock, the Bréhat, Barfleur, la Hague, &c., has taken from the novelty of such structures, and rendered the public more indifferent to their merit; but they must always remain amongst the proudest triumphs of human skill and patience.

The use of oil lamps, instead of candles in lighthouses, is said to have been introduced by the celebrated hydrographical engineer, Borda, about 1780 or 1790; and the manufacture of the reflectors was greatly improved about the same time. The use of dioptric lights had been suggested to Smeaton in 1759, and they had actually been employed in the Portland lighthouse about 1789; but from some mismanagement they had fallen into disfavour until Augustin Fresnel, on 26th July, 1822, read a paper at the Académie des Sciences of Paris, describing a lighthouse apparatus on the dioptric system executed under his orders. In 1825 the French government undertook the comprehensive scheme for lighting their coast, which has since then been so carefully carried into execution; and as they began almost *de novo*, they have been able to adopt, throughout, the dioptric apparatus, whereas in the English lighthouses there were already numerous and costly catoptric lights of a very perfect nature in operation. The other nations of Europe have adopted the dioptric lights; and there seems to be little reason to question that the latter will ultimately replace the other known systems. The Fresnel's dioptric lamps may be popularly described as consisting of a mechanical, four-wicked, oil lamp placed in the centre of an octagonal glass prism; the centre part of each of the sides being formed of a plano-convex lens of about 15 inches in diameter, which is surrounded by a series of glass rings of a spherical triangular form, so as to produce the same effect upon the rays of light as the central lens does. Messrs. Leopold Fresnel, A. Stevenson, Arago and Faraday, have in turn contributed to the perfection of Augustin Fresnel's invention; and it is to the distinguished philosopher, Faraday, that we are indebted for the efficient means of ventilating the lamps of lighthouses now adopted—an apparently insignificant, but really a most important detail in their working.

The only other events of importance connected with the history of lighthouses, are the establishment of light vessels about the end of the last century; the erection of the screw-pile lighthouses and beacons, on Mitchell's plan, the first of the former erected on the Maplin sand, having been lighted for the first time on February 16, 1841; and the erection of the first cast-iron lighthouse at Morant Point, in Jamaica, under the orders of Mr. A. Gordon: it was lighted for the first time on November 1, 1841. Many valuable papers have from time to time been published on the scientific questions involved in this branch of the engineering art in addition to those previously noticed; amongst which attention is particularly called to the report by M. Rossel, 'Sur le Système General d'Eclairage des Côtes'; to a mémoire by L. Fresnel in the 'Annales Des Ponts et Chaussées,' for 1831, on the stability of lofty towers; to another mémoire by the same author on the mode of treating the dioptric apparatus, in the 'Annales Maritimes et Coloniales,' 1836; and a description of the scaffolding and machinery used at the lighthouse at Bréhat, inserted by M. Potel in the 'Annales des Ponts et Chaussées,' for 1835.

It may be as well to add that the French authorities class the lights on their shores in four divisions, according to the power, and the range of visibility, of their lights. The "Phares" of the first class are visible from a distance of 30 miles; those of the second class, from a distance of 25 miles; those of the third class, from a distance of 15 miles; whilst the phares of the fourth class, or the harbour lights, are only visible at distances of about 6 miles. In addition to the harbour lights, the French authorities frequently place bells, with reflectors at the extremities of their piers; these bells are rung in foggy weather, but they are not considered to be of much service.

TRINODA NECESSITAS. This term, in Anglo-Saxon times, signified the three services due to the king in respect of tenures of lands in England for the repair of bridges, the building of fortresses, and expeditions against his enemies. All the lands within the realm were bound to contribute to these three emergencies, on the principle of their necessity for general convenience or safety; and for this reason every man's estate was subject to the *trinoda necessitas*, whatsoever other immunities he might enjoy. Even in royal grants to the Church of privileges and exemptions from secular services, the right of requiring contribution for these purposes was almost always reserved to the king. (Selden's *Janus Anglorum*, i. 42; Cowell's *Interpreter*, ad vocam.)

TRINOMIAL, the algebraical name for an expression which consists of three terms, as $a + b + c$, or $ax - bx^3 + bx^4$. [TERM.]

TRIOXYPROTEIN. A substance said to be obtained from albuminous substances. Its existence is very problematical.

TRIPHOSPHETHYLAMINE. Synonymous with *triethylphosphine*. [ORGANIC BASES. *Organic phosphorous bases.*]

TRIPLE ALLIANCE. [TREATIES, CHRONOLOGICAL TABLE OF.]

TRIPLETS. [DOUBLETS.]

TRIPLICATE. [RATIO.] In the common arithmetical sense, the triplicate of a given ratio is found by taking the cube of each of the terms of the ratio. Thus, when we say that two similarly formed solids, whose linear dimensions are as 4 to 7, are in the triplicate ratio of 4 to 7, it is meant that the bulks of those solids are in the ratio of $4 \times 4 \times 4$ to $7 \times 7 \times 7$, or of 64 to 343.

TRIPOD (*tripus*, τρίπους) is any article of furniture resting upon three feet, whence the name is given to tables, chairs, moveable altars, and other articles of the same kind. (Athen. ii. p. 49.) A chair or an altar of this kind must be understood when we read that the Pythia of Delphi gave her oracles from a tripod. We find also mention of tripods containing a certain measure of fluid (Hom., 'Il.,' xxiii. 264), and in this case we have to understand a bowl resting upon a pedestal with three feet. The crater, or the vessel in which the wine was mixed with water at the banquets of the ancients, was very frequently a tripod of this description.

The ancients made much more frequent use of tripods than we, and from their descriptions, as well as from the numerous representations of tripods on medals, and from the specimens still extant, we see that they were often most tastefully ornamented and of the most exquisite workmanship. They were usually of metal, but sometimes also of marble, and appear to have been made as much for mere ornament as for use. A tripod seems to have been at Athens a usual reward to a successful choragus. The tripod was connected with the worship of several gods, and was one of their attributes; but there is no deity in whose worship tripods occur so frequently as in that of Apollo. Accordingly the Pythia gave her responses from a tripod, tripods were the most common presents (donaria) to his temples, tripods were given to the victors in the games which were celebrated in honour of Apollo, and tripods appear on innumerable coins which have any relation to the worship of that god. Several fine tripods have been found at Pompeii. (Mazois, Donaldson.) In the accompanying cut of a bas-

relief on an altar found in the forum at Pompeii an altar tripod is represented. Some tripods are preserved in the British Museum.

TRIPTYCH, an altar-piece in three divisions. As mentioned under RETABLE, altar-pieces were originally small and portable; they being carried with the other ecclesiastical utensils to the altar for the performance of the service, and removed at its conclusion. The altar-piece usually comprised a representation of some event in the history of Christ, or of an incident in the life of the saint to whom the altar was dedicated. In their oldest form, these portable altar-pieces seem to have consisted of two leaves or tablets of ivory or wood, like the larger two-leaved tablets carried by the Roman consuls and other superior officers, and like them they were called *Diptychs*. It is supposed that this in fact was their origin; the emperors having, when Christianity was recognised and protected, sent to the bishops, as to other high officers of the government, official diptychs, which, when they presided at the mass, were displayed open at the altar as the insignia of their office; but if so, the practice probably early fell into desuetude, and altar-pieces came to be commonly the gift of pious individuals or commissioned by wealthy communities, and they soon began to be made in various forms and of very different materials. The most frequent form was that of the *Triptych*, which consisted of a large central division, in which the principal circumstance was set forth, and two wings, fastened to the centre by hinges, so as when not in use to fold over it like shutters. On the insides of these wings were usually represented circumstances subsidiary to that shown in the central division, or portraits of saints or of the donors of the altar-piece, &c.; whilst on the outside was the Annunciation, the Baptism, or some event symbolising the initiation of the Christian religion, if the Crucifixion or other crowning event were shown inside; or, if the central picture related to a saint, the exterior was commonly made in some way correspondent. Sometimes there were more than three divisions, when it was called a *Polyptych*. Most frequently these portable altar-pieces are framed pictures; but they are very commonly, especially the earlier ones, bas-reliefs carved in wood or ivory. Often they are of inlaid-work, or marquetry, or of metal-work and enamel, the latter being sometimes richly inlaid with gems. Of all these kinds, and extending over a long range of years, there are many, and some very exquisite, examples in the South Kensington Museum, as well as of those large carved and painted triptych retables which so generally prevailed at a somewhat later date in Germany and the Low Countries. [RETABLE.] When the altar-piece came to be treated as an important architectural feature, and the paintings were much larger in size and more important in character, the triptych form was long retained, though, at least in Italy, the wings were no longer made to close over the centre, and certain supplementary parts were added. Of these, examples, either entire (as in that of Jacob Casentius) or portions (as those by Francia, Andrea Orcagna, &c.), may be seen in the National Gallery.

TRISECTION OF THE ANGLE. In the articles DUPLICATION and QUADRATURE, we have given a slight outline of the history of two of those remarkable problems the solutions of which at one time engaged the attention of the learned, and have not yet ceased to be the ambition of a certain class of geometrical students. The trisection of the angle is the third problem of this kind.

The difficulty of cutting an angle into three equal parts is entirely of that geometrical nature which has been alluded to in the articles above cited. Euclid, who confines himself to the description of right lines and circles, could not by these only trisect an angle; but a very slight increase of descriptive power granted to pure geometry would overcome the difficulty entirely. In modern analysis there is no more trouble in trisecting an angle than in finding a cube root: the trigonometrical tables solve the question immediately to a certain number of places of decimals, and the calculation of a series and the solution of a cubic equation may be made to serve for any number of places of decimals. In order to show this, let a be the sine of a given angle, and x the sine of its third part: common trigonometry readily gives the equation—

$$3x-4x^3=a.$$

Now a can be found from the angle by means of the series for the sine; and the solution of the cubic equation is then easy enough. [INVOLUTION.] The three roots of the cubic equation are respectively the sines of the third part of the given angle, and of 120° and 240° more than that same third part. The cause of the geometrical difficulty is seen in the cubic equation, which, as appears above, is essential to the problem: no root of a cubic equation was ever exhibited by Euclid's geometry alone, unless that cubic equation were algebraically reducible to one of a lower degree, which could be solved without the extraction of cube roots.

The old geometers soon reduced the question to depend upon the following preliminaries. Let A, B, C, D be the sides of a rectangle, and E the diagonal passing through the junctions of B, C, and A, D: also let the angle E A be the one which is to be trisected. Through the point common to B, C, draw a line F passing through D and A produced, in such a manner that the part between D and A produced is twice E in length. Then it is easily shown that the angle F A is the third part of E A. Through the point C D draw an equilateral hyperbola, of which the asymptotes are A and B. A chord of this hyperbola, set off from C D towards A produced, and equal in length to twice E, will be a parallel to the line F required. Admit then the hyperbola among the curves of geometry, and the difficulty ceases. Again, if with two-thirds of any given line A as a major axis, an hyperbola be described whose asymptotes make an angle of 120°; and if with A as a base, and a point on the branch of the hyperbola adjacent to the single third of A as a vertex, a triangle be described, the larger of the angles adjacent to A will always be double of the smaller. Consequently, one of the external angles will be triple of one of its internal and opposite angles: so that by describing on the straight line A a segment of a circle containing the supplement of any given angle less than 180°, that circle will cut the branch of the hyperbola in a point which, being joined with the further extremity of A, will give an angle equal to the given angle.

Again, if from any point of a circle a straight line be drawn cutting the circle again, and then a diameter produced, in such manner that the portion externally intercepted between the diameter produced and the circle is equal to the radius, the angle formed by that line and the diameter produced is the third part of the angle made by the two radii, of which one passes through the first point of the circle mentioned, and the other is on the diameter which was produced. The construction can be effected by the CONCHOID of Nicomedes, which curve, if granted, gives the means of drawing a straight line of given length between any straight line and a curve, so that when produced it shall pass through a given point.

Either of the curves known by the name of QUADRATRIX may be made to trisect an angle, as obviously may any curve which assigns a straight line equal to a given arc: for a straight line may be easily trisected. The SPIRAL of Archimedes obviously gives another solution. But there is one particular curve known by the name of the *trisectrix*, which, among curves not geometrical, is peculiarly possessed of this property. It is one of the TROCHOIDAL curves having the deferent and epicycle equal, the motion in the latter being direct and equal to one-half of that in the epicycle. Or, add and subtract the radius of a circle from every one of the chords which passes through a point in its circumference, and the result will be a looped curve, which is the one in question. Let A be the point where the branches unite, and A B the axis of the loop: describe a circle with A as a centre, and A B as a radius; take a point P in the loop, and let A P and B P produced meet the circle in Q and R. Then the arc B R is three times B Q.

Many other modes of trisection have been proposed, some of great geometrical beauty; but the preceding are those to which it is most likely the student will meet with references in his reading. Many false trisections have also been proposed by persons who thought they could conquer the geometrical difficulty. There is not so much to expose in this class of trisections as in the one of quadratures of the circle which corresponds to it. There has never been so much of romance applied to this problem, no explanations of theological points have been made to arise out of it, no mode of converting the heathen asserted to be a necessary consequence, no Number of the Beast taken into the calculation. We shall only notice one false trisection, because it will afford a useful remark. In May, 1830, an Austrian officer announced his having obtained the geometrical solution in the 'United Service Journal,' and various comments appeared in that periodical, running through various months up to March, 1832. In January, 1832, an actual attempt at solution appeared, the work of a British officer then abroad. This at first sight appeared to be a *geometrical* solution; and what is more, it *was* a geometrical solution, and it might have cost a practised mathematician a moment's doubt whether the problem was not actually solved. But, owing to a mistake, a construction was made, which amounted to requiring that two sides of a certain triangle should be together equal to the third, the consequence of which was that the vertex of this triangle was brought down upon the base. Now the angle to be trisected was one of the angles at the base of this triangle, or *equal to nothing;* an angle which no geometer would refuse to declare capable of Euclidean division into three equal parts, each of course equal to nothing. Algebra generally furnishes some proof of the absurdity of the conditions of a problem when they contradict one another: but this is not the case with geometry. A latent assumption which restricts the generality of a solution always produces its effect in the former science; whereas in the latter such an assumption might be made part of a demonstration, and produce its consequences, without pointing out that those consequences are not true of the general figure which was drawn. The accurate use of the ruler and compasses will sometimes correct an error of this sort (and would have done so in the instance before us), *but not always:* solutions have been proposed before now which give so nearly the third part of an angle, that ordinary drawing will not serve to detect their falsehood. Any one who imagines he has discovered a geometrical trisection should take care to submit his construction to an algebraical verification; that is, if any person possessing algebra enough to do so should ever be in such a case.

TRISUCCINAMIDE ($N_2[C_4H_4O_2]_3$). An unimportant organic substance bearing the same relation to succinamide as triethylamine bears to ethylamine. [ORGANIC BASES.]

TRITHIONIC ACID. [SULPHUR.]

TRITYL. [PROPYL.]

TRITYLAMINE. [PROPYLAMINE.]

TRITYLENE. [PROPYLENE.]

TRITYL-SULPHURIC ACID. Synonymous with *Propyl-sulphuric acid.* [PROPYL.]

TRIUMPH (Triumphus) is in general a solemn procession for the purpose of celebrating a victory. Such processions and solemnities have been customary in all warlike nations, but they have never formed so prominent a feature in the history of a people as among the Romans. In a Roman triumph, the general who had gained a victory of sufficient importance to entitle him to this honour, entered the city of Rome in a chariot drawn by four horses; he was preceded by the captives and spoils, and followed by his army. The whole train passed along the Via Sacra up to the Capitol, where the general sacrificed a bull to Jupiter. Such a triumph was the highest honour that a military commander could look for; it was granted by the senate after any victory either by sea or by land, provided it was thought sufficiently important to deserve it.

When a general had gained a victory or had accomplished the object of his mission, he sent in a report to the senate, which then usually decreed a public thanksgiving (supplicatio.) The general returned to Rome, either with his army, or appointed a time when it was to meet him there; but he did not enter the city, and a meeting of the senate was held outside the walls, usually in the temple of Bellona, for the purpose of examining the general's claims to a triumph. The principal conditions upon which a triumph was granted, and which were established partly by custom, and partly by law, are as follows:—1. That the general should have held one of the great offices of the republic, that is, the dictatorship, consulship, or praetorship. 2. That he should have been invested with one of these offices at the time when he gained the victory, and that it should not have expired on the day of the triumph. This regulation however was set aside at an early period, and in cases where the term of office had expired the senate used to grant a "*prorogatio imperii,*" that is, a prolongation of his imperium or authority as general, for the day of the triumph. 3. That the victory should have been gained under the auspices and with the troops of the general who claimed a triumph. 4. That the advantages gained by the victory and the number of the enemies slain should come up to the amount prescribed by law. 5. That the victory should have been gained over a foreign enemy, and not in a civil war. 6. That the dominion of the Roman people should have been extended by the victory, and that it should not be a mere reparation of losses previously sustained. 7. That the war should be actually concluded by it, so as to enable the army to quit the enemy's country.

These rules however were not always strictly observed, and various deviations from them are recorded. Even the sanction of the senate ceased to be thought necessary as early as the fifth century before Christ, and the people in the Comitia Tributa assumed the right to grant triumphs (Liv., iii. 63; Dionys., xi. 50); and there are instances of generals triumphing in defiance of the senate and the people. In later times a general to whom a triumph in the city was refused, used to celebrate it on the Alban Mount. (Liv., xlii. 21.) If however the senate granted it, a sum of money was voted as a contribution towards defraying the expenses of the triumph, and the general was for the day of his triumph invested with the Imperium in the city. During the triumphal procession, the general, standing in his chariot, wore a purple toga embroidered with gold; his brow was adorned with a wreath of bay (laurus), and in his hand he carried a sceptre with the Roman eagle. On reaching the temple of Jupiter he deposited his wreath in the lap of the god. Banquets and other entertainments concluded the solemnity, which was generally brought to a close in one day, though in later times we meet with instances in which it lasted for three days. (Liv. xxxix. 52.)

During the time of the empire, the emperor himself, being the chief general of all the armies, was the only person that could claim a triumph, and it was rarely if ever granted to any one else but a member of the imperial family. Other generals received other compensations. All the triumphs that had been celebrated at Rome were carefully recorded in the Fasti triumphales, and their total number, from the earliest times down to the last, that of Belisarius over the Vandals, has been calculated to amount to 350.

A lesser kind of triumph was called *ovatio*, perhaps from "ovis," a sheep, which the general offered to Jupiter, instead of a bull. It was granted after victories which were not of sufficient importance to deserve the solemn triumph. The principal difference between the two was that in an ovation the general entered the city on foot, and in later times on horseback; he wore only the toga prætexta, and his brow was adorned with a wreath of myrtle. He carried no sceptre, and was frequently not accompanied by his army.

(O. Panvinius, *De Triumpho*, in Graevius, *Thesaurus Antiq. Rom.*, vol. ix.)

TRIU'MVIRI, or TRE'SVIRI, that is, "three men." A great number of offices at Rome, both ordinary and extraordinary (commissions) were held by three persons in conjunction, who thus formed a board which was intrusted with the management or administration of certain things. The office itself was called triumvirate (triumviratus). Extraordinary triumviri were appointed on various occasions and emergencies; for example, when a new colony was to be founded, the whole management of the business, together with the distribution of lands among the colonists, was usually intrusted to triumviri, whose full title was "triumviri coloniæ deducendæ," or "agro dividundo."

The triumvirate which has acquired the greatest celebrity in the history of Rome is that which was established towards the end of the republic by Octavianus, Antonius, and Lepidus. After the republic had been for years distracted by a series of civil wars, the three men mentioned above met near Mutina, in B.C. 43, and assumed, under the title of "triumviri reipublicæ constituendæ," the supreme power for five years, under the pretext of settling the affairs of the state. Their power and its duration was sanctioned by a senatus consultum. They so distributed the administration of the state among themselves, that Antonius received the greater part of Gaul; Lepidus, Spain and a small portion of Gaul; and Octavianus, Africa, together with the islands of Sicily and Sardinia. Lepidus was to govern Rome and Italy, while he exercised his power in Spain by proxy. His two colleagues endeavoured to get rid of the republican party by proscriptions, in which 2000 equites and 300 senators are said to have been put to death. Whole towns were robbed of their property, and their lands distributed among the veteran soldiers of the triumvirs, and hosts of people flocked around the standards of Brutus and other republican leaders, to escape an ignominious death. Consuls were elected during this period as before, but they were either the creatures and friends of the triumvirs, or one of the triumvirs himself held the consulship. In B.C. 38 the time of their office expired, and it was renewed for five years more without any opposition. About the end of this second term the secret enmity among the triumvirs burst out into open hostilities; a new civil war began, which ended in the destruction of republican freedom. The triumvirate of Octavianus, Antonius, and Lepidus is usually called the second triumvirate. The first triumvirate, if we may call it so, was merely a private coalition, or, as it is called in Livy's 'Epitome' (103), a conspiracy entered into by Cæsar, Pompeius, and Crassus, in B.C. 60: the title triumviri was perhaps never borne by them; it was certainly not recognised either by the senate or the people.

The triumviri who were regular magistrates belonged to the minor magistrates. Among them we shall mention, 1, the triumviri Capitales, who were instituted about the year B.C. 292, and were in many respects the successors of the quæstores parricidii. They inquired into capital offences, apprehended criminals and committed them to prison, wherever they discovered them, and also carried into effect the sentence passed upon them. 2, The triumviri Monetales, or the inspectors of the mint. 3, The triumviri Nocturni, whose duty it was to superintend the watchmen in the city at night, and to prevent or put out fires in the city.

TROCHAIC VERSE, a kind of verse used by the Greek and Latin poets, especially by the tragedians and comedians. The foot from which it takes its name and of which it principally consists is the trochee (— ⏑), which is combined, like the iambus and anapæst, into *metres* of two feet each. The most common form of the Trochaic verse is that which is composed of a perfect dimeter followed by a dimeter wanting the last half-foot. This form of verse is the 'Trochaic Tetrameter Catalectic' of the Greeks, which was also called by the Romans *quadratus*, from its containing four metres, and *septenarius*, from its containing seven complete feet. The following is an example in English:—

Alexánder háted thínking,
Dránk aroúnd the coúncil bóard,
Hé subdúed the wórld by drínking,
Móre than bý his cónquering swórd.

In the Greek tragedians the following are admitted as variations on the pure Trochaic verse:—

1. The syllable at the end of the line may be short, since its time is filled up to that of a long syllable by the slight pause which occurs in that place.
2. The trochee may be resolved into a tribrach (⏑ ⏑ ⏑) in any place; but the final long syllable may not be resolved into two short ones.
3. A spondee (— —) may be substituted for the trochee in the second place of each metre, that is, the *even* places of the verse (2nd, 4th, and 6th).
4. The spondee may be resolved into an anapæst (⏑ ⏑ —). But
5. If there is a tribrach in the seventh place, neither a spondee nor an anapæst is allowed in the sixth.
6. A dactyl (— ⏑ ⏑) is allowed, but only in a *proper name*, in any place.

The following table represents the different forms of the verse:—

	1.	2.	3.	4.	5.	6.	7.	8.
	— ⏑	— ⏑	— ⏑	— ⏑	— ⏑	— ⏑	— ⏑	⏑
	⏑ ⏑ ⏑	⏑ ⏑ ⏑	⏑ ⏑ ⏑	⏑ ⏑ ⏑	⏑ ⏑ ⏑	⏑ ⏑ ⏑	⏑ ⏑ ⏑	—
		— —		— —		— —		
		⏑ ⏑ —		⏑ ⏑ —		⏑ ⏑ —		
P.N.	— ⏑ ⏑	— ⏑ ⏑	— ⏑ ⏑	— ⏑	— ⏑ ⏑	— ⏑ ⏑	— ⏑ ⏑	

The first dimeter ought to end at the end of a word. Often also each metre, and sometimes each foot, ends at the end of a word. If the first metre ends with a word after which there is a slight pause or break in the sense, then the second foot of the first metre is a trochee or tribrach, not a spondee or anapæst. The same restriction applies to the sixth foot when it ends with a word followed by a slight break in the sense. These niceties of structure are exemplified in the following lines:—

Phœn. 636. Ὡς ἄτιμος, | οἰκτρὰ πάσχων, ἐξελαύνομαι χθονός.
—— 646. Ἐλπίδες δ' οὔπω καθεύδουσ' αἷς πέποιθα | σὺν θεοῖς.

The comic tetrameter resembles the tragic in every respect, except that sometimes, though very rarely, a tribrach in the seventh place is preceded by a spondee in the sixth, and that the niceties of structure just mentioned are not always observed.

The points of difference between the Greek and Latin trochaic verse are similar to those which exist in the iambic verse, and are explained in the article TERENTIAN METRES. The chief point to be attended to is, that in Plautus and Terence a spondee which has the accent, or *ictus metricus*, on the first syllable, is allowed to stand for a trochee in any place except the seventh. The following line is from Terence:—

Numquam cuíquam nóstrum vérbum fécit néque id ægré tulit.

The *ictus metricus* of the trochaic tetrameter, both in tragedy and comedy, is as follows (according to the notation used in the article ARSIS):—

/ \ // \ / \ // \ / \ // \ / \ //

that is, the *arsis* falls on the first syllable of each foot, and of the two *arses* in each metre the second is the stronger.

The trochaic verse is rapid in its movement, and is generally used where stronger emotions are expressed than in the ordinary iambic trimeter. It is, however, closely connected in rhythm with the iambic verse. If we prefix to the trochaic tetrameter catalectic an introductory short syllable, we obtain an iambic tetrameter: if from the trochaic tetrameter catalectic we cut off the first foot and a half, we have the iambic trimeter; and it must be observed that these results are not only true with respect to quantity, but that the licences and restrictions of the trochaic verse become, by thus altering the order of scansion, the very licences and restrictions of the iambic verse. Thus the *spondee in the even* places of the trochaic verse, the *anapæst* in the *fourth* and *sixth* places, the *dactyl* of a proper name, and the *want of a cæsura* between the two dimeters, produce respectively, in the iambic trimeter which we get by cutting off the beginning of the trochaic tetrameter, the *spondee in the odd* places, the *dactyl* in the *first* and *third* places, the *anapæst* of proper names, and the *penthemimeral cæsura*. The resemblance of rhythm is also seen by dividing each verse at its chief pause, namely, the end of the first dimeter in the trochaic, and the penthemimeral cæsura in the iambic, when it is found that the second portions of the two are identical in every respect; and it is in fact by these concluding portions that the rhythm of a verse is determined.

Troch. — ⏑ — ⏑ — ⏑ — ⏑ | — ⏑ — ⏑ — ⏑ —
Iamb. ⏑ — ⏑ — ⏑ | — ⏑ — ⏑ — ⏑ —

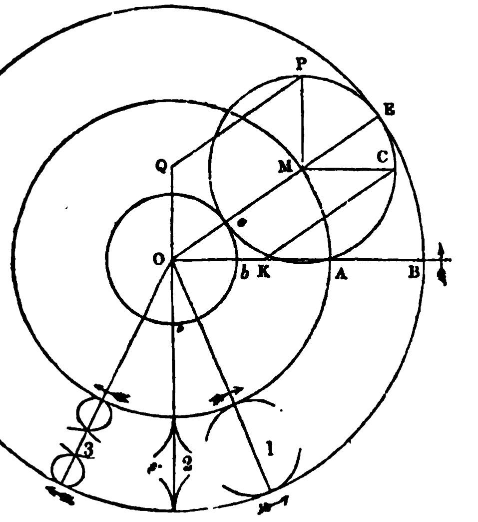
Further particulars respecting the tetrameter catalectic, and an account of other trochaic metres, will be found in Tate's 'Introduction to the principal Greek Tragic and Comic Metres,' and Hermann's 'Elementa Doctrinæ Metricæ.'

TROCHOIDAL CURVES. Under this term are included all lines produced by the composition of two circular motions, including the straight line, the circle, the ellipse, a class of curves called epitrochoids, of which one particular case is called the epicycloid, and a class called hypotrochoids, of which one particular case is the hypocloid. Among these must also be included the extreme case in which one of the motions is rectilinear, which gives the common trochoid, the cycloid, and a class of spirals which includes the involute of the circle, the spiral of Archimedes, and others.

There are two ways of considering these curves. The first, which is universally adopted, may properly be called the *trochoidal* mode (τροχος, a hoop), because in it one circle is made to roll like a hoop, either upon a straight line, or upon the circumference of another circle. The second, which we believe might be advantageously substituted for the first, we shall propose to call the *planetary* mode, because it resembles the consideration of the manner in which a planet and its satellite move round the sun. Here a circle, without any rolling, has its centre carried round the circumference of another. As there is no elementary work which treats of these combined motions, though some understanding of them is necessary even for the purposes of the most elementary astronomy, we shall first enter into this subject at more length than usual, endeavouring to make ourselves understood by those who have the first notions of geometry and of the composition of motion: we shall then, more briefly, consider the application of the differential calculus.

Let the point M (*fig.* 1) be carried uniformly round the circum-

Fig. 1.



ference of the circle A M, and let M be the centre of a circle whose radius is M O (= A B). Let a point P be carried about the moving circle, so that its angular velocity from a line of fixed direction in the moving circle (say M C parallel to A B) always bears a given proportion to the angular velocity of M, say that of $n : 1$; that is, when the line O M has described the angle A O M, the line M P has described the angle C M P, which is n times A O M. It has been supposed that when M was at A, P was at B. The point P will describe a curve which is one of those called *trochoidal*; or, on this explanation, *planetary*. And the circle O P being always contained between two fixed circles, B E and $b\,e$, the planetary curve is always contained between those two circles. We shall now propose a nomenclature for the principal parts of this system.

As in the Ptolemaic mode of considering the planets, let the fixed circle A M be called the *deferent*, the moving circle O P the *epicycle*. Let M be the *mean point*, P the *planet*, O the *centre*, and let the planet be said to be in its *apocentre* or *pericentre*, when it is farthest from, or nearest to, the centre. And as every apocentre must lie on B E, and every pericentre on $b\,e$, let these circles be called respectively apocentral and pericentral. Let O P, as usual, be called the radius of the curve, or its *radius vector*; and the angle A O P its *vectorial angle*. When the revolution is in the direction from A to M, let it be called *direct*; when in the contrary direction, *retrograde*. Let angle A O M be called the *mean* or *deferential angle*, and denoted by ϕ; and let C M P be called the *epicyclic angle*, being denoted of course by $n\phi$. Let the angle contained between the pericentral and apocentral radii be called the *angle of descent*. The following theorems will be readily seen, as soon as these terms are understood:—

1. The planetary curve beginning from its apocentre at B, and the epicyclic motion being direct, and greater than the mean motion, there will be a pericentre as soon as C M P has gained two right angles upon C M E or A O M,—that is, when $n\phi - \phi = 180°$, or ϕ is 180° divided by $n - 1$.

2. But if the epicyclic angular motion, being still direct, be less than the mean motion, so that C M E is greater than C M P, there will be a pericentre when C M E has gained two right angles upon C M P, or when $\phi - n\phi = 180°$, or ϕ is 180° divided by $(1 - n)$.

3. And if the epicyclic motion be retrograde, so that P begins to move the other way from C, there will be a pericentre when C M E and C M P together make two right angles, or when $\phi + n\phi = 180°$, or when ϕ is 180° divided by $1 + n$.

4. When the planet has come to its pericentre, it will begin immediately to ascend towards the next apocentre, in a curve of the same form as that by which it descended, but inverted in position, the parts preceding and following the pericentre being alike, and the part preceding the next apocentre resembling that following the last apocentre. As soon as the second apocentre is gained, the curve will start again, in the same manner as the first. If n be a commensurable number, say $p \div q$, where p and q are integers, and the fraction be in its lowest terms, the curve will return into itself when M has completed q revolutions: there will be, if the epicycle be direct, $p - q$ or $q - p$ apocentres, and as many pericentres; but if the epicycle be retrograde, there will be $p + q$ apocentres, and as many pericentres. But if n be incommensurable, the convolutions will go on for ever, and the curve will never be completed. We have therefore, in order to obtain the form of the curve, only to consider one descent from apocentre to pericentre, or one ascent from pericentre to apocentre: though the general appearance of the curve depends much on the effect of many convolutions.

5. Every planetary curve may be described by two distinct epicyclic motions. For if we describe the parallelogram O M P Q, we see that the point Q describes a fixed circle equal to the epicycle, while Q P is the radius of a moving circle equal to the deferent. If then the radius of the deferent be a, that of the epicycle b, and the epicyclic angular velocity be n times the deferential or mean velocity, it gives the same planetary curve as if the radius of the deferent were b, that of the epicycle a, and the epicyclic velocity $1 : n$th of the deferential. If, then, we take the epicycle to be the least of the two, we do not limit our investigation, provided we consider every possible case of epicyclic velocity.

The actual motion of the planet, compounded of both motions, deferential and epicyclic, may be either direct or retrograde; and the curves may be best classified by observing whether the motions at the pericentres and apocentres are direct, retrograde, or neither. At 1 is represented a case of each motion, pericentral and apocentral, direct; at 2, a case of each motion, when it is neither direct nor retrograde—that is, directly towards the centre; at 3, a case of each motion, retrograde. We shall now consider how to make the separation of these cases.

First, as to the apocentres. When the motion in the epicycle is direct (for abbreviation say when the epicycle is direct), the two motions conspire; the line M C, then at A B, is being carried forward with the velocity of A, while P is being carried from M C. Let angles be measured in theoretical units [ANGLE], and let the deferential or mean velocity be 1, then the linear velocity of A is a, and that of P, when at B, is the linear velocity to an angular velocity n and radius b, or nb. Consequently, $a + nb$ is the apocentral velocity, which is direct; or the apocentral velocity is always direct when the epicycle is direct. But if the epicycle be retrograde, the line M C is advancing with the velocity a, while P is receding from it with the velocity nb. Consequently, when the epicycle is retrograde, the apocentral velocity is direct, neither, or retrograde, according as a is greater than, equal to, or less than, nb.

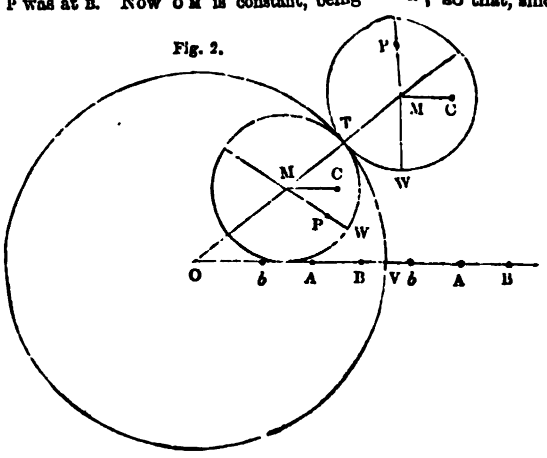
Next, as to the pericentres. We can make a pericentre by supposing the planet to be at b when M C is on A B. Now, if the epicycle be direct [MOTION, DIRECTION OF], the line B b being carried forward with the velocity a, the planet is carried backwards with the velocity nb. Consequently, when the epicycle is direct, the pericentral motion is direct, neither, or retrograde, according as a is greater than, equal to, or less than, nb. But when the epicycle is retrograde, the motion of the planet at b, as well as that of b B, is in advance, and $a + nb$ represents the whole velocity: consequently, when the epicycle is retrograde, the pericentral motion is always direct. Observe that we name the deferential motion with respect to the centre, and the epicyclic motion with respect to the centre of the epicycle: as explained in the article cited, a motion may be direct with respect to one, and retrograde with respect to the other.

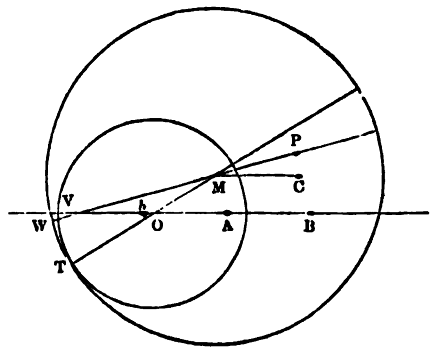
We shall now consider the trochoidal mode of viewing the subject, previously to combining the two. Let the circumference of one circle roll upon that of another, any point on, inside, or outside of the rolling circle (if outside, of course supposed to be fixed to it by a carrying arm) describes a curve by the motion compounded of the motion of the rolling circle round its own centre, and the motion of that centre round the centre of the fixed circle. Three cases may be supposed, as in the following diagrams (*fig.* 2). The two convexities may be opposed, that is, the rolling circle may roll outside the other; or the concavity of one may fit the convexity of the other. This last divides into two cases: first, when the rolling circle is the smaller, in which case it rolls entirely inside the other; next, when the rolling circle is the larger, in which case the fixed circle is always inside the other. Now each of these cases may easily be reduced to a much more intelligible planetary system, by which much of their difficulty will be removed. It should be observed, that when the convexities are opposed, the trochoidal system is called *epi*-trochoidal, and when concavity fits convexity, *hypo*-trochoidal. We call the radius of the fixed circle F, and of the rolling circle R.

1. Every epitrochoidal system is a planetary system in which the epicycle is direct. Taking the circle which rolls entirely outside the

other, P is the point describing the curve, and TW has rolled over TV since P was at B. Now OM is constant, being F + R; so that, since P

Fig. 2.





rolls uniformly round M, here is a planetary system in which OM is the radius of the deferent, MP that of the epicycle (which is direct), and the epicyclic velocity is to the deferential as the angle CMP to AOM. Now the arcs TW and TV are equal, whence AOT being ϕ, and TMW being ψ, we have $F\phi = R\psi$, or

$$\text{CMP} = \left(\frac{F}{R} + 1\right)\phi; \text{ so that } \frac{F+R}{R} \text{ is the ratio of the velocities.}$$

Hence, looking at the double generation of every planetary system, we have either

$$a = F + R,\ b = MP,\ n = \frac{F+R}{R};$$

$$\text{or } a = MP,\ b = F + R,\ n = \frac{R}{F+R}.$$

2. Every hypotrochoidal system in which the rolling circle is the larger of the two is a planetary system in which the epicycle is direct. Here, in the proper diagram, WT has rolled over VT, as before, OM and MP are the radii of the deferent and epicycle, and the epicyclic velocity is to the deferential as the angles CMP and AOM; and $OM = R - F$. If AOM and TMW be ϕ and ψ, we have, from the equal arcs TW and TV, $R\psi = F\phi$, and

$$\angle \text{CMP} = \phi - \psi = \left(1 - \frac{F}{R}\right)\phi; \text{ whence } \frac{R-F}{R} \text{ is the ratio of the velocities.}$$

We have then either

$$a = R - F,\ b = MP,\ n = \frac{R-F}{R};$$

$$\text{or } a = MP,\ b = R - F,\ n = \frac{R}{R-F}.$$

3. Every hypotrochoidal system in which the rolling circle is the smaller is a planetary system in which the epicycle is retrograde. In the proper figure it is now evident enough that OM, the radius of the deferent, is $F - R$; and that AOM and WMT being ϕ and ψ, we have $R\psi = F\phi$, from the equal arcs TV and TW. It is plain also that MP, the radius of the epicycle, moves with a retrograde velocity. Moreover, the epicyclic and deferential velocities are as the angles CMP and AOM, and ($R\psi$ being $= F\phi$)

$$\angle \text{CMP} = \psi - \phi = \left(\frac{F}{R} - 1\right)\phi, \text{ and } \frac{F-R}{R} \text{ for the ratio of the velocities.}$$

Either then

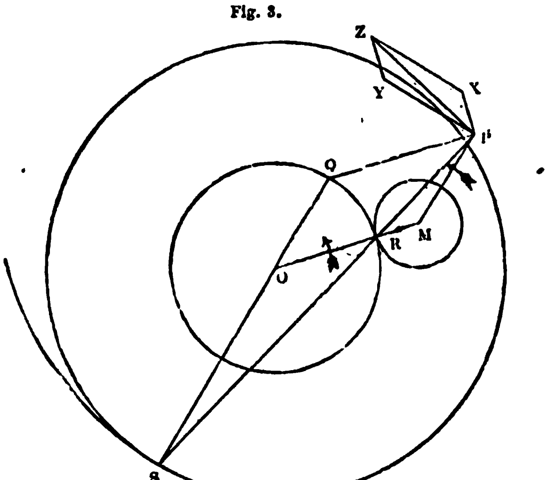
$$a = F - R,\ b = MP,\ n = \frac{F-R}{R};$$

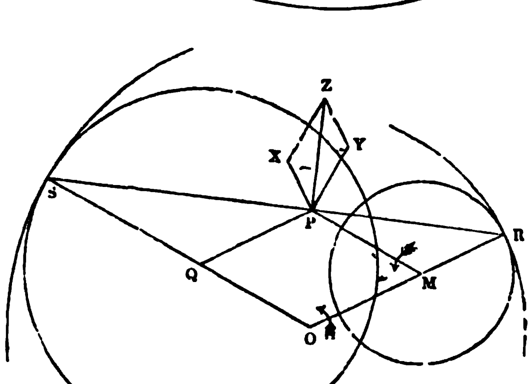
$$\text{or } a = MP,\ b = F - R,\ n = \frac{R}{F-R}.$$

To distinguish the two hypotrochoidal systems, which have very different properties, let that one in which the rolling circle is smaller than the fixed, so that the curve lies entirely inside the fixed circle, be called the *internal* hypotrochoidal system; and that in which the rolling circle always contains the fixed circle, and in which the curve is entirely without the fixed circle, the *external* hypotrochoidal system. It appears then that a planetary system with a direct epicycle belongs to both the epitrochoid and the external hypotrochoid; while one with a retrograde epicycle belongs to the internal hypotrochoid.

We now take the converse problem—namely, given a planetary system, to find the corresponding trochoidal systems. This might be easily done algebraically from the preceding results, but a simple geometrical construction will much assist the beginner, who rarely can get the true phase of a figure out of formulæ. It is required first to construct the real velocity and direction of a planet at any point of its curve. The epicycle is, at any given instant, moving forward perpendicularly to the radius of the deferent with the velocity a, while the planet is moving perpendicularly to the radius of the epicycle with a velocity nb. The composition of these two velocities gives the real motion and direction of motion of the planet for the time being, and shows us how to draw the tangent of its curve.

Fig. 3.





Let OM and MP (*fig.* 3) be radii of the deferent and epicycle (not drawn); and from P, the planet, draw PX and PY perpendicular to OM and MP. Make PX to PY as a to nb, and complete the parallelogram PXYZ. Then PX represents the motion, for the instant, of the whole epicycle, and PY the motion of the planet in the epicycle; whence PZ represents the planet's actual velocity, and PZ is tangent to its curve. In the first of the figures the epicyclic motion is direct, and in the second retrograde, the arrows showing the direct motion of revolution. Also, for variety, the planet is placed much nearer to its pericentre in the second figure than in the first.

Draw PRS perpendicular to PZ, meeting OQ and OM in S and R. Then, the sides of the triangles QPS, PMR, being severally perpendicular to those of PZX, these three triangles are similar to one another. Hence

$$PQ\,(=a) : QS :: PX : XZ :: a : nb, \text{ or } QS = nb$$

$$PM\,(=b) : MR :: ZX : XP :: nb : a, \text{ or } MR = \frac{a}{n}.$$

In the second figure, or when the epicycle is retrograde, it will always be found that R and S are in OM and OQ produced; but the first figure, as drawn, is good only for the case in which n is greater than 1, as was supposed in the construction, and is seen in the result, since QS (or nb) is greater than QO (or b), and RM (or $a : n$) is less than OM (or a). If n had been less than 1, PS would have passed through OQ; but in all cases of direct epicycle, one of the sides OM and MQ is cut externally and the other internally; while in every case of retrograde epicycle, both are cut externally. We have then

Epicycle retrograde $\begin{cases} OS = b\,(1+n), \quad QS = bn \\ OR = a\left(1+\frac{1}{n}\right), \quad MR = \frac{a}{n} \end{cases}$

Epicycle direct $\begin{cases} n > 1 \begin{cases} OS = b\,(n-1), \quad QS = bn \\ OR = a\left(1-\frac{1}{n}\right), \quad MR = \frac{a}{n} \end{cases} \\ n < 1 \begin{cases} OS = b\,(1-n), \quad QS = bn \\ OR = a\left(\frac{1}{n}-1\right), \quad QS = \frac{a}{n} \end{cases} \end{cases}$

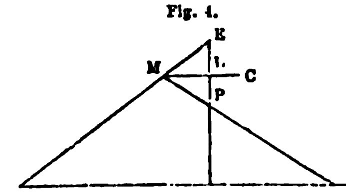
We can now immediately show that every planetary curve can be trochoidally described in two ways, it being already known that every trochoidal curve can be planetarily described in two ways. It appears that OR and OS are the same for every position of the planet in a given system, since they depend only on a, b, and n. Consequently, while the planet moves, R and S revolve in circles about O; and if we now pass to a trochoidal system in which OR is the radius of the fixed, and MR of the revolving circle, the point P, connected with the revolving circle by the arm MP, will describe a trochoidal curve which is identical with the planetary curve, from the elements of which its circles were obtained. Or OS may be made the radius of the fixed circle, and QS of the revolving circle, the arm of connection being QP. For instance, if we take the retrograde epicycle, and make

$$F = b\,(1+n), \ R = bn; \text{ then } b = F - R \quad n = \frac{R}{F-R},$$

which are the equations, already found, of connection between the internal hypotrochoidal system and its corresponding planetary one; and similarly for the other cases. And the result is, as appears from the figure, that every direct-epicycle planetary system is both epitrochoidal and externally hypotrochoidal, while every retrograde-epicycle planetary system is in two different ways internally trochoidal. We are thus enabled to refer the description of all the trochoidal curves to their corresponding planetary systems, which are much more easily followed, especially when, as is always in our power, we make the radius of the epicycle not exceeding that of the deferent. It has appeared that when $a = bn$, the planet has no motion of revolution, at the apocentre in a retrograde epicycle, and at the pericentre in a direct epicycle; the motion must then at those epochs be all from or to the centre, giving curves with such cusps as are shown in a former diagram. Now, looking at the corresponding trochoidal systems, we see that when $a = nb$, QS = QP, and MR = MP, or the point which describes the trochoid is *on the circumference of the rolling circle*. In this case the epitrochoid is called an epicycloid, and the hypotrochoid an hypocycloid. And since in all cases the line which joins P with the point of contact of the circles (R or S) is normal to the curve, or perpendicular to the tangent, it follows that in the epicycloid and hypocycloid, the two chords which join the point that traces out the curve with the two extremities of the central diameter of the rolling circle are, one tangent, and the other normal, to the curve.

We shall now pass on to the consideration of the varieties which planetary curves offer; and first we have to separate some extreme or critical cases from the rest. These are when $n = 1, 0,$ or -1, for we shall now begin to distinguish direct from retrograde epicyclic motion by making n negative in the latter case. When $n = 1$, P (*fig.* 1) will be always in the continuation of OM, either at E or e, as it was first placed; consequently the planetary curve is here only the apocentral or pericentral circle of other cases. If $n = 0$, P will always coincide with C; now C describes a circle equal to the deferent, but having its centre at K, OK being equal to the radius of the epicycle. If $n = -1$, the angle CMP (*fig.* 4) is always equal to MON, and the triangles EON, CMP, are similar; whence EP, or twice LP, is always a given proportion of EN, the ordinate of a circle: it follows, then, that the planetary curve is an ellipse when $n = -1$. But when $a = b$, the point P is always at H, in the line OH, and the planetary curve is as much of the straight line OH as extends from twice OM on one side to twice OM on the other. Looking at the trochoidal character of these varieties, we have, when $n = 1$, either $F = 0$, $R = b$, or $F = 0$, $R = a$; that is, the curve then described is made by a circle revolving round a point in its circumference; in both cases we have a circle. But when $n = 0$, we have $F = b$, $R = 0$, or the trochoidal curve belongs to a point connected with a circle of no radius, which revolves on a circle of the radius b, or OK. This is one of those extreme cases which are rather interpreted

Fig. 4.



than perceived [INTERPRETATION]: if a circle of no radius revolve from K, it can never make any progress, and the arm, KC, which carries the moving point, is always describing a circle. It is the extreme case of the following supposition:—Let a circle of extremely small radius revolve on the circle of radius OK, carrying with it the arm KC; it will make but little progress on the larger circle in many revolutions, during which C will describe many nearly circular folds very close to each other. Lastly, when $n = 1$ retrograde, we have $F = 2b$, $R = b$, or the fixed circle has twice the radius of the rolling circle. When $a = b$, the point which describes the curve is on the circumference of the rolling circle; and thus we have the following theorem:—**When a circle rolls inside another of double its diameter, every point attached to that circle, internally or externally, describes an ellipse; but every point on the circumference of the rolling circle describes a straight line, the extreme limit of an ellipse.**

Since we can always suppose the lesser of the two circles to be the epicycle, and the greater the deferent, when there is a lesser and a greater, there is yet another extreme case in which the epicycle and deferent are equal, so that all the pericentres are in the centre O itself, for now the epicycle always passes through that centre. This case will be best considered after the several other cases of which it is the extreme. We now go on to the general question, namely, having an epicycle less than the deferent, and having both radii given, required the forms of all the varieties of the planetary curve which arise from giving different values to n.

We may recapitulate the formulæ first given with their algebraical character, as follows:—The radius of the deferent is a, that of the epicycle b, the ratio of the angular velocity of the planet in the epicycle to that of the epicycle round the deferent is n, which is negative when the epicycle is retrograde. The angle moved through by the centre of the epicycle since the last epoch when the planet was at its apocentre being ϕ, that moved through by the planet round the epicycle in the same time is $n\phi$, and when the planet has come to its pericentre, ϕ is $180° \div (n-1)$, this meaning, when positive, that the radius of the epicycle has gained 180° in direction upon that of the deferent; and, when negative, that the radius of the deferent has gained 180° upon that of the epicycle. And the apocentral velocity of the planet is $a + nb$, n having its proper sign, its absolute revolution round the centre being direct or retrograde, according as $a + nb$ is positive or negative. The pericentral velocity is $a - nb$, to be interpreted in the same manner. In the corresponding trochoidal systems, F and R being the radii of the fixed and rolling circles, and C the length of the arm which carries the moving point, measured from the centre of the rolling circle to which it is attached, we have either

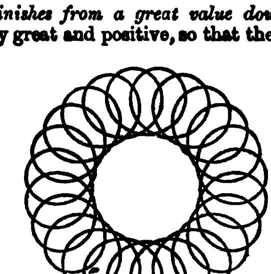
$$F = b\,(1-n), \ R = bn, \ C = a, \text{ or } F = a\left(1-\frac{1}{n}\right), \ R = \frac{a}{n}, \ C = b,$$

where n is to have its proper sign, and

F positive, R positive, denotes an epitrochoidal system;
F negative, R positive . . . . external hypotrochoidal system
F positive, R negative . . . . internal hypotrochoidal system;

or, in fact, that circle only which sees the concavity of the other, is to have its radius counted as negative. This is an induction from the various previous cases, such as the student of algebra will readily make.

I. *When* n *diminishes from a great value down to* a ÷ b. Let us first suppose n very great and positive, so that the angle from apocentre



to pericentre is small, the apocentral revolution direct, the pericentral retrograde. Passing to the trochoidal systems, both circles are large in the external hypo-system; and the fixed circle nearly equal to the deferent, and the rolling circle small, in the epi-system; also the planet is far within the circumference of the rolling circle in the external hypo-system, and far without it in the epi-system. All this must be collected from the formulæ. The curve is then of the foregoing form.

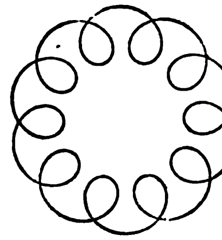
The angle during which the revolution of the planet is absolutely retrograde is always thus found:—Determine ϕ_1 from the equation

$$\cos(n-1)\phi_1 = -\frac{a^2+b^2n}{ab(1+n)},$$

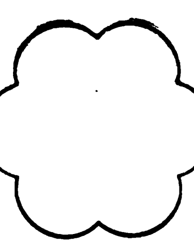
which can always be done if the second side be less than unity. Then the retrogradation begins when $\phi=\phi_1$, and ends when

$$\phi = \frac{360°}{n-1} - \phi_1.$$

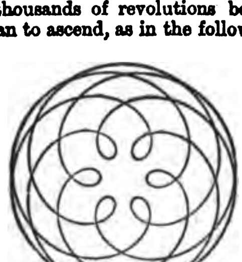
As n diminishes, the angle from apocentre to pericentre increases; the radii of both circles in the external hypotrochoidal system diminish; in the epitrochoidal system the fixed circle grows less, and the revolving one greater, both the circumferences approaching the planet. When n grows small enough, being still so large that $a < nb$, the loops cease to

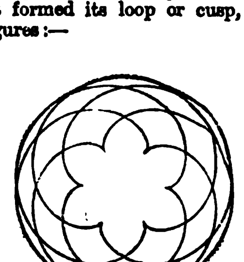


interlace, and become separately visible. This goes on until n is so far reduced in value that $a = nb$, when the pericentral velocity vanishes, both the trochoidal systems have the planet upon the rolling circle, the loops degenerate into cusps, and we have epicycloids, as follows:—



Towards the end of this division the character of the curve may be much affected by the relative value of b and a. At the epicycloid, when $n = a \div b$, the angle from apocentre to pericentre, as subtended at the centre, is $180° \div (n-1)$ or $180\ b \div (a-b)$ in degrees. The nearer $a \div b$ is to unity the greater does this angle become, and if a be near enough to b, it may be increased to any amount: so that a planet might descend from apocentre to pericentre through thousands of thousands of revolutions before it formed its loop or cusp, and began to ascend, as in the following figures:—

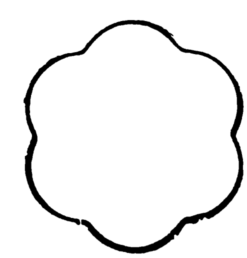




If a be actually equal to b, all these curves have the lower points of their loops in the centre itself, but as n diminishes down to unity, the descent becomes slower and slower; and when $n = a \div b$, or 1, ceases altogether, the apocentral circle itself being the hypocycloid of this extreme case.

II. *When* n *diminishes from* a÷b *down to* 1. When n has become a little less than $a \div b$, the angle from apocentre to pericentre has increased, the velocities at both places are direct, or the planet is never retrograde. In the trochoidal systems, it is now without the rolling circle of the external hypo-system, but within that of the epi-system.

The cusps have given way to points of contrary flexure, as in the following figure:—



The way to find these points of contrary flexure is as follows:—Find ϕ_2 from the equation;

$$\cos(n-1)\phi_2 = -\frac{a^2+b^2n^3}{abn(n+1)};$$

then there is one point of contrary flexure when $\phi=\phi_2$; and another when

$$\phi = \frac{360°}{n-1} - \phi_2$$

As n diminishes, these points of flexure, after approaching somewhat towards the apocentre, cease that approach, and begin to return towards the pericentre, in which they are lost when n has come down to the square root of $a \div b$. But this time they do not unite in the cusp from which they came, but the convex part of the curve disappears, in such a manner as to give a remarkable straightness to the parts adjoining the pericentres.

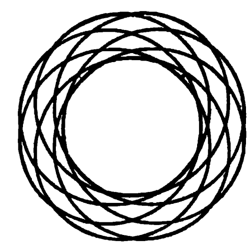
When n is less than $\sqrt{(a \div b)}$ the curve is always convex, and the angle from apocentre to pericentre perpetually increasing, the descent may be made as slow as we please, as in the following:—

At the limit of this case, when n becomes 1, all descent ceases, and the apocentral or pericentral circle is all that is left, as before described.

At the beginning of this section of curves, the planet was upon the rolling circle in both trochoidal systems: it immediately passes outside the rolling circle in the external hypo-system, and inside the rolling circle in the epi-system. Moreover, in the former the fixed circle gets smaller, and the rolling circle approaches the epicycle, so that when $n=1$, the external hypo-system is merely the epicycle revolving round a point in its circumference. But in the latter, as n approaches to 1, the rolling circle approaches the deferent in size, while the fixed circle becomes smaller and smaller: its extreme case coincides with the extreme case of the former system.

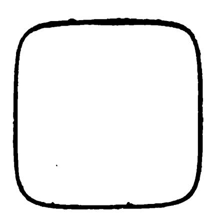
III. *When* n *diminishes from* 1 *to* 0. The angle from apocentre to pericentre, or the angle of descent, as we may call it, which left off infinite at the end of the last section, immediately becomes very great and negative when n is a little less than 1; indicating that the descent is performed by the radius of the deferent gaining upon that of the epicycle, instead of the contrary. The curve is always concave to the centre, and at first, in its long folds, much resembles that of the last diagram. But as n diminishes towards 0, the angle of descent becomes less and less, and is only $-180°$ when $n=0$; and during this time, the descent becomes more and more circular, until, when $n=0$, we have nothing but the circle with centre K and radius KB, as before explained (*fig.* 1). As to the trochoidal systems, the external hypo-system and the epi-system have changed formulæ: in the latter, the fixed radius changes from 0 to b, and the rolling radius from b to 0, the planet being always outside the rolling circle: the extreme case has already been explained. But in the former system both radii increase without limit, and become infinite when $n=0$, the planet being always within the rolling circle. The extreme case must be thus explained [INFINITE]: to construct a planetary curve in which the epicyclic motion is very slow compared with the deferential, by means of its external hypo-trochoidal system, we must take both radii, fixed and rolling, very large, and the larger the slower the relative epicyclic motion without limit.

IV. *When* n *increases negatively from* 0 *to* -1. The angle of descent, which left off at $-180°$, now diminishes in amount, being still negative; and by the time $n = -1$, it brings us, as we have seen, to an ellipse, which gives $-90°$. The apocentral and pericentral velocities are still positive throughout this section, and the curve is a series of shorter concave descents. The final ellipse has $a+b$ and $a-b$ for the semi-axes.

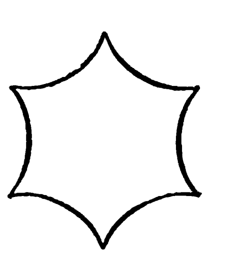


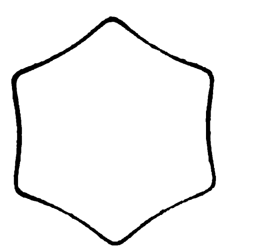
Both the trochoidal systems are internal hypo-systems, the planet being inside the larger of the rolling circles, and outside the smaller. At the extreme case, the ellipse, the two systems are the same, and in both cases the fixed circle becomes double of the rolling circle in diameter. Before the extreme case, the greater rolling circle belongs to the greater fixed circle, and the less to the less.

V. *When* n *increases negatively from* -1 *to* $-$a : b. Something resembling the last continues (the angle of descent still diminishing) until that angle is too small to allow of a descent wholly concave. By the time n becomes $-\sqrt{(a\div b)}$ the descent is almost a straight line, except very near the apocentre, and when n is greater than $\sqrt{(a\div b)}$, taken negatively, there are points of contrary flexure dividing the convex from the concave part as before.



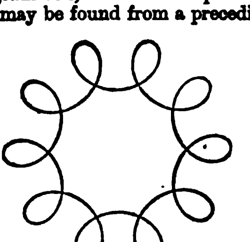
These points of contrary flexure do not, as before, return to the pericentre at which they begin; but as n varies from $-\sqrt{(a\div b)}$ to $-a\div b$, they run up the arc of the curve, and unite at the apocentre, when $n=-b\div a$, in a cusp. This cuspidated curve is the hypocycloid, and up to this point both apocentral and pericentral motions are direct.



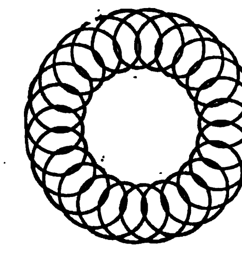


The only change that has taken place during this time in the trochoidal systems is a continual increase of both circles in one of them, and a continual diminution of both in the other. At the hypocycloid both the rolling circles are thus brought to pass through the planet, and the fixed circles become equal. The common radius of the fixed circles is $a+b$, those of the rolling circles are a and b.

VI. *When* n *increases negatively from* $-$a : b. We left off with the hypocycloid at which the apocentral motion (in revolution) is nothing. This apocentral motion afterwards becomes retrograde, the pericentral continuing direct, so that apocentral loops begin to be formed; and the central angle of retrogradation, in which the planet passes through the higher part of a loop, may be found from a preceding formula.

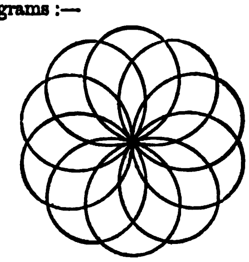


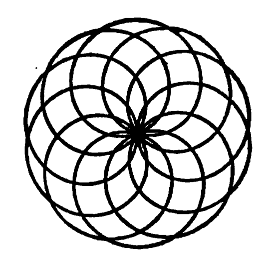
As n increases, these loops become nearer and nearer, and at last begin to interlace, the angle of descent continually diminishing. In the trochoidal systems, both circles of one of the hypo-systems increase without limit with n, while in the other the fixed circle perpetually becomes more nearly equal to the deferent, while the rolling



circle diminishes without limit. As n increases, each of the loops more and more nearly coincides with the epicycle, and the extreme limit is a circle of *no radius*, carrying the planet on an arm equal to the radius of the epicycle, and revolving on a circle equal to the deferent: or a revolution in an epicycle whose centre is fixed. This limit of course is never attained; or perhaps the analyst would say, that when n is infinite, the planet goes over the whole space between the apocentral and pericentral circles.

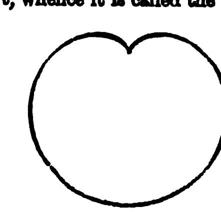
When the deferent and epicycle are equal, or $a=b$, the epicycloid becomes the apocentral circle, and the hypocycloid the straight line. The other curves take various extreme forms, as in the following diagrams:—





There is never any sensible arc of retrogradation; all the retrogradation, as it were, taking place suddenly at the pericentre, that is, at the centre. We shall leave the further investigation of these cases to the student.

When $n=2$, the angle of descent is always 180°, and the epicycloid has the rolling and fixed trochoidal circles equal, and is a curve shaped somewhat like a heart, whence it is called the *cardioide*.



On these curves generally we may remark, that their minor modifications of form are very various. The descent through a point of contrary flexure, for example, gives two curves of very different figures, according as the angle of descent is more or less than a right angle; and the loops may be made very small or very large, compared with the rest of the curve. It must be particularly noticed also, that by the angle of descent we mean simply the angle between the apocentral and pericentral distances, not the vectorial angle described in going from one to the other: the latter may become greater than this angle of descent before the pericentre is arrived at, and then diminish down to the angle of descent.

Let us now suppose the deferent to become a straight line, or $a=\infty$, and let the centre of the epicycle be carried along this line with a velocity a, while the planet moves in the epicycle with an angular velocity ν in theoretical units. Curves will now be described which are called *trochoids*, among which the CYCLOID has the same place as the epicycloid among the epitrochoids, or the hypocycloid among the hypotrochoids. The forms can be readily imagined by conceiving the deferent to be a circle of great radius. It is now of no consequence whether the epicyclic motion be direct or retrograde. If ν be very great, we have a series of interlacing loops; when ν becomes less, these loops separate; when $a=\nu b$, the loops degenerate into cusps, and we have the cycloid; and when a is greater than νb we have only a series of undulations with points of contrary flexure. All this may be represented by a trochoidal system in which a circle rolls upon a straight line, carrying with it an arm to which the planet is attached; and the trochoid is looped, cycloidal, or wavy, according as the planet is without, on, or within, the rolling circle. It will be a good exercise for the student to deduce the centre and radius of the rolling circle from a construction similar to that hereinbefore employed for deducing the elements of the trochoidal from those of the planetary system.

The diagram in MOTION, col. 796, exemplifies the three species of trochoids.

To suppose the epicycle infinite leads to nothing: but if we now take a trochoidal system, and suppose the rolling circle infinite, we have what is equivalent to a straight line rolling round a circle to which it is always tangent, and carrying a planet at the end of an arm which is supposed fixed to the straight line. If the planet be on the straight line, we have obviously the INVOLUTE of a circle; for the unrolling thread described in the article cited may be considered as the part of the rolling tangent which has been in contact with the circle since the beginning of the motion. If the planet can pass through the centre of the fixed circle, the curve becomes the spiral of Archimedes. These spirals must be made complete by using both positive and negative values of the radius vector. [SPIRAL.] They are not of much use except to the mathematician.

The various classes of trochoidal curves must be studied to aid in forming a proper conception of the effect of combined circular motions: one remarkable instance of their application is that of the apparent motions of the planets. These *apparent* motions must be exactly what would take place if the earth were at rest, the sun revolving in an orbit about the earth, which orbit is the deferent; while the sun itself is the centre of an epicycle equal to that of the planet's orbit, in which epicycle the planet moves. And since the epicycle and deferent are convertible, we may in the case of one of the superior planets use the planet's larger orbit as a deferent, and the sun's smaller orbit as an epicycle. Again, since the planet of the smaller orbit always has the greater angular velocity, the ratio of the epicyclic to the deferential velocity, or n, is always, the smaller orbit being the epicycle, greater than unity. Hence, when the planet is retrograde, the loop of its apparent orbit is always turned towards the earth, so that the apparent magnitude of the planet is always greatest in the middle of its retrogradation. To test these things, we ought to have angles of longitude measured in the plane of the planet's orbit; but since the inclinations of those planes to the ecliptic are not very great (with the exception of the new planets), angles measured on the ecliptic, or longitudes commonly so called, will do as well for illustration.

When the planet begins and ends its retrogradation, the tangent of the apparent orbit passes through the earth, and the planet, moving in that tangent, does not sensibly change its apparent position in the heavens for several days: it is then called *stationary*. The angle between these two stationary points is the angle of retrogradation, for which a formula has been given. But we shall simply notice the general figure of the apparent orbits, giving the ratio of the radius of the deferent to that of the epicycle, when the smaller of the two orbits (sun's round the earth, and planet's round the sun) is the epicycle, and the larger the deferent, and also the ratio of the angular motions.

	$a \div b$	n		$a \div b$	n
Mercury . .	2·58	4·15	Jupiter .	5·20	11·86
Venus . .	1·38	1·63	Saturn . .	9·54	28·78
Mars . .	1·52	1·88	Uranus .	19·18	84·01
Small Planets } . . / to	2·4 to 2·8	3·6 to 4·6			

All these must belong to looped curves, going round for ever, and never reuniting, in consequence of the practical incommensurability of the values of n. The angles of the descent are—for Mercury, $180° \div (4·15-1)$ or 57°; for Venus, 286°; for Mars, 205°; for the small planets, from 70° to 50°; for Jupiter, 16°; for Saturn, $6\frac{1}{4}$°: for Uranus, $2\frac{1}{4}$°. The doubles of these angles will be the angular distances between the lower points of two loops. Thus, to construct the orbit of Mercury, take a deferent of which the radius is about $2\frac{1}{2}$ times that of the epicycle, draw the apocentral and pericentral circles, lay down a succession of radii each at 57° to the preceding, draw the ascents and descents in the manner of the figure in § I., and the result will give a sufficient idea of the orbit for mental purposes. The time of the planet moving from the lower part of one loop to that of the next is, roughly, a revolution in the epicycle; that is, a year of the inferior planet for each inferior planet, and a year of the earth for each superior planet.

In the case of the moon we have a the radius of the earth's orbit, b that of the moon round the earth, $a \div b$ is about 400 and n is about 13; whence, since 13 is less than $\sqrt{400}$, or 20, the moon's real orbit round the sun has neither loops nor flexures, but is always concave to the sun. [MOON.]

The mathematical part of this subject labours under the same disadvantage as the more popular explanation, namely, the adoption of the trochoidal mode of viewing the curves, which, though it gives really the same equations as the planetary mode, embarrasses the question by introducing more complicated formulæ. If we take the line drawn from the centre to an *apocentre* of the curve for the *positive part* of the axis of x, and as before, let ϕ be the deferential angle, $n\phi$ the epicylic angle, x and y the rectangular co-ordinates of a point in the curve, r and θ the polar co-ordinates, a and b the radii of the deferent and epicycle, we have (1)

$$x = a \cos \phi + b \cos n\phi, \quad y = a \sin \phi + b \sin n\phi$$

which are the fundamental equations of the curve. Here a and b are both positive, ϕ (and also θ) vanishes at the apocentre, which is on the positive side of the axis of x, and n has its proper sign. But if we place a pericentre on the positive side of the axis of x, other things remaining the same, we have (2)

$$x = a \cos \phi - b \cos n\phi, \quad y = a \sin \phi - b \sin n\phi.$$

If the last terms stand thus, (3)

$$x = a \cos \phi \pm b \cos n\phi, \quad y = a \sin \phi \mp \sin n\phi$$

they may be reduced to (4)

$$x = a \cos \phi \pm b \cos(-n\phi), \quad y = a \sin \phi \pm b \sin(-n\phi)$$

or the case is one of the preceding, the ratio of the velocities being $-n$ and not n. If the first terms be negative, change the signs of x and y, and let the curve thus found make a half revolution; but if the first terms differ in sign, the equation is reduced to one of the preceding cases by changing the sign of ϕ (and of n, if necessary), which shows that what we had was the equation to the curve as described by a contrary motion of the deferent. All this, however, has only reference to the reduction of a particular equation to the form (1), which we shall use throughout. From (1) we readily find

$$r^2 = a^2 + b^2 + 2ab \cos(n-1)\phi \quad . \quad . \quad (5)$$

or the passage from apocentre to pericentre, or from $r = a + b$ to $r = a - b$, is performed, while $\cos(n-1)\phi$ changes from 1 to -1, or $\overline{n-1}\,\phi$ from 0 to π, or to $-\pi$, according as n is $>$ or $<$ 1. We also have

$$\tan \theta = \frac{a \sin \phi + b \sin n\phi}{a \cos \phi + b \cos n\phi} \quad . \quad . \quad . \quad . \quad (6)$$

To determine the period of retrogradation, if any, we must differentiate the preceding, which gives

$$r^2 \frac{d\theta}{d\phi} = a^2 + b^2 n + ab(1+n)\cos(n-1)\phi \quad . \quad . \quad . \quad (7)$$

and there is retrogradation when the second side is negative, from whence the formula already given is deduced, and the condition that nb must be numerically greater than a (a being throughout supposed greater than b). The following formula will help to obtain this condition:—

$$\left\{\frac{a^2 + b^2 n}{ab(1+n)}\right\}^2 = 1 - \frac{(a^2 - b^2)(n^2 b^2 - a^2)}{a^2 b^2 (1+n)^2} \quad . \quad . \quad . \quad (8)$$

From the preceding formula (7), it is easy to obtain $\frac{1}{2}\int r^2 d\theta$, the area included between two radii and the curve. But this is subject to the interpretation of that part of the area which is contained between two radial tangents to a loop, and the lower part of the loop being negative: the total result of which is that the area inside the loop is counted twice, and all the rest once.

To find the arc and points of contrary flexure we must deduce the following equations (9, 10):—

$$\frac{dx^2}{d\phi^2} + \frac{dy^2}{d\phi^2} = a^2 + b^2 n^2 + 2abn \cos(n-1)\phi$$

$$\frac{dx}{d\phi}\frac{d^2 y}{d\phi^2} - \frac{dy}{d\phi}\frac{d^2 x}{d\phi^2} = a^2 + b^2 n^3 + ab(n^2 + n)\cos(n-1)\phi$$

The second formula changes sign at the points of contrary flexure, whence the criterion before given is determined, by help of the following (11):—

$$\left\{\frac{a^2 + b^2 n^3}{ab(n^2+n)}\right\}^2 = 1 + \frac{(b^2 n^2 - a^2)(b^2 n^4 - a^2)}{a^2 b^2 (n^2+n)^2}.$$

The various double points are thus determined. Let ϕ and ϕ' be the two deferential angles belonging to a double point, the first when the curve passes through it the first time, and the second for the second. Since the value of r is the same at points, we have $\cos(n-1)\phi = \cos(n-1)\phi'$, whence we have

$$(n-1)\phi' = 2k\pi \pm (n-1)\phi \quad . \quad . \quad (12)$$

k being a whole number, positive or negative. If $\pi \div (n-1)$, the angle of descent, be called μ, we have $\phi' = 2k\mu \pm \phi$; and if we substitute this in the equations (1) remembering that $n\mu = \pi + \mu$, we find, by ordinary trigonometrical development, that the following equations exist between the co-ordinates of every double point:

$$x = \cos 2k\mu \,.\, x \mp \sin 2k\mu \,.\, y, \quad y = \sin 2k\mu \,.\, x \pm \cos 2k\mu \,.\, y.$$

These two equations should be really the same, and they are so if we take the lower signs, in which case they amount to the following:

$$y = \tan k\mu \,.\, x, \quad \theta = k\mu, \text{ or } k\mu + \pi.$$

If the higher signs be examined, it will be found that the two equations are not identical except when $2k\mu = 2l\pi$, l being a whole number, which can be true only when n is a commensurable fraction. But this case being further examined, shows that no double points are indicated, but only that the curve itself is repeated *in all its points* after a proper number of revolutions of the deferent, as is otherwise sufficiently obvious. Consequently all the double points of a trochoidal curve lie in apocentral or pericentral radii, or in the radii opposite to them. Substitute for y and x their values in $y = \tan k\mu . x$, and this equation is easily reduced to

$$a \sin (\phi - k\mu) + b \sin (n\phi - k\mu) = 0\,;$$

from which the values of ϕ which belong to double points answering to different integer values of k are to be obtained by approximation.

The radius of curvature of any trochoidal curve is obtained from the formulæ (9, 10), and is as follows:—

$$\frac{\{a^2 + b^2n^2 + 2abn \cos (n-1)\phi\}^{\frac{3}{2}}}{a^2 + b^2n^3 + ab\,(n^2+n) \cos (n-1)\phi}$$

It never becomes nothing except at the cusps of the epicycloid or hypocycloid; nor infinite except at the points of contrary flexure, or at the pericentre in the case of great approach to straightness already alluded to. The equation of the Evolute [Involute and Evolute], ξ and η being co-ordinates of a point in it, is involved in the following equations:—

$$\eta = a\,(1-\kappa) \sin \phi + b\,(1 - n\kappa) \cos n\phi$$
$$\xi = a\,(1-\kappa) \cos \phi + b\,(1 - n\kappa) \cos n\phi$$
$$\kappa \text{ being } \frac{a^2 + b^2n^2 + 2abn \cos (n-1)\phi}{a^2 + b^2n^3 + ab\,(n^2+n) \cos n-1)\phi}$$

The evolute, then, of a trochoidal curve may be described as of an extended sort of planetary character, having an epicycle of variable size, and radius $b\,(1-n\kappa)$, which moves upon a deferent, also of variable size, whose radius is $a\,(1-\kappa)$. In one remarkable pair of cases this variation of the elements of the evolute ceases, namely, for the epicycloid and hypocycloid. If $b^2n^2=a^2$, we find that κ becomes the constant $2 \div (1+n)$, and the equations of the evolute become those of a new epicycloid or hypocycloid, having its vertices at the cusps of the original involute.

The arc of the trochoidal curve cannot be obtained without the previous rectification of an ellipse, except in the case of an hypocycloid or epicycloid. In the former case the arc measured from the apocentre or cusp, formed while the deferential angle ϕ is produced, is

$$\frac{4ab}{a+b}\left(1 - \cos \frac{a+b}{2b}\phi\right)$$

and the whole arc of descent is $4ab \div (a+b)$. The same for the epicycloid, the apocentre being now a vertex, is

$$\frac{4ab}{a-b} \sin \frac{a-b}{2b}\phi\,;$$

the whole arc of descent being $4ab \div (a-b)$. All the preceding formulæ may be reduced to those of the trochoidal form by the general equations before given.

The equations of the cycloid and simple trochoids may be, in an article like the present, best deduced from those of the double circular system. Remove the origin from the centre to the circumference of the deferent, we have then for the equations—

$$x = -a\,(1-\cos\phi) + b \cos n\phi, \quad y = a \sin \phi + b \sin n\phi.$$

Let a increase without limit, and let s be the arc of the deferent, described with a velocity α, while ν is the absolute angular velocity of the planet round the epicycle. We have then $s = a\phi$, and $\alpha : s :: \nu : n\phi$. Substitution gives

$$x = -a\left(1 - \cos\frac{s}{a}\right) + b \cos \frac{\nu}{\alpha}s, \quad y = a \sin \frac{s}{a} + b \sin \frac{\nu}{\alpha}s\,;$$

of which, when a is increased without limit, the ultimate equations are—

$$x = b \cos \frac{\nu}{\alpha}s, \quad y = s + b \sin \frac{\nu}{\alpha}s\,;$$

which are the equations of the common trochoidal system. Here an epicycle moves up the axis of y with a velocity α, while a planet revolves in the epicycle with the angular velocity ν. When νb is numerically greater than α, there is a curve with loops; when $\nu b = \alpha$, one with cusps; and when νb is less than α, one with undulations and contrary flexures.

To get the equations of the other extreme case, we must reduce the planetary form of the general equations to the trochoidal, which gives

$$x = (\mathrm{F} + \mathrm{R}) \cos \phi + \mathrm{C} \cos \left(\frac{\mathrm{F}+\mathrm{R}}{\mathrm{R}}\phi\right)$$
$$y = (\mathrm{F} + \mathrm{R}) \sin \phi + \mathrm{C} \sin \left(\frac{\mathrm{F}+\mathrm{R}}{\mathrm{R}}\phi\right)$$

Let $\mathrm{C} = \mathrm{H} - \mathrm{R}$: that is, let H be the distance of the planet from the circumference in contact of the rolling circle. Substitute for C, develop

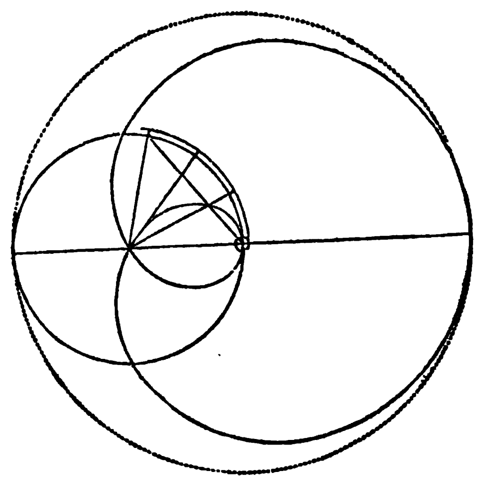
$$\mathrm{R} \cos \left(\phi + \frac{\mathrm{F}}{\mathrm{R}}\phi\right) \quad \text{and } \mathrm{R} \sin \left(\phi + \frac{\mathrm{F}}{\mathrm{R}}\phi\right)$$

into their binomial forms, and then increase the rolling circle without limit. The ultimate equations will be found to be

$$x = (\mathrm{F} + \mathrm{H}) \cos \phi + \mathrm{F}\phi \sin \phi$$
$$y = (\mathrm{F} + \mathrm{H}) \sin \phi - \mathrm{F}\phi \cos \phi$$

Here a tangent rolls over the fixed circle, carrying with it a point attached by a perpendicular arm of the length H. If $\mathrm{H}=0$, we have the involute of the fixed circle; but if $\mathrm{H} = -\mathrm{F}$, in which case the moving point begins from the centre of the fixed circle, we can deduce $r = \mathrm{F}\phi$, $\theta = \phi - \frac{1}{2}\pi$, which gives the spiral of Archimedes. We have touched slightly on these extreme cases, but the mathematical student will find it a useful exercise to develop them more fully.

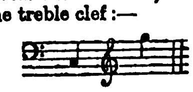
In conclusion, we wish to call attention to the fact that the specimens of curves in this article are all entirely the production of machinery. We are indebted for them to the kindness of Mr. Henry Perigal, a gentleman who practises the higher branches of turning as an amateur, and has devoted much time and money to the investigation of the effects of double and treble motions, as shown in various interesting publications. Most of those given in this article were executed in his lathe by means of Ibbetson's geometric chuck, a contrivance the results of which are well known to turners, but which have never been exhibited, as far as we know, in any article professing to give a mathematical classification of them.



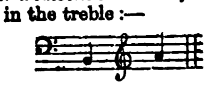
The preceding is the curve called the trisectrix in the article Trisection: it is a wood-cut made in the usual way from a drawing made in the lathe; all the rest are cut in the lathe.

TROMBONE (Italian, *great trumpet*). This ancient instrument was formerly known in England under the name of sacbut, from the old French *saquebute*. It is a deep-toned trumpet, composed of sliding tubes, by means of which every sound in the diatonic and chromatic scales, being within its compass, is obtained in perfect tune. The trombone is of three kinds,—the *alto*, the *tenor*, and the *base*, and these, in orchestral music, are generally used together, forming a complete harmony in themselves.

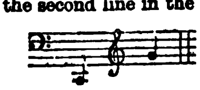
The scale of the *alto-trombone* is from C, the second space in the base, to G, an octave above the treble clef:—



The scale of the *tenor-trombone* is from B, the second line in the base to A, the second space in the treble:—



The scale of the *base-trombone* is from C, an octave below the second space in the base, to G, the second line in the treble:—



The trombone, when judiciously employed, as, for instance, in Mozart's 'Requiem,' and in his 'Don Giovanni,' is most efficacious in producing great and sublime effects; but, by the followers of the ultra-modern school, its power is exceedingly abused, especially in Italian operas.

TROPHY (τρόπαιον, *tropaeum*) contains the same root as the Greek verb τρέπειν, "to turn or to put to flight," and was therefore originally a sign or memorial erected on the spot where an enemy had been conquered or put to flight. The custom of erecting such memorials of victories, either on the field of battle or in the capital of the conquering nation, has been more or less common to all nations from the most remote to the most modern times. It was most general among the

Greeks, who used to erect trophies even after slight advantages; and it sometimes happened that both the belligerent parties, owing to some advantages they had gained, considered themselves entitled to erect trophies (Thucyd. i., 54; ii., 92). It was further a practice among the Greeks seldom to erect trophies in any other place than the field of battle, and that immediately after the victory was gained: when an enemy had been conquered at sea, the trophy was erected on the point of the coast nearest to the place where the victory was gained. A trophy in Greece after a victory on land appears to have consisted of a trunk of a tree fixed on some eminence and adorned with the spoils and armour of the vanquished. An inscription usually recorded the names of the conqueror and the conquered, and the whole trophy was dedicated to some divinity. It was customary not to make trophies of very durable materials, in order not to perpetuate the disgrace of a defeated enemy or to keep up any ill-feeling for too long a period. But this was not always observed. After a naval victory the trophy was usually adorned with the beaks of the captured ships of the enemy, and this custom was adopted by the Romans at an early period. The Romans down to the latter period of the republic never erected any trophies on the field of battle: the spoils of a vanquished enemy were partly distributed among the soldiers, partly dedicated in the temples of the gods, and partly applied as ornaments for other public buildings and places. When however the Romans adopted the custom of raising trophies on the field of battle, they usually consisted of more solid structures than the Greek, such as towers, columns, &c.

TROPICS (*τροπή, a turning*), the circles of the earth parallel to the equator which pass through those places to which the sun is vertical at the solstices, being the extreme boundaries of the torrid zone. The latitude of any spot upon either tropic is therefore the same as the obliquity of the ecliptic, and the interval between the northern and southern tropics comprehends every part of the earth at which the sun is ever vertical. The northern tropic is called the tropic of Cancer, and the southern that of Capricorn, since the sun, when vertical at places in the first, is at the commencement of the astronomical sign of Cancer; and when vertical at places in the second, is at the commencement of Capricornus.

TROUBADOURS, the name given to those poets in the Romance language, or Langue d'Oc, who lived in southern France, eastern Spain, and northern Italy, during the 12th and 13th centuries. [ROMANCE LANGUAGE.] The name is a French form, from the Provençal "trobador," a derivative of the verb "trobare," "to find," and means an "inventor." The word "Trouvère," in northern French, had the same meaning, and served to designate the poets of northern France, or of the Langue d'Oil. The troubadours were distinct from the jongleurs: the former were the real poets, and many of them were knights and men of noble birth, who occasionally occupied themselves with poetical composition; whilst the jongleurs were strolling minstrels, who did not compose poetry, but sang the lays of the troubadours, and accompanied them with their musical instruments, and thence derived their subsistence. Many of the troubadours however were skilled both in music and singing; but those who were not, retained a jongleur in their service. According to the spirit of chivalry, the nobles kept open house for all the wandering followers of war and minstrelsy, and often requited munificently both poets and musicians for their exertions to amuse them.

It was in the south of France that the poetry of the troubadours originated. That fertile region, blessed with a genial climate, had suffered less from the irruptions of the barbarians than the northern provinces of the kingdom, and had retained more of its old Roman civilisation: it hardly felt the civil wars of the Merovingian dynasty, and escaped the devastations of the Normans; and during the decline of the Carlovingians it became independent of the French crown by the revival of the kingdom of Bourgogne, or of Arles, and by the power of the great vassals, the counts of Toulouse and of Poitou and the dukes of Aquitaine. At the beginning of the 12th century the counts of Barcelona acquired by marriage the possession of Provence; and the whole region bordering on the Mediterranean on both sides of the Pyrenees, from the Ebro to the Var, became subject to one dynasty, whilst the people spoke the same, or nearly the same, Romance dialect. It was in the 12th century that the poetry of the troubadours attained its perfection: that poetry was essentially lyrical and mostly amorous, and was characterised by simplicity, or rather paucity, of ideas, and by a strained refinement of expression, and peculiarity of form, which made it quite distinct from the classical models. In that age and country of chivalry, every noble beauty had in her train some admiring poet; and every poet selected some fair lady—sometimes the daughter, but oftener the wife, of the nobleman to whose retinue he was attached—for the object of his poetical passion and the subject of his song. It was a poetical attachment, although it sometimes ended in a real one: its expression was artificial. These remarks apply generally to troubadour amatory poetry, to which however there are exceptions. (Sismondi, 'Littérature du Midi de l'Europe.')

The troubadours wrote also at times of loftier themes. Some of them, who had followed the Crusades and shared the dangers of Eastern campaigns, sang after their return the valiant deeds of the soldiers of the Cross. Others wrote to animate the Christian princes to deliver Palestine from the yoke of the Moslems. Others, especially about the time of the persecution of the Albigenses, wrote bitter satires against the persecutors, the Inquisitors, against the priesthood, the hierarchy, and against Rome itself. That persecution was one of the causes of the decay of troubadour poetry in the 13th century. Many of the troubadours perished, or fled and died in foreign lands. Afterwards Charles of Anjou, who had become count of Provence by marriage with the heiress of the house of Barcelona, having removed to Naples, took with him many Provençal knights and ladies to grace his new court. There they found a new language, the Sicilian or Italian, which was rising into maturity and was well calculated for poetry, and it became the favourite language of the Anjou court. When, in the following century, Queen Joanna I., being obliged to fly from Naples, returned to Provence, she endeavoured but in vain to revive the study of Provençal poetry; and when, many years later, she adopted Louis, son of King John, and the head of the third house of Anjou, that prince, who thus became possessed of Provence, spoke the Langue d'Oil, or northern French, and had no taste for the Provençal. His grandson René, duke of Anjou, count of Provence, and nominal king of Naples, made in the following century some attempts at reviving the poetry of the Langue d'Oc, but the race of the troubadours was now extinct, and the only result of his exertions was the collecting and compiling the lives of the old troubadours by the monks of the isles of Hyères, and after them by Hugues de St. Césaire.

At Toulouse however efforts were made to revive troubadour poetry. The "Capitouls," or municipal magistrates of that city, established an academy called "Del Gai Saber," or "of the gay science;" and seven of the best rhymers of the place, styled "the Seven Troubadours of Toulouse," were placed at the head of it. They fixed upon the 1st of May for holding an annual public festival, to which they gave the name of "Floral Games." The first meeting was held in 1324, and was attended by many poets from various parts of Languedoc. Maistre Arnaud Vidal de Châteauneuf d'Arri obtained the prize, and graduated as doctor of the gay science in consequence of a song in honour of the Virgin. The morality of troubadour poetry, however, underwent a reform under this new institution. It was forbidden by the statutes of the Academy to recite any composition on the subject of unlawful or adulterous love, a frequent theme of the old troubadours. The old language of the troubadours has long since fallen into disuse, and has given way to various patois, the Languedocian, Provençal, Poitevin, and others.

See for a thorough examination of troubadour poetry, with examples, Raynouard, 'Choix des Poesies Originales des Troubadours,' 6 vols. 8vo., Paris, 1816-21; 'Lexique Roman, avec un nouveau Choix des Poésies Originales des Troubadours,' Paris, 1836; also the work of Professor Diez, 'Die Poesie der Troubadours.'

TROUS DE LOUP, in the military art, are pits dug in the ground in the form of inverted cones or pyramids, in order to serve as obstacles to the advance of an enemy: each is made about six feet in diameter, or in breadth, and as many in depth, and a pointed stake is planted upright in the bottom. The pits should be disposed chequerwise in two or three rows, their centres being at distances of about ten feet from one another; and their sides should have such a slope that the enemy's riflemen, should they attempt to occupy them, may not be concealed in them from the view of the troops whom the pits protect.

The earth obtained from the excavations should be formed into a sort of glacis within the line of pits, in order that the enemy may not use it to fill them up. Trous de loup are generally formed before the salient points of field-works or in the intervals between them; and they are sometimes executed in rear of such works in order to protect the gorges when these are without parapets.

TROVER (from the French word *trouver*, "to find"), the name of an action invented for the purpose of ascertaining the right, as between the plaintiff and defendant, to the personal chattels which are the subject of it. This action is maintainable by one who has either an absolute or special property in the chattels and also a right to possession. Thus it may be brought either by the actual owner or an occasional bailee, a carrier, &c., or a mere finder as against all except the rightful owner. The declaration formerly stated that the plaintiff was lawfully possessed as of his own property of certain personal chattels, naming them distinctly, their amount and value; that he afterwards casually lost them, and that they came into the possession of the defendant by *finding*, who, afterwards converted them to his own use; for which the plaintiff claimed damages. This form and the fiction respecting the loss and finding of the goods were contrived for the purpose, by assuming a right of possession in the defendant, of enabling the parties to try the bare question of *right*. These fictions are not now used; and the fact of *conversion*, which is the gist of the action, is proved by showing that the defendant upon request refused to deliver up the goods, or has destroyed them, or has assumed the right to dispose of them. When an act of conversion has once been completed, no subsequent act by the defendant can, as is said, "purge the conversion;" that is, the right of action, having once vested in the plaintiff by the act of conversion, will not be divested by any subsequent act of the defendant. But such a subsequent act, as for instance the return of the goods, may reduce the damages to a merely nominal character. The action is not maintainable by one joint tenant, or tenant in common, or partner against another, unless in the case where the chattel has been destroyed by the other. This rule is founded on the principle that the possession of one is, by reason of the joint property of all, held to be the possession of all, and therefore no act of conversion can be said to have been committed.

The answers to this action are, a denial of the property of the plaintiff in the chattel; or the statute of limitations, namely, that six years have elapsed since the act of conversion was committed; or any circumstances showing that the defendant has a right to detain the goods, as from having a lien upon them, &c.

The plaintiff must prove that the nature and value of the goods are as stated in the declaration. If he succeed in obtaining a verdict, the jury may give damages to the amount of the value of the goods, and also such sum in addition as may cover the amount of interest during the time subsequent to the conversion. This action differs from the action of detinue as being brought to recover damages, while the object of the action of detinue is to recover the actual goods in specie. [DETINUE.]

TROY WEIGHT. Neither the etymology nor the time of introduction of this denomination is well known. The received opinion is that it took its name from a weight used at the fair of Troyes: this is likely enough, since we find more than one large town the weights of which became standards: thus we have the pound of Cologne, of Toulouse, and perhaps also of Troyes.

That there was a very old English standard pound of twelve ounces is a well determined fact; and also that this pound existed long before the name Troy was given to it, another. There were also the merchants' pound of fifteen ounces, and the Tower pound, having twelve ounces of its own, but less than the Troy pound by three-quarters of an ounce. Though the troy pound was mentioned as a known weight in 2 Henry V., cap. 4 (1414), and 2 Henry VI., cap. 13 (1423), the term troy was not applied to the legal standard pound till 12 Henry VII. (1495). The merchants' pound seems to have been the origin of AVOIRDUPOIS weight.

The troy pound has continued to be the legal standard down to the present time, though only actually used in weighing precious metals and stones, and apothecaries' drugs. It had precisely the same limitation of use in the time of Fleta, who is supposed to have lived in the reign of Edward I. There is no doubt that it was originally the pound of silver, the pound sterling, and there is evidence that this pound was sometimes described as divided into twenty parts called shillings. The famous statute of Henry I. (1266) makes a standard for it from the weight of ears of wheat.

The pound troy is now divided, for gold and silver, into twelve ounces, each ounce into twenty pennyweights, and each pennyweight into twenty-four grains. But for medicines, it is divided into twelve ounces, each ounce into eight drams or drachms, each drachm into three scruples, and each scruple into twenty grains. A cubic foot of water weighs 75·7374 pounds troy. [WEIGHTS AND MEASURES.]

TRUCK SYSTEM. TRUCK ACT. Truck, which means exchange or barter, has come to be appropriated to signify the payment of wages of labour in goods, and not in money. By the truck system is meant this mode of paying wages, together with the mass of its tendencies and results. The Truck Act, 1 & 2 Wm. IV., cc. 36, 37, is an act passed in 1831, which, repealing all the previous acts passed for the same purpose, provided anew and more stringently for the prevention of payment of wages in truck in the departments of industry therein enumerated. The wages of agricultural labourers and domestic servants are exempted from the operation of the act.

It is to be observed, in the outset, that the chief part of the evil of what is called the truck system is incidental, and not essential to the payment of wages in truck, and arises out of the power of the master over the workman, which enables the former to use this mode of paying wages to defraud and oppress the latter. A master may pay the wages of his workmen wholly or in part in truck, in articles of food, clothing, &c., either by agreement or with the understood consent of his workmen; and if he supply these articles at prices no higher than those at which they are to be procured elsewhere, and study to meet the various wants of the workmen and their families, the utmost harm that can result is the loss to the workmen of the moral and economical lessons which the disbursement by themselves of weekly money-wages is fitted to supply, and the interference with the business and profits of neighbouring retail shopkeepers; and there will always in such cases be some advantage to set against these, so far as they go, evil results. Where the truck system acts beneficially, it is owing entirely to the justice and benevolence of the individual truck-masters. On the character of the master everything depends. In the hands of masters of opposite character, and under circumstances, whether of scarcity of employment, of isolated situation, or of combination among masters in the same business, or through an extensive district, which place the workman more or less at the mercy of his employer, the payment of wages in truck may be, and continually has been, and is still, extensively used for the defrauding and oppressing of workmen.

The following is a summary of the Truck Act, often known as Mr. Littleton's Act, which was passed in 1831. It declares all contracts for hiring of the artificers afterwards enumerated, by which wages are made payable wholly or in part otherwise than in the current coin of the realm, or which contain regulations as to the expenditure of wages, to be illegal, null, and void. All payment of wages is to be in money entire; and any payment of wages in goods is declared illegal. Wages which have been paid otherwise than in the current coin of the realm are made recoverable; and in an action brought for the recovery of wages, no set-off is to be allowed for goods given in payment of wages, or for goods sold at any shop in which the employer has an interest. Employers are denied an action in return against artificers for goods which have been supplied in payment of wages. If workmen or their wives or children become chargeable to the parish, overseers may recover from their employers wages which have been earned within three months previous, and have not been paid in money. The penalty on employers making the illegal contracts or illegal payments of wages to be, for the first offence, a sum not greater than 10*l.* not less than 5*l.*; for the second, a sum not greater that 20*l.* nor less than 10*l.*; and the third offence is declared a misdemeanor, and the employer who has been convicted to be punishable by fine within the discretion of the convicting magistrates, but not in a sum greater than 100*l.* The convicting justices are empowered to award a portion of the penalty, which shall never exceed 20*l.*, to the informer. The penalties may be sued for and recovered by any one before two justices of the peace having jurisdiction in the county, riding, city, or place within which the offence has been committed. No justice of the peace being engaged in any of the trades or manufactures enumerated in the act, or the father, son, or brother of such person, shall act as a justice of the peace under this act; and provision is made for county magistrates taking the place of borough magistrates thus disqualified. Justices are empowered to compel attendance of witnesses. Power is given to levy the penalties by distress. A member of a partnership is not liable personally for the offence of his partner, but distress may be made on the partnership property. The 19th clause thus enumerates the artificers to whom the act relates:—"Artificers employed in or about the making, casting, converting, or manufacturing of iron or steel, or any parts, branches, or processes thereof; or in or about the working or getting of stone, salt, or clay; or in or about the making or preparing of salt, bricks, tiles, or quarries; or in or about the making or manufacturing of any kinds of nails, chains, rivets, anvils, vices, spades, shovels, screws, keys, locks, bolts, hinges, or any other articles or hardwares made of iron or steel, or of iron and steel combined, or of any plated articles of cutlery, or of any goods or wares made of brass, tin, lead, pewter, or other metal; or of any japanned goods or wares whatsoever; or in or about the making, spinning, throwing, twisting, doubling, winding, weaving, combing, knitting, bleaching, dyeing, printing, or otherwise preparing of any woollen, worsted, yarn, stuff, jersey, linen, fustian, cloth, serge, cotton, leather, fur, hemp, flax, mohair, or silk manufactures; or in or about any manufactures whatsoever made of the said last-mentioned materials, whether the same be or be not mixed one with another, or in or about the making or otherwise preparing, ornamenting, or finishing of any glass, porcelain, china, or earthenware whatsoever; or any parts, branches, or processes thereof; or any materials used in any of such last-mentioned trades or employments; or in or about the making or preparing of bone, thread, silk, or cotton lace, or of lace made of any mixed materials." Domestic servants and servants in husbandry are exempted from the act. The 23rd clause declares that nothing in the act shall prevent the supplying to artificers of medicine or medical attendance; or fuel, materials, tools, or implements to be used in his trade or occupation, if a miner; or of hay, corn, or other provender to be consumed by any horse or beast of burden, or the letting to any artificer the whole or part of any tenement, or the supplying of victuals dressed under the roof of any employer and there consumed; and making deduction of wages on any of the above accounts, or on account of money advanced, "provided always that such stoppage or deduction shall not exceed the real and true value of such fuel, materials, tools, implements, hay, corn, and provender, and shall not be in any case made from the wages of such artificer unless the agreement or contract for such stoppage or deduction shall be in writing and signed by such artificer." The interpretation clause (25th) gives a most extensive meaning to the word contract: "Any agreement, understanding, device, contrivance, conclusion, or arrangement whatsoever on the subject of wages, whether written or oral, whether direct or indirect, to which the employer and artificer are parties or are assenting, or by which they are mutually bound to each other, or whereby either of them shall have endeavoured to impose an obligation on the other."

Such are the provisions of the Truck Act. Well adapted, as it would appear, for the purpose of protecting the workman against this species of oppression by his master, it is yet extensively violated and evaded.

TRUE. (Astronomy.) This word is used in a somewhat technical sense. The place which a star or planet appears to occupy in the heavens is not called its true place, but that which it would occupy if the effects of refraction, parallax, &c., were removed, that is, if the spectator saw from the centre of the earth, and without the light passing through any refracting medium.

TRUMPET, a musical instrument of the highest antiquity, which, under different names and forms, has been known in all ages that have left any records, and in all countries, however remote from civilisation. Ménage derives the word from στρόμβος, *turbo*, a shell, and this etymology indicates the origin of the instrument, which still appears in what probably was its pristine shape among many barbarous tribes in different parts of the globe. [BUCCINA.]

The trumpet is a single tube eight feet long, less in diameter than the horn, doubled up in a parabolic form, sounded by means of a mouth-piece, and subject to the same acoustical laws which govern all instruments of this class. [HORN.] The natural scale of the trumpet, as given by Karl Bargans, is as follows:—

"By the assistance of a small brass tube, called the tuning-pipe, or shank, by which the tube of the trumpet is lengthened, the above number of notes may be increased." [HARMONICS.]

Music for the trumpet, as in the instance of the horn, is always written in the natural key of C, and the key to which the instrument is to be adapted is pointed out by the composer.

TRUNCATED, cut off, or abridged. Thus the part of a cone or pyramid which remains when the vertex and parts adjacent are separated from the rest by a plane section, is called a truncated cone or pyramid.

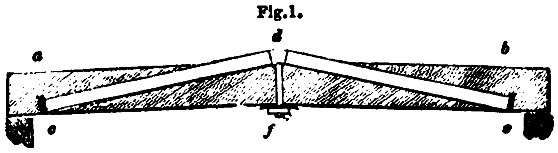
TRUNNIONS. When a heavy body has to be supported so as to be freely moveable in a vertical plane, it is furnished with a couple of strong cylindrical pins, or *trunnions*, projecting from its sides, and resting in semi-cylindrical grooves placed at equal heights in the supporting pillars, so that a line connecting the trunnions is horizontal. In this way the body may be placed in any position in a vertical plane at right angles to such line.

TRUSS. [HERNIA.]

TRUSSING. The principle of trussing, as applied to the timber framework of roofs, is explained under ROOF. It remains to notice some of the methods in which that principle is applied to the support or strengthening of beams or girders, which may, by their judicious application, be made available for much larger spans, and for the support of much greater weights, than simple beams of any attainable dimensions.

The rods or bars which are added to a girder for the purpose of trussing or supporting it may be applied in two sets, one on each side of the girder, and connected together by short cross-pieces at the necessary points; or the beam or girder itself may be divided longitudinally into two halves, or *flitches*, separated just so far as to admit a single truss between them, and held in the right position by the insertion of small blocks. In trussed girders formed in the latter way it is well to reverse the position of one of the flitches, so that the weaker end of one may lie alongside the stronger end of the other. One of the simplest methods of trussing girders is that represented in *fig.* 1, in which *a b* is the beam, resting upon walls or other fixed points of support at its extremities, and *c d* and *d e* are two inclined struts, resembling the rafters of a roof. These abut, at their lower extremities, *c* and *e*, upon iron plates inserted in the timber; and they sustain the centre of the beam by means of a *king-bolt*, *d f*, suspended from their apex, and passing through an iron plate which bears against the under side of the beam. This bolt corresponds with the king-post in the truss of a roof, and the lower part of the beam, between *c* and *e*, acts the part of a tie-beam.

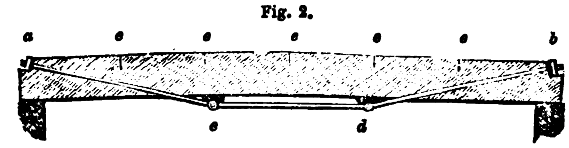
Fig. 1.



By screwing up the nut *f*, on the lower end of the king-bolt, the beam is *cambered*, or slightly curved upwards, as shown in the cut, and so long as it retains this curvature the weight laid upon it must eventually press upon the trussing-bars, being transmitted to them through the king-bolt. The defects of this mode of trussing consist in the circumstance that the beam will not, so long as it retains the cambered form, sustain any part of the load, but will of itself throw considerable strain on the truss; and that the lower edge of the beam, although required to be in a state of tension, to act as a tie connecting the abutments *c* and *e*, is really in a state of compression, because it forms the inner part of the curve, which is necessarily shorter than the outer line formed by the convex top of the beam. "Notwithstanding these obvious defects," observes Mr. Ainger in a communication to the Society of Arts ('Transactions,' vol. xlviii. p. 101), "this mode of trussing continued to be much employed till about the year 1816, when Mr. Barlow, among other valuable experiments, compared girders trussed on the principle above described with a plain piece of timber of the same size, and found the latter to be on the average not considerably weaker." These defects are remedied by connecting the lower ends of the inclined bars, which are, though not very properly, called braces, by an iron rod stretching in a perfectly straight line from *c* to *e*, and capable of being brought to any required degree of tension by means of screws or keys. This addition makes the truss perfect in principle, its strength being limited only by that of the materials employed, which may be either iron alone, or iron and wood. In some cases the inclined bars are not continued upwards until they meet in an apex, and a third bar, in a horizontal position, is placed between their upper ends. This horizontal piece resembles the straining-sill of a truncated roof, and the vertical bolts, of which two are used, take the place of queen-posts.

In the paper by Mr. Ainger above referred to, it is observed that trusses on the above principle are difficult and somewhat expensive to make in an effectual manner; and a more economical plan is described, which, though not equally efficient, adds very greatly to the strength of the timber. The description is illustrated by a representation, of which *fig.* 2 is a copy, of a girder thirty-four feet long, used to support

Fig. 2.



a leaden flat, and which had been found to stand without sensible alteration for two years. The beam *a b* is cambered in a similar degree to that shown in *fig.* 1, and the trussing consists of a series of iron rods, *a c*, *c d*, and *d b*, pulling against iron plates or abutments notched into the timber at *a* and *b*, and connected together at the joints *c* and *d*, by bolts similar to those used in the chains of a suspension-bridge, the rods *c d* being double, and embracing the ends of *a c* and *d b* between them. The truss forms, in fact, a suspension-bridge, supporting the middle of the beam at *c* and *d* by means of small blocks inserted between it and the connecting-bolts. The ends of the truss, *a* and *b*, are prevented from approaching each other by the upper part of the beam, which should therefore be in a state of compression; and in order that it may be so, notwithstanding the extension of the fibres by the cambering of the beam, notches may be cut about one-third through the substance of the wood, as at *e*, *e*, *e*, *e*, *e*, which, after the curving of the beam, are filled in with wedges of hard wood or iron. The upper edge of the beam is thus enabled effectually to resist the tension of the rods, the strength of which forms the only limit to that of the girder. Several varieties of this plan of suspension-trussing are given in Hebert's 'Engineer's and Mechanic's Encyclopædia,' vol. i., pp. 158-161. It may be applied, like the former system, either to single girders or to those consisting of two flitches. Ainger gives a formula for calculating the size of the iron trussing-rods, which, for a beam thirty-four feet long, should have a cross-section of rather more than a square inch for every ton weight to be sustained in the centre of the beam. It was found by experiment that a fir beam eight inches square and twelve feet long between the supports, strengthened by iron rods one inch square, applied as in *fig.* 2, would support between 4000 and 5000 pounds, which is more than double the weight it would sustain without trussing. A girder of the same dimensions, trussed with iron braces on the principle of *fig.* 1, but with the addition of a horizontal tie-bar one inch square, appeared to possess no greater strength to resist fracture, although its deflection under similar loads was less, owing to the iron braces being less compressible than the fir-wood, which, on the suspension principle, has to resist the tension of the rods.

The late Mr. George Smart, inventor of the ingenious truss called the "bow-and-string-rafter," in experiments tried to ascertain how far the strength of a beam is increased by confining its ends, so as to prevent them from approaching each other when the centre is heavily loaded, found that a lath which, when simply laid on two points of support, broke with a load of 11 lbs. placed in the middle, would sustain 270 lbs. when the ends were firmly secured by wedges. These experiments led him to the construction of trussed beams of unusual lightness, in wrought-iron as well as in wood. In 1826 he submitted to the Society of Arts a wrought-iron beam adapted for use in bridges, roofs, floors, and other constructions in which stiffness, strength, and lightness are required, for the invention of which he was rewarded with their silver Vulcan medal. This beam or girder is made by welding the ends of an arched bar of wrought-iron to a longer straight bar, and then turning the ends of the straight bar either up or down, as may be most convenient for fixing, according to the particular use to which it is to be applied. Blocks of well-seasoned wood are then inserted at intervals between the arch and the straight bar, to prevent buckling, and the whole is held together by iron straps inclosing the blocks and the iron bars. Mr. Smart conceived that wrought-iron beams made in this way would support so much more weight than those of cast-iron of similar dimensions, that they might be made of any given strength for one-half the cost of cast-iron girders; and he refers to the application of such a beam to sustain a very heavy mass of brickwork over a gateway leading from the Poultry, under circumstances which would have precluded the use of timber. Very light timber beams were made by Mr. Smart upon the same principle; and so strong was his confidence in the application of trussing upon an extensive scale, that he published a design for a foot-bridge of trussed timber to cross the river Thames at Hungerford by a single span.

Cast-iron beams are frequently trussed with wrought-iron rods, in a similar manner to those of wood, and are applied to purposes for which great strength is required. The brest-summers used over large shop-windows, to sustain the front wall of the house, are often made in this way; and similar girders are much used in the construction of railway bridges. The bridge which supports the London and Blackwall Railway across the street called the Minories is a remarkable example. It has a clear span of sixty-three feet, and is supported by six massive trussed beams, weighing about fifteen tons each. When used in floors or roofing, timber may be applied on each side of the iron, supported by ledges formed for the purpose, to render the fitting of the joists and other timbers easy. Smart recommends the use of bridging and ceiling joists formed of wide hoop-iron riveted together, with a slip of poplar between them to hold the flooring or lath-nails; and he observed that neither fir nor oak will, when thin, receive nails near so well as poplar, without splitting: in addition to which he says that, besides being very durable if kept dry, it has the advantage of being much less combustible.

Trussing has been applied with advantage to the raising of sunken floors, and the repair of beams which, from sagging or from the ravages of dry-rot, have become dangerous. In the forty-second volume of the 'Transactions of the Society of Arts,' pp. 149-152, is an account of a method of raising a sunken floor, which had been successfully practised by Mr. F. Richman, and for which he was rewarded with the large silver medal of the Society. The floor on which he had operated had sunk in the middle to the extent of five inches, and had become very tremulous, in consequence of the removal of a trussed partition, in order to throw two rooms into one. The ceiling and cornice of the room below being valuable, it was desirable to apply a remedy from above, which was accomplished by removing the floor, and applying to each side of the sagged beam a cast-iron arch, of which the span was equal to the length, and the height or spring equal to the depth, of the beam. The ends or abutments of these arches were united by tie-rods of wrought-iron. Four equidistant holes were then cut transversely through the beam near its lower edge, and in each of these was placed a short bar, having an eye projecting on each side of the beam. Through these eyes were passed vertical bars or trussing-bolts, which rose above the top of the beam, and were there connected together by cross-pieces, which rested upon blocks attached to the cast-iron arches. By screwing down nuts upon the upper ends of these bolts, as the arches themselves could not yield, the beam was compelled to rise, and was so restored to its original straightness. The cast-iron arches and their tie-rods were formed of several small pieces, so that they might be very conveniently applied; but for the method of accomplishing this, and for other matters of detail, we must refer to Mr. Richman's account, which is illustrated with engravings. In the same volume (pp. 153-164) is an account of the means adopted by Mr. Alfred Ainger for supporting the decayed timbers of the roof of the church of St. Mary Aldermary, in the city of London, by means of cast-iron trusses or cradles. This operation was performed under circumstances of unusual difficulty, some of the beams being so much decayed by the dry-rot as to have lost all bearing upon the walls. The ingenious contrivances adopted, which were rewarded by the Society of Arts with their large gold medal, prevented the necessity for destroying a richly-ornamented ceiling, the restoration of which would probably have cost 5000*l.*

TRUST AND TRUSTEE. A trust, which is in fact only a new name given to a use, is well defined by Lord Coke in the words employed by him for the definition of the latter term, namely: "A confidence reposed in some other, not issuing out of the land, but as a thing collateral, annexed in privity to the estate of the land, and to the person touching the land, for which *cestui que use* has no remedy but by *subpœna* in Chancery." (Co. Litt. 272 b.) The explanation of the terms of the above definition, and an account of the origin of uses and trusts, and their connection with each other, will be found under USES. The purpose of this article is to give a general account of the nature, constitution, and objects of trusts, of the duties and liabilities of trustees, and of the rights and estate of the *cestui que trusts*, that is, of the persons beneficially entitled under trusts.

The first division of trusts is into simple and special. The simple trust corresponds exactly with the ancient use, and is where property is simply vested in one person for the benefit of another, the terms of the trust not being specified, but left to the construction of law. The special trust, on the other hand, is where property is vested in a trustee for purposes particularly pointed out, and where therefore he is not the simple depositary of the estate, but is bound, in his character of trustee, to the active performance of certain duties. Special trusts are further subdivided into ministerial and discretionary; the former being such as require for their performance only the ordinary qualities of a rational agent, the latter such as involve the exercise of more or less judgment and discretion.

I. Of the creation of trusts.

1. And first, as to trusts created by the act of a party.

A declaration of a trust is regarded in equity as a gift or conveyance of property to the persons who are the objects of the trust, and therefore the capacity to declare a trust is limited by the same rules as the power of disposing of property at law. Thus persons under the disabilities of coverture, infancy, lunacy, or idiotcy are incapable of creating trusts wherever they would be incapable of conveying at law.

By the common law, trusts might be created by parole, but by the seventh section of the Statute of Frauds (29 Car. II. c. 3) it was enacted that "all declarations, or creations of trusts or confidences in any lands, tenements, or hereditaments, shall be manifested and proved by some writing, signed by the party who is by law enabled to declare such trust, or by his last will in writing, or else they shall be utterly void and of none effect." The words "lands, tenements, and hereditaments" in this clause can have no application to personal estate, trusts relating to which are therefore not affected by the statute; but they comprise chattels real (3 Ves. 696) and copyholds (Amb. 151.) It is to be observed that the statute does not require trusts to be *declared* in writing, but only to be *manifested and proved* by writing; and therefore, though the language of the 9th section as to grants and assignments of trusts renders it probable that the intention of the act was that the declaration itself should be in writing, it is established that the statute is satisfied if the trust be manifested by any subsequent acknowledgment on the part of the trustee, however informal or indirect, as by a letter under his hand, his answer in Chancery, or by a recital in a deed, &c.; and though the writing itself must be signed, the terms of the trust may be collected from a paper not signed, provided it can be clearly connected with the signed writing. (3 Ves. 696; 2 Vern. 288; 2 P. W. 412.)

The enactments of the Statute of Frauds with respect to wills, as now modified by 1 Vict. c. 29, also indirectly affect the creation of trusts. As wills must be executed according to certain formalities, it follows that a trust of realty or personalty cannot be created by will without the observance of the proper solemnities; and it has been determined that, if the legal estate be effectually devised, but the declaration of trust be not duly attested, the devisee of the legal estate will be entitled to the beneficial interest (3 Atk. 141); though if there be *mala fides* on the part of the devisee or legatee, as if there be an express or implied undertaking to execute the intent, a court of equity will establish the trust notwithstanding the statute. (2 Vern. 559.)

A trust may be created either directly, by express declaration, or indirectly, without mention of a trust in words, by the expression of an intention, which the court of equity will execute as a trust.

In direct declarations of trust, technical words are not necessary; but it is established as a general rule that, where they are employed, they are to be taken in their legal and technical sense. A distinction however is made in this respect between what are called trusts executed, in which the limitations are complete and final, and trusts executory, in which the expressed limitations are not intended as complete in themselves, but only as directions or instructions for a settlement to be afterwards executed. To the former the rule is strictly applicable, while with respect to the latter a court of equity will endeavour to execute what appears to be the intention of the parties, notwithstanding the use of inappropriate technical words; and the only difference in this respect between executory trusts in marriage articles and in wills is, that the known objects and purposes of the former afford a clue to the intention, which in the latter can in general be collected only from the language of the instrument. (Fearne, 'Cont. Rem.' 94, 114.)

When the owner, or the person otherwise entitled to the disposition of property, shows an intention to exercise it in favour of another, the court, unless where there is a want of consideration, will execute that intention, however informally expressed. Thus when a person has contracted with another for the sale of his estate, he becomes thereby a trustee of the estate for the purchaser; or if a testator, without expressly devising his lands, direct them to be sold for payment of debts and legacies, the lands will descend to the heir as a trustee for the creditors and legatees.

Trustees being considered merely as the instruments through which a trust is to be carried into execution, the Court of Chancery will not allow a trust to fall to the ground from the want of trustees, or their refusal to act, but will appoint proper persons to administer the trust.

In general all persons capable of acquiring the legal estate in property are capable of being trustees, and are bound by the trusts declared of it; though an exception should perhaps be made with respect to property vested in the king, against whom there is no remedy in Chancery, though the subject might sue the crown by preferring a petition of right. (Hardres, 467; 1 Ves. 446.) The fitness of a person for the office of trustee however depends on his capacity to discharge the discretionary part of the trust, and to join in the requisite assurances relating to the property: *femes covert* and infants, on account of the disabilities they labour under, are not proper persons to select for the office of trustees. An alien may discharge the office of trustee of personal chattels, though not of lands or chattels real, as he could not sue or be sued respecting such property; besides which, the legal estate of the property so conveyed to the alien would vest, on inquisition found, in the king. (Gilb. 'On Uses,' 43; 2 Mer. 431.)

2. As to trusts created by operation of law.

Trusts of this kind may arise in three ways: 1st. Where the trust originally derives its existence from operation of law; 2ndly. Where a trust already in existence is revived by operation of law, as against a particular property; and, 3rdly. Where a trust already in existence, and annexed to a particular subject-matter, arises *de novo* by operation of law as against a particular person.

Trusts of the first kind arise either where an estate is purchased in the name of one person, and the consideration is paid by another, in which case a trust of the legal estate arises for the person who advances the purchase-money; or where, upon a conveyance or will, the grantee, devisee, or legatee is intended to take the mere legal estate, and the beneficial interest is left wholly or partially undisposed of: in which case a trust of so much of the beneficial interest as is undisposed of results to the settlor or his heir, if the subject be real estate, and if it be personal estate, to himself or his personal representative. The intention to exclude the person to whom the legal estate is given from the beneficial interest may either be presumed from the circumstances or actually expressed upon the instrument. Whenever, upon a conveyance or will, a trust is declared of part of the estate, and no mention is made of the residue, the partial declaration is considered to have been the sole object of the settlor, and the remaining interest results to him or his representative. But if no trust be expressed of any part of the estate, the grantee or devisee must, in the absence of *mala fides* on his part, be considered as beneficially entitled to the whole. (2 Bro. C. C. 589; 1 Atk. 443.)

A trust of the second kind arises when the estate is converted by the trustee from one species of property to another, either in pursuance or in breach of his duty. If the property in its original form was subject to a trust, the *cestui que trust's* interests cannot be affected by any change in that form. Thus where trust-money has been laid out in the purchase of land, and where the rents and profits of land have been laid out in the purchase of stock, the land and stock have been held bound by the same equity to which the money laid out in the purchase was subject. (8 Ves. 46; 1 Atk. 49.) In the same manner, if a trustee or other person invested with a fiduciary character obtain a renewal of a lease in his own name and at his own expense, the trust which was annexed to the original term will attach upon the renewed lease, and the trustee will be entitled only to the amount of expense incurred. (11 Ves. 391; 1 Eden, 453.)

The third kind of trust by operation of law arises wherever the property passes from the trustee into the hands of a person who takes by a derivative title. The heir, devisee, or personal representative of a deceased trustee takes the property in the same character, and is bound by the same equity. Where the trust estate has passed to a stranger by conveyance, if he be a volunteer,—that is to say, if there was no proper consideration for the conveyance,—he will be bound by the trust, whether he had notice of it or not. (2 P. W. 678.) If, however, the grantee was the purchaser of the estate for an adequate consideration, then, if he took with notice of the trust, he will be bound by it, in the same manner as the person from whom he purchased; but a *bonâ fide* purchaser, without notice of the trust, is not affected by it; and his title, even in equity, cannot be impeached. (15 Ves. 350; 2 B. & B. 318.)

II. Of the estate and office of trustees.

1. Of their estate.

Whenever a trust is created, it is a general rule that a legal estate, sufficient for the purposes of the trust, shall, if possible, be implied; and also that the legal estate limited to trustees shall not be construed to extend beyond what the purposes of the trust require. Thus the court has in many cases extended the estate, so as to make it commensurate with the objects to be effected, and even supplied the estate when it was altogether wanting. (1 Ves. 495.) On the other hand, the court has frequently restricted the estate which trustees would have taken by the wording of the instrument. (7 T. R. 433.) But these rules, so far as they relate to devises, must now be considered with reference to the 1 Vict. c. 26, by the 30th section of which it is declared that where any real estate, other than a presentation to a church, is devised to a trustee or executor, such devisee shall be construed to pass the whole estate which the testator had power to dispose of in the property, unless a definite term of years, absolute or determinable, or an estate of freehold, be thereby given to him expressly or by implication.

The legal estate vested in a trustee has in general the same properties and incidents as if the trustee were the beneficial owner. Thus it is liable to curtesy, dower, and free-bench, and at the common law it was subject to forfeiture to the king and escheat to the lord; but the law is now altered, and the devolution of such estates is not affected by the attainder or conviction of the trustee or mortgagee. The legal estate in the property, whether real or personal, may be conveyed or assigned by the trustee, who may likewise devise or bequeath it by his will, though trust-estates will not always pass in a will by the same words as other property, and the question in each case is one of presumed intention. (8 Ves. 417.)

2. Of the general properties of the office of trustees.

Acceptance of the office by a trustee may either be by express declaration or be implied from his proceeding to perform the duties of it. No general rule can be laid down as to what particular acts will constitute an acceptance of the office by a trustee, which is a question to be determined by the circumstances of the particular case: it may, however, be stated generally that every voluntary interference with the trust-estate will be construed as an acceptance of the trust; and that where a trustee acts ambiguously he will not be allowed afterwards to take advantage of the doubt, and deny that he acted in the character of trustee. (2 Ves. Jun. 678; 1 Ves. 552.)

But as no one is compellable to undertake a trust, it is in the power of the person appointed a trustee to renounce the office by what is called a disclaimer, which, if he intend to decline the office, he ought to execute without delay. A disclaimer ought to be made by deed, and should purport to be a disclaimer, and not a conveyance, which, as it transmits the estate, would, strictly speaking, imply a previous acceptance of the trust, though instruments of this kind receive a liberal construction. (2 Swanst. 372; 2 M. & K. 278.)

The general properties and qualities of the trustee's office may be stated under the following heads:—

(1.) A trustee having once accepted his office cannot afterwards renounce it. The only modes by which he can be released are a decree of a court of equity, a power reserved on the instrument creating the trust, or the consent of all the persons beneficially interested in the estate. (2 Sch. and Lef. 245.)

(2.) The office of trustee, which implies personal confidence, cannot be delegated (2 Ves. 640), though a trustee may sometimes perform a mere ministerial duty through an attorney or proxy. (1 Ves. 413.)

(3.) When there are several trustees, the administration of the estate is vested in all; and therefore if one refuse to act, the others cannot proceed without his concurrence, and the Court of Chancery must take upon itself the administration of the trust. (2 'Eq. Ca. Ab.' 742.)

(4.) Where one of several trustees dies, the joint office may be exercised by the survivors. This is a consequence of the general maxim of law, that though a bare authority given to several determines by the death of one, if the authority be coupled with an interest it survives. (Co. Litt. 113 a, 181 b.)

(5.) One trustee is not liable for the acts of his co-trustee in which he has not joined, and this is equally true whether there is a proviso to that effect in the settlement or not. (Bridg. 35; 18 Ves. 254.) And even if a trustee joins in a receipt for money required for the purposes of the trust, for the sake of conformity only, he will not thereby become responsible for the application of it, though it will be upon him to prove that his co-trustee was the person by whom the money was received. (11 Ves. 324; 1 Ed. 147.) The rule is different with respect to co-executors, each of whom has an absolute control over the property, and who are therefore under no obligation to join in giving receipts (Amb. 219; 3 Swanst. 64); though whenever their joining together in doing any act is necessary, the same rule applies to them as to other trustees. (7 Ves. 197.) But if a trustee allows money to remain improperly in the hands of his co-trustee, or is cognisant of a breach of trust committed by him, and takes no measures to protect the estate, he will become himself responsible. (11 Ves. 319.)

(6.) Trustees cannot derive any private advantage from the administration of the trust, and therefore all profits made by the trustee in the management of the trust estate, in whatever manner, belong not to him, but to the *cestui que trust*. (2 M. & K. 664.)

III. Of the duties of trustees.

Trustees of personal estate are bound to use all due diligence in getting in and reducing into possession all parts of the trust estate that may happen to be outstanding at the time of the commencement of the trust (1 Mad. 290), and in providing for the safe custody of the property. (1 Ed. 148.) They are also bound, where trust-money cannot be applied immediately, to invest it on proper security, so as to render it productive to the *cestui que trust*. In the absence of any specific direction as to investment in the trust-deed, the rule is that the trustees ought to invest in the public funds.

Where a trust-estate consists of renewable leaseholds, it is in general the duty of the trustee to provide for renewals. If there be an express trust to provide for the fines out of the rents and profits, the trustees should lay aside a proper proportion of the annual income for the purpose. (17 Ves. 485.) If there be no express direction for payment of the fines, the estate may be charged with the amount of the fine, and the rule of the court is that the tenant for life and remainder-man must apportion the fine between them according to the value of their respective interests. (1 Bro. C. C. 440; 9 Ves. 560.)

Trustees for sale, whether expressly such or by implication, have, in the absence of any express restriction on their powers, the right to use all reasonable discretion as to the time and manner of effecting a sale. They cannot be compelled to enter into any other covenant than that against incumbrances by their own acts. The general rule is, that a trustee for sale cannot become the purchaser of the trust property either for himself or as agent for another; and the *cestui que trust* is at liberty to set aside any such purchase, however fair, and though no advantage should have been gained by the trustee. (3 Ves. 750.) But a trustee is not absolutely prohibited from purchasing from the *cestui que trust* under certain circumstances, though the transaction is at all times one of great difficulty, and looked upon with great suspicion by the court. (9 Ves. 244.) Upon setting aside a purchase by a trustee, the court will in general allow for all repairs and improvements effected on the property. (11 Ves. 226.) The *cestui que trust* will not be entitled to relief unless he make his application within a reasonable time; and if while *sui juris*, and with full knowledge of his rights he expressly confirms the purchase, he will not be allowed afterwards to set it aside. (5 Ves. 680; 12 Ves. 355.)

IV. Of the powers of trustees.

The powers of trustees are either *general* or *special*. It is impossible to define exactly the general powers of trustees, the extent of which depends in each case upon the particular circumstances of the trust-estate. It may however be laid down as a general rule, that whatever is compellable by suit is equally valid if done by the trustee without suit (4 Ves. 369); though, if a suit has already been instituted for the execution of the trust, whereby the management is taken out of the hands of the trustee, he ought to take no step without the sanction of the court. (10 Ves. 104.)

V. Of allowances to trustees.

It is a settled rule that a trustee is not entitled to charge for his time and trouble in the management of the trust-estate, whether he be a professional person or not; and the rule applies not only to trustees expressly nominated, but to all persons bearing a fiduciary character, such as executors, mortgagees, receivers, and committees of lunatics' estates. (10 Ves. 103.) Exceptions to this rule have been admitted in the cases of trustees for the estates of absentees in the West Indies and executors in India; but the rule against such allowances to trustees is only a general one in the absence of express directions by the settlor to the contrary, and there is no objection to a trustee's receiving remuneration for his services, or to his being allowed to make professional charges, if the intention of the settlor to that effect be clearly expressed. (7 Ves. 480; 3 Beav. 338.) A trustee may even bargain with his *cestuis que trust* for an allowance, though bargains of this kind are very narrowly watched by the court. Trustees not being allowed to charge for their own trouble, may on proper occasions, and where the business of the trust is troublesome or complicated, call in the assistance of agents at the expense of the estate.

A trustee, though not allowed to charge for his trouble, is entitled to all his expenses out of pocket; and even a specific remuneration given by the settlor to the trustees is no reason for their not receiving an allowance for expenses. (7 Ves. 480.) The expenses incurred by a trustee in the management of the trust-estate are considered as a charge upon the estate, to the satisfaction of which the trustee is entitled before he can be compelled to convey.

The general rule with respect to the costs of trustees incurred in legal proceedings is, that they shall be allowed as between solicitor and client, if there be a fund under the control of the court out of which they may be paid. (1 Swanst. 201.) But this rule is subject to numerous exceptions, depending upon the circumstances of the case, and the propriety or otherwise of the conduct of the trustee, either in the course of the suit itself or in the matters out of which it arose. A trustee who disclaims by answer in chancery is entitled to costs as between party and party only. (2 M. & K. 278.)

VI. Of the relinquishment of office by trustees.

A trustee may be discharged from his office by the consent of the *cestuis que trust*, but for this purpose the consent of all must be obtained, however numerous they may be; and if any of the *cestuis que trust* be incompetent to consent, or be not yet *in esse* as in the case of a limitation to unborn children, no complete discharge can be obtained.

A trustee may be discharged in virtue of a special clause to that effect contained in the instrument under which he is trustee. A proviso to this effect is usually introduced into settlements combined with a power either to the *cestui que trust*, or to the co-trustees, to nominate a new trustee in the event of any of the number happening to die, or being desirous of being discharged from, or refusing or declining, or becoming incapable of acting in the trusts. The transfer of the trust is not complete until the new trustee has been nominated by the donee of the power, and a conveyance or assignment of the property has been executed. Powers of appointing new trustees are strictly construed, and cannot be properly exercised except under the precise circumstances contemplated in the power, and it is always considered that the original number of trustees ought to be maintained. For this reason it would be improper to appoint one trustee to do the duty of two retiring trustees (2 M. & K. 682); and where there is a direction that upon the trustees being reduced to a certain number others should be nominated by the survivors, it has been determined that they might supply vacancies before the numbers were so far reduced, but that then they were compellable to do so. (5 Ves. 825.)

Two recent acts, known as the "Trustee Relief Acts," have provided facilities for trustees wishing to discharge themselves from the responsibility of administering funds which may have come into their hands.

VII. Of the estate and rights of the *cestui que trust*.

1. As to what it consists of. In cases of the simple trust the whole rights of equitable ownership consist in the right of possession and the right of disposition.

The equitable owner has in general a right to the possession of the estate, but where there are several parties interested either contemporaneously or in succession, it is in the discretion of the court of equity to determine whether possession ought to remain with the trustee or be given up to the *cestui que trust*. The right of possession of the *cestui que trust* is recognised in a court of equity only, for at law the trustee is considered as the owner, and the *cestui que trust* as tenant at will only. The trustee as tenant of the legal estate may recover in ejectment from his own *cestui que trust*, who has no defence to the action at law, and is only entitled to apply for an injunction in equity. (8 T. R. 122; 1 B. & B. 445.)

Upon the ground that the *cestui que trust* is the beneficial owner of the estate, he is entitled, either by the express language or by the equitable construction of statutes, to various privileges connected with real estate. Thus the 2 Hen. V. st. 2, c. 3, and the subsequent statutes relating to persons entitled to serve as jurors, have been construed to apply to the *cestuis que trust*, and not to the trustee. By 7 & 8 Will. III. c. 25, s. 7, the right of voting as a freeholder of a county was conferred on the *cestui que trust*, if in possession; and by the 2 Will. IV. c. 45, s. 19, the *cestui que trust* of copyholds or of any lands whatever except freehold, of the required yearly value, is entitled to vote at elections of members of parliament whether in possession or not.

The *cestui que trust* of chattels is also entitled to the use and possession of them during the continuance of his interest; and upon this ground they do not, upon the bankruptcy of the tenant for life, fall under the rules as to goods in the order and disposition of the bankrupt with the consent of the true owner. (19 Ves. 491.)

A *cestui que trust* who is entitled to the whole equitable interest may, in virtue of the *jus disponendi*, call upon the trustee for a conveyance of the estate. But he has no such right when the trustee holds upon trust for the benefit of others, or even when he is entitled to the whole usufructuary interest, but the continuance of the estate in the trustee is necessary to answer some ulterior purpose relating to the trust, such as to preserve contingent remainders. (5 Mad. 429.)

In cases of special trust, the right of the *cestui que trust* is to have a specific execution of the intention of the settlor to the extent of that *cestui que trust's* interest. If there be but one *cestui que trust*, and he capable of consent, the specific execution of the trust may be departed from; and so where there are several *cestuis que trust*, who all agree; but no variation can be made so as to affect the interest of any *cestui que trust* without his consent.

2. Of the nature and properties of the estate of the *cestui que trust*.

Equitable interests may be assigned, and the assignee may, like the original *cestui que trust*, compel a conveyance from the trustee by bill in equity, without making the assignor a party. (3 Russ. 583.)

Femes covert entitled to equitable interests in lands and equitable tenants in tail, might, before the Fines and Recoveries Act (3 & 4 Will. IV. c. 74), have passed their equitable estates by those assurances, and may now do so under that act by the same modes of assurance and with the same formalities as if the estates were legal.

The purchaser of an equitable interest should take care to inquire of the trustee whether he has had notice of any prior incumbrance upon the equity of the vendor, which will give the purchaser a remedy against the trustee in case of his misrepresentation (10 Ves. 470); and the purchaser should also, upon the execution of the conveyance, give notice to the trustee of his own equitable title, whereby he will secure precedence of all prior incumbrances who have not given such notice. (3 Russ. 30.)

Equitable interests in property are transmissible by devise, and require the same solemnities as legal interests. (1 Vict. c. 26, s. 3.) Possession or receipt of the rents and profits of equitable estates is considered in equity equivalent to seisin at law, and adverse possession of the one is attended with the same effects on the title as disseisin of the other. (2 J. & W. 1, 153.)

A trust of freeholds or copyholds is subject to the courtesy of the husband, but was until lately exempt from dower and freebench: now, however, by the 3 & 4 Will. IV. c. 105, the title of dower attaches upon equitable in the same manner as upon legal estates, though subject in either case to be defeated by the alienation, devise, or other declaration of intention on the part of the husband.

The effect of marriage is the same upon equitable as upon legal interests, and therefore a husband may assign the trust of a term of years belonging to his wife, in the same manner that he may assign her chattels real at law. (9 Ves. 99.)

Judgment creditors have, by the Statute of Frauds, sec. 10, execution at law against the equitable freehold estate of a debtor in the hands of his trustee, when the debtor has the whole beneficial interest; but if he have a partial interest only, or the estate be not freehold, the judgment creditor has no execution at law, but he may in a court of equity obtain the same satisfaction out of the beneficial interest as he would be entitled to at law out of a legal estate. (4 Mad. 504.)

The estate of the *cestui que trust* is governed as to descent by the rules of the common law.

Trusts of chattel interests were always considered as assets in equity, but it was a question whether a trust of a freehold was assets in the hands of the heir until the Statute of Frauds, by the 10th section of which a trust in fee-simple was declared to be assets by descent, in the same manner as a legal estate. The enactment however applies to simple trusts only, and not to special trusts or equities of redemption (2 Atk. 293); but now, by the 3 & 4 Wm. IV. c. 104, all a persons' *estate or interest* in lands, tenements, or hereditaments, corporeal or incorporeal, or other real estate, whether "freehold, customaryhold, or copyhold" (which words apply equally to legal and equitable estates), are made assets for the payment of debts as well by simple contract as on specialty. Trusts of chattel interests will be legal assets in the hands of the executor. (Mod. 858; 4 Ves. 541.) Simple trusts of real estate are made legal assets by the above-mentioned section of the Statute of Frauds; and it seems that complicated trusts and equities of redemption, which are not within the statute, will be considered legal assets as to specialty creditors by analogy to law. (2 'Ch. Rep.' 143.) It appears that under the 3 & 4 Wm. IV. c. 104, real estates are, with respect to simple contract debts, to be taken as equitable assets, but that the act does not alter the mode of administration of trusts of chattels nor of equitable freehold interests, in so far as they were assets before the act.

3. It is a maxim of equity that a trust shall not fail for want of a trustee. If the intention of the settlor be clear, but he has omitted to name a trustee, or the trustee dies or becomes incapable of taking the estate, the trust attaches upon the person on whom the legal estate has devolved. (Wilm. 21, 22.) When powers given to trustees are not discretionary, but imperative, they are, as above mentioned, considered as trusts, and the court will protect the *cestui que trust* from the failure or neglect of the donee of the power. Where the discretion of the trustee was to be governed by a rule which the court can apply, it will do so; but where there is no rule or measure by which the discretion of the trustee was to be governed, the court executes the power in the manner which appears most reasonable, and in general proceeds upon the principle that equality is equity. (2 Ed. 332; 'Eq. Ca. Ab.' 194.) Where a discretion is given to the trustee in respect of the objects to whom an appointment is to be made, questions sometimes arise, when the power comes to be executed by the court, as to the objects to be included and the mode of distribution. When the power is in favour of "relations," the court, except under particular circumstances, appoints to relations within the statute of distributions, when it seems that the distribution will be made *per capita*, and not *per stirpes* (1 Bro. C. C. 33); and the words "next of kin" occurring in such a power are settled to mean "nearest of kin," to the exclusion of those who would take by representation under the statute. (2 M. & K. 780.)

4. The *cestui que trust* is entitled to have the administration of the trust-estate placed in proper hands. Thus the court will dismiss a trustee upon its being shown, upon application by bill to the Court of Chancery, that he has acted improperly, or has become incapable of executing his office (4 Ves. 592; 5 Ves. 707); and where the original number of trustees has been diminished, the *cestui que trust* may have the vacancies supplied. (5 Ves. 772.) The *cestui que trust* may also file a bill against his trustee, either for the purpose of compelling him to the execution of an act of duty, or to restrain him from doing any act not within the scope of the trust, or which would be prejudicial to the estate. (1 Bro. 'C. C.' 177; 6 Mad. 10.)

5. If a trustee aliens the trust-estate, the *cestui que trust* may follow the estate into the hands of any person who has acquired it, whether he had notice of the trust or not; and even into the hands of a purchaser for valuable consideration, if he had notice at the time of his purchase. The limit of time and extent within which the *cestui que trust* may institute proceedings for the recovery of his estate is fixed by the 3 & 4 Will. IV. c. 27.

In case of a breach of duty by the trustee, the *cestui que trust* has also a remedy against him personally by way of compensation. The amount of the loss is considered as a simple contract debt against the estate of the trustee, and payment of it may be enforced in the same manner as for any other similar debt. The circumstance of the trustee having derived advantage or not from the breach of trust, makes no difference as to his liability. Where trustees are jointly implicated, it was formerly thought that the *cestui que trust* might proceed against any of them singly; but the contrary has since been settled. (8 Sim. 219.) But the *cestui que trust* will not be entitled to any remedy against his trustee, if he himself, being under no legal incapacity, has concurred in the breach of trust, or subsequently acquiesced in it, or *à fortiori* if he has executed a formal release to the trustee. (3 Swanst. 64.)

Owing to the inadequacy of the law to meet the case of defalcations and frauds of trustees, bankers, and other persons entrusted with the care and management of the property of others, a statute was passed (20 & 21 Vict. c. 54) whereby offences of this kind were made misdemeanours punishable with penal servitude for three years, or imprisonment not exceeding two years, with or without hard labour.

VIII. There are two rules of equity with respect to trust-estates which are of very general application. The first is, that what the settlor has directed to be done shall be considered as done; so that it shall not be in the power of trustees, by neglecting the performance of their duty, to affect in any way the interests of the *cestuis que trust*. Thus where money is directed to be laid out in land, or land is directed to be sold, equity will consider the conversion to have taken place, and deal with the property accordingly. This constructive conversion, however, subsists only until a *cestui que trust*, competent both from interest and personal capacity to elect, declares his intention as to the character in which he will take the property. [ELECTION.]

The second rule, which is almost a consequence of the first, is, that no act of the trustee shall alter the nature of the *cestui que trust's* estate. This rule, of course, is to be understood only of acts not authorised by the trust; and with respect to *cestuis que trust*, who are *sui juris*, is universal, but is subject to some exceptions with respect to trust-estates belonging to lunatics. The court, though it will not in general alter the condition of the lunatic's property to the prejudice of his representatives, will not refuse to do so if it appear to be clearly for the benefit of the lunatic himself. (2 Ves. Jun. 72.) It was formerly thought that the court might exercise a similar discretion with respect to the estates of infants, but it is now settled otherwise. (19 Ves. 122.)

TRUSTS, CHARITABLE. [USES, CHARITABLE.]

TRYTYLENE. [PROPYLENE.]

TUBE. The surface of a tube is generally a cylinder, but this word may be made use of in mathematics. When a tube is bent, there is no distinct geometrical name for its surface, but the following definition might do very well: Let a surface be called a tube when it is formed by a circle which moves with its centre upon a given curve, and its plane always perpendicular to the tangent of that curve. This would include the straight tube, or common circular cylinder, and every species of bent tube.

TUBE-DRAWING. There are certain peculiarities in the fabrication of metal tubes which place them in a separate rank from other manufactures in metal.

Some varieties of lead-pipe are produced by casting a thick cylinder, of which the internal bore corresponds with the intended bore of the pipe, and then reducing the external diameter by drawing through a series of dies, smaller and smaller as the process proceeds, as described in LEAD MANUFACTURE. Mr. Hick has devised a mode of making *tapering* tubes; that is, tubes which taper or diminish in diameter from one end to the other. They are first made parallel or cylindrical and are tapered afterwards; the machine employed effects this by rotating grooved rollers; and a greater or less degree of taper is obtained by varying the proportion between the rate at which the tube is drawn through the machine and that at which the rollers revolve. The tubes for many locomotives are made in this way, taper within and cylindrical on the outside; the metal is cast hollow, and is drawn on a taper mandril through a plate; when used, the thick end is placed nearest to the fire-box. One of the early ways of making wrought iron tubes was to provide a strip of sheet iron, and beat it up by hand hammers and swages nearly to a cylindrical form; this was then laid in a semi-cylindrical cavity, with a mandril running through it; and then many blows were given by a heavy tilt-hammer, the lower face of which had a hemispherical or rather semi-cylindrical form. An improvement upon this was to draw the tube through grooved rollers after having been thus far fashioned. Another mode afterwards adopted was that of raising a strip of iron to a welding heat; beating up one end of it nearly to a cylindrical form; drawing the whole piece through a kind of tongs having bell-shaped jaws; and welding without the aid of any mandril. This method has been found available for tubes up to six inches diameter. Common brass tubes are often made by beating a strip of brass round into a cylindrical form, soldering the edges, and drawing it through holes to make the exterior true; without paying much regard to the interior. Telescope tubes, &c. are drawn inside and out, and are hardened at the same time; the soldered tube, being placed upon a steel mandril, is drawn through a draw-plate, by which the tube is lengthened, pressed everywhere close to the mandril, and rendered smooth and dense. Fluted tubes for pencil-cases are drawn through a fluted hole, upon a mandril usually cylindrical. Very small tubes, used by silversmiths, are drawn upon steel wire as a mandril. Many kinds of brass tubes are made exactly in the same way as the lead pipes described in LEAD MANUFACTURE; that is, by casting a thick cylinder, and then drawing it by machinery through a series of holes, smaller and smaller in regular order, so as to elongate the thick cylinder into a thin tube. Mr. Muntz patented a few years ago a process for making tubes of the *Muntz metal* introduced by him, which metal consists of about 2 parts of zinc to 3 of copper. A short thick tube is cast, and is then rolled out to a great length and reduced thickness; but having no mandril within it, it is squeezed flat; the proper shape is afterwards given to it by drawing through a circular hole. There is something in the quality of the metal which enables it to be elongated in this way, inapplicable to most other kinds. Mr. Webster, of Birmingham, has a curious method of making elastic metal tubes, suitable for forming the junctions of pipes exposed to variable temperature; or of pipes which are otherwise strained or required to bend, such as the tube-couplings connecting locomotives with their tenders, hose with fire-engines, or the like. The tubes are made with transverse corrugations, so as to yield to slight bendings, contractions, &c. Each corrugation is very narrow and deep. A plain tube is made first, and is then corrugated by degrees; this is effected by rolling, the rollers successively used being gradually deeper and deeper in their grooves, until the exterior of the tube is well puckered. Such a tube may be stretched, contracted, or bent within certain limits, without injury to its strength or soundness; they imitate in a humble way the snake-like structure. Triangular and rectangular tubes are much used in France for sliding scales and measures; these are made nearly in the same way as ordinary cylindrical tubes, the sectional form being dependent on the draw-hole and the mandril. The small collapsible colour-tubes, so much used by artists, were at first made like common brass and lead pipes, by successively drawing a thick tube till it becomes very long and very thin; but they are now made more quickly by a peculiar kind of stamping, only possible with such a soft metal as tin. Mr. Ritchie has devised a mode of making tubes thicker at the middle than the ends, by giving them a reciprocating motion between rollers, half way through and back again.

Plans have been devised for making copper tubes by electro-deposit. The method will be understood from the principles explained under ELECTRO-METALLURGY.

TUBERCLE is the name given to that form of deposit which is observed in the tissue previous to scrofulous ulceration [SCROFULA], and also in the lungs when they are affected with phthisis [PHTHISIS] or pulmonary consumption.

TUBERCULOSIS. [SCROFULA.]

TUBULAR BEAMS. In addition to what has been said on the subject of the resistance of hollow girders, [under GIRDERS AND RESISTANCE], it may be desirable to state that the investigations by Mr. Tait of the experiments made by Mr. Fairbairn have led to the recognition of the following laws upon the subject:—1. The strength varies nearly as the area of the top, or of the bottom flange, multiplied by the depth, divided by the distance between the points of support, and affected by a coefficient determined by experiment. 2. When the depth and distance between the points of support are the same, the breaking weights are as the areas of the top, or of the bottom parts. Mr. Tait gives, as the practical formula derived from these laws; calling W the breaking weight of a rectangular tubular beam; a, the area of the bottom web; d, the depth of the beam; l, the clear bearing, and c, a coefficient found to be equal to 18 tons; all the dimensions being in inches; then $W=\frac{c\,a\,d}{l}$. 3. In hollow cylindrical beams formed of thin plates, the breaking weight in tons is equal to the continued product of the sectional area, by the depth, and by a constant (14¼ tons), divided by the distance between the supports; and Mr. Tait asserts that square tubular beams possess 1⅓ times the strength of cylindrical ones: if this be correct, rectangular cells at the top of a large tubular girder are preferable to circular ones. 4. In hollow elliptical beams the breaking weight in tons is equal to the continued product of the sectional area, the depth and a constant (15 tons) divided by the distance between the supports: all these dimensions being, as before, in inches. The formula becomes of course, with the change in the value of the coefficients, the same as above, $W=\frac{c\,a\,d}{l}$; and as it is so much easier in rectangular beams to modify the area of the bottom flange, so as to ensure in it the requisite ratio between it and the top flange, there must evidently be an advantage in their use.

The tubular girders for beams of wrought iron appear to have been used on a large scale, for the first time, in the bridge over the turnpike road at Blackburn, by Mr. William Fairbairn; since that period, the system has been extended by other engineers in a most extraordinary manner, as in the instances of the Britannia and of the Saltash bridges; and at the present day the tubular wrought iron beams are very often substituted for the cast iron girders which were, previously so much used in general construction. In the latter case, the superior lightness of the wrought iron tubular girders, and their greater powers of elasticity, render them preferable to the weightier, and more brittle and uncertain, cast iron; but the wrought iron tubes do not admit of artistic treating in the same manner that cast iron ones do, and therefore are less fitted for picturesque structures. The works of Messrs. Hodgkinson, Tate, Clark, Fairbairn, Morin, Love, &c. must be consulted by the student of this branch of the arts of construction; and in the 'Annales des Ponts et Chaussées,' and in the 'Journal des Travaux Publique de la Belgique,' may also be found some interesting, practical, and theoretical articles on the subject. The Swiss and American engineers have for many years used species of tubular girders in their timber bridges of large span; but these were designed upon the ordinary principles of carpentry as applied to ordinary framing, and did not depend for their strength in any important manner upon the cross bracing and roof which converted them virtually into tubular beams.

TUCA'NUS (the Toucan). A southern constellation of Bayer, situated between Phœnix and the south pole, and near to the bright star in Eridanus. The following are the principal stars in this constellation:—

TUESDAY. [WEEK.]

TULIP. Of all the plants which have obtained attention on account of the beauty of their flowers, perhaps tulips have had the most. In estimating the excellence of a particular flower, the florist is not so much guided by its beauty of form and colouring as by its rarity; and sorts which have at one time obtained great prices on account of their rarity have become little thought of when they became more abundant. There are, however, several points considered by florists as essential to the character of a fine tulip. "The stem should be strong, elastic, and erect, and about 30 inches above the surface of the bed. The flowers should be large, and composed of six petals (*phylli*): these should proceed a little horizontally at first, and then turn upwards, forming almost a perfect cup, with a round bottom, rather widest at the top. The three exterior petals should be rather larger than the three interior ones, and broader at their base: all the petals should have perfectly entire edges, free from notch or serrature; the top of each should be broad and well rounded; the ground colour of the flower, at the bottom of the cup, should be clear white or yellow, and the various rich-coloured stripes, which are the principal ornament of a fine tulip, should be regular, bold, and distinct on the margin, and terminate in fine broken points elegantly feathered or pencilled. The centre of each leaf or petal should contain one or more bold blotches or stripes, intermixed with small portions of the original or breeder colour, abruptly broken into many irregular obtuse points." ('Cyc. of Gard.') For the botanical character, see TULIPA in NAT. HIST. DIV.

The varieties of cultivated tulips have been divided by florists in many ways for the sake of convenience. Parkinson, who wrote in 1629, enumerates 140 varieties, which were divided into *præcoces*, early blowers; *sertinæ*, late blowers; and *dubiæ mediæ*, doubtful or middle blowers. The first division consisted principally of varieties of *Tulipa suaveolens*; the latter divisions were chiefly composed of varieties of *T. Gesneriana*. Amongst modern florists in Great Britain, the varieties of the latter tulip, of which upwards of 600 are enumerated in modern catalogues, are divided into four families—Bizarres, Byblœmens, Roses, and Selfs.

Bizarre tulips have a yellow ground marked with purple or scarlet of different shades. *Byblœmen tulips* have a white ground, lined, marked, striped, or variegated with violet or purple only of various shades. *Rose tulips* are marked or variegated with rose, scarlet, crimson, or cherry colour on a white ground. *Selfs*, or *plain-coloured tulips*, are those which have a white or yellow ground without any marks. The first three of these families are again divided into *feathered* and *flamed*, according as the intermingled colours are in narrow stripes or pencillings, or in a broad central stripe.

It is from amongst the last family of tulips, the *Selfs*, that what are called *breeders* are selected. In a state of nature the tulip is mostly a self, that is, it has but one colour; but under certain circumstances all the other colours that are found in tulips will be developed in these simple-coloured tulips. It is thus that the last variety of tulips has been obtained that at present exists; and as each variety can be propagated by offshoots from the parent bulb, and as the colours of tulips will admit of an infinity of modes of blending, there is hardly a limit to the number of varieties of these flowers which may be obtained. Selfs are always raised from seeds, but the circumstances which are most favourable to the "breaking" of the Selfs, as the development of other colours is called, are not well understood. A florist will have to wait sometimes twenty years without having the pleasure of seeing his Self "break."

To develope all the beauty of form and colour of which the tulip is susceptible, requires the greatest care in its cultivation, and perhaps it is only amongst the amateurs of Holland and Belgium that this flower can be seen in all its glory. Tulips are mostly planted in beds, which should be made in an open, airy situation. A bed of tulips is planted in what are technically called *rows*, consisting uniformly of seven, arranged with regard to the harmony of their colours, the tallest occupying the centre, and the bed may be thus of any length, while the row always consists of seven. The soil should be dug out for about 20 inches deep, and the bed filled in with a mixture of about two parts of a fresh, rich, loamy soil, rather of a sandy character, and one part of well-rotted cow-dung. The best time for planting the bulbs is from the end of October to about the 10th of November. They should be planted about seven inches apart, and about four inches deep, or less according to their size, in the ground. The leaves will appear in February, and the blossoms in April or May. The bed of flowers should be protected by an awning, which must not be used till the flowers are opened, and should be so constructed that the light and air may be freely admitted during the intervals between the coolness of the night and the brightness of the sun at noonday. Tulips should never be artificially watered. When the petals fall off, the seed-vessel should be removed, as its remaining on weakens the bulb. When the top of the stem begins to wither and dry up, and the leaves become brown, the bulbs should be taken up and placed in a dry situation. In the following August or September the loose skins and fibres and the easily separable offsets should be taken off the bulbs, and they should be deposited in drawers. In propagating the tulip from seeds, they should be sown in deep boxes, filled with good garden-mould mixed with sand. The young plants will not require water, and they may be expected to blossom by the fourth or fifth year, or at latest the seventh.

(Loudon, *Cyclopædia of Plants*; *Cyclopædia of Gardening*; MacIntosh's *Book of the Garden*; *Diction. des Sciences Naturelles*; Paxton's *Botanical Dictionary*; Redouté, *Liliacées*; Hogg, *Supp. to Practical Treatise*, &c.)

TUMBREL, or TUMBRIL, a machine formerly used for the punishment of scolding women, consisting of a stool or chair attached to the end of a long pole, mounted in such a manner that the chair, with the offender placed in it, might be swung over a pond, and immersed as often as might be necessary. Several notices of the use of this apparatus, which was also called a *trebuchet*, a *cucking-stool*, or a *ducking-stool*, are given in Brand's 'Popular Antiquities,' art. 'Cucking-stool.' It appears to have been used as early as the era of the Saxon government in England, and to have been a common punishment in some places at least as late as the time of Gay, who mentions it in his 'Pastorals.' The tumbrel was also used as a punishment for brewers and bakers who transgressed the laws relating to them. Fabian (quoted in Strutt's 'Horda Angel-cynnan,' vol. ii., p. 9) says that, in the 42nd year of Henry III., bakers were, for "lack of size," punished by the *tomberell*, whereas before that time they used to be punished by the pillory; and he adds, that the tomberell was "a kind of pillorye, made foure-square, that turned round about." The name tumbril is also applied to the covered carts used to carry tools, &c., in a train of artillery.

TUMOUR. It is not possible to define exactly the diseases which are commonly classed under the name of Tumours, and any definition in which the character of *swelling* (which is the true meaning of tumour) is included is unnatural; for there are several diseases which agree in the most important respects with some of those called tumours, but are not attended by any obvious enlargement or swelling of the part in which they are situated; and the same disease exists in some cases with and in others without swelling. The greater part of the diseases which have been classed as tumours are examples of a large class of what may be called morbid or parasitic growths; diseased structures, which are not mere alterations of previously existing parts, but new organisms or living substances which have grown within the tissues of the body by powers of development peculiar to themselves, and which depend upon the surrounding parts only for their supply of blood or other nutritive fluid. In this class are included all those diseases described as solid or sarcomatous tumours, and those which are closely related to some kinds of tumours, but are not accompanied by swelling, such as tubercle, certain forms of diffused cancerous growths, and some others.

The diseases called Encysted Tumours are entirely different from all others of the class in their pathological characters, and are considered in a separate article. [WEN.] The chief cancerous growths are treated of under their appropriate heading [CANCER; MELANOSIS]; and tuberculous growths under the name of the disease which is consequent on their development [PHTHISIS; SCROFULA]. The present article will be chiefly devoted to the history of those morbid growths which are commonly described as innocent tumours.

All morbid parasitic growths may be divided into *malignant* and *innocent*. The practical distinction between the two classes, from which they derive their names, is that an innocent growth or tumour is not likely to recur after being removed by operation, but a malignant growth is likely to recur in the same or some other part. These two names may safely be retained to mark the two chief divisions of morbid growths; for although the test of the result of a surgical operation cannot be applied to those which from their locality do not admit of extirpation, yet the names indicate important characteristics in the progress of the two kinds of growth, wherever seated. Independently of the practical distinction, the most essential characters of malignant growths are:—1. That they may occur in almost any part of the body, although some parts are more liable than others, and each kind of growth seems to find its most appropriate seat in a certain organ, as cancer in the breast, tubercle in the lungs, melanosis in the liver, &c. 2. That they have a tendency to infect the adjacent parts, and to propagate themselves from one part to another, probably by germs carried from the primary disease into the blood, with which they circulate till they meet with an organ in a fit state to supply them with the means of increase. 3. That they tend, through an intermediate process of softening (which appears to be consequent on the death of their constituent particles), towards ulceration; that this ulceration is of a kind which is at present incurable; and that in its progress it involves almost without distinction of tissue all the adjacent natural structures of the body, the particles of which, by their contact or combination with those of the malignant growth, seem first to assume a nature similar to their nature, and then to perish with them. 4. That in general the minute structures of which they are composed are dissimilar to those of the natural organs of the body; and that their development does not proceed to the formation of any structure similar to the fully developed tissues.

The distinctive characters of innocent growths are chiefly negative. Certain of them may present one, but they rarely present more than one, and never all, of the characters just described. Thus:—1. The number of tissues in which innocent growths occur is comparatively few: in many parts in which malignant growths are common they are never seen; and when, as sometimes happens, many innocent tumours exist in the same body, they are (at least as a general rule) all found in the same tissue, or in or near the same organ. Thus, many fatty tumours may grow at the same time, but they all lie in the tissue of the natural fat: many fibrous tumours may occur together, but all are in or near the uterus. On the contrary, when many cancerous growths co-exist, they are commonly found in many different organs and tissues. 2. The tissues adjacent to innocent growths are not further altered than in consequence of the pressure and the inflammation which the growth excites; neither is there any evidence that such growths propagate themselves from one part to another. 3. Innocent growths have no natural tendency to ulcerate or slough; those changes happen to them only in the same manner and under the same circumstances as to the natural tissues of the body. Moreover, in ulcerating or sloughing they have no more tendency than the natural tissues in similar conditions have to involve the adjacent parts in their destruction. 4. The tissue of an innocent growth is in general similar to that of some natural and fully-developed tissue of the body.

The class of innocent growths includes most of those to which the name of Sarcoma is now commonly given. Their appearances are so various, that the most practised morbid anatomists frequently meet with examples which they cannot certainly refer to any described variety: yet there are some well-characterised forms, within the descriptions of which may be included a great majority of those which occur in the human body; and these we shall describe under the names of the Fatty Tumour, or Growth; the Cellular; the Fibrous, or Tendinous; the Cartilaginous; the Osseous; the Fibro-cartilaginous.

The Fatty or Adipose Tumour, to which the name of Lipoma is often given, is the most common of all the tumours occurring in the human body, and, happily, the most innocent, and the most usually capable of remedy by extirpation. Its general seat is in the subcutaneous cellular adipose tissue; but in rare cases it is situated more deeply, and then has a more compact structure and more intimate connection with the surrounding parts. It usually occurs singly; but sometimes twenty or more of various small sizes are seen in the same person. Its elementary tissue is exactly like that of the fat in which it lies, but from which it is separated by a layer of compact cellular tissue, and is generally distinguished by the smallness and distinctness of the lobes composing it. Its blood-vessels are few and of small size, and usually enter it at its base, where it is more closely than elsewhere connected with the adjacent tissues. It is insensible, and commonly grows very slowly, without producing pain, or any other inconvenience than is due to its weight or its pressure on adjacent parts. When left to itself, the adipose tumour may grow to an enormous size. Mr. Copeland removed one weighing 22 lbs.; Sir Astley Cooper, one of 37 lbs. 10 ozs.; and M. Dagorn of Morlaix, one which weighed 46 French pounds. The size of the wound necessarily made in the removal of tumours of such magnitude renders the operation somewhat dangerous; but, except for this circumstance, the extirpation of fatty tumours may usually be undertaken with full confidence of success. If not removed, they are apt, through the distension and thinning of the skin over them, to give rise to ulceration and other more painful affections.

The Cellular Tumour, which derives its name from the similarity of its tissue to that of the common cellular tissue of the body, is a very rare disease. It is composed of a compact substance, infiltrated by a serous or half-gelatinous fluid, and may attain a great size. Mr. Lawrence, in his 'Lectures on Surgery,' has described the best example yet known of it: perhaps also the disease which Mr. Abernethy, in his 'Classification of Tumours,' named Common or Vascular Sarcoma, was of this kind. But altogether very little is known of this form of tumour: the great enlargements of the skin of the scrotum, supposed by some to be of the same nature, are widely different from it.

The Fibrous or Tendinous Tumour (the fleshy tubercle of Dr. Baillie) is a very frequent and well-marked growth. Its ordinary, perhaps its only, seat is in the walls or in the neighbourhood of the uterus. Its natural form is almost exactly globular; but when it hangs in a dependent position it generally becomes pyriform. Its tissue has the same microscopic character as that of the natural fibrous and tendinous tissues, and is equally little vascular. Its section presents a very compact and firm semi-transparent basis, intersected by numerous shining, tough, fibrous fasciculi, arranged sometimes in rays proceeding from its centre, but more frequently in irregularly arched and undulating lines. It grows slowly, and at first without pain; but when it has attained some size it usually excites painful and dangerous affections of the uterus; and this is especially the case when the tumour projects into the cavity of that organ. One such tumour may grow alone in the uterus; but more commonly two or more grow together, and sometimes there are from ten to twenty. They may increase so as to form masses nearly a foot in diameter, and in this case they usually end fatally by their pressure on important organs, or by hæmorrhage when they project externally. In advanced stages of their growth, or at any time if they cease to increase in size, they are apt to be calcified; earthy matter being deposited around or within them, so as to form a shell or a coral-like mass of hard substance, which bears some resemblance to ivory, but has none of its microscopic characters.

The Cartilaginous Tumour is that which has been named Chondroid or Cartilaginous Sarcoma: it is the Enchondroma of Müller, and one of the numerous forms of growths which have been heaped together under the term osteo-sarcoma. Its usual, and perhaps its only, place of growth is within or upon the bones, and it occurs in connection with the bones of the fingers and the last phalanx of the great toe more frequently than in any other part. It grows slowly, and usually without any pain, and may continue to increase for thirty or more years. It is most commonly isolated, but sometimes two or more tumours of the same kind occur on one or both hands. The most usual form of the cartilaginous tumour is globular, with an irregular nodulated surface; and a section shows that it is composed of numerous round masses of a grayish-white semi-transparent substance, closely resembling the cartilage composing the skeletons of cartilaginous fishes, and presenting all the microscopic characters of ordinary fœtal cartilage. The component masses, which are especially obvious when the tumour is large, vary in size from two lines to half an inch in diameter, and in different specimens vary much in consistence: they are held together by portions of tough fibro-cellular tissue, in which blood-vessels run, but are themselves little, if at all, vascular before the process of ossification has commenced in them.

The cartilaginous tumour may grow to an enormous size: one in the College of Surgeons, which had almost completely ossified, measures a yard in circumference. It is situated on the upper part of the tibia. But even in the most advanced states they may be removed by the amputation of the part on which they are situated, without fear of their recurring; and this is always an advisable proceeding: for besides the inconvenience produced by their weight and pressure on adjacent parts, large cartilaginous or osseous tumours are apt to produce ulceration and sloughing by their distension of the skin which covers them.

The greater number of those called Osseous Tumours, or osseous exostoses, are only ossified cartilaginous tumours,—examples of what may be called the second stage of the disease last described. It is doubtful indeed whether any tumour possessing the true osseous microscopic structure is formed xcept through a preceding cartilaginous state. Many other kinds of tumours connected with bones are incorrectly called osseous or osteo-sarcomatous. Such are those connected with medullary or soft cancerous diseases, of which some are only the osseous skeletons upon which the malignant disease was fixed; others are the remains of the original bone expanded and broken out by the growth of the malignant disease in the interstices of its tissue. And again, other hard tumours connected with bones result from what should be called the calcification rather than the ossification of a previous softer growth: for in these the earthy matter is deposited irregularly, and they never acquire the structure of true bone. Most or all of these calcified tumours are of a malignant nature. One of the best characterised forms is that of which Dr. Baillie ('Morbid Anatomy') gives the history, in a case in which, after Mr. Hunter had amputated the patient's leg, calcareous masses, similar to that which had formed within and around the femur, were developed within the lungs and upon the ribs.

The history of the Fibro-cartilaginous Tumour is as yet more imperfect than that of any of the preceding, except the cellular. It is most frequently, or always, connected with the bones, and is most commonly met with upon the jaws, from which it may be removed without fear of recurrence. It has usually a round or oval form, and its surface is less deeply nodulated than that of the cartilaginous tumour. It may attain a great size, and commonly leads to sloughing and ulceration of the tissues over it, if not timely removed. It is composed of a very firm, compact, pale, whitish or yellowish, albuminous tissue, in which small spicula of bone are often scattered, but which does not become truly or entirely osseous. It may grow within a bone, but more usually it commences on its exterior: in the former case it generally expands the shaft or body of the bone into a shell around it; in the latter the surface of the bone is broken up, and seems to coalesce with the tissue of the tumour.

In different examples the fibro-cartilaginous tumour presents various degrees of consistence, and not a few apparent diversities of internal structure. In some examples its substance is homogeneous, in others obscurely fibrous; and from these last, which are the most frequent, it derives its name, which is intended to express its general aspect rather than its minute structure, for the firm tissue of which it is chiefly composed has not the microscopic or chemical characters of cartilage. In other examples again the fibrous structure rather predominates over that which resembles cartilage; and in others numerous cells, containing a glairy or a serous fluid, are scattered through the interior of the mass. From the existence of such diversities, it is not unlikely that more than one kind of tumour is included in this name; but the gradations, from the examples in which the tissue is most nearly homogeneous to those in which it is most fibrous, or contains most cells, are so numerous and gradual, that it seems more probable that they are all of one kind, modified by accidental circumstances, or examined in different stages of their development.

The treatment of the tumours whose natural history has been described may be summed up in a few words. There is no remedy for them but their removal: not one of the medicines proposed for exciting their absorption is worthy of a trial. Of the means of removing them (when removal is possible), none is so safe, so expeditious, or productive of so little pain or inconvenience, as the knife; and whenever it can be employed, the sooner it is used the better, for, in general, delay can only increase the severity of the operation. For the operation itself, the only general rule is, that the whole of the diseased mass must be removed; any portion which is left will most probably become the nucleus of a similar growth. The particular proceedings must be varied according to the size, locality, and other circumstances of the tumour.

TU'MULUS (or Barrow), a Latin word, signifying a "little hill." Tumuli, or artificial mounds of earth, of various sizes and forms, are found in many parts of the globe, and are for the most part tombs, or sepulchral memorials of persons of distinction, or of warriors slain in battle. That some of these artificial mounds were originally raised for, or at least appropriated to, other objects than that of sepulture, is probable; but of this we have no satisfactory evidence. We limit our present remarks to the consideration of tumuli as sepulchral monuments.

In the book of Joshua mention is made of heaps of stones [Cairns] raised over dead persons, which in course of time would assume nearly the appearance of barrows at the present day. This practice seems, however, to have been done in the case of enemies only, and was doubtless intended as a mark of abhorrence. The earliest account of tumuli as honorary memorials of the dead is by Homer. His descriptions of the funerals of Patroclus and of Hector, in the 'Iliad,' differ in very trifling particulars; but in each the same mode of inhumation is commemorated. The ceremony of burning the body took place during the night, and at the dawn the embers were quenched with wine. The ashes of the deceased were inclosed in an urn, placed near the centre of the space occupied by the pyre, which was surrounded by an artificial substructure, or a foundation, and the loose earth was heaped above it. The word used by Homer to denote the throwing up of such loose earth (χεύω) is strikingly picturesque; and its propriety will be readily acknowledged by persons who have seen the outline of many of those primitive sepulchres, which has evidently resulted from the loose earth being allowed to settle at the angle which it would form when thrown up.

In later ages we find accounts of immense sepulchral tumuli. Such was that of Alyattes, the father of Crœsus, which is described by Herodotus and by Strabo. A sepulchral mound which still exists near the site of Acanthus was raised by the army of Xerxes, in memory of a noble Persian who had superintended the construction of the canal which was cut across the isthmus of Athos.

Tacitus, from whom we derive the first satisfactory account of the Germans, observes that their funerals were distinguished by no empty pomp. "The bodies of illustrious men were consumed with a particular kind of wood; but the funeral pile was neither strewed with costly garments nor enriched with fragrant spices. The arms of the deceased were committed to the flames, and sometimes even his horse. A mound of earth was then raised to his memory, as a better sepulchre than those elaborate structures which, while they indicate the weakness of human vanity, are at best but a burthen to the dead." ('Germania,' xxvii.)

Whether the body was preserved entire or committed to the flames, the custom of depositing the remains of dead bodies under a mound of earth has been observed in nearly every part of the world; by the ancient Scythians on the banks of the Borysthenes (Herod., iv. 71), and by the aborigines of North America on the banks of the Ohio and Mississippi (Jefferson, 'Notes on the State of Virginia'; Squire and Davis, 'Ancient Monuments of the Mississippi Valley,'); and such mounds are still to be seen in great numbers in Denmark, Sweden, Germany, France, Spain, Portugal, and Great Britain.

Of the sepulchres of the Scythian nations, many are found in the Kuban. They are described as perfect tumuli, sometimes of great height, on a base formed by a square wall of large stones. In some cases the earth is excavated to a considerable depth; in others it merely covers the body. The deposits, with the remains of the dead, are weapons and implements of war, domestic utensils, and idols.

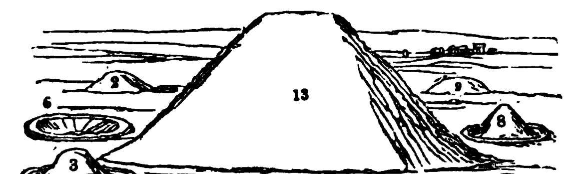
Vast numbers of the tumuli scattered over various parts of Germany have been examined. They have been distributed by the antiquaries of that country into four classes:—1. Tumuli without bodies, or urns. 2. Tumuli with bodies, but without urns. 3. Tumuli without bodies, but with urns baked. 4. Tumuli with both bodies and urns. Of the last class, several were opened in the neighbourhood of Sinzheim, and skeletons were found in them, with rings of brass and iron about the arms, feet, and fingers, ear-rings, and chain or other ornament surrounding the neck. (Meidinger, 'Die Deutschen Volkstämme geographisch und geschichtlich belaüchtet,' p. 208, &c.) Mr. Kemble, who "opened at least three thousand interments in North Germany," and found in the whole only two skeletons, whilst in another part (Sinzheim) he found in 14 barrows, "70 interments and not one sure case of cremation," thinks that the appearance of the barrows hitherto opened proves that the custom of cremation was at one time general among all the Teutonic races, and that it only slowly disappeared before the progress of Christianity, which imposed the practice of burying the bodies of the dead unburnt. For a time it seems to have been usual to inter the unburnt bodies in the tribal inclosures, and even to open, for their reception, the old barrows to which family and other associations had given a kind of sanctity. This custom seems to have continued as low down into Christian times as the 7th century, and in many places much later, but eventually the custom became universal among the German races to inter their dead within the precincts of their churches, and hence every churchyard became a place of sepulture. We have quoted above Tacitus's description of the ancient German manner of burning and burying the dead; and there can be little doubt, from the appearances presented by the major part of the more conspicuous barrows which have been opened that, at least as regards distinguished persons, his account is sufficiently accurate; but Mr. Kemble, who investigated this point with great zeal and diligence, has shown that one and perhaps the ordinary mode was to burn the body upon a stone structure raised for the purpose. As the result of numerous explorations of previously unopened barrows, and a comparison of passages and allusions in old German and Scandinavian literature, he infers that "a heap of stones was built, having a hollow for the body; the materials for a fire were laid in this, and the stones made red-hot, and then the corpse placed in the trough, and covered over with combustible materials till all was consumed. The hollow was then filled up with more stones, and the whole surmounted with earth to form a barrow." ('Archæological Journal,' vol. xiv.)

Of late years great attention has been paid by the northern antiquaries to the primeval remains of Denmark, Sweden, and Norway, and the barrows of those countries have been carefully and systematically explored. Along with certain local peculiarities they bear a general resemblance to the barrows occurring throughout the north of Germany, Holland, parts of France, and in our own country. From their contents the Danish antiquaries have classified them into barrows of the Stone, the Bronze, and the Iron periods—a division already suggested to English antiquaries by the contents of English barrows. Those of the Stone period are the oldest. They are often of great size, and are "peculiarly distinguished by their important circles of stones and large stone chambers, in which are found the remains of *unburnt* bodies, together with objects of stone and amber." (Worsaae, 'Primeval Antiquities of Denmark,' Thoms's Trans., p. 93.) The earth has been removed from many of the more remarkable of these barrows, so as to leave only the stone circles, chambers, or cromlechs, exposed; but enough remains, as Mr. Worsaae observes, to show that they must have been works of enormous labour; and they afford a proof that the people who formed them, and who were probably the earliest inhabitants of Denmark, however rude, "could scarcely have led a mere nomadic life, but must have had settled habitations, and that they were a vigorous people, who cherished care and reverence for the departed."

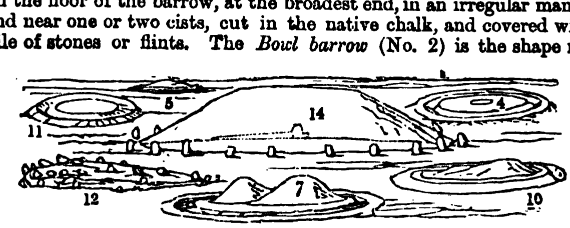
The tumuli of the Bronze period, according to the same author, "have no circles of massive stones, no stone chambers, in general no large stones on the bottom, with the exception of stone cists placed together, which, however, are easily to be distinguished from the stone chambers. They consist, as a general rule, of mere earth, with heaps of small stones, and always present themselves to the eye as mounds of earth, which, in a very few rare instances, are surrounded by a small circle of stones, and contain relics of bodies which have been burned and placed in vessels of clay with objects of metal." These tumuli belong evidently to a later period than the preceding, and to a people more advanced towards civilisation. In the rudest ages the people usually bury their dead; later, the practice of cremation is resorted to and accompanied with much religious ceremony; and it is only when the pagan rites yield before the progress of Christianity that a return is made to the simpler custom of interring the corpse unburnt. In the Scandinavian burials of the Bronze period, the body seems to have been burnt on a pile of wood; the bones and ashes were then collected, and, together with various bronze implements and ornaments belonging to the deceased, put into an earthen vessel, or rude stone chest (cist), which formed the nucleus of the intended barrow. This central vessel was surrounded with small stones, and then covered with earth, so as to form a barrow. (Worsaae.) Only persons of eminent rank or merit seem to have had an entire barrow; in most cases the barrows seem to have belonged to families, while some are evidently the ordinary burial-places of the poor, excavations being made in the barrows in order to insert urns containing bones, probably burnt at a common burning-place, as described by Mr. Kemble. The barrows of this period are usually formed on high ground, and, whenever practicable, so as to be seen far at sea. They are especially numerous in the islands, and in Jutland, Sleswig, and Holstein.

Of Danish barrows of the Iron period the examples are comparatively few, and their date is evidently comparatively recent. In external form they resemble those of the Bronze period, and they are not unlike them in their internal arrangement; but they contain only *unburnt* bodies. Swedish and Norwegian barrows occur, however, in which burnt bodies are found. A distinctive feature of the barrows of this period is that they contain "not only remains of the warrior but also those of his horse," together with his trappings. Some of them have chambers of wood, and all display traces of costly habits and comparative refinement of manners in trinkets of gold, silver, and glass, figures not inelegantly carved and engraved of birds and other animals, runic inscriptions, &c.; and in some, as indeed in some of the Bronze period, trunks of oaks, rudely hollowed out like a coffin, have been found.

The first careful investigations into the tumuli of this country were made by Dr. Stukeley in the neighbourhood of Stonehenge a century and a quarter ago. (Stukeley's 'Account of Stonehenge,' fol., 1740.) The attention of the public was a second time drawn to the subject by Douglas, in his 'Nænia Britannica,' published in 1793: his researches were confined to the southern coast of England, and chiefly to the county of Kent. The investigations begun by Stukeley and Douglas were prosecuted, with ample means to carry them into effect, by the late Sir Richard Colt Hoare, whose attention was first directed to the subject, and who was materially assisted in his researches and literary labours, by Mr. Cunnington, a tradesman and self-taught antiquary of Wiltshire. In no part of Europe had tumuli been so completely explored as by Sir R. C. Hoare in Wiltshire, and he minutely and carefully explained their contents in his 'Ancient Wiltshire,' 2 vols. fol., 1810, 1821. The classification of tumuli according to their shape, proposed by Sir R. C. Hoare, has been so generally adopted by English and French antiquaries that it may be useful to give it at length, without however accepting the conclusions which the author arrived at, and which indeed are scarcely consistent with the present state of archæology. "We must not," he observes, "consider every barrow as a mere tumulus, or mound, loosely and fortuitously thrown up, but must rather view them as works of evident design, and executed with the greatest symmetry and precision. The *Long barrow* (see No. 1, annexed illustration), from its singular form and large size, claims the first notice. These barrows differ considerably in form as well as magnitude.



Some resemble the half of an egg cut down the middle; some are almost triangular; some form a ridge of equal breadth throughout; but the greater number are wider at one end than the other, and that end is usually turned towards the east. They are commonly placed on elevated situations, and stand singly. They differ materially from circular barrows in their contents; for brass weapons, or trinkets, are never found in them. With few exceptions, bodies appear to have been laid on the floor of the barrow, at the broadest end, in an irregular manner; and near one or two cists, cut in the native chalk, and covered with a pile of stones or flints. The *Bowl barrow* (No. 2) is the shape most usually found.



It abounds on the Mendip Hills, in Somersetshire, and is sometimes surrounded with a shallow ditch. Dorsetshire also contains many barrows of this class. The *Bell barrow* (No. 3), from the symmetry of its shape, is probably an improvement on the bowl barrow. It occurs in the vicinity of Stonehenge.

Of the *Druid barrow*, as it was miscalled by Stukeley, Sir R. C. Hoare distinguishes three varieties (Nos. 4, 10, and 11). The outward vallum, with the ditch within, is moulded with great care. In the area are sometimes one, two, or three small mounds, which in most cases have been found to contain small articles, such as cups, and lance-heads, also amber, jet, and glass beads. Two other varieties of the Druid barrow have been casually observed. One is a low mound, inclosed within a vallum, and occupying almost the whole area (No. 5). In the other, the area is perfectly flat, and rises in a curved line from the vallum (No. 9).

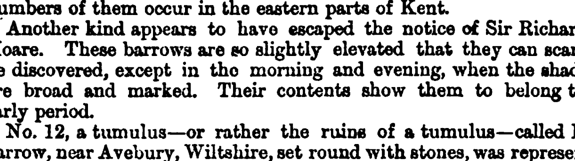
The *Twin barrow* (No. 7) consists of two conical mounds within a foss. The *Broad barrow* (No. 9) resembles the bowl barrow, but is wider and flatter at top. All these are regarded as belonging to the Celtic or ancient British period.

Two other forms are mentioned—the *Pond barrow* (No. 6) and the *Cone barrow* (No. 8). Of the cone barrow, only a single example has been noticed, near Everleigh, on Salisbury Plain. Small cone-shaped barrows placed together in groups are usually of Saxon date: large numbers of them occur in the eastern parts of Kent.

Another kind appears to have escaped the notice of Sir Richard C. Hoare. These barrows are so slightly elevated that they can scarcely be discovered, except in the morning and evening, when the shadows are broad and marked. Their contents show them to belong to an early period.

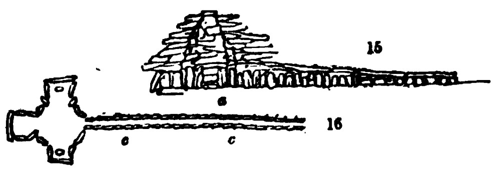
No. 12, a tumulus—or rather the ruins of a tumulus—called Mill-barrow, near Avebury, Wiltshire, set round with stones, was represented and described by Dr. Stukeley, in his work on Avebury, fol., 1743: it is fully described and figured under AVEBURY, in GEOG. DIV.

Tumuli frequently occur arranged in a row. In *fig.* 17 is shown a series of four known as the Bartlow Hills, in the county of Essex, on the south border of Cambridgeshire. They vary in size, as indicated in the diagram. The largest, *a*, measuring 142 feet in diameter by 44 feet in height, was explored in 1835 by Mr. J. G. Rokewode and other gentlemen, who excavated a passage or gallery on the surface of the natural earth, from the extreme base to near the centre of the barrow. This line or gallery is marked (No. 18) *a*, extending 56 feet, where the workmen were ordered to extend the open space on each side; and at the distance of 13 feet they came to a square inclosure, or



chest (*c*), which was found to contain various antique relics of genuine Roman or of Brito-Roman manufacture. These were glass urns or bottles, a bronze lamp and cup, a patera, a præfericulum (a long or tall vase, with a particular handle), glass vessels, a folding chair, bronze strigils, an enamelled vase, &c. The last and the bronze præfericulum are elegant and extraordinary vessels, and the only examples of the kind ever found in any of the tumuli of Great Britain. A particular account of these objects is given in the 'Archæologia,' vol. xxvii.

At a place called the New Grange, near Drogheda, Ireland, there was a remarkable tumulus, which was explored in 1770 by Governor Pownall, who wrote an account of the barrow, and of other objects in the vicinity, for the Society of Antiquaries of London, and published the same in vol. ii. of the 'Archæologia.' He states that the mound consists mostly of large pebble stones, which must have been conveyed about 12 or 14 miles; and, by calculation, the whole weighed at least 189,000 lbs. The height is 70 feet, and the diameter about 400 feet. Surrounding its base was a series of rude stones, placed in a circular form, on their ends, as indicated (No. 14). A gallery formed of upright stones, *c c*, with others placed on their tops, extended from the outer edge to near the centre of the tumulus, where there was an area surrounded by other stones, and covered by a dome or cupola, *a*. Branching from this area were three square recesses, *b*, *b*, *b*. The accompanying diagrams show a plan and section of the gallery.



15

16

Silbury Hill, near Marlborough, Wiltshire, is one of the largest barrows in the world. [Avebury, in Geog. Div.] See the cut in the preceding column, No. 13.

Some very remarkable examples of tumuli, cromlechs, and stone chambers in Jersey, Guernsey, and other of the Channel Islands, have been explored and described with great acumen by Mr. Lukis. ('Archæol. Journal,' &c.) They bear, in many particulars, a curiously close affinity to the Scandinavian barrows, as described by Worsaae and the Royal Society of Antiquaries, Copenhagen. [Cromlech.]

Sir Richard C. Hoare considers the deposition of the body entire, and its reduction to ashes by fire, to have been practised in England at the same time. There are, however, varieties of both. In the most ancient interments the body is inclosed in a cist, with the legs and thighs drawn up, and the head generally turned towards the north. The second is of later date. The body is deposited at full length; but the head is placed in no particular position, and arms and various instruments of iron accompany the skeleton: these burials of unburnt bodies in English barrows bear in all respects a close similarity to those described by Mr. Kemble in North Germany. In the same manner, two modes of depositing the remains, after they were burnt, have been practised. In the more ancient, the fragments of the burnt bones were collected and laid on the floor of the barrow, or in a cist excavated in the native soil. In the second, which is clearly the later, the bones and ashes were inclosed in a funeral urn, which was placed in a cist, usually with the mouth downward. In these cases portions of the cloth which enveloped the urn have occasionally been discovered, as well as small brass pins, by which the cloth was apparently fastened.

Of urns, many varieties have been found in exploring the tumuli. The first or largest class was properly the sepulchral urn, and is always found to contain bones. The second is different both in shape and design: it contained neither ashes, bones, nor trinkets; and as the custom prevailed of depositing articles of food with the dead, these have received the name of drinking-cups, from a supposition that they were intended to hold fluids. Such vessels are frequently found with skeletons, and are placed either at their head or feet. They are always ornamented with patterns, and would contain about a quart. The third are smaller still, and more fantastic in shape. They are too diminutive to have been receptacles for ashes. They were probably intended for perfumes, and have somewhat fancifully been named incense-cups. At one time, there can be little doubt that barrows might have been found throughout the country; but they have been destroyed as cultivation advanced. Yet even now they are traceable over a large part of the land, and they exist in considerable numbers where the land remains untilled—largely, for example, in such widely-separated places as Wiltshire, Derbyshire, Kent, and the Channel Islands.

We may add that the remains found in the British barrows, equally with those of the barrows of other Teutonic races, indicate three distinct stages or eras of society. The first was before the introduction of metals, when arms and implements consisted of spear-heads of flint, and arrow-heads of flint or bone; the second, when these articles were of bronze; and the latest, when iron instruments, arms, and utensils accompany the deposit. Of the sepulchral urn also there are two varieties, indicating different periods of mechanical art. In the first the urn is fashioned by hand, without ornaments, or with those of the rudest kind, and dried by the heat of the sun. In the second, it was evidently wrought on the lathe, ornamented by the application of some instrument with zigzags and other patterns, and finished and baked with different degrees of skill and attention. Possibly the first of these may belong to the earliest known inhabitants of Britain; and the others may perhaps be assigned to the latest Belgic colonists. The later Saxons buried their dead in cemeteries of considerable extent, and without barrows.

TUN. [Ton.]

TUNE, in Music, a short air, or melody, with both or either of which terms it is synonymous. A vocal *Tune* is a song, or a ballad, in England; an *ariette*, a *vaudeville*, in France; a *gesang* in Germany; a *canzonetta*, an *arietta*, in Italy; a *seguidilla* in Spain; &c. In instrumental music a *Tune* is variously denominated,—dance, hornpipe, jig, *gigue*, *giga*; waltz, *valse*, *waltzer*, *fandango*, &c., according to the country in which it had its origin or is naturalised. [Air; Melody.]

TUNGSTEN (W). *Wolframium*. This element was discovered by Scheele in 1781, but was not isolated till some few years later. The name indicates "heavy stone," in allusion to the high specific gravity of its Swedish ore.

The chief, if not the only form in which tungsten occurs in nature, is that of tungstic acid; sometimes free, but more often combined: it is usually found in company with tin-stone, and till within the last few years has been regarded only as a mineralogical curiosity. Recently, however, tungsten has been combined with iron, and the alloy found to possess the properties of the best steel.

Tungsten may easily be obtained from tungstic acid, by reducing with hydrogen or carbon at a high temperature. The most convenient method is to knead a mixture of tungstic acid and charcoal into a paste with oil, and expose the mass in a carbon crucible to the heat of a blast furnace. It is a steel-gray metal, susceptible of considerable lustre, exceedingly hard and infusible, and of specific gravity 17·6. It does not readily oxidise in the air, and is not magnetic. It is a good conductor of heat and electricity, and by strong oxidising acids is converted into tungstic acid.

The equivalent of tungsten is 92.

Tungsten and *oxygen* form two definite compounds; *binoxide* (WO_2) and *teroxide*, or *tungstic acid* (WO_3). A dark indigo-blue coloured oxide (W_2O_5) has also been described, but it is probably a mixture, or possibly a compound of binoxide and teroxide ($W_2O_5 = WO_2, WO_3$).

Binoxide of tungsten, or *tungstous oxide* (WO_2), is a dark copper-coloured, almost black powder, obtained on passing hydrogen over tungstic acid at a low red heat. It has also been formed in lustrous scales. Binoxide of tungsten has a great tendency to absorb oxygen, but forms with soda a compound that is not acted upon by any acid, except hydrofluoric.

Tungstic acid (WO_3).—The anhydrous acid, or *tungstic anhydride*, may be procured by decomposing Wolfram (tungstate of iron and manganese $MnO, WO_3 + 3FeO, WO_3$), with aqua regia, evaporating to dryness, digesting the residue in ammonia, re-crystallising the tungstate of ammonia, drying, and heating to redness. It is a yellow powder, insoluble in water and acids, but soluble in alkalies, and in alkaline carbonates with effervescence.

Hydrated tungstic acid (HO, WO_3) is a yellow precipitate, formed on adding excess of hydrochloric acid to a solution of tungstic anhydride in alkali.

Tungstates.—Those of the alkalies are formed in the manner just indicated, and others may be obtained by double decomposition. *Tungstate of soda* ($NaO, WO_3 + 2Aq.$) possesses the important property of rendering fabrics uninflammable. Muslin soaked in a solution of 20 parts of this salt with 3 of phosphate of soda in 100 parts of water may readily be ironed and otherwise prepared for wear, and is then only charred when brought into contact with fire; it does not itself burn with flame and, therefore, does not propagate its combustion. *Tungstate of lead* rivals the carbonate as a pigment. A modification of tungstic acid in which two equivalents combine with one of base has been termed *metatungstic acid* (HO, W_2O_6).

Tungsten and *phosphorus* form two compounds. The first is a dark gray powder (W_3P_2) produced when phosphorous vapour is passed over the metal. The second (W_4P) occurs in crystalline groups of lustrous prisms, and is obtained on reducing two equivalents of phosphoric acid and one of tungstic acid in a carbon crucible at a very high temperature.

Tungsten and *sulphur* form *bisulphide* (WS_2) and *tersulphide* (WS_3). The former is a bluish-black, crystalline, plumbago-like powder, which remains undissolved when a well fused mixture of equal parts of bitungstate of potash and sulphur is treated with water. The tersulphide is produced on dissolving tungstic acid in an alkaline sulphide, and precipitating by an acid: it is slightly soluble in water, and is a powerful sulphur acid.

Tungsten and *chlorine* combine in two proportions. On passing the dry gas over the heated metal, both chlorides are formed, the relative proportions depending on the amount of chlorine. The *bichloride* (WCl_2) is less volatile than the *terchloride* (WCl_3). Both of them crystallise.

The compounds of tungsten are not poisonous. Their solutions are not precipitated by sulphide of hydrogen, or sulphide of ammonium. Sulphuric acid and zinc when added to a solution of tungstic acid produce a deep blue coloration in the liquid. With borax in the blow-pipe flame, the compounds of tungsten yield a yellow bead, becoming blood-red on cooling. The metal is estimated in the state of tungstic anhydride, which contains 79·32 per cent. of metal.

TUNGSTIC ACID. [Tungsten.]

TUNING. [TEMPERAMENT AND TUNING.] In column 118 we alluded to the prospectus of certain tuning-forks, of which it was stated that *each one* was tuned to the true standard by a "scientific process." We have received an explanation, by which it appears that this is the advertiser's way of saying that a good standard tuning fork having been first constructed by a scientific process, every tuning fork sold was carefully compared, by ear, with that original. This is quite as it should be; but the terms used express something different.

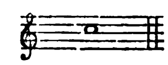
TUNING-FORK. A steel instrument with two prongs springing out of a handle, and so adjusted as to length that when struck a certain fixed note is produced, by which the pitch of the voice or of musical instruments is regulated. In England the tuning-fork is made with parallel prongs, and is vibrated by striking one of the prongs when both unite and reinforce each other; the note becomes much more resonant by placing the handle on a sounding-board, or even on a table. In France, where the instrument is called a *diapason*, and in Germany a *diaspason*, the prongs are bent into the form of an exaggerated horse shoe, and a cylinder of wood being placed in the widest part of the opening, is moved quickly upwards so as to separate the prongs further apart, and they continue to vibrate for some time. The fork is usually tuned to A or C in the tenor, a separate fork being provided for each pitch required. Mr. Klein has, however, introduced a fork which admits of adjustment for pitch by means of a small brass clamp, which slides on one of the prongs, and can be fixed in certain positions by means of a clamping screw. By varying the place of the clamp upon the prong the pitch of the fork can be raised or lowered, and certain marks are engraved upon the prong, showing the position for the clamp for giving the pitch adopted by each of the principal orchestras in Europe.

It would be very desirable if a uniform pitch could be agreed on in the musical world; but so long as each nation continues to use its own weights and measures, it will naturally claim the privilege of regulating its own musical pitch. Under ACOUSTICS, CONCERT PITCH, and TEMPERAMENT and TUNING, some remarks are made on this subject, by which it appears that for many years past the pitch has been rising, to the injury of the voices of our public singers. Messrs. Broadwood, the well-known pianoforte makers, employ three tuning-forks, all of different pitch: the first is the philharmonic standard of thirty years ago, and is used for tuning pianos which give the accompaniments at vocal concerts; secondly, a fork higher in pitch, used for tuning pianos that take part in orchestral compositions; and thirdly, a fork of still higher pitch, used as the opera and philharmonic standard of the present day. Indeed there is a difference of about a semitone between the first and third of these forks.

It is stated that the middle C-fork used in Paris in 1699 was equal to 489 vibrations per second, while in 1859 it had increased to 538. In the last-named year the opera standard fork used in London, St. Petersburg, and Berlin, was even somewhat higher than that of Paris; and cases have frequently occurred in which a band intended to take part with a cathedral organ, such as that of St. Paul's, London, found it impossible to tune down all their instruments to the pitch of the organ. The object of thus raising the pitch has been to improve the brilliancy of the instruments. Opera bands and military bands have both raised their pitch. The conductor of the band of the *Guides* of Brussels employs two forks, one which is too high for vocal music, being used to give brilliancy to military instruments.

Attempts have been made at various times to settle the standard of pitch by reference to scientific principles. Fischer's experiments, or rather their results, obtained in 1823, are noticed under ACOUSTICS. About thirty years ago the Philharmonic Society adopted a fork of a certain pitch, which for a time seemed to check the tendency to rise in the standard. The maker informed us that this fork was entirely settled by ear, and that Sir George Smart directed him to make it a little sharper or a little flatter until in the course of about half an hour, a pitch was hit upon which satisfied Sir George's musical ear. In 1834 some of the leading musicians of Germany met at Stuttgard, and agreed upon an A-fork of 880 vibrations per second, corresponding with 528 for the tenor C. The next attempt to secure a uniform standard was made by Mr. Hullah, in 1842. When this gentleman introduced the system of teaching singing on the Wilhem method, under the sanction of the Committee of Council on Education, it was quite necessary to secure a common standard of pitch for the sake of uniformity in the various classes, and among the teachers instructed by Mr. Hullah, who themselves had classes in various parts of the kingdom. The great and successful gatherings in Exeter Hall, where 1500 or 2000 pupils under this method united their voices, would evidently have been impossible unless a standard of pitch had been adopted. Accordingly, Mr. Hullah and his publisher, Mr. Parker, applied to Mr. Tomlinson to prepare a new fork; the necessity for which will be further apparent when it is considered that the A-fork or the C-fork of one maker did not by any means imply the same A-fork or C-fork of another maker; nay, even forks of the same name, and bought at the same shop, were not, as a rule, in unison. Mr. Hullah expressed great anxiety that the pitch should be kept down as much as possible, but he left it to Mr. Tomlinson to decide what number of vibrations per second should be assigned to the note which it was agreed should be the middle C of the pianoforte. In a letter addressed to Mr. Hullah on April 18, 1842, Mr. Tomlinson stated his reasons why the number 512 should be adopted. We will quote a few remarks from the printed description which was written when this fork was issued, and which has been given with every fork that has been sold, ever since:—

"The tuning-forks now in use are themselves regulated—not upon any definite principle—but by the imperfect system of *copying*; each one being attuned in (apparent) unison with others. The workman, having no test but his ear to depend upon, is liable to fall into inaccuracies, the precise amount of which he has no means of determining: hence the standard itself may vary from time to time; and indeed it is known to musicians that the standard of musical pitch is higher in this country at the present time than formerly, any given note being now a little *sharper* than the similarly-named note in the times of our earlier composers. And not only so, but different vocalists of distinction, instrumental performers, and musical instrument makers, adopt certain standards of their own, which often differ considerably one from another. These discrepancies, and the rapid extension of vocal music in England under the auspices of the Committee of Council on Education, have led to the opinion that the present is a favourable time to attempt the formation of a *rigorous standard* of pitch; one which, by depending on an unchanging scientific principle, will be independent of local and temporary usages. The principle here alluded to is that on which the pitch wholly depends—namely, *the number of vibrations per second which produces the given note.* The great rapidity of these vibrations renders the determination of the number a point of much difficulty: but science furnishes many resources whereby this determination can be made with great nicety. Any note might be chosen as a standard, but the note "Do" or C, represented musically thus, has been selected as the one most generally useful:—



This note in the new standard tuning-forks, is produced by 512 vibrations per second, a number, the simplicity of which renders it peculiarly valuable. It forms part of the geometrical series, 1, 2, 4, 8, 16, 32, 64, 128, 256, 512, 1024, 2048; each term of which thus becomes a representative of the natural note "Do" (except the first five terms, which vibrate too slowly to produce musical sounds); every term being the octave of the next below it. Under such a system the lowest C on a grand pianoforte would be due to 32 vibrations per second; the highest C to 2048, and the highest note of the instrument to 2730. By careful experiments, made expressly for the present object, it has been recently determined, that the philharmonic C, the most authoritative standard in this country, vibrates a smaller number of times per second than 512; while Fischer, of Berlin, found, a few years ago, that the average of the pitch note A, in four celebrated Continental orchestras, gave a number which would raise the C to about 516 vibrations per second. Thus the numbers of vibrations per second of the pitch-note A at the principal Berlin and Paris theatres were as follow:

	Vibrations per Sec.		Vibrations per Sec.
Berlin Theatre . . .	$437\frac{32}{100}$	which would give for the note C . .	$524\frac{78}{100}$
Paris Grand Opera Français .	$431\frac{34}{100}$	" "	$517\frac{61}{100}$
Opera Comique . . .	$427\frac{61}{100}$	" "	$513\frac{13}{100}$
Opera Italien . . .	$424\frac{17}{100}$	" "	509

"In selecting, therefore, the number 512, we not only obtain that which is theoretically most correct, but one which is also a convenient mean between various existing standards; it gives a very trifling elevation to the general English pitch, and furnishes a standard, which, for the first time in this country, can be *numerically* expressed in connection with the tuning-fork."

It is further stated that "every fork is tested by an uniform standard, and stamped with a device expressive of the velocity of its vibrations = 512 per second."

It is remarkable that this fork should have been almost entirely confined to the use of Professor Hullah's singing-classes, and that when the Society of Arts committee was appointed the existence of a standard for nearly twenty years, of which many thousands had been issued to the public, should have been known only to a few of the members of that committee. This committee seems to have been appointed in consequence of the imperial government of France having in 1858 appointed a commission to inquire into the best mode of settling a *diapason normal.* The commissioners, among whom were some eminent composers, as well as men of science, presented their report early in 1859, in which it was admitted that the standard of pitch differs in different countries; that it differs among different musical establishments in the same country; that there is a tendency everywhere to an elevation in pitch; and that great confusion arises from these circumstances. It was agreed that the Paris Opera standard ought to be lowered; and in order that existing musical instruments might be readily adapted to a lower pitch, about half a semitone of diminution was recommended: namely, that the Opera A fork should be lowered from 896 to 870 vibrations per second, equivalent to a lowering of the tenor C from 538 to 522. A decree of the Emperor sanctioned this standard, and made it compulsory on all musical establishments in any way supported by the state to adopt this standard at Paris from the 1st of July, 1859, and in the provinces from the 1st of December following.

The preliminary meeting of the Society of Arts was held on the 3rd of June, 1859. A large number of musical gentlemen and one lady, Madame Goldschmidt (Jenny Lind), attended, together with a few scientific men. It was agreed that the pitch had gradually risen, was still rising, that it ought to be checked, and that the settlement of a definite standard, once for all, was very desirable. Madame Goldschmidt stated that within the short space of twelve years the pitch had risen sufficiently to make the change painful to the singers of soprano music. A committee was appointed to examine and report on the question: the deliberations lasted twelve months. It is worthy of remark that Sir John Herschel addressed a letter to the committee, in which he expressed his astonishment that the French commission should have fixed upon the number 870 for their A fork, or 522 for C; and he expressed his conviction that sooner or later the mathematically simple and easily calculated 512 must be adopted. His proposal was to re-form the pitch effectually, and once for all, by the adoption of that number. The instrument-makers, he remarks, would be somewhat puzzled by *any* change, but that the embarrassment would not be increased by making the full required alteration at once. The committee, however, reported in favour of a number between the two extremes—namely, 528, or the pitch established by the Stuttgard musicians in 1834. The instrumental performers stated to the committee that they could lower the Opera pitch of 546 down to 528, but if they had to lower it to 512 some of them would have to purchase new instruments. On the other hand, the vocalists who would have preferred 512 were content to accept 528 as a compromise in the right direction. Besides this, 528 was recommended as a good number for the fundamental note of the octave, since it admits of the other notes of the scale being expressed in whole numbers without fractions. At the presentation of the report a strong attempt was made to obtain a vote in favour of 512, but without success; so that for some time to come this number will probably only reign in Professor Hullah's singing-classes.

The scientific process by which the number of vibrations per second is determined, consists in the use of one of three or four methods. The first is by means of the monochord, a string of known length and diameter, stretched by a known weight usually in a horizontal position. The length of the string is the vibrating portion between two well-defined edges or bridges, and the weight is guided over a very small pulley. Fischer was, we believe, the first to point out a source of error in this arrangement, namely, that in the horizontal position the string is prevented by friction from experiencing the full effect of the weight, and the calculation will give the number of vibrations in excess of the true value. The string must therefore be in a vertical position. The formula convenient for calculation results from the mathematical theory of the vibrations of a stretched cord:—

Let l = the length *in inches* of the cord or wire.
c = the length *also in inches*, whose weight would be equal to that by which it is stretched.

Then the number of vibrations per second will be

$$N = \frac{\sqrt{c}}{l} \times 9{\cdot}8257,$$

in which 9·8257 is $\frac{1}{2}\sqrt{g}$, g being the accelerative force of the gravity of the earth at its surface, expressed in inches.

Mr. Woolhouse ('Essay on Musical Intervals') took a piece of the stoutest plain string of the pianoforte, weighing very nearly 2 grains to the inch: 272 inches weighed just 9 drams or 540 grains. A length of 7·28 inches, stretched in a vertical position by a weight of 28 lbs. avoir., sounded the common pitch-note A: hence, according to the preceding formula, $c = 98726$ inches; $\sqrt{c} = 314{\cdot}2$ inches; $\sqrt{c} \times 9{\cdot}8257 = 3087{\cdot}2$ inches; and $N = \frac{3087{\cdot}2}{7{\cdot}28} = 424$. "We therefore conclude that the pitch-note A vibrates about 424 times in one second. This may differ one or two vibrations from the truth, on account of the unavoidable small defects of the materials used in the experiment." According to this determination the notes of the octave have the following values:—C 254, D 286, E 318, F 339, G 382, A 424, B 477, and C 509 vibrations per second respectively.

The second mode of determining the pitch of a given note is by means of the SYREN, and the method of doing so is briefly, but perhaps sufficiently, described under that head. For the method of BEATS, we may refer to that head, and likewise to the articles ACOUSTICS, and TEMPERAMENT and TUNING. But the most rapid and striking method of determining the number of vibrations in a given note is that recently introduced by M. Lissajoux [NODAL POINTS AND LINES]. By means of an electro-magnetic machine a disc one metre in circumference moves with strict uniformity, and makes one revolution in one second. This disc is covered with a thin layer of copperplate printer's ink, and the fork is furnished with a small ivory point. On vibrating the fork and bringing the point up to the rotating disc, it will engrave a number of tooth-like waves, which have only to be counted in order to determine the number of vibrations per second of the fork.

The law which regulates the vibrations of a tongue of metal fixed at one extremity, and free to vibrate at the other, is that the number of vibrations of similar tongues, but of different lengths, are in the inverse ratio of the squares of those lengths. Thus if one tongue be twice as long as the other, the shorter will perform four times as many vibrations in a given time as the longer. The method of tuning a fork by a standard is to sound the fork with that standard, and if it agrees with it, the two notes will sound in unison as one; if it do not agree, a system of beats will be heard more or less rapid according to the divergence. The tuner then adopts one of two methods: by means of a flat file he rubs off a portion from the ends of the prongs, thus reducing them in length, and making them vibrate quicker; or he introduces a rat's tail file and removes a portion from between the prongs, thus increasing their effective length and causing them to vibrate slower.

It is undoubtedly true, that the pitch even of the tuning-fork is liable to slight variations from change of temperature. While writing this article we have performed the following experiment: two forks were sounded together and found to be strictly in unison; one of them was plunged into hot water for a few seconds, then wiped dry, and again sounded with the other fork, when a very painful beat was evident.

On striking a tuning-fork briskly on a hard substance, other notes besides the fundamental note may sometimes be heard. This arises from nodal divisions in each limb, after the manner of strings and tubes [PIPE], but not following quite the same laws. Where there is one node it is at a distance from the fixed point, a little greater than two-thirds the length of the prong; the note then given by this, which is called the second mode, is much sharper than when there is no node (or by the first mode), and the relative number of vibrations is $\frac{25}{4}$. A still higher note corresponds to two nodes (third mode), and one still higher to three nodes (fourth mode). These subdivisions of vibrating rods may also be produced in tubes. The squares of the odd numbers 3, 5, 7, 9, &c., represent with sufficient exactness the relations of the number of vibrations corresponding to the second mode, third mode, fourth mode, &c. Under all these circumstances it may be stated:—1. That the number of vibrations of similar springs of different lengths is in the inverse ratio of the squares of the lengths; 2. That the number of vibrations of springs of the same length, but of different thicknesses, is proportional to their thicknesses; 3. That the width of a spring has no influence on the number of its vibrations, provided it be small with respect to its length, and that it vibrates after the first mode; 4. That springs of equal size, but of different material, such as wood, glass, steel, &c., do not give the same note, because the number of the vibrations depends upon the density and rigidity of matter.

A tuning-fork may be made to furnish several beautiful illustrations of interference. [INTERFERENCE.] If a vibrating tuning-fork be held to the ear and turned gradually round, the sound will increase and diminish in a remarkable manner; when the prongs are presented at an angle of 45° the sound is scarcely if at all perceptible. In such cases, when the prongs coincide, or are equally distant from the ear, the waves of sound combine their effects, whilst in intermediate positions they reach the ear in different phases, and interfere and produce total or partial silence. A similar effect is produced by fixing the fork to the mandril of a lathe, the length of the fork coinciding with the axis of motion; if the fork be vibrated no sound will be heard while it is rotating. If a vibrating tuning-fork be held with its handle obliquely in contact with the table, the resonance of the table is heard while the fork is at rest; but if the fork be moved parallel to itself along the surface of the table, the resonance ceases, from the interference of the planes of vibration with each other. The moment the handle is brought to rest, the resonance is again heard. If the tuning-fork be held vertically, the resonance is not interrupted by moving it about, since the planes of vibration coincide. If a vibrating tuning-fork be held over a cylindrical glass vessel of suitable length, the air in the glass will be made to vibrate and produce a tone. If a second glass cylinder be held at right angles to the first, so that the respective openings of the two vessels form a right angle, the musical tone previously heard will cease, but will sound again on removing the second vessel, an effect which arises from the interference of the vibrations of the air in the two vessels.

TUNNEL, in civil engineering, an arched passage formed underground to conduct a canal or road on a lower level than the natural surface. The derivation of this word, which, in the sense above given, is unnoticed by most lexicographers, is rather uncertain. Richardson places it among the derivatives of *tun*, and defines it as "any inclosure, inclosed way or passage;" as a chimney-tunnel, or passage for smoke, in which sense the word *tunnel* or *tonnell* is used by Spenser and other early English writers; a passage for liquor, in which sense, as well as in that last mentioned, it is convertible with *funnel;* or a net shaped like a tunnel for liquids, wide at the mouth, and diminishing to a point. He also observes that "Tooke thinks *tun* and its diminutive *tunnel* (Anglo-Saxon, *Tœnel*, *tenel*) are the past participles of the [Anglo-Saxon] verb *tyn-an*, to enclose, to encompass."

Long tunnels are usually made through hills in order to avoid the inconvenience and loss of power occasioned by conducting a canal, road, or railway over elevated ground, and the enormous expense of such an open excavation as would be necessary in order to preserve the requisite level. Those of less extent are frequently constructed to avoid the opposition of landowners, or to afford uninterrupted passage under a road, canal, or river. Many tunnels of the latter character differ in no material point from bridges; but in the case of oblique crossings a tunnel is distinguished from an oblique or skew bridge by its faces being at right angles with the direction of the lower passage, instead of being parallel with the direction of the upper passage. Of this character are the tunnels under the Hampstead Road, between Euston Square and Camden Town, and the Kensall Green tunnel, under the Harrow Road, both on the line of the London and North-Western railway; and on the West London railway, passing under the Paddington canal at Wormholt Scrubbs. The Thames tunnel is the most remarkable example of tunnelling under a river, and, although far less extensive than many other tunnels, it is, from the almost insuperable difficulties of its situation, perhaps the most astonishing work of the kind ever executed. Another class of tunnels are those made under towns, in order to form a canal or railway communication with points which are inaccessible by an open passage, except at great expense. The Regent's canal, for example, passes under Islington, London, by a tunnel three-quarters of a mile long; and the Liverpool and Manchester railway is conducted from the station at Edge Hill, on the outskirts of Liverpool, to the docks at Wapping, for goods traffic, and to Lime Street, in the centre of the town, for passenger traffic, by two tunnels, each of which is about a mile and a quarter long.

The construction of tunnels is by no means of recent origin, although it is only of late that they have become common. The outlet for the drainage of the lake Copaïs in Bœotia [Bœotia, in Geog. Div.] is one of the oldest monuments of the labour of man. The great tunnel in Samos, which was seven stadia, or 4200 Greek feet, in length, was driven through a mountain 900 feet high, for the purpose of serving as the bed of a channel to convey water from a natural source to the city of Samos. (Herod., iii. 60.) The Posilipo near Naples, which is at least as old as the beginning of the reign of Tiberius, is a tunnel three-quarters of a mile long. The tunnel which was made at an early period in the Roman republic for the partial drainage of the Alban Lake is above a mile in length. Of ancient works of this character there is a remarkable example in the subterranean canal from lake Fucinus, or the lake of Celano, to the river Siris, originally formed by the emperor Claudius, and cleared out some years since by order of the Neapolitan government. This extensive tunnel, which is about three miles long, thirty feet high and twenty-eight wide at the entrance, and nowhere less than twenty feet high, passes in part through solid rock, and is lined in other places with masonry; and it appears to have been constructed in a manner resembling that now usually followed, the excavation having been carried on by several parties or gangs simultaneously, by means of vertical shafts, and inclined passages or galleries from the sides of the mountain. A minute account of the tunnel, as it appeared during the clearing-out, is given in the thirty-eighth volume of 'Blackwood's Edinburgh Magazine' (p. 657), in a paper entitled 'Eight Days in the Abruzzi.' The object of this tunnel is to carry off the superfluous waters of the lake; but in more recent times similar works have been executed for navigable canals. These are generally in England of small transverse dimensions, being calculated for the passage of single boats, and very often without towing-paths, in which case the boats are either hauled through by a rope or chain, worked by a steam-engine, or propelled by men lying on their backs on the deck, or on projecting boards provided for the purpose, and thrusting against the sides or roof of the tunnel with their feet. This dangerous practice has occasioned much loss of life, and is also objectionable on account of its tediousness, as boats are often detained for a long time at one end of the tunnel while a boat is coming from the opposite end. In the evidence before the House of Lords on the Great Western Railway bill, in 1835, it was stated that great delays were experienced at the Islington tunnel when any accidental derangement prevented the steam-engine and chain from working; because, although boats were occasionally "legged" through in as little as seventeen minutes, the ordinary time required for working a light barge through the tunnel, by two men, was half an hour, and for a loaded barge three-quarters of an hour, or frequently an hour. In such cases boats arriving in the opposite direction had to wait at the mouth of the tunnel, until, frequently, as many as half a dozen were collected, which, when their turn arrived, passed through in a train. At some of the longer tunnels this inconvenience was even greater. At the Harecastle tunnel, on the Trent and Mersey, or Grand Trunk canal, two hours were formerly required to effect a passage of little more than a mile and a half. "This place is so frequented," observes the Baron Dupin, in his 'Commercial Power of Great Britain,' "that at the moment when the passage begins, a file of boats a mile long is often seen." To prevent confusion, those going towards Liverpool were allowed to pass in the morning only, and those in the contrary direction in the evening. This tunnel, which was formed by Brindley, and was one of the earliest works of the kind executed in this country, was commenced about the year 1766. It is 2880 yards long, 12 feet wide, and 9 feet high, and is in some parts as much as 70 yards beneath the surface. It is lined with a semicircular brick arch, and was completed for the small sum of 3*l*. 10*s*. 8*d*. per yard. Increased traffic upon the canal having rendered it necessary either to construct a new tunnel or to enlarge the old one, the former alternative was adopted; and in 1822 Telford was engaged to superintend the work. The new tunnel, which runs parallel with that of Brindley, is 2926 yards long, 14 feet wide, and 16 feet high; and, notwithstanding its greater dimensions, it was executed in less than three years: the original tunnel occupied eleven years. The new tunnel has an iron towing-path, so supported as to allow the water to play freely beneath it, which gives the advantage, so far as the play of the waves is concerned, of a waterway of the full width of the tunnel. It is perfectly straight, and the light can be seen from end to end; and so agreeable is the travelling through it, that one of the bargemen said, after passing it, that he wished it extended all the way to Manchester.

Although in some cases the adoption of a tunnel on a line of railway or canal may be decided by the necessity of non-interference with property on the surface, it is more generally a question of expediency, which involves the consideration of many important points, among which the nature of the ground is one of the first. The ground should be examined by numerous borings, because sudden breaks or faults in the strata, which may occasion great difficulty and expense in tunnelling, may otherwise escape notice. The Kilsby tunnel, on the London and North-Western Railway, presents a case in point; the trial shafts having been accidentally sunk just beyond the limits of a bed of sand and gravel, so full of water as to resemble a quicksand, occasioned so much difficulty that the contractors had to relinquish the work, which had been let for 99,000*l*., but ultimately cost upwards of 320,000*l*., or about 133*l*. per yard. If the first small borings appear satisfactory, shafts of at least four feet diameter should be sunk along the line of the tunnel, down to its extreme depth; and the quantity of water which appears in these shafts in a given time be noted, in order to ascertain, as nearly as possible, what draining power is requisite. If the trial shafts be judiciously placed, they may subsequently be used as working shafts, which will render the expense of forming them of large diameter immaterial. When the quantity of water and the nature of the strata have been thus tested, the engineer possesses data for calculating the comparative cost of a tunnel and an open cutting, in doing which it is necessary to consider the adjoining works of the line. If embankments be required within a reasonable distance of the proposed tunnel, it may become a question whether it will be more economical to make a cutting, and to carry the excavated earth to the embankment, or to adopt a tunnel, and to obtain the required quantity of earth for the embankment from side-cutting, or in any other way. Sometimes it may be necessary to deposit the material taken out of the tunnel in spoil-banks, in which case the power of obtaining sites for them, and of making convenient temporary roads or tramways for the removal of the earth, must be considered in selecting the positions for the working shafts. These are only a few of the points to be considered in estimating the expense of a tunnel, among the less prominent of which is the probability of being called upon for damages owing to the intersection of springs, which may occasion mischief at a great distance. Cases have occurred in which the water has been drawn from wells a mile from the tunnel. This evil may often be remedied by sinking the wells to a greater depth, but in some cases it is better to offer compensation at once. The cost of the actual making of the tunnel varies very greatly, according to the nature of the ground and the amount of brickwork required. Lecount, in the article 'Tunnel' in the 'Encyclopædia Britannica,' states that many of the old canal tunnels were made for less than 4*l*. per lineal yard, and that railway tunnels of the ordinary dimensions vary from about 20*l*. per yard, in sandstone rock, which is at once easy to excavate, and able to stand without any lining of brickwork or masonry, up to from 100*l*. to 140*l*. per yard in very loose bad ground, such as a quicksand, which may require a lining of brickwork twenty-seven inches thick. The cost of the Thames tunnel was about 1200*l*. per yard; but in this case, in addition to the unparalleled difficulties attending the excavation, the amount of brickwork is much greater than in ordinary tunnels, and there are two arches, each of which may be considered a distinct tunnel.

Rocky strata, if the stone be of a nature to work freely, are usually the cheapest for tunnelling, owing to the absence of lining, and the power of saving labour by the use of gunpowder. In the extraordinary tunnels and rock excavations at Bishopton, on the Glasgow, Paisley, and Greenock railway, 314 tons of gunpowder were used in a length of 2300 yards in hard whinstone, some veins of which were so hard that the rate of progress at each face of the excavation varied from three feet six inches to six inches only per diem. The Box tunnel, on the Great Western railway, passes for a considerable distance through strata of Bath freestone, geologically termed the great oolite formation, and presents some features worthy of notice. Major-General Pasley was deputed by the Board of Trade to examine this tunnel, and from his report, dated August 12, 1842, the following particulars are derived:—"The tunnel occurs on a gradient or inclination of 1 in 100, ascending from west to east, while the natural dip of the oolitic strata is about the same in the opposite direction: they are nearly horizontal in a direction from north to south, or transverse to that of the tunnel. The strata vary in thickness from 2½ to 4 feet and upwards, and are intersected by vertical fissures, of trifling width, but of considerable height; the direction of which is generally at right angles with that of the tunnel, but in some cases 'obliquely across it." The eastern end of the tunnel is, for a short distance, lined with masonry; beyond which, for about half a mile, the excavation is left without any support from masonry or brickwork, its extreme width being, in this part, 30 feet, and its height varying from 30 to 40 feet, in order to avoid finishing above in any stratum of doubtful character, which, though sufficiently strong in the sides, might not be so trustworthy as a roof. The sides of the excavation are cut in the form of an oblong elliptical or nearly a Gothic arch; but the uppermost bed of oolite, which forms the roof of the tunnel, has not been completed in that form, but has, for greater strength, been left flat for a width of two or three feet; and in order to avoid the risk of exfoliation which would have attended the cutting of the edges of the strata to a thin wedge shape, had the curved line of the tunnel been continued unbroken where it intersects them in the sides of the roof, they are cut in the form of steps, each stratum presenting a thick blunt edge; so that, in the words of Pasley's report, "the upper strata of the oolite being supported by those below them, beyond which they each successively project in a moderate degree, like corbels in architecture, the whole enter into that sort of combination which has the strength of an arch without its form; provided that the vertical fissures do not cut through them longitudinally," of which no symptom was apparent. The remaining portion of the Box tunnel, passing in the centre through beds of fullers'-earth and clay below the great oolite formation, and towards the western extremity through the inferior oolite, is arched over with brickwork, varying in thickness from four to seven concentric half-brick rings, and at the western entrance containing nine such rings. An inverted arch is introduced excepting where the oolite forms the foundation or bottom of the tunnel; and in some parts a portion of the side walls has been formed of the inferior oolite, unprotected by brickwork, although it has not in any instance been trusted for the roof. The judicious adoption of such changes in the amount of masonry forms an important part of the duty of the engineer, and is essential to the construction of tunnels at a moderate expense, although it may occasionally lead to failure, as in the case of the Summit tunnel at Littleborough, on the Manchester and Leeds railway, where, in passing through a stratum of blue shale, the invert had been discontinued for a short distance; but the shale, although apparently hard and firm, was so affected by the atmosphere as to soften and yield under the pressure of the sides, rendering it necessary subsequently to put in a strong invert of masonry.

Tunnelling in clay is frequently attended with formidable difficulties which render it very expensive. It is, when tough, a difficult material to remove, blasting being of no use, and spades and pickaxes being almost inapplicable. Lecount states that in such cases hatchets may be used to advantage, but that cross-cut saws answer best. The Primrose Hill tunnel, on the London and North-Western railway, passing through the London clay, is an example of the difficulties of such a material. The engineers, warned by the failure of the tunnel attempted some years before through the same material at Highgate, on what is now called the Archway road, which fell in owing to the insufficiency of the brick lining, adopted unusual precautions in the first instance, excavating only nine feet in advance of the brickwork, and supporting the clay by very strong timbering until the arching was complete. Owing however to the extraordinary mobility of the moist clay, the pressure upon the brickwork was so great as to squeeze the mortar from the joints, and to bring the inner edges of the bricks in contact. The evil was augmented by the form of the bricks, which, according to the custom in and near London, were made with hollow surfaces, and were consequently unfit to bear great pressure, because their edges only could come in contact. The result was, as stated in Lecount's 'History of the Railway, connecting London and Birmingham,' pp. 32, 33, that "by degrees the bricks were grinding to dust, and the dimensions of the tunnel insensibly, but irresistibly, contracting." This difficulty was overcome by the use of very hard bricks laid in Roman cement, which, by setting hard before the external pressure became so great as to force the bricks into actual contact, enabled the whole surface of the brick, instead of its edges only, to resist the pressure. The thickness of the brickwork was also increased, so that in most parts of the tunnel it amounts to twenty-seven inches. The occurrence of a similar material in the line of the Fareham tunnel, on the Gosport branch railway, occasioned great expense, and produced a slip of the superincumbent earth which carried away about forty yards in length of the brick arching, although it was of the unusual thickness of three feet.

Tunnels formed through chalk are often impeded by faults or cavities filled with wet gravel or sand, which pour a flood of semifluid matter into the excavation as soon as they are cut into. The irruption of such loose materials, as well as of water alone, has in many cases occasioned difficulties almost insurmountable. In the Watford tunnel, on the London and North-Western railway, which passes through the upper chalk formation, where it is covered with a thick irregular bed of gravel, such breaks occasioned great inconvenience. The chalk had occasional fissures, sometimes as much as one hundred feet deep, filled with clean gravel, "which," observes Lecount ('History,' &c., p. 114), "when worked into, rushed down with such violence, as to plough the walls of the tunnel as if bullets had been shot against it." Such an accident, occurring at the foot of one of the working shafts, overwhelmed ten men who were at work in the tunnel, and led to the construction of the large ventilating shaft near the centre of the tunnel, which occupies the site of the cavity. Loose sand is perhaps the most difficult soil that can be met with in tunnelling, but it has been in several instances successfully passed through. In the tunnel on the Leicester and Swannington railway, one of the earliest railway tunnels, a loose dry running sand was encountered for a distance of five hundred yards, in which it was necessary to make a wooden tunnel to support the soil while the brickwork was executed. When water occurs with the loose soil the difficulty is still greater. This was the case in part of the Wapping tunnel at Liverpool, a portion of which fell in, to a depth of thirty feet from the surface. The Kilsby tunnel, before alluded to, is a more striking example of this kind of difficulty. Mr. Stephenson, the engineer, conquered this obstacle by sinking shafts, a little beside the line of the tunnel, for pumping out the water, and so draining the sand until it was sufficiently dry for tunnelling. These shafts were sunk through the quicksand by means of wooden tubbing, and from them headings were driven to collect the water and to conduct it to the pumps. Steam-engines were erected to work the pumps, which were used incessantly for nine months before the sand was dry enough to allow the work to proceed: during a great part of that time two thousand gallons of water were removed per minute. When the working of the tunnel was recommenced, headings were driven from the pumping shafts to the bottom of the working shafts, by means of which the tunnel was freed from water. The quicksand extends over about four hundred and fifty yards of the length of the tunnel, and its bottom dips to about six feet below the arch. On the occasion of an irruption of water in another part of the tunnel, in which it was desirable to complete the arching of a portion already executed before it was possible to get rid of the water, that object was effected by floating the men and materials to the spot upon a raft. Water has been met with in large quantities in several other tunnels. It flowed so freely from fissures in the freestone rock through which the Box tunnel is driven, that in November, 1837, the steam-engine employed in pumping proved insufficient, and the water filled one division of the tunnel, and rose to the height of fifty-six feet in the shaft, thereby suspending the work until the following July, when the water was overcome by means of a second engine, of fifty-horse power. After another irruption in the same tunnel, the water was pumped out at the rate of thirty-two thousand hogsheads a day. The progress of the Merstham and several other tunnels was stopped for a time in like manner. In no case however has the irruption of water or the badness of the ground proved so serious a difficulty as in the Thames tunnel.

Short tunnels are occasionally excavated from the ends only, but those of considerable length are usually formed by sinking vertical shafts, about nine feet in diameter, down to the level of the tunnel, and excavating in each direction from the bottom of those shafts, until the several parties of workmen meet in the intermediate portions. By this means the work can proceed at any required number of points or faces, so as to bring the execution of the tunnel, whatever may be its length, within a moderate period of time. The accurate junction of these detached workings is provided for in the following manner:—In setting out the tunnel, the engineer plants a transit-instrument in an observatory erected in the line of the tunnel, supporting it on a pier insulated from the building to prevent vibration. If a road happen to pass near the observatory, the ground should be excavated round the pier to a depth of from six to ten feet, according to the traffic, for the same purpose. A distant mark should then be selected in the line of the tunnel, and a fixed point placed as an adjusting spot for the line of direction, which point should be at a considerable distance. Intermediate marks for the working and ventilating shafts may then be set out correctly; and as these shafts are sunk, the points determined by the transit-instrument are carried downwards by carefully suspended plummets, which should be of iron, and let down in buckets of water, or, which is better, in cups of mercury, to check vibration. When the shafts are cleared out at the bottom, other transit-instruments may be placed in them, the plumb-line and transit being kept as far apart as possible. The intersection of the vertical hairs in the transit with the plumb-line will then enable the engineer properly to set out the work. By these means junctions are effected between the several workings, or *shifts*, with surprising accuracy. In a length of 1520 feet between two shafts of the Box tunnel, which has a slope of 1 in 100, the junction of the two shifts was perfect in point of level, and did not deviate more than an inch and a quarter in any place at the sides. Even in curved tunnels, although the difficulty is increased, great exactness is attainable. In those on the Glasgow and Greenock railway at Bishopton, the deviation from perfect correctness nowhere exceeded two inches.

The number of working shafts in a given length of tunnel is determined by the nature of the ground and the time allowed for excavation. They should be so near together as to allow the tunnel to be excavated and lined, if brickwork be requisite, for a length equal to one-half of the distance between two shafts, at least two months before the time appointed for the completion of the tunnel; that time being desirable to allow for accidents, for building the tunnel-fronts, ballasting and laying the railway, &c. The shafts are usually 9 feet in diameter in the clear, and lined with brickwork 9 inches thick, laid in cement; all the bricks being laid as *headers*, or with their ends towards the centre of the shaft; but the substance of the brickwork must vary with circumstances, and engineers are by no means uniform as to the dimensions of their shafts. Those of the Box tunnel are mostly 25 feet in diameter, while some tunnels have been excavated with shafts of only 3 or 4 feet. Down to a depth of 50 or 60 feet the earth may be removed by means of a simple roller or winch worked by two men; and when the depth is greater a horse-gin may be erected to draw up the loaded skips or buckets. The depth at which the horse-gin becomes preferable is however dependent in some degree upon the nature of the strata to be excavated; because when they are hard, the men above may have to wait occasionally for the coming up of the skip; and it is better to have only two men at a stand-still instead of a horse, a horse-boy, and a banksman or skip lander. The roll or winch is, at the commencement of the shaft, supported by four bars or cills laid across each other on the ground; and the excavation is continued until the earth exhibits signs of weakness. A wooden curb or ring about 3 inches thick, and as wide as the brick lining is to be, is then laid in, and upon this the brickwork is laid. When the lining of this portion of the shaft, which is frequently but half a brick, or 4½ inches in thickness, is completed, the excavation is recommenced, and is carried down in a vertical line even with the inner surface of the brickwork, which is then supported by the earth left under the curb, which may be further supported if necessary by diagonal timber props. When the excavation has been carried so much deeper that the ground again appears weak, a second curb is inserted in a groove cut in the earth, and the ground between the two curbs is divided into four, six, or eight vertical masses, of which one or two are removed to a depth equal to the thickness of the brickwork. The wall is then built up in its place, and a further portion of earth is removed, and so on until the lining is complete. When the shaft is carried down to the full depth, the miners begin to excavate laterally by forming a heading or driftway along the level of the upper part of the tunnel. Sometimes such a drift is formed throughout the whole length of the tunnel before any part is opened out to the full size; but in other cases it is made in short portions, little exceeding the lengths in which the excavation of the tunnel itself is carried on, which may vary, according to the ground, from 3 to 15 feet. In the former case the driftway, which is about 4 feet wide and 5 feet high, affords a satisfactory test of the strata to be passed through, and of the probable quantity of water to be met with, for which it may in some cases serve as an adit or drain; and for these reasons such a heading is occasionally formed before letting the contracts for the tunnelling.

In addition to the working shafts, the contractor is usually allowed to sink any number of small air-shafts of 3 or 4 feet diameter, as may be necessary to prevent the accumulation of foul air in the workings of the tunnel; provided that no such shaft shall open into a public road, or be within 50 feet of a working shaft. These are formed in a similar manner to the working shafts, and both are finished at their lower ends by resting upon a cast-iron curb or ring imbedded in the masonry of the roof of the tunnel, and at the upper ends, after the works are completed, by building them about 10 feet above the surface, and coping them with stone. In very long tunnels one or more large permanent shafts are desirable for the purpose of ventilation, and also to admit light, so as in some degree to lessen their gloom. In the Kilsby tunnel, which is between a mile and a quarter and a mile and a half long, there are two such ventilating shafts, 60 feet in diameter and about 100 and 132 feet deep respectively. These were built from the top downwards, in the manner above described, in portions 10 feet deep, and from 6 to 12 feet wide. Lecount gives the following directions for the brickwork of such a shaft, if made in unfavourable ground:—The tunnel itself at the point of intersection should be of stone. The lower part of the shaft, to the height of 46 feet, should be 3 feet thick; the next 17 feet, 2 feet 8 inches thick; the next portion of the like extent, 2 feet 3 inches; and the uppermost 16 feet, 1 foot 10 inches. The bricks should be laid in alternate courses of headers and stretchers, and each brick should be well flushed up. The top may be finished with a stone coping and an iron railing, and protected by an iron fence wall, to prevent the risk of anything being thrown down the shaft either by accident or design. In some tunnels a large oblong excavation, called an *eye*, is introduced in lieu of a circular ventilating shaft. In the Bishopton tunnel there is such an eye 300 feet long; and there are two similar openings in the Glasgow tunnel of the Edinburgh and Glasgow railway.

After the completion of the driftway, either through the tunnel or to the length of a single stage only, the miners excavate the tunnel to its full dimensions, beginning by cutting downwards, and propping up the earth with timbers as they proceed; those which support the roof being at such an elevation as to allow the centering to be set up and the brick arch to be built beneath them. The bars which immediately support the earth, extending from the top or outside of the completed brickwork to a framework placed against the face of the excavation, are called *side bars*, and are in favourable earth required at the upper part of the tunnel only; but in bad ground they are required sometimes as low as the springing of the inverted arch which forms the bottom of the tunnel. When a complete brick lining is required, the invert is the part first built, and it is completed by a course of stone laid along each side, at the point where the side walls spring from it. These courses of stone, which are marked *a, a, a, a*, in the subjoined cuts, *figs.* 1 and 2, consist of blocks about three feet long, well bedded in mortar, upon a few courses of brickwork laid as a footing. The

Fig. 1.

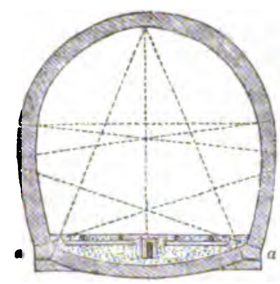


Fig. 2.

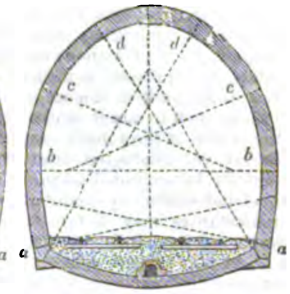

side walls are next raised, with such a batter or curvature as may enable them best to sustain the pressure of the external earth; and when they are raised to the level of the springing of the arch, beams of wood, called *cills*, are laid across the tunnel and built in with the brickwork. Upon these cills the trusses of the centering are set up, and adjusted with wedges to the proper height. Laggins, or pieces of wood stretching longitudinally from one centering to another, are then added, and upon these the bricks are laid. In some cases the cills are supported upon trestles, instead of being built into the walls; and where this is not the case, the holes left in the masonry must, after the removal of the cills, be carefully filled up. The excavation should always be made as nearly as possible of the size and shape of the intended masonry; and as the building proceeds, every cavity left outside the brickwork should be carefully filled up. Well-pounded clay may for this purpose be rammed under the invert, and almost any other material may be used for the sides and roof. The ramming of the sides may be performed after the laying of every second course of brickwork, and that above the arch as frequently as convenient. The timbers used to support the superincumbent earth are in most cases removed as soon as the arch is completed; but in very bad ground it is sometimes necessary to leave them imbedded in the earth. When the work has proceeded so far that the excavations from the two adjoining shafts are within about fifty yards of each other, if no driftway have been previously made through the tunnel, it is advisable to drive a heading through the intervening earth, to insure a perfect junction of the two shifts.

Many of the earlier tunnels were constructed with vertical sides and a semicircular arch; but it is now more usual to have the sides curved or battered, the degree of curvature, as well as the shape of the arch which forms the roof, being varied according to the nature of the ground, as soft semi-fluid ground will press much more equally in every direction than strata of a harder and drier character, and will therefore require a nearer approach to the circular form. The annexed cuts represent two varieties of form, the details of which are taken from the first series of Brees's 'Railway Practice.' *Fig.* 1 is the form of the Primrose Hill tunnel, in movable London clay. The invert, which consists of three concentric half-brick rings, is a curve of 25 feet radius; the arch, of four half-brick rings,* is struck with a radius of 11 feet 9 inches; and the sides are arcs of 27 feet 6 inches radius. The width of the tunnel is 21 feet 5 inches at the springing of the invert, and 24 feet 8 inches at the widest part. The clear height of the tunnel is 21 feet 8 inches, the remaining depth of 3 feet 4 inches being occupied by the ballasting, drain, &c. The side walls are 18 inches thick, like the arch which constitutes the roof. *Fig.* 2, which represents the transverse section of the Linsdale and Kilsby tunnels, both on the North-Western railway, has an elliptical arch, consisting of several circular arcs, of which the lower pair, extending from the invert to the point marked *b*, are struck from radii of 42 feet 8 inches, the centres being upon an horizontal line 8 feet 4 inches above the springing of the invert; the portion from *b* to *c* has radii of 21 feet, the centres being on the same horizontal line; that from *c* to *d* has radii of 14 feet 4½ inches; and the crown of the arch is a curve of 9 feet radius. In this case also the invert, instead of being struck from a centre in the crown of the arch, has its centre some feet below it. The internal height of this tunnel is altogether rather more than 27 feet, and its greatest width is 24 feet. These dimensions are rarely much exceeded on railways of the ordinary gauge, where two tracks are provided for; and for a single track perhaps 12 feet wide and 16 feet high may be taken as an average. Both the invert and the arch should be built in half-brick rings, care being taken to put in the proper number of bricks to each ring, that the bearing may be uniform. In tunnels of the ordinary dimensions, each ring should contain five more bricks than that immediately within it. The side walls may be built in what is called English bond, consisting of alternate courses of headers and stretchers. The bricks should always be of the best quality, and, when the form of the tunnel requires it, moulded of a taper shape. In the laying also care is requisite, and every brick

* As before stated, it was found necessary, in most parts of this tunnel, to increase the thickness of the brickwork from 18 to 27 inches.

should be bedded with a wooden mallet, and the joints, if in mortar, well flushed up. The thickness of the lining is regulated by the nature of the ground; but Lecount says that 27 inches at the top and sides, and 18 in the invert, if laid in cement, will be sufficient, even in a quicksand: there are, however, instances of a thickness of 10 rings, or 45 inches. It is sometimes considered advisable to lay the first or inner ring of the roof without mortar, and then to grout it, by which means an equable pressure is insured.

A brick drain, built in Roman cement, with the joints left open for about half an inch to admit water from the ballasting, should be laid along the centre of the tunnel; and if the shafts let in water, it should be collected and conducted down the inside of the arch by pipes. Water should be excluded as much as possible during the building of the tunnel and shafts, by puddling with clay, or such other means as the circumstances may dictate; but whatever precautions may be used, water will frequently percolate through the brickwork to a serious extent. At the Chevet tunnel, near Wakefield, this inconvenience has been remedied by lining the roof with sheet zinc. In the Thames tunnel there is an interior lining of cement, behind which channels are provided in the brickwork for the passage of water. A remarkable instance of difficulty arising from this cause occurs in the Beechwood tunnel, 302 yards long, upon the London and North-Western railway. It passes through alternate strata of rock and marl abounding in springs; and, in the first winter after its erection, a chemical action took place, which partially destroyed many of the bricks. It was proposed to line the arch with cement; but an apprehension was entertained that it would not adhere, owing to the constant dropping, and it was determined to apply an interior lining of brickwork, 9 inches thick, and to cut chases in the old work, which, when closed in by the new arch, should become so many drains, 4½ inches square, to conduct the water to the central drain or culvert. The tunnel was divided longitudinally by a temporary partition, and the work was executed in one-half of the tunnel at a time, without stopping the passage in the other half. After executing as much as possible of the brickwork in this way, a series of bearers was laid overhead supporting a close flooring, on which the men stood to complete the arch. The details of this curious operation, which was completed in forty days, in the latter end of the year 1840, were fully detailed by Mr. T. M. Smith, in a paper laid before the Institution of Civil Engineers.

In laying the roadway in a railway tunnel care should be taken to avoid the use of any ballasting of a character likely to retain water. The ballast is sometimes thrown down the shafts on to an inclined plane at the bottom, which conducts it in the right direction. In spreading it, it should be well beaten down with wooden rammers, and the blocks or sleepers should be bedded with great care. As it is especially desirable to avoid all risk of accident in travelling through tunnels, while their darkness might prevent the immediate detection of any derangement of the rails, some engineers, for greater security, place the sleepers or points of support closer together in tunnels than on other parts of the line. The temperature being more uniform than in the open air, renders it easy, with proper care, to provide more accurately than usual for alterations in the length of the rails by expansion and contraction.

Although, in the majority of cases occurring in railway and canal practice, tunnels are constructed in the manner just described, there are exceptions which require notice. In tunnelling near the side of a hill expense is occasionally saved by driving horizontal or nearly horizontal passages, which are called *galleries*, from the face of the hill to the line of the tunnel, and removing the excavated earth through them. The double tunnel through the Shakspere Cliff, near Dover, on the line of the South-Eastern railway, was constructed in this way. A benching or road was formed along the face of the cliff, to afford the means of access for the workmen; and the tunnel was excavated by means of seven galleries opening in the face of the cliff, and inclining towards the sea at the rate of 1 in 176. Their average length was about 400 feet; their width 6 feet, and their height 7 feet; and the excavated chalk was conveyed along them in small tram-waggons, and tipped into the sea. There are also seven vertical shafts of 6 feet diameter, and of an average depth of 180 feet. The tunnel consists of two arches or passages, 12 feet wide, separated by a wall of chalk 10 feet thick; they are about 19 feet high to the springing of the arch, which is of a Pointed or Gothic form, and about 30 feet high in the centre; and each has a single track or line of railway laid through it. The chalk of which the cliff is composed is very hard, but it consists in many places of small detached masses, so that brick lining is required for about two-thirds of the whole length of the tunnel. The arching consists generally of three half-brick rings, and is strengthened at intervals of 12 feet by counter-forts, which are carried up and stepped back, so as to sustain the weight of any flat beds of chalk that appear of doubtful stability.

Another variation from the ordinary process occurs in those tunnels which are formed by means of an open cutting, and subsequently covered in. Such are called *open tunnels*, and are sometimes preferred where the object of the tunnel is to avoid the permanent severance of lands rather than to penetrate ground too elevated for an open cutting. The short tunnel on the London and North-Western railway, at Kensall Green, and parts of the Underground railway, in London, were formed in this way. In such cases the sides of the cutting are made nearly vertical, and supported by timbers until the brickwork is executed.

While the projects for some of the earliest English railways were before parliament, much discussion took place relative to the ventilation and lighting of tunnels, and to the effect which they might have upon the health of persons riding through them. Most of the objections raised against tunnels during the period referred to are now exploded, and some of them appear not a little ridiculous. It was urged by their opponents that the damp cold air common to all subterraneous excavations would prove highly detrimental to health; that the noxious gases emitted from the locomotive engines would accumulate and render the air irrespirable; and that the sudden transitions from light to darkness, and *vice versâ*, would be very injurious to the sight. The discomfort arising from these evils, so far as they really exist, and from the deafening noise of tunnel-travelling, are amply sufficient to give a preference to an open cutting, when such a line is obtainable at moderate expense, but they by no means bear out the predictions of the alarmists. Some interesting experiments made in the tunnel on the Leeds and Selby railway are recorded in a paper by Mr. Walker 'On Ventilating and Lighting Tunnels,' in the 'Transactions of the Institution of Civil Engineers,' vol. i. p. 95. While the tunnel alluded to was in progress, it was determined to leave the working shafts open, to promote ventilation and to admit light. The former object was sufficiently attained to prevent any serious inconvenience to passengers, but, so far as the trains are concerned, little benefit is derived from the light admitted by them, although attempts were made to diffuse it by means of tin reflectors. The experiment succeeded so far as to enable a person to read the larger print in a newspaper advertisement in any part of the tunnel; but it is stated that, owing to the rough and dirty state of the walls and the obliquity of the rays thrown upon them, the rays reflected from them were too feeble to be useful in a case of such sudden transition from the light of day as that experienced by persons passing through with a train. Reflectors would also be rendered useless during the passage of a train by the quantity of steam emitted by the engine. In order to settle the question as to the supposed unhealthiness of tunnels, in February, 1837, Dr. Paris, Dr. Watson, Mr. W. Lawrence, lecturer on anatomy and surgery, Mr. R. Phillips, lecturer on chemistry, and Mr. Lucas, surgeon, were requested to visit and report upon the Primrose Hill tunnel. Although the ventilation was then imperfect, owing to the western extremity of the tunnel being unfinished, and the steam was allowed to escape from the engine for a space of twenty minutes, during which it remained stationary in the tunnel, those gentlemen reported that for so many feet above their heads the atmosphere remained clear, and apparently unaffected by steam or effluvia of any kind, and that neither damp nor cold was perceptible. They further express their opinion "that the dangers incurred in passing through well-constructed tunnels are no greater than those incurred in ordinary travelling upon an open railway or upon a turnpike-road; and that the apprehensions which have been expressed that such tunnels are likely to prove detrimental to the health or inconvenient to the feelings of those who go through them are perfectly groundless." These opinions are fully corroborated by the observations of Drs. Davy, Williamson, and Reid, upon the Leeds and Selby railway tunnel, which, as well as the report on the Primrose Hill tunnel, were given in evidence before the Select Committee of the House of Commons on the London and Brighton railways, in 1837. The objection arising from darkness is obviated on the London and North-Western and many other railways by the use of lamps in the roofs of the carriages, which afford an agreeable though small degree of light in the interior; but in a few cases the tunnels themselves are lighted by gas-lamps attached to the side walls.

The above description of the practical operations of tunnelling is founded upon the methods used by railway engineers; but there is no difference between the execution of a railway or of a canal tunnel. A list of some of the most important tunnels is added, and their cost per yard lineal is affixed wherever it is possible so to do. It may, however, be added that all the works enumerated seem likely to be surpassed in magnitude by the tunnel in course of execution under the Alps of the Mont Cénis range: it is proposed to be about 13,787 yards in length, under a mountain nearly 9000 feet above the level of the rails.

Railway tunnels are usually made about 24 feet wide, and from 23 to 25 feet high, on the narrow gauge; those on the Great Western line are made 30 feet wide by 35 feet high; canal tunnels are rarely executed of larger dimensions than 16 feet 6 inches in breadth by 18 feet in height.

There had been two or three schemes for forming a tunnel under the Thames, prior to that brought forward in 1823 by Mr. (afterwards Sir) Isambard Mark Brunel:—one proposing to connect Gravesend with Tilbury, another to commence at Rotherhithe, a little below the site of the present tunnel; and works had been actually begun at both these places but soon abandoned. Brunel proposed to effect his object by means of a framework or shield, which should support the face of the excavation and allow the earth to be removed on many points simultaneously; the frames or divisions of the shield being then moved slowly forward, and closely followed by a solid mass of brick-work enclosing two arched passages 16 feet 4 inches in height from the invert of the arch, and 13 feet 9 inches span at the springing of the arch. Great difficulties were experienced in the course of the work, and some serious accidents happened from the river breaking through the moist sand and clay through which the tunnel had to be carried. But ultimately all obstacles were overcome, and the work was in 1842 brought to a successful termination, about seventeen years from the commencement of the excavations.

TURBARY, COMMON OF, is a right to dig turf in another man's land, or in the lord's waste. This description of common right may be appendant or appurtenant to a house, but not to land; for the turfs dug in virtue of the right are to be burnt in the house. The right is therefore confined to such quantity as is sufficient for the consumption of the house to which the common of turbary is appendant, and never extends to a right to dig turf for sale.

Where common of turbary is appurtenant to a house, it will pass by a grant of the house with the appurtenances. (2 Rep. 37, *Common*.)

TURBINE. A turbine is a water wheel fixed upon a vertical revolving axis, receiving and discharging water in various directions round its surface. This description of prime mover consists of a drum, bearing a number of suitably formed *vanes*, curved in such a manner as to allow the water leaving them, after it has glanced off from them, to escape with as little velocity or power as possible. Turbines possess the advantage of occupying, comparatively with the power exercised, a very small bulk; and of being equally efficient with large or small falls.

There may be considered to be three classes of turbines: 1st. Those in which the water is supplied and discharged in a direction parallel to the axis; they are technically known as the *parallel-flow turbines*, according to the classification proposed by Professor Rankine, in his 'Treatise on Prime Movers.' 2nd. Those in which the water is supplied and discharged in currents radiating from the axis: or the *outward flow turbines*. And 3rd. Those in which the water is supplied and discharged in currents converging radially towards the axis, or the *inward flow turbines*. The leading principles affecting the working of these various machines are the same, though the details are necessarily dissimilar; they may be briefly described as follows:—

Whatever description of turbine be used, it is desirable that little or no change of velocity of flow should take place in the current, during the passage of the water through the wheel; and that the water should enter without shock, and leave without a whirling motion. The latter condition is attained when the ratio of the entering velocity is to the outgoing velocity in the same ratio as the radius of the receiving to that of the discharging sides; or calling this ratio n, it $=1$, in parallel flow turbines; $\sqrt{2}$ in outward flow turbines; and $\frac{1}{2}$ in inward flow turbines. The angles of obliquity of the blades to the line of flow, differ according to the velocity required in the wheels, and to their peculiar form: thus, in the parallel flow turbines, the angle may vary between 20° and 35°; in the outward flow turbines, between $14\frac{1}{2}$° and $26\frac{1}{2}$°; and in the inward flow ones, between 36° and 54°, the best velocity at the middle of the rings of the vanes appears to be ascertained by the formula (for all kinds of turbines)—calling v the velocity, h the head in the supply chamber, and g the accelerating force of gravity: then $v=0{\cdot}655\sqrt{2gh}$.

From General Morin's experiments it would appear that the efficiencies of the respective descriptions of turbines, with reference to the powers exerted upon them, are comprised within the limits of from 75 to 80 per cent. of the power exerted in the parallel flow turbines; in inward flow turbines the limits approach closely the average of 73 per cent.; and in outward flow ones, they are on the average 68 per cent.; on the average then, the efficiency of all classes may be taken to be about 70 per cent. of the total power. The reaction wheel may be considered to constitute a modification of the turbine; and it will be discussed more fully under Water Power.

The best descriptions of this class of engines are to be found either in Rankine's work before quoted; in Morin's 'Leçons de Mécanique Pratique;' in Armengaud's 'Traité Pratique des Moteurs Hydrauliques;' and in several of the practical papers on machinery by Mr. Fairbairn. M. Fourneyron has published a description of the outward flow turbines he himself invented, with full instructions for ascertaining the proportions of the several details.

TURF, the sod which covers the surface of pastures, and is composed of a portion of the soil with the roots of natural grasses or other plants; which gives the whole a consistence, and allows of its being raised in slices by the plough, or the paring tool made for the purpose.

The word is often also applied to the substance which is generally called *peat*; and when the latter is taken from the surface where living plants are growing, the name of turf is very applicable to it. It is derived from the Dutch word *torf*, which is generally applied to perfect peat as well as to turf. The origin and composition of peat have been described under that head. [Peat.] We shall here only notice the uses to which turf is applied, when we mean a sod taken from the surface on which some living plants are still or have lately been growing. Near extensive heaths which have never been reclaimed, and in situations where no regular peat-bogs are to be found, turf becomes a very useful fuel. It is pared off the surface with the heath growing on it, in dry weather, in sods of a convenient size, generally round, and about one foot in diameter. The thickness of the sod depends on the depth and abundance of the roots found in it, as they are the sole cause of the turf continuing to burn when the blaze caused by the burning of the heath is over. As the soil of the places where turf is usually cut is generally of a sandy nature, turf ashes are not so valuable for manuring the land as peat ashes; still they contain portions of potash and other vegetable salts, and produce a very good effect when spread as a top-dressing on moist meadows the soil of which is chiefly composed of clay. In sufficient quantities they are excellent to raise turnips; and it is generally observed that where poor heathy pastures are pared for the purpose of burning the turf on the spot and spreading the ashes, the turnips sown there seldom fail. For the advantages and disadvantages of this operation, see Paring and Burning.

Where the poor can readily obtain turf for the trouble of cutting it and drying it for use, a degree of comfort is diffused through their cottages which cannot be found where fuel is scarce. In the large open chimney the whole family can be seated by a pile of turf burning on the hearth.

Turf is used for many other purposes, as well as for fuel. Laid like tiles on a roof, overlapping each other, they form an excellent and cheap protection against rain. Cut somewhat thicker, and in the shape of bricks, they serve to build the walls of cabins, which are warm and durable, provided the eaves of the roof project sufficiently to cover them. The soldier who has served through many campaigns knows from experience that a conical hut of turf can be raised in a very short time, if the material is at hand.

When clay is burnt to improve the texture of the soil, the operation is best performed in a circular hearth made of turf, with certain flues to regulate the supply of air to the burning mass. The turf is a slow conductor of heat, and by its means the mass is kept burning steadily in the interior of the heap, without being cooled by the effect of the external air. When the turf-wall itself begins to burn through, it is generally the proper time to mix the whole and extinguish the fire.

The turf which we have been considering is taken from the surface of uncultivated land, and in the course of a certain number of years the wild heaths and other plants natural to the soil spring up again, and by their stems and roots produce a fresh turf. To assist this renovation it is usual to cut the flat turfs of a circular shape with a thin paring tool, as we observed before, so that there remain portions of the surface which are not disturbed, and from which the heath and wild plants soon spread over the surface which has been cut. In this way the same spot may be made to give a fresh supply of turfs every seven years. This is only done where the soil is absolutely barren, and where its cultivation is not thought of; for at last every remnant of good earth is carried off the grasses disappear entirely, and nothing but the common heaths can find food for their vegetation.

The surface of good pastures, especially of commons, is often pared for the purpose of forming an artificial turf for ornament or for the purposes of pasture. In the first case those spots are chosen where the grass is of the finest and closest pile. The surface is pared as thin as can conveniently be done, so that the sward shall not break. A proper spot having been chosen, it is divided by the spade, or some sharp instrument like a knife stuck across a long handle, into strips about a foot wide; and a very sharp flat instrument with a bent handle, so as to work horizontally, is thrust an inch, or a little more, below the surface, paring off the strip which has been marked. As the workman who cuts the sod advances, another rolls it up before him, until it is of a proper size to be carried off. A cut is then made across the strip, and another roll is begun. Thus a large space may be completely bared, or parallel strips may be cut out, leaving some of the turf uncut between them. In this case the loss of the herbage will be soonest repaired by the spreading of the grasses from the strips which are left. When an ornamental lawn is to be formed by laying down the turf, the ground is levelled, or laid in any desired form. It is well rolled and beaten, to make it firm, and, if the weather be dry, it is well watered before the turf is applied. As lawns require frequent mowing, a close, slow-growing turf is a great advantage: it should therefore be taken, if possible, from a poor thin soil. The turf which lies immediately over the chalk is best adapted to this purpose. If the ground to be covered is of a rich quality, it is best to remove the soil and lay some of the poorer subsoil bare, to place the turf on. A rich moist soil would make the grass grow too rank, and require constant mowing and rolling to keep it down. Brickbats and rubbish are often spread over the ground, where a lawn is to be formed by turfing it over: these not only form a poorer soil, but also keep it drier by their porosity. It need not be observed, that where turfing is resorted to, to cover bare places in meadows or pasture, the reverse of all this should be done, and manure spread over the places where the turf is to be laid, so that the roots may be invigorated, and a rich pile of grass may spring up.

When there are banks and inequalities in pastures, it is often useful to pare off all the turf, rolling it up, from the places which are to be levelled. The superfluous soil is then removed, and if it has been long in the form of a dry bank, it is spread over the grass, which it greatly invigorates. The new surface is enriched with manure, if it requires it, and in moist weather or after watering it, the turf is rolled over it and well beaten down. A heavy roller drawn over it will greatly assist its rooting, and thus an unsightly bank, on which the grass was usually either coarse or burnt up, according as the season was wet or dry, becomes a good and neat pasture. Another important use of turf is to cut it into small strips and divide these into pieces of a square inch in size, or somewhat more, for the purpose of laying land to grass by *inoculation*. This is only a partial turfing, which extends rapidly, and in the course of a very few years converts a field which was not very productive as arable land into a valuable meadow, especially if it is so situated as to be capable of occasional irrigation.

The advantage of an extent of fine turf for the exercise of high-bred horses has given a name to the pursuit of breeding and training horses for the purpose of racing. The annals of the turf record the deeds of famous horses and the success of their owners. The turf has its rules and codes of laws, and the highest individuals in the nation often sit in judgment on some disputed point of turf law, with as much gravity as they would decide the most important interests of the state.

TURKISH CHRONOLOGY. The Turks, like all the other Mohammedans, have adopted the æra of the Hijra, which begins with the 16th of July, A.D. 622. [ÆRA.] The year of the Hijra contains 12 months of alternately 30 and 29 days, or, more exactly, 354 days 8 hours, and 48 minutes; and 32 of our (solar) years are equal to 33 Mohammedan (lunar) years, 6 days, 8 hours, and 16 minutes. On these facts is founded the following easy rule for finding the Christian year which corresponds to any given Mohammedan year:—

The number of centuries contained in the given Mohammedan year is multiplied by 3; to the product are added as many units as the period of 33 years is contained in the number of those years which are in the given Mohammedan year besides the centuries; the sum thus obtained is deducted from the given year; and to the rest is added 621, or the number of full Christian years before the beginning of the Hijra: the sum thus obtained corresponds to the Christian year.

Example: What year of Christ corresponds to the Mohammedan year 1188 (peace of Kuchuk Kaïnarji)?

11 (the number of centuries) × 3	=	33
2 (the units of the period of 33 years contained in 88) + 33	=	35
1188 (the given year) − 35	=	1153
621 (the number of years before the Hijra) + 1153	=	1774

This is correct, the peace of Kuchuk Kaïnarji having been signed in A.D. 1774.

To change a Christian year into a Mohammedan year requires only an inversion of the preceding rule.

Example: What Mohammedan year corresponds to the Christian year 1774?

1774 − 621	=	1153
11 (the number of centuries in 1153) × 3	=	33
1 (the number of times which 53 contains 33) + 33	=	34
34 + 1153	=	1187

We have seen above that the Mohammedan year corresponding to the Christian year 1774 was 1188; but the result is correct notwithstanding the different results in the two cases; for the beginning of A.D. 1774 falls in the latter part of A.H. 1187, and the beginning of A.H. 1188 and the greater part of this year falls in A.D. 1774. Thus the latter rule is only the complement of the first, and by employing both the reader will always know whether a given Mohammedan year falls entirely in one Christian year, or whether it falls in part of one and in part of another Christian year; and he will know the same for a Christian year with regard to a Mohammedan year. If this be true, the consequence will be that, if a Mohammedan year falls entirely in the course of one Christian year, there will be no difference in the result obtained by employing successively both the rules. This is in fact the case, as may be seen by the following example:

The year A.H. 522 begins on the 5th of January, A.D. 1128, and ends on the 24th of December of the same year 1128.

Rule 1—for A.H. 522 : 5 × 3	=	15
522 − 15	=	507
507 + 621	=	1128
Rule 2—for A.D. 1128 : 1128 − 621	=	507
5 (centuries) × 3	=	15
15 + 507	=	522

from which we may conclude that the year 522 A.H. falls entirely in the course of the year 1128 A.D. To make this more intelligible, we observe that the Mohammedan year being composed of lunar or moveable months, its beginning is likewise moveable, and in the course of 33 years it goes successively through all the twelve months of our year. The above-mentioned two rules will be good till A.H. 1401 (A.D. 1980). The determining of the corresponding days of the two eras presents considerable difficulties, and cannot conveniently be given here.

TURKISH LANGUAGES AND LITERATURE. The Turkish languages form a particular family, which differs from the Arabic, the Persian, the Mongol, and the Chinese. The principal Turkish languages are the following:—

1. Uighur. This language is considered the most ancient of all the Turkish dialects, and is still spoken in eastern Turkistán, especially in the country between Káshghar and Kámul. The Uighur was originally written with fourteen, and afterwards with sixteen letters, which, according to Abel Rémusat, are an imitation of the Syriac alphabet, although there is some reason to believe that they have been invented by the Uighurs themselves. They were afterwards adopted by the Mongols, who however have modified them. The Uighur language was cultivated at a very early period, and, as it seems, has had considerable influence on the Chinese literature. The number of foreign words introduced into the Uighur is not very considerable, and this language is consequently the purest of all the Turkish dialects. The Bodleian Library contains a beautiful Uighur manuscript, the 'Bakhliyár-Námeh,' written in A.H. 838 (A.D. 1434). Two other Uighur manuscripts on Mohammedan divinity are in the Royal Library at Paris, and a fourth, the 'Kúdatku-bilik,' or 'The Science of Government,' was sent to Paris by Von Hammer Purgstall. This work was computed about A.H. 460 (A.D. 1069), during the reign of Alp-Arslán, sultan of the Seljuks; but the copy of Von Hammer dates only from A.H. 843 (A.D. 1459). The Uighur language is very little known in Europe.

2. Jagatái, in the greater part of independent Turkistán. This language, which was originally written with the Uighur characters, and which, in ancient times, greatly resembled the Uighur language, is remarkable for its strength, perspicuity, and simplicity. Turkistán, especially Samarkand and Bokhara, having been the centre of the power of the successors of Genghis-khan and Timur, the Jagatái was cultivated at an early period, and many Arabic and Persian words were introduced into it. The Arabic characters were substituted for the Uighur letters, but not till a considerable time after the Mohammedan religion had been introduced into Turkistán. The Jagatái language has a valuable literature. The 'Wáki'áti Báburí' is an autobiography of Sultan Báber, the conqueror of Hindustán (A.H. 900 till 938; A.D. 1494 till 1531). It has been translated into English under the title 'Memoirs of Zehir-ed-dín Muhammed Baber, Emperor of Hindustan, written by himself;' translated partly by the late John Leyden, M.D., and partly by W. Erskine, Esq., 4to., London, 1826. It has also been translated into Persian. The famous 'Genealogical History of the Turks,' by 'Abú-l-ghází (Bahádür Khan, Sultan of Khowarcsm), was originally written in the Jagatái language. The first manuscript of this work known to Europeans was discovered by Swedish officers, who, after the battle of Pultawa, were sent as prisoners to Siberia.

One of them translated it into French, from which language it was re-translated into English, under the title 'The Genealogical History of the Tatars,' which forms the first volume of 'A General History of the Turks, Moguls, and Tatars,' 2 vols. 8vo., London, 1730. The text of 'Abú-l-gházi has been edited by Frähn. (Kazan, 1825.)

3. Kiptshak dialects, in the eastern part of European Russia and Western Siberia. The purest among these dialects is that of Kazan, in which several books have lately been printed. Some of these are much mixed with Finnish words.

4. Kirghiz, the language of the Kárá Kirghiz, and the Kirghiz Kaïsák, who live a nomadic life between the Ural and the Chinese frontier.

5. Caucaso-Danubian, in several subordinate dialects spoken by the Noghaïs, the Kazi-Kumüks, and other Turkish tribes in southern Russia.

6. Turkomán.

7. Austro-Siberian dialects. They are very numerous, and more or less mixed with Mongol or Samoyedo words. They are spoken by the Turkish tribes that live in the middle, eastern, and southern parts of Siberia.

8. Chuwash, spoken by the Chuwashes, who live between the Sura and the Wolga, and in some adjacent countries of eastern Russia. The Chuwash differs considerably from the Kiptshak dialects in the neighbouring countries, and it contains a great number of Finnish words. (Schott, 'De Lingua Tschuwaschorum Dissertatio.')

9. Osmanli, or Turkish, commonly called so. This dialect, which is spoken by the Turkish conquerors of the Byzantine empire, must be considered as a compound of the ancient Seljukian language and that of the tribe of the Káyi, from which the Osmanlis are descended. It is the richest and most polished of all the Turkish dialects; and its regularity, precision, and elegance are such, that Jaubert says, if any academy were commissioned to make a language, it would not form one more perfect than the Turkish. Another principal feature of this language is its dignity, with regard to which Sir William Jones says, "The Turkish language has an admirable dignity. The Persian is fit for joyous and amatory subjects, the Arabic for poetry and eloquence, but the Turkish for moral subjects. Turkish is now the the diplomatic and official language not only of Turkey, but Egypt, Tunis, and Tripoli, and formerly of Algiers. The Osmanlis having received their civilisation from the Arabs and the Persians, and the Korán (which among the Mohammedans is never translated from the Arabic into any other language) being still the source of theology and legislation, a great many Persian and Arabic words have gradually found their way into the Turkish language. However the groundwork is Turkish, and the Turks pronounce the Arabic words in a much softer way than the Arabs, a difference which is principally remarkable in the pronunciation of the gutturals and the long vowels.

The Turkish alphabet is composed of thirty-three letters, twenty-eight of which are taken from the Arabic alphabet: four (*pü*, *chim*, *yä*, and *ghief*) from the Persian; and one, the "Saghir nún" (*ñ*) is exclusively Turkish. These letters are written from right to left. Turkish is also, and very frequently, written with Armenian characters, especially by the merchants. There is no article, but the demonstrative pronoun "bu" ("that" or "this"), and the cardinal number "bir" ("one") sometimes take its place. There is no gender. The declension of the nouns is easy: the plural is formed by annexing "ler" or "lar" to the word, and there are six cases as in Latin. The adjectives have neither declension nor gender. The declension of the pronouns is analogous to that of the nouns, but not always exactly the same. There are eight kinds of verbs, namely, auxiliary, active, passive, negative, impotential, causative, reciprocal, and personal. The infinitive of all regular verbs is formed by means of the syllables "mek" or "mak;" they become passive by taking the syllable "il" before "mek" or "mak." The verbs have six moods—indicative, imperative, optative, suppositive, conjunctive, and infinitive; and there are five tenses—present, imperfect, preterimperfect, preterperfect, and future. The different kinds of verbs are formed as follows: *sewmek*, to love; *sewmemek*, not to love; *sewehmemek*, not to be able to love; *sewilmek*, to be loved; *sewilmemek*, not to be loved; *sewilehmemek*, not to be able to be loved; *sewdürmek*, to make love; *sewildürmek*, to make that somebody is loved; *sewishmek*, to love each other; *sewinmek*, to love oneself, &c. There is a considerable number of irregular verbs. The Turkish construction resembles that of the Latin language, and generally a sentence cannot be perfectly understood till the reader comes to the last word. The Turks form new words by means of composition with as much ease as the Greek, the German, and the Persian; in this respect the Turkish language differs radically from the Arabic.

The Turkish literature is of ancient origin. During the reigns of Osman and his successors, a great number of Arabic, Persian, Greek, and Latin works were translated into Turkish. Mohammed II. ordered a translation of Plutarch; Soliman I. had the 'Commentaries' of Cæsar translated; and Aristotle and Euclid were translated in the commencement of Turkish history. Mustafa III. made a translation of the 'Principe' of Machiavelli, and of the 'Anti-Machiavel' of Frederic II., King of Prussia. Some of the works of Boerhaave, Sydenham, Bonnycastle, Vauban, Lalande, Cassini, and, in later times, a great number of English, German, and French works on history, geography, medicine, chemistry, mathematics, and the military sciences, have likewise been translated into Turkish. The original literature of the Turks is valuable, though less so than the Arabic. Jem, the brother, and Selím and Korkud, the sons of Bayazid II.; Soliman II., Ahmed III., and Mustafa III., were distinguished poets, and their works have come down to us. The oldest Turkish poet of renown is 'Ashik-Pasha, who lived during the reign of Osman and Urkhan. The reign of Bayazid II. was distinguished by the following poets:—Nejáti, who was considered the first lyric poet of his time, and who translated several Arabic works into Turkish; Mesíhí, whose 'Ode on the Spring,' translated by Sir W. Jones and by Baron Hammer, is known as one of the finest specimens of poetry; A'fitabí, Munirí, Prince Korkud, and the female poet Mihrí, a native of Amasia. Bakí is the greatest Turkish poet. He was three times high judge of Rúm-ili, and died in A.H. 1008 (A.D. 1600); his 'Diwan,' or 'Collection of Poems,' has been translated by Von Hammer, under the title 'Bakí's des grössten Türkischen Lyrikers Diwan,' Vienna, 1825. Nabí Efendi, Seyed Refet, and Rághib-Pasha, were renowned in the past century. Rághib-Pasha, grand-vizír under Osman III., was equally renowned as an historian and a poet, and his countrymen used to call him "the Sultan of the poets of Rúm." The number of historians is very great, and several of them are highly esteemed for their impartiality, judgment, and the concise beauty of their style. Such are 'Ali, the contemporary of Bakí, whose work, 'Kunhol-Akhbár' (Mines of History), finished in A.H. 1006 (A.D. 1597), is one of the best sources concerning the earlier and middle periods of Turkish history; the author speaks with great impartiality about the Christians. Solak-záde has written 'Taríkhí 'Ali Osman li Solak-záde,' a short, but very exact history of the Osmanlis, which finishes with the year A.H. 1054 (A.D. 1644). Pechewí is the author of a history of the period from the accession of Soliman I. (II.) to the year A.H. 1032 (A.D. 1622). Hájí Khalfáh, who died in A.H. 1068 (A.D. 1658), is the author of several excellent works on history and geography, which are written partly in Arabic, partly in Turkish. His 'Takwimuk Tewárikh,' or 'Chronological Tables,' are classical. They were published at Constantinople by the printer Ibráhím, in A.H. 1146 (A.D. 1733), and an Italian translation by Rinaldo Carli was published at Venice as early as 1697. Hájí Khalfah's Geography of Rúm-ili and Bosnia has been translated into German by Von Hammer. From the time of Bayazid II., Turkish history has been written by imperial historiographers, a list of whom is contained in Hammer-Purgstall's 'Geschichte des Osmanischen Reiches,' vol. viii., p. 591-92. The best of these historians are—Edris, or Idris (died in A.H. 930; A.D. 1523); Mustafa Jelal-záde (died in A.H. 940; A.D. 1533); Sead-ed-dín, who became Mufti (died in A.H. 1007; A.D. 1599); 'Abdi-Pasha Nijánjí (died in A.H. 1102; A.D. 1690); Naïma (died in A.H. 1128; A.D. 1715), whose history contains the period from A.H. 1000 till 1070 (A.D. 1592 till 1659); Rashid continued the history till A.H. 1134 (A.D. 1721); 'Asim, the continuator of Rashid, till A.H. 1141 (A.D. 1728); Subhí continued it till A.H. 1156 (A.D. 1743); Izí till A.H. 1163 (A.D. 1763); and Wassif till A.H. 1188 (A.D. 1774). The annals of Naïma were published at Constantinople in A.H. 1147 (A.D. 1734); those of Rashid in A.H. 1153 (A.D. 1740); those of Subhí in A.H. 1198 (A.D. 1784); those of Izí in the same year; and those of Wassif in A.H. 1188 (A.D. 1774); and afterwards in A.H. 1243 (A.D. 1827). The Annals of Wassif have been partly translated into French by M. Caussin de Perceval.

Among the numerous Turkish biographers, Latifi deserves particular mention. He wrote the lives of about two hundred Turkish poets, one hundred and two of which have been translated into German by Chabert (Zürich, 1800, 8vo). A list of the works published in Turkish, at Constantinople, is contained in Hammer, cited above, vol. vii. p. 583-595; and a continuation of it, which goes down to the year A.D. 1830, in vol. viii., p. 518-523. The 'Wiener Jahrbücher' contain a list of the Turkish works published since A.D. 1830.

Turkish literature has been enriched by numerous works on morals, divinity, and philosophy. Their philosophy, which originated from the famous school at Bokhara, has a mystical character, and resembles in many points the speculative doctrines of Schelling, especially with regard to pantheism. More than one Turkish sheikh has proclaimed the possibility of the identification of the soul with God, and the intellectual re-creation of the world; a doctrine which has likewise been professed by Hegel.

(Toderini, *Letteratura Turcha*; Hammer-Purgstall, *Encyclopädische Uebersicht der Wissenschaften des Orients*, and *Geschichte der Osmanischen Dichtkunst*, 4 vols. 8vo; the *Turkish Grammars* of Davids, of Jaubert, of Hindoglu and of Barker; and the *Dictionaries* of Kieffer, of Bianchi, and of Redhouse; as well as the great *Arabic, Persian and Turkish Dictionary* of Meninski.)

TURMERIC. [COLOURING MATTERS; CURCUMA LONGA.]

TURNBULL'S BLUE. *Ferricyanide of Iron.* Professor Graham's account of this variety of Prussian blue is nearly as follows:—It is formed by adding ferricyanide of potassium (red prussiate of potash) to a protosalt of iron. It results from the substitution of three equivalents of iron for three equivalents of potassium. The same blue precipitate may be obtained by adding to a protosalt of iron a mixture of yellow prussiate of potash, chloride of soda, and hydrochloric acid. The tint of this blue is lighter and more delicate than that of Prussian blue. It is occasionally used by the calico-printer, who mixes it with perchloride of tin, and prints the mixture, which is in a great measure soluble, upon Turkey red cloth, *raising* the blue colour afterwards by passing the cloth through a solution of chloride of lime, containing an excess of lime. The chief object of this operation is to discharge the red and produce white patterns, where tartaric acid is printed upon the cloth, but it has also the effect incidentally of precipitating the blue pigment and peroxide of tin together on the cloth, by neutralising the chlorine of the perchloride of tin. This blue is believed to resist the action of alkalies longer than ordinary Prussian blue.

TURNER'S YELLOW. *Cassel Yellow: Patent Yellow.* This is an oxychloride of lead, which may be prepared by different processes. When litharge, or the protoxide of lead, is acted upon by a solution of common salt, there are formed soda, which remains dissolved, and a white compound, which is hydrated oxychloride of lead; and this, when heated, loses water, becomes of a yellow colour, and is the compound required. It is composed nearly of one part of chloride and nine parts of oxide of lead: it may also be obtained by heating chloride and oxide of lead together in the requisite proportions, or by heating a mixture of one part of chloride of ammonium with ten parts of protoxide of lead. In fusing these compounds, it is requisite to be extremely careful to avoid any admixture of carbonaceous or combustible matter, as that would reduce a portion of the oxide of lead to its metallic state, which would injure the colour of the product. [LEAD: *Oxychlorides of Lead.*]

TURNING is the art of giving circular forms to articles of wood, ivory, metal, and other materials. The kinds of wood mostly used for common toys are alder, beech, birch, and willow; for the best Tonbridge ware, holly, chesnut, sycamore, apple, pear, and plum; for hard general turnery—beech, box, elm, oak, and walnut; and mahogany and pine for various purposes.

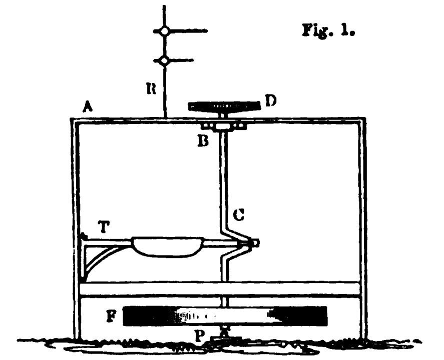
Nearly all kinds of turning are effected by the aid of the *lathe.* The principles of this valuable machine may be summed up in a few words. For every point marked by the workman, it produces a circle; and it may be described as a machine for moving the material to be wrought in such a manner that, being fixed opposite to the tool, any point in the circumference will act upon the whole circle in precisely the same way.

Pole-lathe.—This is the primitive and most simple kind of lathe. It consists of two upright pieces, each having a conical iron or steel point fixed on the side opposite the other, the two points being exactly in a line; one of these uprights, or *puppet-heads,* as they are called, is stationary; the other can be moved along and fixed at any part of the bed by a wedge beneath. The wood to be turned being cut of proper length, the centre of one of its ends is pressed against the point of the fixed puppet; the point of the other puppet is then brought against the centre of the other end, and the puppet wedged firmly in its place. Over the lathe, and at right angles to it, is a long flexible wooden pole or lath, whence the name lathe; one end, fixed firmly overhead; the other, just over the end of the work nearest to the left-hand puppet, has a cord or catgut attached to it, which passes once or twice round the work, and is fastened at the lower end to a treadle. The depression of the treadle and counteraction of the pole give an alternate rotatory motion to the work. The cutting tool is held upon the top of a fixed piece, between the two puppets and close to the work, called a *rest,* but can only be applied during the fall of the treadle; and thus a great loss of time is occasioned. On this account the pole-lathe is now but little used. When commencing, a groove is cut to the extreme left of the work for the cord to work in; and if it is required to use that part, the band is afterwards shifted to a finished part. The beginner has one great difficulty to overcome in turning soft wood. The tool requires to be held firmly almost on the top of the work, and the superfluous material shaved off; while the softness of the wood and the velocity with which it revolves cause the work to be easily spoilt by the least unsteadiness of hand. In other turning, the tool is held nearly opposite to the centre of the work, and the superfluous material is scraped away with little comparative danger of accident.

A modification of the primitive pole-lathe is used by watch-case makers, on account of the facility with which it can be arrested at any point of its rotation. Some case-makers, the French in particular, make use of a large *turning-tool* instead of a lathe. It consists of an iron bar upon which slide three puppets, two to support the mandril with its back screw, and the other the rest; a long steel bow worked by the left hand serves instead of the pole and treadle. This turning-tool works easily, costs but little, and where many workmen are employed effects a great saving of room. Tools of this sort, from six inches to two feet long and upwards, are in use among jewellers, goldsmiths, watch and clockmakers, and many other artificers; and others without any mandril, in which the work is held between two points, as in the pole-lathe. One of this latter sort may be converted into a very useful lathe for small work at a trifling expense, and still answer as a turning-tool if required.

The *Potter's-wheel* is the simplest description of rotatory lathe; but it differs from other lathes in being vertical instead of horizontal. C, *fig.* 1, is an iron crank, upon the lower part of which is placed a heavy foot-wheel, F; the lower end of the crank works upon a centre, P, fixed on the floor; the upper in a collar, B, fastened to the work-bench, A, and supports the turnboard or chuck, D, upon which the clay to be worked is placed. Motion is given to the crank by means of a treadle placed at the back, and connected with the throw of the crank by a

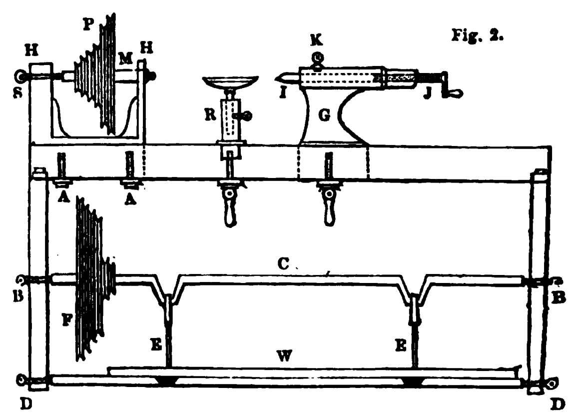
Fig. 1.



hook or rod. For large work the wheel is provided with a winch and bevil gear, and is turned by a boy. [EARTHENWARE.]

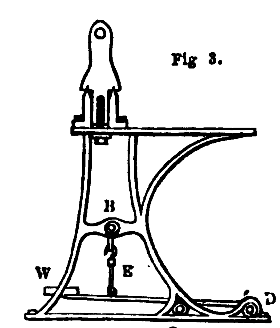
Foot-lathe.—*Fig.* 2 is the front-view of a foot lathe, adapted to all

Fig. 2.



ordinary work, whether in metals, ivory or wood. The headstock, H H, is of cast-iron, with a conical steel ring let into the front puppet within which the mandril works. A steel-pointed screw in the back of the headstock keeps the mandril steadily in its place. The beds are of cast-iron, shown in the end view, *fig* 3, which also shows the manner in which the headstock is fitted upon and between the beds, to which

Fig 3.



it is firmly fastened by two screws, A A, *fig.* 2. The crank, C, is of wrought-iron, supported at each end by a screw, B, *fig.* 2, 3, in the standard of the lathe. The fly or foot wheel, F, has four or five grooves on its edge, and gives motion to the mandril by means of a catgut band, which connects it with the smaller part of the mandril pulley, P. The object of having several grooves upon the wheel and pulley is to allow of the speed of the lathe being regulated according to the sort of work to be turned. But this arrangement only modifies what is called the quick motion. It is frequently necessary that the mandril should move more slowly than the crank; for which purpose a large pulley is placed upon the mandril, and a small one upon the crank, and the two are connected by a band. The treadle is formed of a long iron bar suspended between two points at the back of the frame, D, *fig.* 2 and 3, and carries two shorter transverse bars at right angles, passing under the throws of the crank, and being connected with them by the hooks, E E: the front ends of these two pieces are screwed to the treading-board, W. The standards of the lathe are prevented from altering their position by a rod passing close to the ground, and screwed to each standard at Q. The front-head, G, is of cast-iron fitted on to the beds nearly in the same manner as the headstock. The point of the cylinder, I, to support one end of the work, must be exactly opposite to the centre of the mandril. There are several methods of arranging the cylinder and its screw; but the most convenient is as in the figure, with a screw J, and a winch-handle. K is a small screw with a binding-piece beneath, which rests upon a flat filed on one side of the cylinder, and prevents the latter from shaking during turning. The rest, R, has a jointed lever binding-screw, and several tops to suit different purposes, with a small screw to hold them steadily in the socket.

This completes the lathe itself, but many adaptations are necessary before it is in order for work. Of these the principal are the *chucks* used to connect the work with the lathe. The *screw-chuck* is a circular plate of metal with a boss at the back, tapped to screw upon the nose of the mandril: the face is turned perfectly true, and in the centre is a coarse conical screw to hold any large piece of wood to be turned. The *hollow-chuck* is a strong circular cup of metal with perpendicular sides: the work is either driven into it with a mallet, or, if smaller than the inside of the cup, held by the ends of four screws in its rim. The *drill-chuck* is a strong iron chuck about an inch in diameter, with a square hole in the centre to receive drills and other tools. In drilling, a mark being made with a punch where the hole is to be, the work is held against the point of the drill, and the front-head being brought up to the back of the work, the cylinder is pressed forward, as the drill proceeds, by turning the screw J. The *universal chuck* is a circular disc of metal, with three narrow slits cast in it, extending nearly from the centre to the circumference. The face is turned perfectly true when on the mandril, and the work being laid upon the face of the chuck, is fixed to it by screws which pass through the slits into nuts at the back of the plate. The *concentric chuck* is of the same form as the last described, and the face in like manner must be turned perfectly true to the mandril. Instead of three slits, it has but two, in a straight line with each other, and extending nearly the whole diameter; the opening of these slits is wider at the back than front. Within these slits lies a spindle, having a bearing in the centre and one at each extremity, with a right-hand screw upon one and a corresponding left-hand screw upon the other; these screws move two steel studs which fit accurately within the slits, and have projecting heads about an inch square, that move steadily and smoothly along the face of the chuck. Upon the heads are fitted two other square pieces, having their sides hollowed out in curves of different diameters varying from two to eight or ten inches, and which can be placed with either of their sides towards the centre, to fit the circumference of the work to be held between them.

All the chucks that we have described are adapted principally for work which does not require supporting at both ends. When a long piece of wood is to be turned, a chuck is used having a piece of steel with three points standing out upon its face; the centre of one end of the work is pressed against the middle point, and the other end is supported by the cylinder of the front-head.

The *carrier* is used in metal-work for the same purpose as the three-point chuck for wood. If the ends of the work are pointed, it is supported between the hollow end of the cylinder in the front puppet S, *fig.* 4) and the nose of the mandril, which is similarly shaped for the purpose: if, on the contrary, the ends are hollow, the cylinder is reversed and the point-chuck (*fig.* 5) screwed upon the mandril. The carrier (C, *fig.* 4) is fixed upon the end of the work by its screw, as shown on a larger scale in the side view *fig.* 6; and motion is given to

Fig. 4.

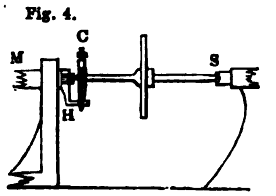


Fig. 5.

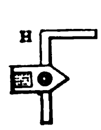

Fig. 6.

the work by the driver H, *figs.* 4 and 5, either screwed upon the nose of the mandril or attached to the point-chuck.

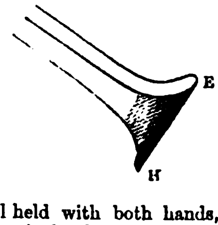
Wood and ivory turners make use principally of box and other wood chucks altered at the instant to suit their purpose. One chuck, however, requires notice, called the split or *ring-chuck*, *fig.* 7: a piece of

Fig. 7.

wood is tapped and screwed on to the mandril and then turned conical; it is afterwards drilled down the centre to the bottom, and two slits cut with a saw at right angles to each other, from the point of the chuck to the nose of the mandril; the work, when in the chuck, is held in its place by the ring on the outside.

The *tools* used in turning are numerous and varied. For soft wood scarcely any are required besides gouges or round chisels with circular points, to rough out the work, and chisels with an oblique cutting edge, sharpened by being ground and rubbed at a very acute angle on each side. To give the workman power to prevent the tool dipping or trembling, the tools are set in very long handles, the ends of which the turner holds between the upper part of his arm and his side. For hard wood, ivory, and bone, similar gouges and chisels are used; but they are smaller, and sharpened at a less acute angle. Some of the work, as in gold, silver, and light brass-work, is performed by gravers with straight, oblique, and curved faces, to suit different sorts or parts of the work. These are sharpened by an angle on the under side only, and the cutting-edge is applied nearly opposite to the centre of the work. For inside work, drills placed in angles are used to make the first opening, which is afterwards enlarged by other tools with this general characteristic, that the stalk is made narrower than the cutting part of the tool, to allow of undercutting or making the hollow within larger than the opening through which the point of the tool is introduced. The principal tools used for turning iron are the hook-tool, *fig.* 8: E is the cutting-edge; the heel, H, is placed firmly upon the top

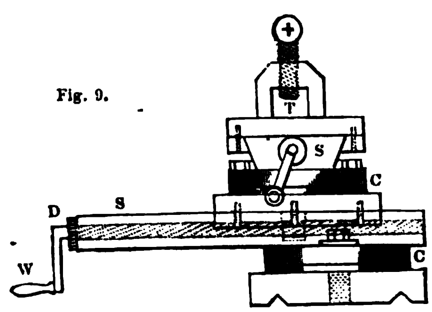
Fig. 8.



of the rest and the tool held with both hands, the end of the handle resting against the turner's shoulder. For finishing the work, gravers of different sizes and shapes are used, similar to those for hard wood, gold, silver, brass, and ivory, but stronger, and sharpened at a more obtuse angle. Screw-tools are very important appendages to a lathe, and, with the engineer, in constant use: they are filed up with several teeth exactly the shape of the spaces between the intended threads. For inside screws the teeth are cut on the side, instead of the front of the tool: *taps* however are much more generally used. A circular saw is often fitted to a lathe, particularly for ivory-turning: the saw is placed upon a spindle against a projecting collar, and held in its place by a washer and nut. A parallel rule is fitted upon the table by the side of the saw to regulate the width of the pieces cut off.

In the lathe, as previously described, the tool is held in the hand, and is consequently subject to any unsteadiness in the workman. To get rid of this imperfection in certain cases, and so arrange that the tool could be withdrawn at pleasure and replaced in the same position, and always be steady, was a great desideratum. This was effected by the invention of the *slide-rest*, which is now attached to all but the most ordinary kind of lathes. The principle of the slide-rest is that the tool is fastened to a plate, moved in the required direction by means of screws, instead of being held in the hand. *Fig.* 9 shows a

Fig. 9.



very usual and convenient form. T is the place for the tool, which is held down by the screw above: the tools are long square pieces of steel reaching beyond the edges of the plate upon which they are fixed. This plate has two small slips or dovetails screwed on to its under surface and fitting the sides of the plate S, which has a screw along its centre, working in a nut in the upper plate: so that by turning the winch-handle the tool can be moved backward or forward along the plate S, which is about twice the length of the upper or tool plate. Beneath the plate S is a circular piece C, divided by a line into two unequal portions; the upper and thicker portion is screwed to the plate S; the lower is in fact only a circular fillet left upon the plate below: in the centre of the latter is fixed an accurately-turned pin fitting into a corresponding hole in the former, which turns upon it as a centre, and can be set at any required angle to the lower plate (which is graduated for the purpose) and fixed in its position by two binding screws, shown in the figure on each side of S. Beneath are a second slide and circular plate, counterparts of those above, and the whole is mounted on a plate, P. The manner of using the rest will be easily understood. Hollow and spherical surfaces may be cut with the slide-rest with equal accuracy as rectangular figures, either by an adaptation to the common slide-rest, by which the lower slide is made to act upon the other, or by one constructed for the purpose. The slide-rest is of great value in producing any number of pieces of work of exactly the same form, of opposite forms and fitting each other, or in any given proportions; each slide-screw is fitted with a small circular graduated plate, and sometimes also with a micrometer screw and plate, so that the greatest nicety can be observed.

It is, however, only in conjunction with the *power-lathe*, that the full value of the slide-rest is exhibited. The beds, headstock, and slide-rest of the power-lathe, *fig.* 10, are made in the same manner as

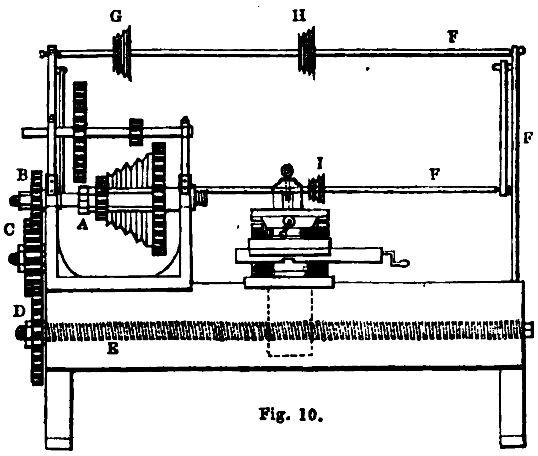


Fig. 10.

in the foot-lathe, but stronger; the mandril works in bearings to allow the end B to project beyond the back puppet and carry a toothed wheel; between the beds and along their whole length is a screw, E, which works in a nut attached to the under part of the rest; on the end of the screw is placed another toothed-wheel D, which is turned by the mandril-wheel B by means of the connecting wheel C. By varying the size of the wheels B and D, the rest can be made to move through any required space along the beds of the lathe at each revolution of the mandril. The spindle of the connecting wheel C fits in a curved groove to accommodate it to the different sized wheels used on the mandril and rest-screw; when the rest is required to move in the opposite direction, two connecting wheels are used. The size of these connecting wheels, having no influence on the relative rates of B and D, may be varied according to circumstances. The pulley, instead of being fixed upon the mandril, as in the foot-lathe, is mounted upon a metal tube or cannon which fits and turns smoothly upon the mandril. The lathe, when set in motion, will require no more attention until a fine spiral line is cut, enveloping the cylinder along its whole length; the rest has then to be shifted to where it started from, or by a simple contrivance be made to work its way back again, the tool being set out a little deeper each time until the surface is completed. In screw-cutting with the power-lathe, the point of the tool is made exactly the shape of one of the spaces between the intended threads and having the same rake or inclination; at each revolution of the mandril the rest must move through the distance from one thread to the next. The circumference of the screw has no effect upon any part of the arrangement but the inclination of the tool. When the screw is required to be double or treble-threaded, that is, having two or three intervening spirals upon the same stem, the rest must be moved forward a proportionate distance at the commencement of the second and third threads. In *fig.* 10, F F F is the *drilling-frame*, for working drills and cutters, fixed in the rest, by aid of the pulleys G, H, and I. If it is required to drill any number of holes in a plate, the drill-stock, *fig.* 11, is placed in the slide-rest and connected with the pulley I. By drawing the drill-frame to or from the centre of the work, holes may be drilled in straight lines across the centre, and, by shifting the dividing-plate, in circles; by the combination of the two movements the holes may be placed in curves and spirals in any direction. By

Fig. 11.

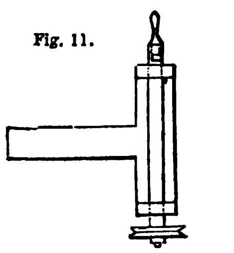

Fig. 12.

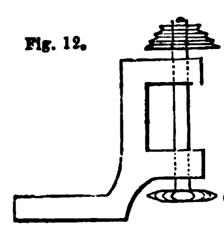


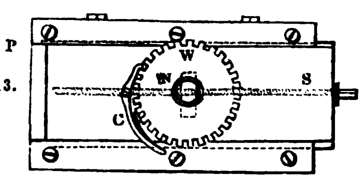
giving motion to the mandril, and connecting it with the slide-rest screw, spiral grooves may be drilled upon the surfaces of plates, cylinders, or cones.

We may here notice a contrivance, introduced by Mr. Miles in 1859, for turning pieces of wood so long that they would vibrate or swag if operated upon in the ordinary way. The wood does not rotate. The cutters advance *along* it and turn *round* it, being supported by a travelling carriage. Two dogs or props are placed beneath the wood at certain points, which may be moved out of the way when the cutters approach.

The cutting of toothed wheels is one of the most valuable applications of the lathe. [WHEEL-CUTTING.] The circular cutter used in this process may be employed in many other ways, such as cutting grooves and flutes, which, except for sudden curves, it performs better and much more rapidly than the drill. For cutting straight grooves both the drill and cutter are entirely superseded by the *planing-machine*, a modern invention of the greatest importance. It supplies what was one of the greatest wants of the engineer, and might appropriately be called the *straight-lathe*. For cutting grooves or flutes in cylindrical work, two small puppets carrying centres are screwed to the table to support the work, and the parts where the grooves are required are brought under the tool by means of a division-plate fixed to one of the puppets: a revolving cutter may be used instead of a fixed tool for cutting long pinions and terminating flutes.

Excentric Turning.—In enumerating the different chucks, we purposely omitted the *excentric* and *oval*, as they give their names to the respective kinds of turning for which they are used, and may therefore be considered rather as parts of the lathe itself than as mere appurtenances. *Fig.* 13 represents a *single* excentric chuck. It consists of a

Fig. 13.



strong plate which screws on the nose of the mandril; two dovetailed pieces are screwed upon it near the edges, between which the slide, S, works. Upon the slide is fitted a circular plate, which turns upon a centre, and has its edge cut into a number of teeth according to the size of the chuck; C is a click with one or two teeth fitting between the teeth of the wheel, and held in its place by a spring under the other end. The nose, N, for carrying the work, is fixed to the upper plate. The *double* excentric chuck is made in the same manner, but it has a second slide, at right angles to the first, on the back of the ground plate. In common turning the use of the excentric chuck is to bring any required point in the work in a line with the centre of the mandril; thus circular holes may be cut in any part of a plate, the edge may be hollowed out by any number of curves of the same or different radii, and polygons with curvilinear sides may be produced with the greatest accuracy. *Figs.* 14, 15, and 16 represent three among

Fig. 14.

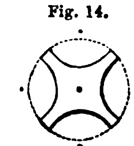


Fig. 15.

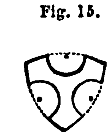

Fig. 16.

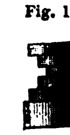

an infinite variety of figures produced in this way. In ornamental turning the excentric chuck is mostly used for cutting patterns upon the surface of the work without altering its general outline. Thus, in ornamenting ivory or wood-work, circles and curves are laid in an infinite variety of positions upon the face and edges of the work. The ivory-turner frequently uses a small instrument called an *excentric cutter*; it is formed like the drill-stock, *fig.* 11, and moved by a bow; the cutting point can be fixed at different distances from the centre by means of a groove and screw. In conjunction with a click plate upon the mandril, the cutter answers many of the purposes of the single excentric chuck. With the single-slide excentric chuck and the mandril at rest, the cutter will produce patterns which would otherwise require the double excentric.

Geometric Turning.—When the work revolves on the lathe, and the excentric cutter is driven by a band in connection with the mandril, a great variety of very complicated and beautiful epicycloidal and other curves may be cut. This geometric chuck is an excentric with the addition of an arrangement for giving motion to the work upon the chuck, and independent of the mandril. Fixed to the headstock and concentric with the mandril is a toothed wheel which, as the chuck revolves, drives another and smaller wheel on its under surface: this latter is connected with another toothed wheel which causes the click-plate and work to revolve. The patterns may be infinitely varied by altering the relative sizes of the wheels; and by introducing an extra wheel, and so causing the work and chuck to revolve in opposite directions at the same time; and lastly by changing the position of the tool. The number of different curves that can be produced by these changes and the great dissimilarity to each other can hardly be conceived. The excentric and geometric chucks are much used in producing patterns on plates and blocks for printing and embossing.

Oval Turning.—Until the invention of the oval chuck the production of true ovals was a matter of considerable difficulty, and the cutting of them upon the lathe an impossibility; with it we can turn ovals of all sizes and proportions with almost the same ease as circles. The construction of the chuck is simple. Upon the front of the headstock, H, *fig.* 17, is placed a ring, held by screws through its two arms and the projecting pieces on each side of the headstock; a screw is placed in one arm of the ring to draw it out excentric to the mandril. *Fig.* 18 shows the front of the chuck with a slide moving between dovetails on a ground-plate; the ground-plate, as shown in *fig.* 19, has two

Fig. 17.

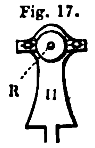

Fig. 18.

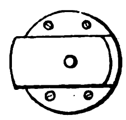

Fig. 19.

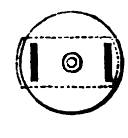
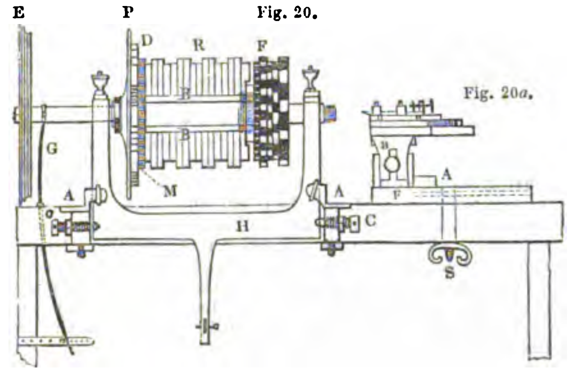


slits cut from the centre boss, which screws on to the mandril, nearly to the circumference; two small studs are cast upon the back of the slide, which are made to work easily in the two slits, and stand up just above the face of the ground-plate. When the slide is in its place two steel rubbers with straight polished faces are screwed to the studs, and stand out at the back of the ground-plate at right angles to the slits, as seen in *fig.* 19. The ring being fixed in its place upon the headstock, the chuck is screwed upon the mandril, the rubbers clasping the ring, which must be kept perfectly smooth and well oiled; the excentricity of the ring, acting upon the rubbers, draws the slide out of the centre in opposite directions alternately, and upon the tool being applied an oval will be described upon the face of the work, having the shorter diameter in proportion to the distance of the tool from the centre, and the longer to the excentricity of the ring. For ornamental work the oval chuck is provided with a click and sometimes a micrometer plate, like the excentric chuck, for placing the ovals in different directions.

Rose-engine Turning.—Of all the different sorts of ornamental turning this is by far the best adapted for embellishing small articles. It is in very general use for gold, silver, and gilt-work; it is besides applied to the production of ground tints, borders, and ornaments on copper, steel, and wood rollers for printing and embossing calico, leather, and paper; and many other sorts of ornamental work. An unsteady lathe, which in revolving produces an irregular circle, is a rude approach to the rose-engine, and may very possibly have furnished the first hint for its invention. We shall now describe it. H (*fig.* 20)

Fig. 20.



is a headstock, supported upon the conical points of two screws, C C, in the two metal standards, A A, fitted and bolted to the bench or bed. In the front and back of the headstock, near the bottom, are two sunk centres to receive the conical points of the screws. The screws are secured by washers that run upon them, and tighten against the standards. The upper part of each standard carries two other screws at right angles to those described, for the purpose of holding the headstock steady when the rose-engine is to be used as a common lathe. Two of these screws are shown in the front of the engine (*fig.* 21). Upon the mandril are mounted the pattern guides, or rosettes, circular plates of gun-metal or brass, each about half an inch thick, and having two patterns or waves upon its rim. The rosettes are of two sorts, fixed and shifting. The fixed, F, are screwed to a collar turned upon the mandril itself; the moveable, R, are fixed upon a cannon, B (*fig.* 20); the plate M is fixed to the cannon, and the rosettes are prevented from turning by a feather which fits into a notch in each of the rosettes: a nut at the end of the cannon screws all tight against the plate M. The plate D is put on the mandril at the back of the cannon plate M, but independent of both; behind this is another plate, P, fitted on to the mandril, and turning with it; at the back of this plate is a nut, which is tightened until the cannon requires some little force to turn it upon the mandril with the hand. On the large plate P, is a spring-click, which falls into notches cut in the plate D, which itself carries an endless screw working into a half thread cut on the edge of the cannon plate M. T is a carriage for holding the rubber R, by means of the two screws in the top of the carriage: the rubber is a small bar of steel, three or four inches long, and the breadth of the rosettes. Screwed into the bottom of the headstock is a strong arm, *h* (*fig.* 21), with a square hole near the bottom, to receive a smaller arm pierced with

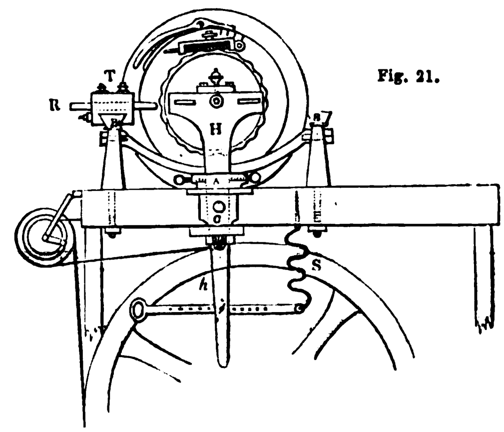


Fig. 21.

holes; one end of this latter is attached to a strong spring, S, and by placing a pin in one or other of the holes in the small arm, the spring may be made either to press or pull the arm *h* with less or greater force. The rubber-carriage T being moved along the bar B till the end of the rubber is exactly opposite the face of the rosette to be employed, and fixed there by the back-screw, the spring set to *pull* the arm *h*, and the side screws in the standards A turned back until the face of the rosette rests upon the rubber R, the engine at each revolution will produce a copy of the indentations upon the face of the rosette. The engine is moved by a hand-winch with a band passing round a foot-wheel, and another connecting a small pulley on the crank with the mandril-pulley E, in the same manner as the slow motion of the foot-lathe (*fig.* 2). The slide-rest is adapted to the rose-engine in the following way. The tail-piece of the rest F (*figs.* 20, 22) has a hollow

Fig. 22.

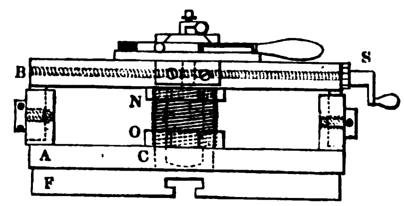

Fig. 23.

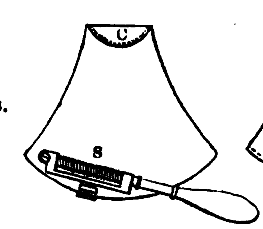

Fig. 24.

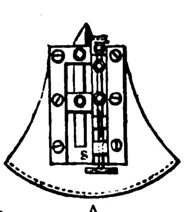
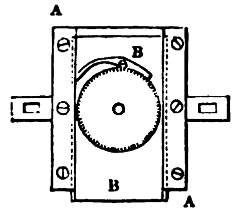


cylinder, C, fixed in the middle of one end. The bar B, which has a piece at each end fitting into dovetails in the sides of A, has a cylindrical piece which fits accurately into the hollow cylinder C, and can be raised or lowered at pleasure by a ring or nut, N, working upon the outside of C, the rest being placed in the required position, and fixed to the bench by the screw S (*fig.* 20). The stock A moves round upon the cylinder C, and can be fixed at any required angle by the binding nut O. The top of the rest, which traverses along the bar B, by means of a screw throughout its length, provided with an index-plate and winch-handle, S, is composed of two parts, the ground plate (*fig.* 23) and another plate (*fig.* 24), which carries the tool-slide. The engine is also capable of turning the sides and edges of work, for which purpose it is provided with a separate set of waves cut upon the sides of the rosettes, some of which are made of larger diameter than others for that purpose. The rubbers are shaped at the side to correspond; the mandril has an endway-motion within its bearings, and is acted upon in either direction by the lever-spring G (*fig.* 20), which has its fulcrum upon the bench: its upper end is forked, and fits a groove in the mandril, and the lower held by an arm and pin. For side-work the slide-rest is placed parallel with the bench as in common turning.

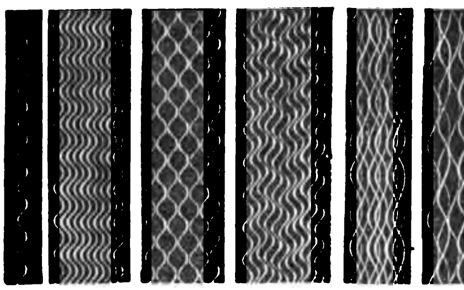
The *square*, or *straight-line chuck*, is peculiar to the rose-engine, and forms a very material part of it; the object of it is to lay the patterns in a straight instead of a circular direction. *Fig.* 25 represents the straight-line chuck; the square frame, A A, is fastened to the two arms of the headstock, shown in *fig.* 21, by bolts and nuts, or wedges; B, B, is a slide connected with the nose of the mandril either by a chain or, what is better, a rack and pinion. On the face of the slide are

Fig. 25.



click and screw-plates, and a nose to receive the chucks, as in the excentric and oval chucks. A, *fig.* 26, is the wave of which the patterns

Fig. 26.



B, C, D, E, and F are composed, by notches in the plate. These specimens will serve to show the immense number of patterns which may be produced with twenty or thirty rosettes and their combinations. Many curious patterns are produced by using two rosettes, one fixed to the mandril, the other on the cannon. For cutting copper and steel-plates, or wood blocks, the tool is sharpened with two acute angles; but in turning gold and silver work the quantity of metal taken off is required to be so minute that the two faces of the tool must be rubbed to such an obtuse angle as to appear almost straight. Close to the side of the tool in the rest is placed a stop, or touche, as it is called, to regulate the depth of the cut. The touche has a very small face, highly polished, which rubs upon the work in advance of the tool.

The number of adaptations, on account of the various and irregular shapes of the different pieces of work to be engine-turned, is very large, and would take up far too much space to describe. Cutting the rosettes, which every engine-turner ought to do for himself, is an operation of considerable nicety, as the waves are mostly very shallow, and the rosettes large, to make them work easily, and the slightest fault in a wave will be repeated through the whole work. Two superior machines for engine-turning were invented by Messrs. Perkins and Heath, some years ago, in which the rosettes are dispensed with, and their place supplied by an excentric wheel, or cam, which produces one wave only; but by means of toothed wheels, as many of these waves as are requisite are introduced during each revolution of the mandril. This engine produces an immense variety of patterns, with the very great advantage of all the waves being precise counterparts of each other. Work of this description is generally cut with a diamond, as a steel tool is liable to break, or get dull, and destroy the uniformity of the effect.

TURNIPS. *Brassica rapa.* This well-known plant is cultivated for its bulbous roots both in the garden and the field. As a culinary root it has been prized from the earliest times, and many varieties have been cultivated for the table; but it is those of a larger kind, cultivated in the fields, which form so important a part of the most improved systems of agriculture on all light soils, that the success of the farmer is, in general, proportioned to the quantity of turnips raised on his farm. They are the great foundation of all the best systems of cropping, by supplying the manure required for the subsequent crop, and, at the same time, clearing the land of all noxious weeds, by the numerous ploughings, stirrings, and hoeings which they require.

Turnips were first raised upon land which had already borne a crop that was reaped early in summer, and on fallows which had been worked and cleared early, so as to leave a sufficient interval between the last ploughing and the time of sowing winter corn to have a tolerable crop of turnips. These turnips however, which are still cultivated by the name of stubble or eddish turnips, never grow so large as those which had been sown earlier on land well prepared and highly manured.

The regular cultivation of turnips on a large scale was originally introduced from Flanders into Norfolk two centuries ago, and from Norfolk was carried into the south of Scotland and the north of England about a century after. It was long confined to one or two individuals, who cultivated turnips very successfully; but at last it spread, and was greatly improved by introducing the row culture, according to Tull's system, which acquired the name of the Northumberland mode of cultivation. The usual mode of sowing turnips both in Flanders and in Norfolk was broadcast, and, as the labourers in both countries became very expert in hoeing them out at regular distances, this mode was long preferred. All farmers however, who have any pretensions to a good system of cultivation, now adopt the Northumberland plan. The great object on poor light lands, especially those which have lately been brought into cultivation, is to raise a crop of turnips: for when once this is obtained, and the land has been improved by the folding of sheep upon it, there is no great difficulty in maintaining the fertility thus produced by judicious management and frequent green crops. Great improvement in poor soils has been effected by the introduction of ground bones and superphosphate as a manure. It is however the best plan to unite the regular application of farm-yard dung with that of the bone-dust. For this purpose the best farmers prepare their land, where they intend to sow turnips, early after harvest, by giving it as complete a cultivation as they can before winter; and they put on it a good coat of manure, and plough it in. In the beginning of summer another ploughing is given, with repeated harrowings, to destroy the weeds which have sprung up. If the subsoil is dry, or the land has been thoroughly drained, the seed may be drilled in rows from 2 feet to 30 inches apart, with bones or any equivalent artificial manure on the flat surface. The turnip-seed can scarcely fail to vegetate soon: less danger arises from dry weather than if they were on the top of a ridge, and the intervals can be readily stirred by horse-drawn tools. The manure, which has had time to incorporate with the soil and to impart to it the various products of its decomposition, is in the best state to nourish the young plant, until it can push forth its roots and feed, as it were, on the bone-dust: a more rapid growth is ensured, which is the best preservative against the fly; and experience has proved that this is a much more certain way to insure a good crop of turnips, especially of swedes, than the old method of putting all the manure immediately under the seed in the rows, where it often remains inert if dry weather comes on soon after the seed is sown. The quantity of manure put on in autumn, or very early in spring, depends on the means of the farm: if ten cubic yards of short dung can be afforded per acre, the crop of turnips will amply repay it, and twenty bushels of bone-dust or less per acre will be sufficient to drill with the seed. Long fresh manure may be safely ploughed in before winter, which would be very improper in a light soil if used in summer. This will be rotten before the turnips are sown, and all the expense of forming dunghills and turning them over is saved. There is no danger of the manure being wasted; for whatever weeds may be produced will be ploughed in and returned to the soil. All the nutritious parts of the decomposing dung will be absorbed by the earth, and none of them will evaporate. Where farm-yard manure is scarce, half the above quantity may be used, and a fair crop of turnips may still be expected.

The early vegetation of the seed is essential to a good crop of turnips. In its young and tender state it is liable to a variety of accidents. Its great enemy is the turnip-fly (*altica nemorum*), which appears always in great quantities, if there is any continuance of dry weather. The more frequently turnips are sown on the same ground the more abundant is the fly, but where the surface has been pared and burned there is seldom any loss from this cause. It is generally found that in moist weather the fly does comparatively little harm, as then the vegetation is rapid, and the plant, when once it has put forth its rough leaves, is considered safe. Whatever therefore accelerates the vegetation, will secure the growth of the turnip. Hence the advantage of dunging the soil before winter, by which means it is enriched uniformly, and a great portion of the manure, having become soluble, absorbs moisture from the atmosphere. And in dry weather it is well to sow the seed with the water drill. As soon as the turnip-plant has put forth its rough leaves, the intervals between the rows should be stirred with a light plough drawn by one horse. The plough can be made to go within an inch or two of the plants, throwing the earth from the row into the interval: a small harrow, which can be set to any required width, is then drawn between the rows to loosen the earth raised by the plough. This greatly increases the absorption of moisture and invigorates the young plants. They may now be thinned out and even singled in the rows by means of a hoe about 12 inches broad, leaving plants a foot or more apart. Thus the turnips are left at a proper distance, and, having ample room, will soon cover the rows. A horse-hoe is now drawn between the rows to eradicate all weeds and keep the soil open for the fibres of the roots to shoot in. It is not advisable to throw the earth over the turnips, unless it be just before winter, to protect them from the frost; on the contrary, in wet weather the earth is more likely to cause the turnip to rot than to help its growth. The fibres which draw the nourishment strike in the soil below, and spread between the rows wherever they meet with a loose and mellow earth.

In order to have a heavy crop, especially of Swedish turnips, it is advisable to sow the seed early, that is, in southern counties, towards the end of May. They will then have the advantage of the summer showers, and be beyond the reach of the fly in a very few days, and when the dry weather sets in they will already have a supply of moisture in their roots, and the fibres, having struck deep, will not suffer any check. The only inconvenience of sowing early is that many of the plants are apt to run to seed. This is in many cases owing to the seed which is used. If the seed has been raised from fine roots which have stood the winter, there is little danger of the plants running to seed in the first summer; but, as is often the case, if small imperfect roots are taken, or those which run to seed in autumn, then the plants will have a tendency to produce seed and not bulbs. The white Norfolk turnip and its varieties should be sown about midsummer to have a good and heavy crop before winter. The distance at which they may be left in thinning them out must depend on the variety, whether it has a wide spreading top or not. The best crops both of swedes and common field turnips are generally those where the tops are vigorous and moderately spreading. A small top will not nourish a large bulb: but when the growth is chiefly in the leaves, the bulbs are seldom large.

It may be considered as a general rule, that the most advantageous mode of consuming turnips is to draw them and cut them in slices in the field, to be there consumed in troughs by sheep, to which corn or oil-cake, as well as hay, is regularly given. When the crop of turnips is abundant, part of them may be stored for the cattle in the yard or fatting-stalls, and for the milch-cows and heifers. They will require nothing but good straw, if they have plenty of turnips, and no hay whatever need be used, unless it be for the horses; and even they will thrive well on Swedish turnips and straw with a small quantity of oats.

Turnips are often left in the field all the winter, which greatly deteriorates them. If they cannot all be fed off before Christmas, they should be taken up, and the tops being cut off within an inch of the crown of the root, they may be stored in long clamps five feet wide and four feet high, sloped like the roof of a house and covered with straw and earth, in which state they will keep till they are wanted. It is advantageous to have different varieties of turnips, which will come to perfection in succession; and it is useful to sow some at different times for this purpose. The small turnip, which from its rapid growth is called the nimble turnip, may be sown as late as the end of August, and in mild seasons will produce tolerable bulbs in winter and early in spring. The frost will not injure a growing turnip so readily as one which is come to perfection and the leaves of which are withered. Some varieties, like the yellow Aberdeen and the green round turnip, are hardier than others, and will stand the winter well in a light and dry soil.

There are so many varieties cultivated, that it is difficult to enumerate them. The Swedish turnips may be classed according to the colour and size of their tops and the shape of the bulb. The best have but little stem rising from the bulb and a good tuft of leaves. The substance of the turnips is of a bright yellow and has a strong smell, especially when they have been kept some time. No frost will hurt them, if they are kept dry; but alternate rain and frost will do them harm. When they are stored, it is advantageous that the air should have free access; and for this purpose it has been recommended to place them between hurdles set upright and to slightly thatch them with straw to keep out the rain. In this way they keep longer sound than when put in clamps covered with straw and earth.

Of the field turnip there are numerous varieties. The common Norfolk turnip is round and flat, the bulb being half buried in the ground; it throws out no fibres, except from the slender root which proceeds from the centre of the bulb. There is a subvariety which is reddish at the insertion of the leaves, and another of a green hue: the latter is the hardiest. The globe turnip takes its name from its shape; it rises more out of the ground, and grows to a greater size; like the last it is either entirely white or red or green near the crown. It is on the whole the most productive and hardy. The tankard turnip rises high out of the ground, and approaches in shape to the mangel-wurzel. It grows to the greatest size; but it is apt to become spongy if left long on the ground, and its weight is not in proportion to its bulk. There are red tankards and green tankards, as well as white. The green round turnip is considered very hardy, and is usually sown late, to be consumed after the winter. The yellow Aberdeen, although somewhat less, is compact, and stands the winter well: it is a very useful variety.

Those who are possessed of a good variety will do well to raise their own seed, as that which is bought cannot always be depended upon; the best-shaped middle-sized bulbs should be chosen, the leaves being cut off not nearer than an inch from the crown. They should be planted in a mellow soil, in rows three feet wide, and a foot from bulb to bulb in the rows, about March or April. When the pods are well filled with seeds, and these are round and hard, the stem should be cut close to the root and carefully laid under a shed to dry. The seed will ripen there without shedding, and when the pods are quite dry, the seed is easily beaten out with a stick or light flail. Birds are so fond of it, that a constant watch must be kept, and this is the reason why so few farmers grow their own seed. Turnip seed is often raised in the gardens of cottagers, whose children keep off the birds, and it is a branch of industry which every farmer should encourage. He can readily see that good bulbs only are used, and he secures the seeds he wants, while the cottager is well paid for his trouble. This is perhaps the most convenient mode of raising the seed on a large farm. It is best to use fresh seed, as it always germinates sooner. Machines which sow the seed and manure in drills at the same time may be had of most of the manufacturers of improved agricultural implements.

TURNPIKE ROADS. [ROADS.]

TURNPIKE TRUSTS. Turnpike-roads are a peculiar species of highways placed by the authority of acts of parliament under the management of trustees or commissioners, who are invested with certain powers for the construction, management, and repair of such roads.

Besides the various local acts, there are several acts of parliament called General Turnpike Acts, the provisions of which extend and apply to all existing and subsequent local acts, and which are too numerous for citation here. The General Highway Act (5 & 6 Wm. IV. c. 50) also contains certain provisions applicable to turnpike-roads; but, by the 113th section, does not extend to them except where expressly mentioned.

The trustees of turnpike-roads consist of persons nominated for that purpose in the Local Acts, who must be persons possessed of a certain property qualification, and of the justices of peace of the county or counties through which the roads pass; but all persons who are contractors or otherwise personally interested in the roads are disqualified from being trustees. (3 Geo. IV. c. 126, ss. 61, 62, *et seq.*) They are exempt from personal liability for acts done in pursuance of their powers, and may sue and be sued in the name of their clerk. (7 & 8 Geo. IV. c. 24, ss. 2 & 3; 3 Geo. IV. c. 126, s. 74.)

For the purpose of providing the necessary funds for making and maintaining the roads under their charge, trustees are usually empowered to receive moneys by way of subscription, upon which interest is payable to the subscribers out of the produce of the tolls which the trustees are by the local acts empowered to levy upon persons using the roads. Power is also given them to borrow money upon mortgage of the tolls. (3 Geo. IV. c. 126, s. 81.)

The enactments of the General Highway Act (5 & 6 Wm. IV. c. 50, s. 94), relating to summary proceedings before justices to compel repairs of highways, extend the jurisdiction of the justices to turnpike officers, where the highway out of repair is part of a turnpike-road; and while the liability to statute labour existed, it was exigible as well in respect of turnpike-roads as other highways; but the obligation of statute labour seems to be now entirely abolished by the repeal, in the 5 & 6 Wm. IV. c. 50, of the statutes under which statute labour was compounded for.

The amounts of toll exigible on any turnpike road are regulated by the table of tolls which is contained in the local act by which the trust is constituted, and no tolls can be charged except such as are given by clear and unambiguous language in the Act; and there are various cases of exceptions.

Tolls upon turnpike-roads are in most cases made payable once a day only at any one gate, and payment at one gate generally gives exemption from payment at other gates within a certain distance. Post-horses having passed through any gate may return toll-free before nine o'clock in the morning of the following day, and when horses, having passed through a gate, return the same day or within eight hours, drawing a carriage, the toll paid on the horses is to be deducted. (3 Geo. IV. c. 126, ss. 29, 30.)

The General Turnpike Acts contain various provisions regulating the weights to be allowed to carriages passing along turnpike-roads, and imposing additional tolls for overweight, and also provisions regulating the amount of toll leviable upon waggons and carts depending upon the construction, breadth, and tire of their wheels. (3 Geo. IV. ss. 7, 9, &c.; 4 Geo. IV. c. 95, ss. 2, 5, &c.)

Trustees are enabled to erect toll-gates and toll-houses, the property in which is vested in them, and are required to put up at every toll-gate a table of the tolls leviable thereat, and to provide tickets denoting payment of toll to be delivered to persons paying the same. (9 Geo. IV. c. 77, s. 3, &c.; 3 Geo. IV. c. 126, ss. 37, 60; and 4 Geo. IV. c. 95, s. 28.) The remedies for the recovery of tolls, and the penalties for evading them are contained in 3 Geo. IV. c. 126, s. 39, &c.

The trustees of every turnpike-road have power to enter into compositions for any term not exceeding a year at a time, with any person for tolls payable at any toll-gates under their management. (4 Geo. IV. c. 95, s. 13.) They may also, though not empowered to do so by the local act, reduce the tolls leviable under the authority of the act, and advance them again to any amount not exceeding the rates authorised by the act; provided that where money has been borrowed on the credit of the tolls, no reduction shall be made without the consent of the persons entitled to five-sixths of the money due. (3 Geo. IV. c. 126, ss. 43, 44.) Trustees may also farm out the tolls, though no express power be given in the local act.

The General Turnpike Acts contain, besides numerous provisions with respect to the appointment and duties of officers, the meetings and proceedings of trustees, the making of causeways, ditches, and drains, the erection of milestones, the watering of roads, the prevention and removal of annoyances and nuisances, the marking of carriages and regulations as to drivers, the apprehension of offenders, the recovery and application of penalties, the limitation of actions, &c.; all which general enactments have been made from time to time for the purpose of shortening and lessening the expense of private road bills, so that almost the only objects which now require to be attended to in the construction of road acts are the appointment of trustees, the number and situations of toll-gates, and the amounts of tolls. (Chitty's 'Statutes,' vol ii., *Highways.*

TURNSOLE, or TOURNSOLE. [ARCHIL; COLOURING MATTERS.]

TURPENTINE. The well-known liquid to which the word turpentine is now so commonly applied, is only the volatile portion of turtentine properly so called. True turpentine is really an oleo-resin, a liquid of about the consistence of honey. It flows naturally, or by incision, from the wood of most coniferous trees, such as pine, larch, fir, pistachia, &c., and by distillation yields spirit, essence, or volatile *oil of turpentine*, the non-volatile portion being common *resin*, or *colophony*. [RESINS.] Oil of turpentine is very largely used in the preparation of paints and varnishes, and also, when rectified, for burning in lamps under the name of camphin. The derivation of the word turpentine is not very evident. It was known and described by Marcus Græcus in the eighth century.

The turpentine met with in English commerce is nearly all imported from the States of America, North Carolina and Virginia supplying the greater part. It is the produce of *Pinus palustris*, *P. tæda*, and *P. abies*. French or Bordeaux turpentine is mainly obtained from *Pinus maritima*, a tree growing abundantly on the coasts of Southern Europe.

The method of procuring turpentine is very simple. An incision, or hole, is made in the bark of the tree, or a small piece of the bark is removed, in the spring of the year. From this wound the turpentine slowly exudes, and is collected either in a little trough attached to the stem, in a hollow made at the foot of the tree, or by some similar contrivance. It is from time to time transferred to casks made to hold about 2 cwt. The first gathering is sometimes called *virgin turpentine*, and contains about 20 per cent. of oil; that collected towards the end of the season, in October, has a more solid but still soft consistence, and is not so rich in oil. As might be expected, the crude turpentine frequently contains portions of twigs, chips, and leaves; these are sometimes separated by straining the melted turpentine, and the latter is then termed *refined*. *Venice turpentine* is the variety produced from the larch tree (*Larix Europæa*); *Canadian turpentine*, or *Canada balsam*, exudes from the *Abies balsamea*; and *Chian turpentine* is obtained from the *Pistacia terebinthus*.

Turpentine slowly hardens when exposed to the air. This is partly due to evaporation of the more liquid portion, and partly to resinification of the fluid part by oxidation. It is probable that in the tissues of the plant turpentine is simply a mobile juice, and that in the ordinary state of oleo-resin it is a product rather than a simple vegetable educt. It softens and liquifies when heated, readily takes fire in the air, and burns with a somewhat smoky flame. It is completely dissolved by alcohol or ether, and by distillation with water yields oil of turpentine.

Oil of turpentine ($C_{20}H_{16}$). As already indicated, this is obtained by distilling turpentine with water; it then forms the upper layer of the condensed product. For most purposes it is re-distilled with caustic alkali, acid matters and traces of resin being thereby removed.

Oil of turpentine is a colourless mobile liquid, of characteristic odour and hot pungent taste. It should be neutral to test-paper, of specific gravity 0·86, boiling-point about 320° Fahr., and a vapour density of 4·76. It rotates a ray of polarised light, to the left or right according to origin. It is very soluble in ether and absolute alcohol, less so in ordinary (hydrated) alcohol, and is not miscible with water. It is a good solvent of resins, oils, sulphur, phosphorus, and caoutchouc. Pure turpentine, as obtained by re-distillation in vacuo, has constant, well-defined, lævo-rotation. Berthelot distinguishes it as *terebenthen*.

Modifications and Derivatives of Oil of Turpentine. Under the influence of heat, or of chemical re-agents, or of both combined, oil of turpentine yields several interesting substances. *Isoterebenthen* is one of the products into which oil of turpentine is resolved on heating, in a closed vessel, to about 470° Fahr. It is a colourless liquid, having an odour of stale lemons, sp. gr. 0·843 at 71° Fahr., boiling-point 350° Fahr., possesses lævo-rotation of varying intensity on polarised light, yields a solid hydrate and hydrochlorate. *Metaterebenthen*, like isoterebenthen, has the same composition as oil of turpentine; it is formed under the same circumstances as isoterebenthen, but remains in the retort after the heat has been raised to 660° Fahr. It distils, however, at a temperature slightly higher than 660°, and then forms a yellowish, very viscid liquid of sp. gr. 0·913 at 68° Fahr. It has a disagreeable odour, and exerts lævo-rotation on polarised light.

When oil of turpentine is agitated with five per cent. of strong sulphuric acid, it becomes of a dark red colour, and viscid. On standing, the mass separates into two portions, and the upper clear liquid furnishes, on distillation, a body having the same boiling-point and composition as the original oil, but of an odour resembling that of oil of thyme: it is called *tereben*. *Colophen* is produced at the same time as tereben; its density, however, is twice as great, and its boiling-point is between 590° and 600° Fahr. It may also be obtained from colophony, hence its name. Neither tereben nor colophen has any action upon polarised light.

Water combines with oil of turpentine to form definite *hydrates*, of which three are solid and one liquid. When the oil is exposed to intense cold, crystals of *binhydrate* ($C_{20}H_{16}$, 2HO) sometimes separate, but generally a *hexahydrate* ($C_{20}H_{16}$, 6HO), called *terpin*, in large prismatic crystals, is deposited. The latter may be obtained in quantity by well mixing four parts of oil of turpentine, one of nitric acid (sp. gr. 1·36), and three of alcohol (sp. gr. 0·840), and setting aside for several weeks. When sublimed, the hexahydrate loses two equivalents of water, and is converted into a *quadhydrate* ($C_{20}H_{16}$, 4HO). The quadhydrate is also formed on exposing turpentine and water to a continued heat of about 120° Fahr. It is more soluble in hot than cold water, and is readily taken up by alcohol, ether, or benzole. A fourth hydrate, termed *terpinol* ($C_{20}H_{16}$, HO), which is a fluid at common temperatures, is formed on distilling either of the other hydrates with water containing a little hydrochloric or sulphuric acid. It has an odour like that of the hyacinth, boils at 334° Fahr., and is of sp. gr. 0·852.

Hydrochloric acid combines with oil of turpentine, and forms several liquid and solid bodies. The latter have very much the appearance and odour of camphor, and hence are termed *artificial camphors*. The *monohydrochlorate* ($C_{20}H_{16}$, HCl), called also *hydrochlorate of camphen*, or *of dadyl*, is best obtained by passing dry hydrochloric acid gas into artificially cooled oil of turpentine until absorption ceases. If the product be exposed to a freezing mixture of snow and salt, it soon becomes half filled with white prismatic crystals, having the characteristic aromatic smell and taste of camphor. They are insoluble in water, soluble in alcohol or ether, fuse at 239° Fahr., and boil at 329°, undergoing partial decomposition. The liquid portion of the above product is also a monohydrochlorate, having the same composition as the solid; it is termed hydrochlorate of pencyl, or of terebilen, inasmuch as that when distilled with quicklime it furnishes *pencyl* or *terebilen*, a liquid hydrocarbon isomeric with oil of turpentine, but possessing no rotatory power on polarised light. The solid hydrochlorate by similar treatment yields *camphen*, *camphilen*, or *dadyl*, also isomeric with oil of turpentine; boiling-point, 273° Fahr. A solid and liquid *bichlorhydrate of turpentine* ($C_{20}H_{16}$, 2HCl), *artificial lemon* or *citron camphor*, are formed when oil of turpentine or of lemons is placed in contact with excess of strong aqueous hydrochloric acid for several weeks. A liquid *subhydrochlorate* ($2C_{20}H_{16}$, HCl) has also been obtained. Hydrobromic and hydriodic acids form compounds with oil of turpentine somewhat resembling the hydrochlorates.

Chlorine attacks oil of turpentine, and yields a *quadrichlorinated* derivative ($C_{20}H_{12}Cl_4$). The latter furnishes a *bichlorinated* compound ($C_{20}H_{14}Cl_2$) on being heated. A *quadribrominated* oil ($C_{20}H_{12}Br_4$) has also been obtained. Tereben and chlorine give a colourless viscid liquid, termed *chlorotereben*, and artificial camphor and chlorine yield crystals of *chlorocamphen*.

Oil of turpentine is very susceptible of oxidation. The spontaneous production of resins from it has already been alluded to. By distillation with bichromate of potash and sulphuric acid it yields abundance of formic acid, and when gently heated with oxide of lead gives formic acid and *teretinic acid* ($C_{18}H_{14}O_{10}$). The latter crystallises in acicular tufts, and forms salts that, like itself, are insoluble in water but soluble in alcohol. A small quantity of oil of turpentine placed in a jar of oxygen gas standing over water and exposed to sunlight, rapidly absorbs the oxygen, and yields crystals of *hydrated oxide of turpentine* ($C_{20}H_{16}O_2$, 2HO), which are deposited on the sides of the vessel; it is soluble in alcohol, ether, and boiling-water. Strong nitric acid acts very violently upon oil of turpentine, the temperature frequently rising high enough to cause inflammation of the mixture. When diluted, however, nitric acid merely resinifies the oil, and produces, among other substances, terebic acid, which will presently be described in detail in connection with resin; *terephthalic acid* ($C_{16}H_6O_8$) isomeric with phthalic acid [NAPHTHALIC GROUP]; *terebenzic acid* ($C_{14}H_7O_4$?), fusible at 336° Fahr., and sublimable like benzoic acid; and *terechrysic acid* ($C_{12}H_6O_8$), of golden yellow colour, uncrystallisable, and very soluble in water.

The chief properties of the non-volatile or resinous constituents—the *resin*—of turpentine have already been described. [RESINS.] It now therefore remains only to notice the relations of the constituents individually, and shortly describe their derivatives.

Turpentine Resin, as a whole, is acid, and has the composition (HO, $C_{40}H_{29}O_3$). In reality, however, it contains three distinct acids isomeric with each other, but having dissimilar physical properties; their names are pimaric, sylvic, and pinic acids. The two latter are, no doubt, mere modifications of the first, and probably owe their dissimilarity to the action of heat. *Pimaric acid* is best obtained from the white resin or *galipot* of Bordeaux turpentine. The resin is powdered, digested in a mixture of six parts of cold alcohol and one of ether, which separates matters other than pimaric acid, and the residue is finally boiled with alcohol. On standing for a few days, the solution deposits crystalline tufts of the acid under consideration. It is very soluble in ether and hot alcohol, less so in cold alcohol. It fuses at 257° Fahr., but does not re-solidify till cooled down to 154° Fahr. The fused acid is clear and transparent as glass; when powdered it may be perfectly dissolved in its own weight of alcohol, but in a few minutes the solution begins to deposit elliptical crystals, which, like the non-fused acid, require ten times their weight of alcohol for solution. By distillation in vacuo pimaric acid furnishes sylvic acid, at first thought to be new, and called *pyromaric acid*. *Sylvic acid* may be obtained from powdered resin. The latter is well washed with cold alcohol to remove pinic acid, and the residue dissolved in boiling alcohol; on standing, the sylvic acid crystallises out. Its crystalline character is more pronounced than that of pimaric acid; in other respects the two much resemble each other. *Pinic acid*, or the amorphous resin of colophony, is obtained on evaporating the mother liquor from the preparation of sylvic acid; by heat it is partially decomposed, and changed to another isomer, *colopholic acid*.

By destructive distillation at a low temperature, turpentine resin yields the hydrocarbons *resinein* or colophen and tereben already referred to. At a higher heat it gives a liquid hydrocarbon containing *retinaphtha* or *toluen* ($C_{14}H_8$) [TOLUENIC GROUP]; *retinyl* ($C_{18}H_{12}$), isomeric with *cumen* [CUMINIC ACID]; and *retinol* ($C_{64}H_{32}$?), an inodorous and tasteless oil, of sp. gr. 0·9, and boiling-point about 460° Fahr. Retinol is a solvent of sulphur and iodine. It absorbs many times its volume of sulphurous and other gases, and is not acted upon by alkalies.

The acids of resin are monobasic, difficult to obtain in a definite crystalline state, are mostly insoluble in water, and soluble in ether. The alkaline resinates are of course true soaps, but are inferior in detergent qualities to the stearates, oleates, and margarates.

By prolonged ebullition with strong nitric acid, turpentine resin yields AZOMARIC ACID and *terebic* or *terebilic acid* ($C_{14}H_{10}O_8$). The latter is almost insoluble in cold water, moderately soluble in hot water, and readily taken up by alcohol or ether. Submitted to destructive distillation, it gives *pyroterebilic acid*, a colourless oily liquid of sp. gr. 1·01, and boiling-point 392° Fahr.

TURPENTINE, MANUFACTURE OF. The common turpentine used in the arts is mostly imported from America, in barrels and casks. [TURPENTINE.] It is used for very few purposes in the state in which it is imported. The process of distillation is in most cases resorted to, as a means of separating it into solid *resin* and liquid *oil* or *essence* of turpentine. Turpentine-works, where this distillation is carried on, are managed with much caution on account of the inflammable nature of the substance operated on. The viscid turpentine is put into a still and exposed to heat; it melts into a liquid, gives off its essential or oily portion in the form of a vapour, and there remains a liquid resin in the still. The vapour, on leaving the still, passes through a refrigerator or cooling vessel, and is collected as a clear and limpid oil or spirit of turpentine. The residue is taken from the still as *resin*, *black* or *yellow* according to the kind of turpentine which has been employed.

A patent was taken out in America a few years ago, for making soap at the same time as distilling turpentine. Raw turpentine and alkali were put into the still; the spirit of turpentine passed off into a condenser, while the resin became partially saponified by combining with the alkali, and prepared to enter into the composition of soap.

Considered as an ingredient in house-painters' colours, spirit of turpentine, or *turps*, is an important substance. Chevreuil has pointed out three kinds of service which turpentine renders to oil-colours. It facilitates the application, by diminishing the viscidity of the oily mixture; it allows the painter greatly to modify the appearance of his work, by varying the degree of gloss or of dullness; and it prevents the appearance of cracks which would otherwise be visible when the work is varnished. As, however, the durability of the work depends chiefly on the oil, the best mode is found to be to use as little turpentine as possible when the work is neither to be dead nor varnished.

Common or crude turpentine is imported to the extent of about a quarter of a million cwts. annually (246,458 cwts. in 1858, and 256,663 in 1859). A small import duty, imposed many years ago, has been since repealed.

TURPENTINES, *Medical Uses of.* Common turpentine, or Resina liquida (*Terebinthina vulgaris*), as the natural combination is termed, yields two distinct articles to the Materia Medica, namely,—1. Oleum terebinthinæ, obtained by the distillation of the liquid resin; 2. Resina, or simply resin or rosin, which is resin with a little water, remaining after nearly all the oil has been distilled off: but if the process of distillation be carried as far as possible without causing new combinations of the elements, all the water is driven off, and the residuum becomes black, and is termed colophony, and sometimes fiddler's rosin. The resin is used merely to make cerates, ointments, and plasters, which are more or less stimulant.

As turpentines have a very disagreeable taste, it is customary to form them into pills or boluses; but since this is rather difficult, it is well to be aware that magnesia affords a convenient means of accomplishing it, as in the case of the oleo-resin of copaiba. The kind of magnesia and the quantity to be used vary in the different kinds of turpentine. Bordeaux turpentine (from *P. maritima*, or *P. pinaster*) requires one twenty-one part of magnesia usta to form a pill-mass. Venice turpentine (from *Larix Europæa*), called also turpentine of Briançon, requires a quantity equal to its own weight of carbonate of magnesia to form a pill-mass. But the quantity of magnesia must vary with the age of the turpentine, more being required when it is very fresh than when the turpentine is old and more solid. The durability of the mass also varies with the proportion of magnesia used.

One ounce of Venice turpentine united with one ounce of hydrated carbonate of magnesia formed a mass which was slow of consolidating, and the pills soon lost their globular form: but three ounces of the magnesia formed a persistent mass. One ounce of turpentine and one ounce of Bordeaux turpentine, with six drachms one scruple of carbonate of magnesia, furnished a slowly hardening mass, which at last resolved itself into powder; while one ounce of the same turpentine with eight grains of magnesia formed a soft mass, which, after thirty-six hours, was sufficiently consistent to form pills. Some days afterwards it became harder, and did not for a long space become friable. With a yet smaller quantity of magnesia these changes take place more slowly, so that it is requisite in magistral formulæ never to order less magnesia than the one-fiftieth part of the turpentine. This proportion forms in a few minutes a transparent pill-mass with a vitreous fracture. But the finer sorts of turpentine may be administered in the liquid form; the coarser must be in pills.

Oleum Terebinthinæ, Oil or Spirits of Turpentine, as it occurs in commerce is never pure, but contains more or less resin formed by the action of the air; and to obtain it pure, it is ordered to be distilled a second time, and then called Oleum Terebenthinæ purificatum, and sometimes Oleum Pini purissimum. The commercial oil of turpentine has an acid reaction, the purified has not.

Oil of turpentine is one of the most energetic of the volatile oils: the vapour is quickly destructive to plants, and in large doses it acts as a poison to both vertebrate and invertebrate animals. Like all volatile oils it acts powerfully on insects which respire by the whole surface, hence it instantly kills wasps, lice, fleas, and worms. It has a more potent action on the lower animals than on man, both externally and internally. Applied to the skin of horses, it blisters it more rapidly than the skin of man; and two drachms administered to a dog (Schubart, in Christison) caused death in three minutes, while human beings have taken three ounces without any serious consequences. Indeed Dr. Christison states that he is not aware that it has ever proved fatal. Horses also have taken for some days as much as ten or twelve ounces.

In moderate doses it acts as a stimulant to the stomach and whole intestinal canal; manifested by a grateful feeling of warmth, with greater activity in the mucous membrane of the intestines, and of the liver. The increasing secretions of these organs, particularly of the bile, causes more frequent evacuations; further, it promotes the secretion of the kidneys, and likewise, but less evidently, of the skin, the pulmonary surface, and also of the uterus. It communicates the terebinthaceous odour to the cutaneous perspiration, and sometimes even causes an eruption on the skin.

Its effect on the vascular system is equally stimulant: Dr. Copland made many experiments on himself, when in health, and found that his pulse became more frequent, small, and contracted; with feelings of intoxication, anxiety, shiverings, a sensation as if the intestines were drawn towards the vertebral column, unpleasant eructations, thirst, and a sharp hunger; sensations which food caused gradually to subside, without vomiting or diarrhœa. Very large doses often produce temporary intoxication, and sometimes a kind of trance, lasting twenty-four hours, without any subsequent bad effect.

Implicit reliance is placed on oil of turpentine against the tape-worm. It is in general recommended to be given in large frequently-repeated doses, mixed with mucilage, syrup, and cinnamon-water, and is thought to directly kill the worm, rather than destroy it by removing the means of its further nourishment. But this mode of administration is by no means so eligible as that of small doses (ʒj to ʒij) per diem for a continuance, a plan recommended by Vogt ('Pharmacodyn.,' vol. ii., p. 163), and proved by Dr. Graves to be effectual. "Turpentine is of value in leading to the expulsion of flukes (distomahepaticum [WORMS; also BOTRYLLIDÆ, in NAT. HIST. DIV.] of sheep, or the rot), and is one of our most valuable anthelmintics." Professor Simonds' Report to the Royal Veterinary College, Dec. 14, 1860.

In chronic affections of the liver, obstructions from gall-stones, &c., if no inflammatory state be present or approaching, oil of turpentine with twice its weight of spirit. æther. sulphur. in the dose of from 10 to 20 drops, in yolk of egg, is often very useful; in melæna and obstructions of the liver, and vena porta, &c. It is most likely, from its action on the liver, that it proves serviceable in chronic rheumatism. In sciatica, Dr. Cheyne recommends it in small doses. It is useful in atony of the intestines, lacteals, particularly of old and phlegmatic people, especially of the lower orders. Even typhus fever, if there be a tympanitic state of the abdomen, is benefited by it, and Dr. Chapman has found it valuable in the yellow fever of Philadelphia. Dose from 1 to 2 drachms per diem. In cholera asiatica, with spirits of ammonia. In obstinate constipation, in large doses. In scarlet fever, when the eruption does not come freely out, 10 to 60 drops in one to three tea-spoonsful of castor-oil. (Dr. Delany, of Georgia, U.S.) In chronic cramps, convulsions, and epilepsy (with only temporary benefit). In atony of the kidneys and bladder. In catarrhus vesicæ, gleet, gonorrhœa, and leucorrhœa, it may often be advantageously substituted for copaiba. In atonic hæmorrhages it is very useful. In puerperal peritonitis, applied externally, it is of great utility. Externally in burns, the linimentum terebinthinæ, or hot dressing, is useful. In peritonitis with a tympanitic condition of the abdomen it is very excellent. The vapour of oil of turpentine can be used as an anæsthetic, and as a substitute for chloroform.

Chian or *Cyprus Turpentine*, called also true turpentine, is obtained from the *Pistachia terebinthus*, a native of Barbary, Syria, the south of France, and, above all, of the Grecian Archipelago. Eight or ten ounces are the utmost obtained from one tree; hence it is very dear. It is of the consistence of new honey, tenacious, pellucid, of a light yellowish-green colour. The odour is pentrating and peculiar. It has a slightly bitter taste; but when adulterated with any of the coniferous kinds, its odour is strong, its taste acrid, and of a sensible degree of bitterness. It consists of a volatile oil and resin, and when by time the former is dissipated or oxidised, it becomes hard and translucent.

This article is scarce in a pure state, it being mixed largely with Venice turpentine, and indeed in many instances altogether supplanted by that article. It was greatly esteemed by Hippocrates; and in the present day is chewed by the inhabitants of Turkey, Persia, &c., as mastic is, to sweeten the breath. But it likewise improves the digestion, having a very beneficial influence on the secretions of relaxed mucous membranes. Hence it is useful in chronic catarrh, both of the lungs and genito-urinary organs. For the latter it is advantageously combined with sulphate of zinc.

TURPETH MINERAL. [MERCURY. *Bisulphate of mercury.*]

TUSCAN ORDER. [COLUMN; ROMAN ARCHITECTURE.]

TUSCAN SCHOOL OF PAINTING. [PAINTING.]

TUSSILAGO FARFARA (Coltsfoot), a perennial plant belonging to the order of compound plants, common in damp, clayey fields, road-sides, and the banks of rivers, the yellow flowers of which are seen in spring preceding the nearly heart-shaped, smooth-toothed leaves, which, from their resemblance to a young horse's hoof, have received the popular name of coltsfoot. The whole plant is nearly devoid of odour. The root has a styptic bitter taste; the leaves and flowers are bitter and mucilaginous. The chief constituents are mucilage, bitter extractive, tannic acid, colouring-matter, salts, and woody fibre. The watery infusion becomes of a dark green and turbid appearance on the addition of a solution of sesquichloride of iron. Its properties may easily be inferred from the above statement; they are demulcent, slightly astringent, tonic, and expectorant. Its name both in Greek (βηχιον) and in Latin proves the estimation in which it was held as a means of relieving cough—a reputation which it does not maintain in modern times among professional observers, except a very few; but with the vulgar it is still in great esteem. The young leaves make a wholesome salad in early spring. The ancients smoked it rather than used it in any other form; and in the north of Europe, and even with our own vulgar, this mode is employed, what is sold under the name of British Herb Tobacco being chiefly coltsfoot. This at least is harmless; not so the nostrum called Essence of Coltsfoot, which is a combination of balsam of tolu, compound tincture of benzoin, with a large quantity of rectified spirit of wine, and not a particle of the substance from which it takes its name. In chronic coughs accompanied by much local or general irritation, still more in genuine tubercular consumption, such heating ingredients must be very hurtful; though a plain decoction of real coltsfoot would be unobjectionable, and might be beneficial. The leaves of coltsfoot form, when moistened with warm water, an excellent emollient poultice.

TUTANIA. [BRITANNIA METAL.]

TUTELA. [TUTOR.]

TUTENAG, an alloy used in China in the manufacture of the *gong.* It is white, resembling silver in appearance, and is very sonorous when struck. Its specific gravity was found by Dr. Fyfe to be 8·432; it is susceptible of a fine polish, and does not readily tarnish; at common temperatures, and even at a red heat, it is malleable, but when heated to whiteness it is rendered brittle.

It has been analysed by Dr. Fyfe, who found it to consist of—

Copper	40·4
Zinc	25·4
Nickel	31·6
Iron	2·6
	100·

It may therefore be regarded as a kind of German silver.

TUTOR. By the Roman law a male under the age of fourteen, and a female under the age of twelve, were called Impuberes. A male who was impubes was incapable of doing any legal act by which he might be injured; his property was under the care of a tutor, who was so called from his office of defending or protecting (tuendo) the impubes in the transactions which were necessary for the administration of his property. The office of the tutor was tutela; and the impubes, who with respect to his tutor was called pupillus, was said to be in tutela, in tutelage. The tutor's business was to manage the property of his pupillus, and to add to his acts the legal sanction (auctoritas). The tutor's office as tutor was confined to the property of his pupillus, who, as to his person, was under the care (custodia) of his mother, if he had one; if not, we must suppose that the tutor would sometimes have the care of his person also. When the pupillus attained the age of puberty, he had the capacity of contracting marriage, and of doing other legal acts, and was freed from the control of his tutor. But though the law gave full legal capacity to the pupillus on his attaining puberty, it still gave him some further protection until he was twenty-five years of age. [CURATOR.]

A father could appoint by testament a tutor for his male children who were impuberes and in his power: he could also appoint a tutor for females who were in his power, even if they had attained puberty. He could also appoint a tutor for the wife of a son, who was in his power, and for his grandchildren, unless by his death they should come into the power of their father. A man could also appoint a tutor for his wife, who was in manu, for she stood to him in the legal relation of a daughter; and he could also give her the power of choosing a tutor. The origin of this testamentary power was probably immemorial custom, which was confirmed by the Twelve Tables. Tutors thus appointed were called dativi: those who were chosen by a wife under a power given by the husband were tutores optivi. If a testator appointed no tutor, the tutela was given to the nearest agnati by the Twelve Tables: such tutores were legitimi. If there were no agnati, the tutela belonged to the Gentiles so long as that part of the law (Jus Gentilitium) remained in force. When there was no person appointed tutor, and no legitimus tutor existed, a tutor was appointed for persons at Rome under the provisions of a Lex Atilia, and for persons in the provinces under the provisions of a Lex Julia et Titia.

Though a pupillus could not do any legal act which should be to his injury, he could enter into contracts which were for his benefit. The tutor's office was defined to consist in doing the necessary acts for the pupillus, and interposing or adding the legal authority to his proper acts (negotia gerere et auctoritatem interponere: Ulpiani, 'Frag.,' tit. xi., s. 25). The doing of the necessary acts applied to the case of the pupillus being infans, that is, under seven years of age, absent, or lunatic (furiosus). When the pupillus ceased to be infans, he could do many acts himself, and the auctoritas of the tutor was only necessary to make them legal acts.

A tutor might be removed from his office if he misconducted himself in it. The pupillus had also an action against him for mismanagement of his property. The tutor was allowed all proper costs and expenses incurred by him in the management of the affairs of the pupillus; and he could recover them by action. Security was required by the prætor from a tutor for the due management of the affairs of a pupillus. unless he was a testamentary tutor, for such tutor was chosen by the testator, and, generally, unless he was appointed by a magistratus, for in such case he had been selected as a proper person.

The tutela of women who were puberes was a peculiar Roman institution, founded on the maxim that a woman could do nothing without the auctoritas of a tutor. But there was this difference between the tutela of pupilli and of women who were puberes: in the case of pupilli the tutor both did the necessary acts, particularly when the pupillus was infans, and gave his auctoritas; in the case of women who were puberes, the tutor only gave his auctoritas.

The Vestal virgins, in virtue of their office, were exempted from tutela. Both libertinæ and ingenuæ were exempted from it by acquiring the Jus Liberorum, which was conferred by the Lex Julia et Papia Poppæa on women who had a certain number of children. The tutela of a woman was terminated on her marriage, by which she came in manum viri; and also by other means.

A woman had no right of action against her tutor as such, for he did not do any act in the administration of her property; he only gave to her acts their legal validity by his auctoritas.

TUTTY. [ZINC.]

TWELVE TABLES. The Roman writers speak of the Twelve Tables under various names: they call them Leges Decemvirales, Leges XII. Tabularum, sometimes simply Lex, the Law, as being pre-eminently the foundation of Roman Law; and by other names. After some struggle between the patricians and the plebs, the story runs that a plebiscitum was passed (B.C. 454) with the assent of the senate, in pursuance of which three commissioners were sent to Athens and other Greek states to inquire about their legislation, that the commissioners returned in B.C. 452, and that in the following year ten patricians (Decemviri) were appointed to draw up a code of laws, whence the name Leges Decemvirales. The Decemviri, at the head of whom was Appius Claudius, formed a code of Ten Tables, which were approved by the senate, and received the final sanction of the Comitia Curiata. The code being considered defective, Decemviri were again elected (B.C. 450), and two more tables were added, whence the name Twelve Tables. The laws were cut on tablets of bronze and set up in a public place: they were not promulgated till B.C. 449, after the overthrow of the Decemviri, who had attempted to perpetuate their power against the terms of their appointment.

It is impossible to ascertain from the scanty history of the Decemviral legislation how far the story of this mission to Greece is true. It is very doubtful whether the codes of the Greeks at all affected this the first Roman attempt to form a system of law, but it may safely be assumed that the basis of the Decemviral code rested on the customary law of the Romans, and that except in those few general features in which all early codes of law bear resemblance to one another, the Roman Decemviral code is one and distinct. It is said that the Twelve Tables perished in the destruction of the city by the Gauls, but there appears to have been no difficulty in reconstructing the tables. No Roman writer suggests any doubt of their genuineness.

The Twelve Tables are called by Livy (iii. 34), "Fons publici privatique juris"—the source of Public and Private Law,—according to a division of the matter of law which was familiar to the Romans. That part which concerned the Jus Publicum, which bears some analogy to our term constitutional law, was changed in the course of time; but the Jus Privatum, which determined the rights and duties of the citizens, was never formally repealed, and only so far modified as it was affected by the changes in circumstances by which some of the laws of the Twelve Tables fell into desuetude, and by the gradual growth of the Jus Prætorium. In course of time the language of the tables became obscure, and this, with the great change of circumstances, must have rendered many of their provisions inapplicable. In the later times of the republic, Cicero observes that since his boyhood the practice of learning the Twelve Tables had been superseded by the growing importance of the Edict.

The Roman jurists made commentaries on the Twelve Tables. Six books of a commentary by Gaius are mentioned, which shows that at least as late as the time of Antoninus Pius the decemviral law was in substance still in force, that is, that the fundamental principles of Roman law (the Jus Privatum) were still to be sought in the then antiquated language of the Decemviri.

Much has been written on the subject of the Twelve Tables. The last and most complete history of the labours of modern critics on the Twelve Tables is by Dirksen, in his 'Uebersicht der bisherigen Versuche zur Kritik und Herstellung des Textes der Zwölf-tafel Fragmente,' Leipzig, 1824. The fragments of the Twelve Tables appear in the several parts of the work, and are also collected at the end.

For an excellent dissertation upon the Twelve Tables as illustrative of the archaic form of the Latin language, the reader is referred to an able article in the late Dr. Donaldson's 'Varronianus.'

TWILIGHT, the name given to the light which remains after the sun has set, or which is seen immediately before it rises. The reason of this appearance is explained in SUN (col. 915), being the effect of the light which is reflected from the higher strata of the atmosphere, in a manner which will be understood from the diagram in the column cited.

In our latitudes, at the summer solstice, a portion of the twilight continues from the setting of the sun to its rising, circling, as the hours of night and morning proceed, from the western horizon through the north, to the east; which is the cause of there being scarcely any true night at that period of the year.

J. H. Lambert endeavoured to distinguish, besides the primary twilight, a secondary and even a ternary twilight, both the latter being caused by the successive reflection, by the clouds and the air, of light already reflected from other regions of the atmosphere, their clouds, &c. In conformity with these views, Sir John F. W. Herschel has attributed to such a cause the phenomenon, seen in the clear atmosphere of the Nubian deserts, which has been described by travellers under the name of the "after-glow." To a corresponding cause must be ascribed the rose-coloured illumination of the summits of high mountains after sunset (often witnessed of those of Mont Blanc and Monte Rosa), but in these cases the reflected light is coloured by its traversing tracts of the air of which the vapour is in an opalescent state, imparting to it various hues of red and orange. [VAPOUR.]

The astronomer last named, always careful to explain the physical processes which are operative in the production of astronomical phenomena, in addition to the mathematical principles on which they depend, has pointed out that a portion of the light of the sun and moon reaches us after they are set, by means of the atmosphere, "by *reflection* upon [and from] the vapours and minute solid particles which float in it, and, perhaps, also on the actual material atoms of the air itself." (See 'Outlines of Astronomy.' ed. 1858, par. 44, 45.)

The observations which have been made during the last two or three total solar eclipses are very instructive, in two respects, concerning the light ordinarily received by the earth, including that of twilight. The character of the darkness, while the totality continues, so much more intense than that of night caused by the mere aversion of the hemisphere from the sun, evinces how intrinsically dependent upon that luminary for light the earth really is; while the amount and peculiarity of the illumination actually existing at the same time, shows in how great a degree we are indebted to the reflective and refractive powers of the atmosphere, and to the reflection by the floating particles alluded to, by aqueous vapour becoming visible but not yet cloud, by the clouds themselves, and by the earth, reciprocally and unitedly, for the light we enjoy after the commencement and during the progress of that aversion.

But all this is, of course, affected by the degree of transparency of the atmosphere and its difference at different altitudes, the less transparent, in the mass, so far as we know, being those nearest the earth; while there are facts which indicate that air perfectly free from aqueous vapour, such as we must conclude it to be above a certain height, is less transparent, or more absorptive of light, than the mingled atmosphere of air and aqueous vapour incumbent on the earth's surface, when the temperature is such as to sustain the latter in a perfectly gaseous condition. When the sky is thus free from visible vapour and cloud, however, the transparency of the atmosphere is almost invariable, as Professor Seidel has shown.

Another consideration affecting this subject relates to the probable nature of the highest regions of the atmosphere, on which the amount of reflected light causative of twilight must be greatly dependent. If, as inferred by Graham and Poisson [SURFACE OF THE EARTH, col. 982], the terminal stratum be solid—air-ice—the reflection from its inferior surface, and from the inferior surfaces of the comparatively dense strata immediately below it, must be more powerful than that from the rare, purely aëriform strata (of which alone the highest regions are commonly supposed to consist), and hence may exert a marked effect in prolonging the twilight, as well as in lessening the darkness during the entire time when the sun is below the horizon. It may be that this reflection is the principal agent in producing the remarkable amount of light still remaining during a total eclipse of the sun, as noticed above. What may be the bearing upon this subject of the observed polarising power of the sky during such eclipses has not been investigated, though the materials for such an inquiry, we believe, have been obtained, especially from the eclipse of July 18th, 1860. It seems probable that the polariscope would furnish the means of determining whether such reflection does in reality take place, and also, if taken in conjunction with the atmospheric refraction of the heavenly bodies, of determining what the structure and constitution of the upper regions of the atmosphere really are.

Intimately connected with this particular subject is the application of the phenomena of twilight, or rather of the amount of depression of the sun at the close of twilight, to determine the height of the atmosphere, first proposed by Kepler, and which, in fact, gives a height nearly agreeing with that inferred from the law of elasticity of the air, of between forty and forty-five miles. But the argument from the observed depression of the sun is inconclusive, because we do not know when twilight has ceased, nor, indeed, whether it ever ceases. According to Leslie, admitting, from the fact that in clear weather in no climate is there total darkness, even at midnight, "that the body of air extends to such an altitude, as to receive the most dilute glimmer, after the sun has attained his utmost obliquity, and sunk ninety degrees below the horizon," the elevation of the atmosphere must be equal at least to 1638 miles. In this reasoning, however, no account is taken of the necessary limitation of the atmosphere by the cold of interplanetary space, which must have effect at a point greatly nearer the earth. On the other hand, the actual demonstration of the existence of a solid or liquid stratum at the summit of the atmosphere, by the means suggested above, would probably involve also, the determination of its altitude, and, conversely would enable us to fix, definitively, the extent of twilight upon the earth's surface. [ATMOSPHERE; METEOROLOGY.]

A question here arises as to the photographic intensity and properties of the reflected light from which the phenomenon of twilight proceeds, as compared with those of the direct sun-light itself. But this comparison does not appear to have been made in any express manner. According to the photo-chemical researches of Bunsen and Roscoe ('Phil. Trans.' 1859, p. 898), the chemical illumination, that is, the affection by the chemical rays, of the earth's surface, is merely a function of the sun's zenith-distance; all the elements of the sun's radiation (so to call them), light, heat, and chemical action, diminishing equally with his altitude. As the diffused light of day is all, in its immediate origin, reflected, and as it, in common with that reflected from the clouds, possesses normal chemical action, differing only in its intensity from that of the direct light of the sun, we may infer that a similar difference only exists in the case of twilight.

TWINKLING OF STARS, or SCINTILLATION (*scintilla*, "a spark of fire"). This term is applied to a phenomenon which has attracted the attention of astronomers and scientific men in all ages. It consists in rapid variations in the brightness of a fixed star when observed with the naked eye, and is often accompanied by changes in the colour, and alterations in the apparent diameter of the star or in the length of the diverging rays which appear to dart from its centre in different directions. It is commonly stated that the twinkling disappears when the star is viewed through a telescope; such, however, is not the case, although under such circumstances the phenomena are modified.

This subject occupied but a very small space in scientific works, if indeed it was to be found at all in them, until M. Arago devoted one of his searching scientific notices to the subject in the 'Annuaire pour l'An 1852, publié par le Bureau des Longitudes;' nevertheless the importance of the subject has never been forgotten, and Kepler even invited scientific men to a conference on the subject, and appointed Frankfort as the place of rendezvous.

The changes in colour which accompany scintillation, and form one of its most important features, were noticed by early observers. Indeed the name given by the Arabs to Sirius refers to this fact; they call it *barakesch*, or "the thousand-coloured star." Tycho, writing in 1572, respecting the new star of that year, compares it to the reflections of a cut diamond moving in the presence of light. Kepler also refers to the Dog Star as presenting by turns all the colours of the rainbow. Hooke, in his 'Micrographia,' refers to the various colours which accompany the scintillation of stars, appearing red at one moment, yellow at another, and blue at a third. Forster ('Phil. Mag.,' 1824) remarks that sometimes the intensely red light appears after two dilatations of the star, under other circumstances after three, but often without any apparently regular law. Several observers notice the scintillation of the planets; but no astronomer refers to their change of colour. Scintillation in their case is a simple change in the intensity of the light.

The scintillation of a star, when viewed through a telescope, was first described by Simon Marius, who recommends that the eyepiece be removed from the telescope, and the eye be substituted for it, at a time when the sky is very clear and the air tranquil. The scintillation will then appear like a fulmination or ebullition of the substance of the star, and certain determinate and distinct colours will appear in greater or less abundance according to the stars observed. Thus

Sirius presents green, yellow, red, and blue repeatedly following in the same order. Nicholson also in 1813 remarks that the circular disc of a star vacillates in such a manner as to give the idea of a number of discs passing in succession before each other. These discs are of different colours: the light appeared to come from different sides, and the most frequent colours were blue, steel-blue, pea-green, brilliant copper, red, and white. The same observer viewing Sirius through an achromatic by Ramsden, magnifying twenty-four times, and the eye-piece adjusted for distinct vision, the observer struck lightly on the tube a series of rapid blows with his fingers, so as to make the image of the star describe a luminous line, every part of which displayed the most lively colours, and it was calculated that the light of Sirius changed in colour before arriving at the eye at least thirty times in a second.

Scintillation presents phenomena too remarkable to have been allowed to remain without attempts, at least, at explanation. Aristotle, who noticed the scintillation of the fixed stars, and the steady light of the planets, speaks of a want of fixity in our sight for such distant objects, while the planets being comparatively near can be viewed with a steadier gaze. Ptolemy also refers to the trepidation of the organs of sight, and the consequent trembling of the heavenly body. Alhazen and Vitellion refer the twinkling of stars to the effects of refraction which the stellar rays experience in our atmosphere. Aguillonius explains it by the rapid movement of rotation of the stars. Tycho adopts such an explanation as when a diamond cut into facets rotates, but the planets do not scintillate because he imagined them not to rotate. Cardan adopts Aristotle's explanation. Scaliger, among other attempts at explanation, refers to the intermittent light of an incandescent body, and to the changes in the intensities of the stellar light produced by vapours floating in the atmosphere. Galileo's explanation assumes a vibration which stars impress upon their own light. Kepler compares the stars to diamonds cut into facets so that the least movement produces iridescent colours, or in other words he supposed a star to contain angular surfaces unequally luminous. Scheiner imagines scintillation to be an optical illusion. Descartes explains the phenomenon by means of his favourite vortices or tourbillons, which he supposed to surround all celestial bodies. Huyghens explains scintillation by means of the vapours of the earth; and Gassendi attributes it to a vibratory motion in the eye. Riccioli calls in the aid of atmospheric vapours, and imagines also that particles of dust and opaque filaments floating in the air influence the phenomenon. Hooke explains it by the irregular refractions of the stellar rays in our atmosphere, arising from the unequal distribution of heat. Sir Isaac Newton refers to the refractive power of the humours of the eye, and also of the atmosphere, and speaks of a trembling movement in the latter. Jurin endeavours to explain scintillation by means of Newton's theory of fits of easy transmission and reflection. Cassini explains it by supposing a sort of luminous coma to surround the stars, and to undergo refraction and reflection in our atmosphere, but that these scattered rays being united through the intervention of a telescope the twinkling is less apparent. Long explains twinkling as the momentary disappearance of the stars, in consequence of the interposition of motes floating in the air. Mairan refers it to an undulatory movement like that of the horizon seen over a vast plain illuminated by the sun. Michell's explanation is based on the corpuscular theory of light. Lalande refers to the agitation of the air, and to motes floating in it, forgetting, as Long had done, that these motes must be at least equal to the diameter of the pupil of the eye. Muschenbroeck refers to the vivacity of light and to the activity with which it acts on our organ of sight. Darwin explains twinkling by means of the theory of accidental colours which was much discussed in his day, and explains it by the law of contrast. Saussure speaks of the oscillation of the luminous rays produced by the alternate condensations and dilatations of certain parts of the atmosphere. Dr. Thomas Young says,—"The cause of the twinkling of the stars is not fully ascertained, but it is referred, with some probability, to changes which are perpetually taking place in the atmosphere, and which affect its refractive density. It is said that in some climates, where the air is remarkably serene, the stars have scarcely any appearance of twinkling." Arago remarks on the singularity of the fact, that the author of the doctrine of interference of light, and indeed "of the only really new experiment which has been made on scintillation from the time of Aristotle to our own day, should not hesitate in facing the difficulties of the problem to say, 'I do not know.' There is more true merit in this candour than in the former unsatisfactory attempts at explanation." Nicholson, however, was equally candid, for he professed his inability to find in any of the known properties of light the cause of the phenomena of twinkling. Biot in his 'Astronomie' bases his explanation on the unequal refraction of the rays by our atmosphere. Forster imagines that the changes in colour which accompany twinkling must be due to some change in the star itself, or that our atmosphere acts like a prism on the rays of light. Capocci refers the phenomena to our eye and not to any changes in the star, while Kämtz, in his 'Meteorologie,' refers to a supposed oscillation of the star as a mere point of light about its mean position, while a planet having an apparent diameter of from 30 to 40 seconds, it is more difficult to appreciate its apparent change in volume.

Lastly we come to the explanation of Arago himself. That keen observer was very much struck with the experiment of Nicholson, who observed Sirius through a telescope, and caused the image to vibrate by tapping on the tube, when it appeared like a coloured luminous ribbon. On applying this experiment to other stars the coloured ribbon was observed with stars up to the sixth magnitude, but no trace of colour was observed with a star of the seventh. Another method of studying scintillation is to direct an achromatic telescope towards a brilliant star and then to move the eyepiece out of focus. The image then becomes an irregular disc approaching a circular form, and of a diameter greater or less according to the position of the eye-piece. The disc oscillates as though a number of discs of different colours were in motion. A third method of observing scintillation through a telescope is to contract the aperture by means of an opaque screen with a hole in the centre placed before the object-glass. On viewing the image of a star out of the focus, and consequently enlarged, its centre will appear to be pierced with a dark but regular hole. The opaque screen used by M. Arago had a central opening of only three or four centimètres in diameter; the image of a star at the focus was round and precise, but surrounded with a series of light and dark rings perfectly well defined. The lustre of these rings constantly varied in different parts of their contour, often disappearing, at certain points entirely. Under these circumstances, if the eye-piece were gradually pushed inwards, the image of the star would gradually dilate, and a well-defined black spot would appear in the centre. A further motion of the eye-piece inwards caused the dark spot to dilate into a small luminous disc, occupying the centre, surrounded by a dark ring, and this by a larger luminous ring. Or in a third position of the eye-piece, still nearer to the object-glass, the centre of the image is obscure, but surrounded by a large brilliant ring, succeeded by a dark ring, and this again surrounded by a luminous ring.

All these phenomena plainly refer the phenomena of scintillation to the interference of light. [Interference.] Luminous rays proceeding from a point, such as a fixed star, and passing through our atmosphere, subject as it is to great variations in heat, moisture, and density, must have very unequal velocities; if such rays be brought to a focus by means of a lens, as they are by the lens of the eye, the effect of their reaching us with different velocities will be seen by the alternate brightening and darkening of the image in such focus, by the known laws of interference. If, however, the rays proceed not from a point, but from a disc, such as a planet, the effects would so far disturb each other as to prevent their being observed, or if observed, but imperfectly. M. Arago has contrived three methods, or instruments (*scintillometers*, as he calls them), based upon the change of the central spot from dark to light, which occurs the more frequently in proportion as the scintillation is strong; for example, in preparing a telescope as a scintillometer as above directed, with a pierced screen before the object-glass, on directing it to the stars named in the first column of the following table, at the heights above the horizon indicated in the second column, the central point became luminous, in the course of five minutes, the number of times mentioned in the third column:—

January 14, 1851.

Sirius	20°	40
Rigel	31°	17
Aldebaran	57°	13
La Chèvre	81°	8

By observations of this kind M. Arago thinks it possible to decide what are the climates, the seasons, the elevations, and other circumstances, under which scintillation entirely disappears.

While writing this article, we have received from M. Andrès Poey, Director of the Physico-Meteorological Observatory of Havannah, a Memoir entitled 'Loi de la Coloration et de la Décoloration des Etoiles, du Soleil, et des Planètes,' reprinted from the 'Annuaire' of the Meteorological Society of France, vol. viii., 1861. Our space will not allow us to do more than point out one remarkable result obtained by M. Poey, namely, that when, in viewing a fixed star through a telescope, the eye-piece is drawn out the series of rings obtained are complementary in colour to those seen when the eye-piece is pushed in towards the object-glass.

TYCHE, in the Greek mythology, one of the goddesses of Destiny: with the Romans Fortuna was nearly the correspondent deity, but uniting in herself the attributes of the Greek goddesses of destiny was on the whole of a somewhat sterner character. Tyche was the daughter of Zeus the liberator. She was the guider of the affairs of the world, the bestower of good fortune, the impersonation of chance, uncertainty, and transitoriness. In art, on gems, coins, &c., she is frequently represented with attributes indicative of one or other of those qualities; with the rudder as providence; the wheel or ball as chance and uncertainty; with the horn of plenty, or with a patera in the right hand, and ears of wheat and poppies in the left, as the bestower of gifts; as the good-fortune of cities she is figured as a richly draped female with a crown of towers, a cornucopia and other attributes of prosperity. Tyche had temples devoted to her worship at Smyrna, at Pharae in Messania, at Ægiria in Achaia, at Thebes, and elsewhere. (Zoega, 'Tyche und Nemesis;' Müller, 'Archäol. der Kunst,' and 'Denkmäler der Alten Kunst.')

TYPE-FOUNDING. [Printing.]

TYPE METAL. The alloy formerly used for printers' types consisted of lead and antimony in about the following proportions:—

Lead	75
Antimony	25
	100

Recently, however, a harder description of metal has been found necessary, especially for the smaller letters, and the necessary quality has been attained by the partial or even total substitution of tin for lead in the above compound. The alloy of this description most commonly used is the following:—

Lead	50
Tin	25
Antimony	25
	100

Another alloy known as Didot's metal consists of—

Lead	30
Tin	30
Antimony	30
Copper	10
	100

The latter alloy, although very hard, appears to be too brittle for the purposes of the printer.

TYPES. [Organic Chemistry, *Constitution of organic compounds.*]

TYPHOON. [Wind.]

TYPHUS. [Fever, Continued.]

TYRANT. The words tyrant and tyranny come respectively from the Greek *tyrannos*, *tyrannis* (*τύραννος*, *τυραννίς*), through the Latin. The earliest instance of the word tyrannus is perhaps in the Homeric hymn to Ares (Mars). It is used by the earliest extant Greek historians, Herodotus and Thucydides, to signify a person who possessed sovereign power and owed it to usurpation, or who derived it from a person who had obtained such power by usurpation, and who maintained it by force. A familiar example of a tyrant is Pisistratus, who usurped the supreme power at Athens B.C. 560, and was succeeded in it by his eldest son Hippias. A Greek tyrant who obtained sovereign power was a monarch in the proper sense of that term. [Monarch.] If he acquired a power which was somewhat less than sovereign, he was not a monarch; but in either case he would perhaps be called tyrannus; and accordingly the word does not express with accuracy the degree of political power which an individual acquired, but it rather expresses the mode of acquisition, or refers to its originally illegal origin. Still the term tyrant, as used among the Greeks, always indicates that the person so called was at the head of the state, and possessed at least more power than any other individual or any number of individuals in it. The word, as used by the older Greek writers, did not carry with it any notion of blame: it simply denoted a person possessed of such political power as above mentioned, whether he used it well or ill. Many so-called tyrants were popular with the mass of the community, and were men of letters, and patrons of literature and art. They might appropriately be called kings or princes in the modern acceptation of those terms, except perhaps that the uncertainty of their tenure of power and the want of a recognised hereditary succession in the tyranny, or a regular mode of succeeding to it, would render the application of any modern name inappropriate.

In some passages in Herodotus (iii. 80, &c.; vi. 23, &c.; vii. 165) the words monarch and tyrant are used as synonymes to express an individual who possesses sovereign power; and in one instance at least (vi. 23, 24) he calls the same person king (*βασιλεύς*) and monarch (*μούναρχος*). Aristotle ('Polit.', iii. 7), after stating that a polity or government must either be in the hands of one or of a few, or of the many, adds that we are accustomed to call a monarchy which has regard to the interests of all members of the state a kingship (*βασιλεία*); and that a monarchy which has regard only to the interests of the monarch is a tyranny. In the case of Miltiades, who became tyrant of the Thracian Chersonesus, Nepos ('Miltiad.') remarks that "all persons are considered and called tyranni who enjoy lasting power in a state which has once been free." This definition seems to express pretty clearly the old Greek notion of a tyrant, but it leaves out of consideration the mode in which the power was acquired. Nepos remarks that Militiades was called "Tyrannus sed justus," "tyrant, but tyrant in constitutional form" (not *just*), for he had been elected by the people. Accordingly, he says in another place, he had the dignity or rank of king without the name. This is consistent with Herodotus (vi. 36), who says that the people made Miltiades tyrant (*τύραννον κατεστήσαντο*).

Among the Roman writers tyrannus is often used as simply equivalent to king, especially by the poets. Cicero couples dominus and tyrannus, thereby intending to use tyrannus in a bad sense, which was perhaps the more common acceptation of the word among the Romans in his time and subsequently. Seneca seems to refer to the original sense of tyrannus when he says, "A tyrant is to be distinguished from a king (rex) by his conduct, and not by the name: for Dionysius the elder (who was called a tyrant) was a better man than many kings; and Lucius Sulla may be appropriately called a tyrant, for he only ceased from slaughter when he had no more enemies to kill." (Facciol., 'Lex—Tyrannus.') According to this, a man might be called tyrant without being a cruel governor, for there were instances of persons so called who had used their power with moderation; and yet a man who had not the title of tyrant might be called tyrant on account of his cruelty. It seems as if Seneca was trying to distinguish the popular use of tyrant in his time from its earlier historical signification. Tribellius Pollio has written the 'History of the Thirty Tyrants' who sprung up in the Roman empire in the time of Gallienus and Valerian. These so-called tyrants were not more tyrannical, in the modern sense of the term, than many Roman emperors.

The use of the modern words tyrant, tyranny, tyrannical, has been as vague as that of most other political terms. The term tyrant is properly limited to the government of one man who is sovereign, and the popular application of the term expresses disapprobation of his conduct. Aristotle's definition of tyranny would apply well enough to a modern tyrant: he is a sovereign who looks only to his own interest, or what he considers his own interest, and cares not what he does in order to accomplish his objects. But if he were a wise sovereign, and administered the state solely with a view to his real interest, that would be found in the main to coincide with the interest of the people, and he would not be called a tyrant, though perhaps he would come within Aristotle's definition. But Aristotle's language, though apparently precise, is not so, and he means by a tyrant administering the state for his own interest, that he also administers it to the detriment of the people. The word tyrannical is now often applied to acts of governments which are not monarchies; but this is an improper use of the word. We may say that the laws enacted by the sovereign power in Great Britain are sometimes impolitic, unwise, or injurious to the state generally; they may also be sometimes called oppressive; but they cannot with propriety be called tyrannical, though such an expression may be and often is used in the vulgar sense of characterising a law which for some reason the person who uses the term does not like.

Confusion in the use of political terms, which is an index of confusion of thought, leads to absurdity in conduct. It is therefore a matter of some moment to clear up such confusion, which all people should try to do who presume to speak or write on matters political. A careful perusal of the following articles in this work, even if they should not be quite free from error, will put a man in the way of coming to right notions as to the meaning of Aristocracy, Constitution, Democracy, King, Law, Monarch, Republic, Sovereignty.

TYROSIN ($C_{18}H_{11}NO_6$). A colourless crystalline organic substance obtained along with Leucin, by the action of potash upon albumen, fibrin, casein, horn, hair, feathers, &c. It also exists ready formed in cochineal. It possesses neither acid nor alkaline properties.

U

U is at one extremity of the series of vowel sounds, lying next to the vowel *o*. In the Hebrew alphabet it does not appear, and was probably originally wanting in that of the Greek tongue. For the different forms of the letter see ALPHABET.

1. The close connection between this vowel and the vowel *o* might be inferred from their relative position in the vocal gamut, and has been already the subject of remark under the article O.

2. *ū* is interchangeable with the diphthongs *oe* or *oi* in Latin. Thus cūra, ūtor, ūnus, mūnio, mūrus, often appear in the older dialects of that language as coira or coera, oitor or oetor, oenus (observe the *w* sound at the beginning of the English word *one*), moinio or moenio, moerus. Hence the verb ūro is probably connected with oestrum, and also with aestus, aestas, as well as Vesta, Vesevus. In the same way foetus, foecundus, are formed from the old verb fuo, by the addition of the common suffixes *tus* and *cundus*, which are so often attached to verbs. Again the variation in the forms of Poeni and Punicus is an example of the same principle. It may be added, that all the words munus, munire, communis, immunis, munia, murus, are connected both in form and meaning with the Greek words, such as *μοιρα*, denoting *division*.

3. *u* with *au*, as in the Latin forms claudo and cludo, and the Latin mus compared with the German maus, a mouse.

4. A short *u* with *ă*. Thus those who represent the Arabic article in English characters are divided between al and ul.

5. A short *u* with *ĕ*. Thus the Greek tongue, or rather pen, prefers the syllable *el* where the Latin writes *ul*, particularly in the penult syllable: as Σικελος, Siculus: compare also the cry ελελελευ with the Latin ululare. The Germans again prefer *el*. Hence the Latin tabula, fabula, appear in German as tafel, fabel. The vowel *u* is also preferred by the Romans before *n*, if a *d* or *t* follow. Hence rediens has a genitive redeuntis, and faciundus is as common as faciendus.

6. A short *u* with *ĭ*. See I., s. 2.

7. For the interchange of *du* with *b* and *v*, see B, D.

8. For the interchange of *l* with *u*, see L.

9. *Ou* not unfrequently results from *on*, particularly in the Greek language, as *οδους* for *οδονς*; *τυπτουσι* for *τυπτοντι*; and the accusative plural of the second declension, *οικους*, is a corruption of *οικονς*, being formed from the singular *οικον* by the addition of the affix for plurality. Mr. Payne Knight appears to be wrong in inserting a digamma in this form.

10. For the loss of an initial *c* before *u*, see C. In confirmation of what is there stated, it may be observed that *uter* appears in an inscription which is determined by its contents to belong to the Augustan æra, in the form *cuter*, at least *neuter* is written *necuter*. The copyists, scandalised at such a form, altered it into *nec vero*, to the utter annihilation of the sense, until Marini again restored the true reading of the stone.

11. The insertion of a *y* sound before *u* is not limited to an initial *u*, as in union, university; but occurs in the middle of words. Thus, in Norfolk "true" is sometimes pronounced "tryoo." It is probably in this way that the English have adopted the orthography *ew* in so many words, as new, few.

12. For the intimate connection of *u* with V and W, see those letters.

UDAL TENURE. The Norwegian term "Udal," or "odel," appears to be the same as the German "adel," or "noble." Tenure is an improper name as applied to Udal land, for the land so called in Norway is not held by any tenure, but is free from all services. There is neither superior nor vassal, nor any of the consequences of such feudal relation as exists in many countries in Europe. (Laing's *Norway*.)

ULCER. [INFLAMMATION.]

ULEMA ('Ulemá), the collective name of the body of learned men in Turkey, is the plural of the Arabic "'Alim," "wise," and signifies originally "the wise men." The learned men in Turkey form a corporation which received its organisation from Mahmud-Pasha, grand-vizir of Mohammed II., the conqueror of Constantinople. In the larger meaning, the ulema consists of three classes, the mollahs mukreji, the mudaris, and the moultazims. From the first two classes are taken the interpreters of the laws, the principal mollahs, cadis, nazibs, muftis, and sheikhs; from the third, the lower cadis and khatibs. The imams and the inferior ministers of worship are not members of the ulema. The mufti, or Sheikh-ul-Islam, is the president of the ulema, and formerly had great political influence. No one can become a "muderri" (professor) or "kadi" (judge) except a member of the ulema, nor can any one be appointed chief judge or mufti without having previously occupied a subordinate place as judge or professor. An individual belonging to the ulema is called by the general name "mollah," or "a man of the law." In important cases, the mufti assembles the ulema, or as many of them as he judges convenient, and takes their opinion on the subject.

ULLAGE, a name given by gaugers to the part of a cask which is not filled with liquor: thus, if a cask, capable of holding 90 gallons, have only 80 gallons of spirits in it, there are 10 gallons of ullage.

ULMIC ACID. *Ulmin.* Some trees, and more especially the elm when it is old, secrete a liquid which dries as it exudes: the dry residue consists principally of mucilaginous matter, with some carbonate or acetate of potash, and eventually the mucilaginous matter undergoes a change, and, combining with the potash, forms a substance which was first examined by Vauquelin and Klaproth, and to which Dr. Thomson gave the name of *ulmin*. This name was changed by Berzelius to that of *geic* acid, because on treating soils with alkalies a considerable quantity of a similar compound is obtained.

Ulmin, or ulmic acid, may be artificially obtained, according to Braconnot, by the following process:—heat in a silver crucible equal weights of potash and sawdust, with a little water; the mixture is to be continually stirred: the mass softens and swells rapidly, and is then to be removed from the heat and stirred till cold: during the operation oxygen is absorbed from the air, owing to which the ulmic acid is formed. When cold, the product, which contains ulmate of potash, is dissolved in water, filtered, and treated with dilute sulphuric acid, which combines with the potash, and precipitates the ulmic acid from combination with it: the acid thus obtained is to be washed and dried. The properties of this ulmic acid are, that it is of a deep brown colour, very brittle, and breaks in angular fragments, and is almost insoluble in water. When precipitated from its solution in an alkali, it is in the state of hydrate, and it then dissolves in 1500 times its weight of boiling water, in 2500 times between 60° and 70° Fahr., and in 6000 times at 32°. The solution in cold water is brownish-yellow; that in hot is deep brown. *Moss water* owes its dark brown colour to the presence of ulmic acid.

It is insoluble in acidulated water or in saline solutions: sulphuric acid dissolves it without apparent alteration, and becomes blackish: water precipitates it from this solution. Ulmic acid reddens tincture of litmus. It is dissolved by alcohol, from which it separates in crystalline scales by spontaneous evaporation.

It has been already mentioned that ulmic acid may be obtained from soils: it may also be procured from rotten leaves, bog-earth, wood-soot, or turf, by digesting them in a weak solution of potash: by this a brown-coloured solution of ulmate of potash is formed, from which acids throw down ulmic acid.

According to Boullay, ulmin consists of—

Hydrogen	4·70
Carbon	57·64
Oxygen	37·66
	100·

Malaguti and Boullay, by treating sugar with dilute sulphuric acid, obtained two substances, which they supposed to be identical with ulmin and ulmic acid; but, according to Liebig, they are of a different nature, and he has given them the names of *sacchulmin* and *sacchulmic acid*.

ULMIN. [ULMIC ACID.]

ULMUS CAMPESTRIS, *Medical Properties of.* The bark of this species is officinal: it should be collected in spring from branches not too old: the outer bark is removed, and the interior, or *liber*, retained for use. When recent it is of a whitish-yellow colour, but when dried it is externally of a cinnamon hue, and curled up; the inner surface smooth; it is from a quarter to half a line in thickness, tough, fibrous, not easily powdered, devoid of smell, with a mucilaginous, bitterish, astringent taste.

The cold watery infusion becomes green on the addition of a solution of sesquichloride of iron, and a precipitate is thrown down by a solution of gelatine. It possesses demulcent, tonic, and astringent properties; and taken in full doses it accelerates the pulse, acting ultimately as a diaphoretic and diuretic. Though known from an early period as an astringent, it is little used at the present day, notwithstanding the testimony of Lettsom and others in favour of its utility in cutaneous diseases of a scaly kind. To do good it must be persevered in for many months, and the greater its action on the kidneys the greater the probability of ultimate benefit. Its agreeable taste reconciles many to the prolonged use of it, who would reject less pleasant medicines. It is one of the best substitutes for sarsaparilla. It is commonly administered in the form of decoction, but as the bark contains much starch, this is objectionable. An infusion made with cold water is far preferable. A pint or more of this is to be taken daily.

The *Ulmus fulva*, tawny-budded or slippery elm bark of America, is a very valuable demulcent, tonic, and astringent, and of great utility in the diarrhœas and dysenteries of the southern parts of the United

States. As an emollient this bark is of great service as an external application to wounds, bruises, chilblains, and cutaneous eruptions; for these it is generally made into a poultice. The bark of this tree is probably that which is termed *cortex unguentarius*, which is in high repute with the aborigines for the cure of wounds.

ULTRAMARINE. This beautiful blue pigment was originally made from the stone called *lapis lazuli;* and as the process was a tedious one, the price was enormously high. The lapis lazuli was analysed by Clement and Desormes; and their analysis led Guimet to the conception of producing artificial ultramarine. Other chemists, including Gmelin and Robiquet, devised other modes of attaining the same end; and now artificial ultramarine is a regular manufacture. The substance is made largely in Germany, but not much in England. One of the processes consists in taking equal parts of silica, sulphur, and carbonate of soda, grinding them up into a bluish-green mass, igniting them in the open air, and applying various finishing processes to the bluish powder which results. The artificial ultramarine thus produced is saleable at so low a price as 1*s*. 3*d*. per lb. It is very much cheaper than real ultramarine, and though inferior to that as a pigment, is more beautiful than smalt; hence it has come largely into use. The scientific journals have lately given a description of the ultramarine factory of Messrs. Zeltner and Heyne at Nürnberg, the chief makers of this pigment. The buildings are said to cover seven acres. The central building is a polygon of 24 sides; it has 12 compartments, 96 furnaces, 12 high chimneys, and 12 lines of tramways. The polygon is 136 feet in diameter. In various parts of the area are mills, steam-engines, washing apparatus, long ranges of drying rooms, and store rooms for 5000 or 6000 cwts. of artificial ultramarine. Two hundred persons are employed in this single manufacture. The best kinds of artificial ultramarine, used only by artists, pass through no less than eighty separate processes; but the commoner kinds, which are commercially more important, are coming largely into use in paper staining, sealing-wax making, calico printing, colour printing, and dyeing.

According to the experiments of Dr. Elsner, ultramarine must contain sulphuret of iron as well as sulphuret of sodium, and he has given the mean of several analyses of artificial ultramarine, of natural lapis lazuli, and of an artificial product by Varentrapp:—

	Lapis Lazuli.	Artificial, from Meissen.	Elsner.

UMBER. [Colouring Matters.]

UMBILICUS. This word has sometimes been applied to the focus of an ellipse; but in modern works, it stands for a point of a surface through which all its lines of curvature pass. At such a point the two principal curvatures are equal; but *point of spherical curvature is a better name*. ('Differential Calculus,' 'Library of Universal Knowledge,' p. 440.)

UMBRA. The Latin word has been used to signify the shadow of the earth or moon in an eclipse: the word *penumbra* is still retained [Eclipse] to signify that portion of the heavens which is partially shaded.

UMBRELLA, a shade carried over the head as a shelter from the rays of the sun, or from rain and snow. Although the name is applicable in either case, and perhaps most strictly in the former, the term *umbrella* is usually applied in this country only to such of these articles as are used as a protection against rain; while the name *parasol* is given to the light kind of umbrella carried by ladies as a defence from the heat of the sun. The French have a better distinction between the two kinds of umbrella; using the name *parasol* for those used to ward off the rays of the sun, and *parapluie* (from *pluie*, rain) for those used as a defence against inclement weather. Umbrellas were introduced into Europe, in comparatively recent times, from the East, where they have been used for shelter against the sun from time immemorial. Although pretty well known in London more than a century since, they did not come into general use for many years later. Jonas Hanway is said to have been one of the first men who commonly used an umbrella in England. At first they were kept in the halls of genteel houses, for holding over persons as they stepped to their carriages; and even long after they began to be used by pedestrians, they were considered signs of effeminacy if carried by males. Increased attention to comfort, and the reduced price of umbrellas, owing to improvement in their manufacture, have now rendered them almost as essential as articles of dress, even to the humblest classes.

The construction of common umbrellas, and the contrivances by which they are made to expand or collapse at pleasure, are too familiarly known to need description; and it is unnecessary to do more than mention some of the ingenious improvements which have been

devised. In umbrellas of the ordinary construction the ends of the ribs are connected with the fixed ring upon the end of the stick, and the ends of the metallic rods called stretchers are attached to the sliding-tube, by rings of wire; so that the axes upon which they turn when the umbrella is opened and closed form arcs of a circle, instead of straight lines, by which excessive friction and destructive wear are occasioned. The outer ends of the stretchers, also, are connected with the ribs by means of axes or pins passed through the latter, by which they are so weakened that they frequently break. These defects are remedied in some modern umbrellas, by the adoption of ingenious though simple joints. Another new kind has a joint for connecting the stretchers with the ribs, allowing the framework to collapse into less space than usual, and preventing the fretting or wear of the cover at the ends of the stretchers. Very light and compact umbrellas are made with ribs of steel instead of whalebone or cane, which latter material, stained to resemble whalebone, is used in those of the commoner sort; and some of the best umbrellas and parasols are made with hollow or tubular metallic sticks, which combine lightness with strength.

In some of the umbrellas of recent invention, the ribs, sticks, strips and fillets are made of vulcanised india-rubber, a very tough yet elastic material. In Fox's patent umbrellas the ribs and stretchers are made of thin steel bent into the form of a hollow trough, by passing strips of metal between suitably shaped rollers, and annealing them frequently; the ribs and stretchers are thus made very strong although light, and their ends are properly shaped between steel dies. By Holland's patent, the ribs are made of elliptical hollow tubes. Mr. Pitton makes telescopic handles, and steel ribs with a folding hinge or joint. Many firms at Birmingham carry on the manufacture of umbrella furniture on a large scale, employing machines for every part of the work; even the little hinges which allow the handles of parasols to be folded are made to the extent of severals *tons* yearly.

UMBRIAN SCHOOL OF PAINTING. [Painting.]

UMPIRE. AWARD. The word umpire is sometimes used to denote the person who in the first instance decides a controversy; but in its legal sense it means a person named in the Submission, or under its authority, by the arbitrators [Arbitration] to decide the matters referred, which the arbitrators either cannot or will not decide.

The rules which govern an arbitrator regulate the conduct of the umpire also. If arbitrators agree upon certain matters referred to them, but are unable to agree upon others, the umpire may adopt and incorporate in his umpirage the former, and may himself decide upon the latter. If again arbitrators are unable to decide upon matters concerning which they have heard the evidence, they may report that evidence to the umpire, and his award thereon will be good, provided that before it was delivered neither party required of him to hear the evidence afresh.

UNCIA, the twelfth part of the As. The mathematicians of the 17th century frequently used this word to signify the numerical coefficient of an algebraical letter. Thus Halley ('Phil. Trans.,' No. 216) talks of "that admirable invention of Mr. Newton, whereby he determines the *Unciæ*, or numbers prefixed to the members composing powers," meaning to speak of what we should now call the numerical coefficients, which enter in any particular case of the binomial theorem.

UNDECAGON, a figure of eleven sides.

UNDETERMINED (Mathematics), not known, as distinguished from indeterminate, which cannot be known. Thus, "What numbers are those whose sum is 100?" is indeterminate: many numbers will satisfy the condition, but the problem contains no mode of distinguishing the answer which is wanted, nor of giving a preference to one answer over another. But an undetermined quantity may be determinate, or capable of being determined. There is, however, frequently a want of proper distinction in the use of these words. [Indeterminate.]

UNDULATORY THEORY OF LIGHT, a theory in which it is attempted to explain the phenomena of light by the supposed vibrations of an ethereal medium.

Descartes is considered as the first who entertained the opinion that vision might be so explained; but that philosopher only states that light may be a certain movement or action of the molecules of air and other pellucid substances. He supposes that the effects may be instantaneously transmitted to the eye; and he compares the apprehension of external objects by vision to that which a blind man obtains when, holding a staff at one of its extremities in the hand, the opposite extremity comes in contact with an obstacle. ('Dioptrices,' cap. 1.) Mallebranche appears to have conceived that there existed an analogy between the phenomena of sound and those of light; ascribing the former to vibratory movements of the particles of air, and the latter to the like movements of the particles of an ethereal medium between the luminous body and the eye. But Huygens ('Tractatus de Lumine') both advanced the undulatory hypothesis and explained by it the laws of reflection and refraction of light, not only for ordinary media, but also for Iceland spar, which possesses a powerful double refraction. Newton, however, adopted the corpuscular theory, having been influenced it would seem chiefly by the difficulty of accounting for the rectilinear propagation of a pencil of light, and the existence of shadows, on the undulatory hypothesis. The great reputation of

Newton, the simplicity with which the existence of rays fell in with the corpuscular compared with the undulatory theory, the want of sufficient familiarity with the conception of undulations, and the mathematical difficulties inherent in their investigation, conspired to retard the progress of the undulatory theory, and caused the corpuscular theory to be that chiefly in vogue up to the commencement of the present century. About that time the undulatory theory was revived by Dr. Young, who, guided by the analogy of sound, was led to the discovery of the important principle of interference [INTERFERENCE], and applied it successfully to the explanation of the colours of thin plates, and of the fringes seen in the middle of the shadow of a slender opaque body, which latter were proved to be *incontestably* due to interference, since they disappeared when the light which passed, or was about to pass by one side of the opaque body was intercepted by a screen, though the light which passed by the other side remained the same as before. The same principle, in the hands of Dr. Young, led to an explanation far more complete than any that had hitherto been given of various others of the curious phenomena of diffraction [DIFFRACTION OF LIGHT], and at his suggestion Dr. Wollaston undertook an experimental investigation of the laws of extraordinary refraction in Iceland spar, which ended in a complete verification of the construction which Huyghens had given under the guidance of the theory of undulations, a construction which was further verified by Malus in France, by observations made in a totally different manner.

Later still, Fresnel, in his celebrated memoir on diffraction, reduced the explanation of the phenomena of diffraction to two principles, Huyghens's principle, and the principle of interference, which are necessary consequences of the most fundamental assumptions of the undulatory theory, and proved by exact measures the accordance of theory and observation; and Fraunhofer, by observations on pure diffraction spectra, admitting of almost astronomical precision, verified the formulæ which result for that case from the principle of interference. Meanwhile a new and splendid class of phenomena, those relating to polarisation and the colours of crystalline plates, &c., engaged the attention of the most celebrated experimentalists; and though these for a time seemed difficult of explanation on any theory, they fell naturally into their places when the hypothesis of transverse vibrations [POLARISATION OF LIGHT], which occurred independently to Young and Fresnel, was introduced into the undulatory theory. Guided by this hypothesis, and by dynamical considerations, Fresnel constructed his celebrated theory of double refraction, which, without being, or professing to be, a perfectly rigorous mechanical theory, is one of the most wonderful scientific generalisations which the human mind has achieved; and while it explained the previously known laws of double refraction, and the polarisation of each of the refracted rays, corrected in some respects the laws previously assumed by experimentalists, and led to the discovery of new and unexpected phenomena. Thus while in the progress of optical science the corpuscular theory remained almost entirely barren of results, beyond the explanation of the laws of reflection and refraction and of the aberration of light, and even appeared to be contradicted by certain phenomena, the theory of undulations has continually been acquiring fresh strength, by bringing complicated phenomena into harmony with one another, and with the fundamental hypotheses of the theory. And within the last few years M. Foucault, by proving, *by direct experiment*, that light travels faster in air than in water, has given the *coup de grâce* to the corpuscular theory.

The fundamental assumptions of the undulatory theory are these: 1. That all space to the remotest visible star is filled with a rare and elastic medium, or *ether*, which also penetrates the substance of air, water, glass, and bodies in general. 2. That light consists in a succession of tremors or undulations propagated in this ether. 3. That self-luminous bodies, or rather their ultimate molecules, are in a state of vibratory agitation, which they are capable of communicating to the ether, in which they are propagated onwards by virtue of its elasticity, just as sonorous bodies are in a state of vibration, and communicate their vibrations to the surrounding air, by which they are propagated onwards in waves of sound. 4. That these ethereal vibrations are capable of affecting the nerves of the retina so as to produce the sensation of light, in a manner bearing a more or less close analogy to that in which the vibrations of the air affect the auditory nerves so as to produce the sensation of sound. 5. That, as in sound, *pitch* depends upon the frequency of the aërial vibrations, while for a note of given pitch *loudness* depends on the amplitude of the excursions to and fro of the particles of air, so in light *colour* depends on the frequency of the ethereal vibrations, while for light of a given kind *brightness* depends on the amplitude of the excursions of the particles of ether. 6. That the ethereal vibrations within refracting media are affected by the presence of the material particles in such a way as to be propagated with less velocity than in vacuo, whether it be from an increase of density of the ether, or a diminution of its elasticity, or from the ether having to thread its way among the material particles, or from some similar cause.

To a reader acquainted with the theory of sound the conception of an undulation is already familiar; but for the sake of others it may be well to use one or two illustrations. Conceive then a long rope to be stretched horizontally between a fixed support at one end, and the hand of a person holding it at the other. If the person now rapidly move his hand laterally and back again, the rope near the operator will be thrown into the form of a curve, and this curve will be seen to *travel* along the rope towards the fixed end. Yet it is evident that what so travels is not matter, but an affection of matter. The different portions of the rope merely move laterally to and fro: what progresses is a certain *state of things*, a state of displacement and motion which the different portions of the rope *assume in succession*. Again, if a stone be dropped into still water, a series of circular waves travel outwards from the point of disturbance, but the particles of water do not so progress, as may be seen by watching the motion of a floating cork, but merely move a little backwards and forwards, and up and down, oscillating about a mean position. Lastly, take the case of a gun fired in air. Here the air compressed by the explosion presses upon the quiescent air surrounding it, compressing it and at the same time moving it a little forwards; this shell of air acts in a similar manner upon the shell immediately outside it, and so on. Thus a wave of condensation (immediately followed, in point of fact, by a wave of rarefaction) is propagated outwards from the place of discharge, while the particles of air themselves merely move a little to and fro in the direction of propagation. In the first example undulations are propagated along a *line*, in the second along a *surface*, in the third *in space*, or in three dimensions; and in this respect the third example best illustrates the undulations which we contemplate in the theory of light.

In all cases of undulation we must carefully distinguish between the *velocity of propagation*, or the rate at which a certain *form* or *state of things* is propagated, and the *velocity of the particles* of the medium in which the undulations take place. The former depends only on the density and elasticity of the medium. Density we must conceive to be measured by the inertia of the portion of the medium contained in a given volume, and therefore we must attribute *inertia* to our supposed ether; but whether it possesses *weight*, whether it is subject to the influence of gravitation, is a question which we need not speculate about. By elasticity is merely meant the force whereby the medium tends to regain its primitive state, whether by resisting change of volume, as in the case of air, or change of figure, as in the case of india-rubber. We know that the velocity of propagation of sound in air is about 1100 feet per second, that of light in vacuo about 192,000 miles per second. The velocity of the particles may, however, be as small as we please; and in the theories of sound and light (with the exception, at least, of the explanation of certain phenomena relating to very violent sounds), it is sufficient to treat the motions of the particles as indefinitely small, so that we may apply the general dynamical principle of the superposition of small motions. In other words, if the medium (air or ether) would be disturbed in one way by one cause acting alone, and in another way by another, the actual disturbance at any point when the two causes act together will be got by compounding the disturbances (expressed by displacements or velocities, as the case may be) due to the two causes taken separately. The actual direction of motion of the particles of the medium may be left a perfectly open question so far as relates to the conception of an undulation and the explanation of phenomena thereby, and by the application of the principle of the co-existence of small motions. Thus, in the example of the rope, the motion is rectilinear, and perpendicular to the direction of propagation; and if the operator, instead of moving his hand backwards and forwards moved it round and round, the path of any particle would be a curve lying in a plane perpendicular to the direction of propagation. In the example of waves on water, each particle moves in a curve lying in a vertical plane passing through the direction of propagation; while in the third example the motion is simply to and fro in the direction of propagation.

A single pulsation of air is audible as a *noise*, though it does not convey the idea of pitch; but even in the most transitory light, such as that of the electric spark, the phenomena of dispersion and interference indicate that we have to deal with a succession of a great number of similar undulations. Returning, for simplicity of conception, to the illustration of the rope, let us therefore suppose that the operator moves his hand backwards and forwards in a regular periodic manner. The rope will be thrown into the form of a sinuous curve, which travels along it. The distance from any particle to the next before or behind which is in the same state of motion, is called the *length of a wave*. It is evident that a single wave-length comprises two bow-shaped portions of the curve, the displacements in which are on opposite sides of the mean position, and which may be distinguished as positive and negative; and also that any two points distant by half a wave's length are in exactly opposite states of displacement and motion, at least if we suppose the positive and negative portions of the curve exactly alike. If we reflect on the motion of any particular particle, we shall readily see that it goes through its changes once while the wave-form progresses by one wave's length. Hence, if v be the velocity of propagation, λ the length of a wave, and τ the periodic time of vibration of a single particle, we have the fundamental relation $\lambda = v\tau$, which applies to undulations in general, since what was said in the case of the rope holds good generally. In the case of light, the absence of prismatic colours when a star is displaced by aberration from its mean position, the absence of changes of colour when one of Jupiter's satellites enters or emerges from his shadow, and the existence of periodic stars, such as Algol, which rapidly change in brightness without changing in colour, indicate that the velocity of propagation of light in vacuo is the same for all colours. The phenomena of interference furnish us with means of measuring the length of a wave of light, which is found to vary from about 266 to 167 ten-millionths of an inch, in passing from the extreme red to the extreme violet. We infer, therefore, from the known velocity of propagation, that from about 458 to 727 millions of millions of vibrations must take place in one second.

The locus of the particles, which at a given instant are in the same state or *phase* of their motion, is called the *front of a wave.* When light diverges in the first instance in vacuum, or any singly refracting medium, from an element of a self-luminous body, the front of a wave is of course spherical, or, at a sufficient distance from the body, when we have to consider a small portion only of the front, sensibly plane, but after reflection or refraction it may be of any other form.

We now come to a principle of constant application in the theory of undulations, which is called Huygens's principle. It may be thus stated:—The front of a wave of light, either at a given instant, or as the parts of it arrive in succession at a given surface, may be divided into elements, of which each is conceived to be the centre of an elementary disturbance which spreads in all directions with the velocity appropriate to the medium in which it is propagated. The disturbance in front of the primary wave may be regarded as the aggregate of the elementary disturbances due to these secondary waves; and as these are insensible when taken separately, the aggregate disturbance will not be sensible except in the immediate neighbourhood of the envelope, or surface of ultimate intersection, of the secondary waves. If we confine our attention to a small portion of the primary wave, we shall have a corresponding small portion of the envelope, or general wave, in its advanced position, in the neighbourhood of which alone the disturbance due to the small element of the first wave is sensible. Hence the course of a *ray* from any point of the first wave is the line along which the point of ultimate intersection of the secondary waves which start from the neighbourhood of that point of the first wave is displaced. This is evidently the straight line joining the point last mentioned with the point of ultimate intersection at a given instant; or, again, the straight line joining the point in question of the first wave with the point in which the secondary wave thence diverging is touched by the general envelope.

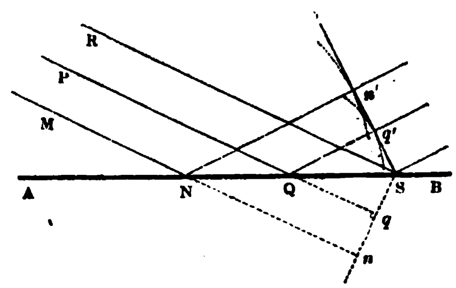
The legitimacy of thus conceiving a wave to be broken up is a direct consequence of the general dynamical principle of the co-existence of small motions. The secondary waves will have an envelope behind as well as in front of the primary wave; yet we must not infer that the latter is propagated backwards as well as forwards. The explanation of the non-propagation in a backward direction, notwithstanding the legitimacy of thus supposing a wave broken up, belongs to the dynamical theory of diffraction, and is much too difficult a subject to be entered upon here. (See a paper in the 'Cambridge Philosophical Transactions,' vol. ix., p. 1.)

The complete explanation of the existence of rays requires this principle to be combined with the principle of interference, but for the present we shall confine ourselves to its application to the demonstration, according to the undulatory theory, of the laws of reflection and refraction. We may notice, however, in the mean time some features of the propagation of light in a uniform medium.

Conceive, then, a surface of any form to be at a given instant the front of a wave propagated in a uniform medium, and first suppose the velocity of propagation the same in all directions. If we conceive the wave broken up as above explained, the secondary waves, which will be all of the same magnitude, will by our supposition be spherical; and by very simple geometry we arrive at the following construction for determining the form of the wave in its onward course. At all points of the front of the wave at the time t draw normals, at the side towards which the wave is travelling, equal in length to $v\,t'$; the locus of the extremities of these normals will be the front of the wave at the time $t+t'$, and the normals themselves will be the courses of the rays. We learn also that it is not any arbitrarily chosen system of straight lines, the equations of which contain two arbitrary parameters, that can represent a possible system of rays; the lines must admit of being cut orthogonally by a system of surfaces. This geometrical property, so readily suggested by the theory of undulations, may of course be demonstrated as a consequence of the geometrical laws of reflection and refraction independently of any theory, the system being supposed to consist of rays which, having originally emanated from a point, have undergone any number of reflections and refractions. If the medium in which the wave is propagated be uniform, but differently constituted in different directions, as in the case of Iceland spar, for example, the velocity of propagation will vary with the direction, the secondary waves will no longer be spherical, and the course of a ray, while still rectilinear, will no longer be perpendicular to the front of the wave.

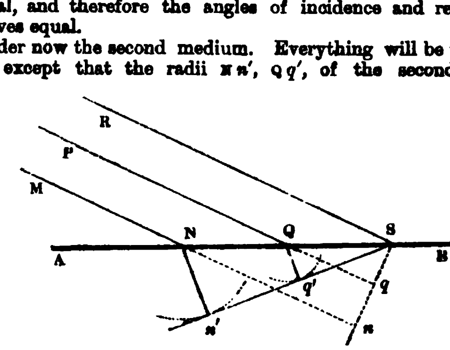
We come now to the explanation of ordinary reflection and refraction on the undulatory theory, according to the principles laid down by Huygens. We shall in the first instance, for the sake of simplicity, suppose the reflecting surface to be plane, and the incident waves to be plane likewise. Let the plane of the paper be the plane of incidence, and therefore perpendicular at the same time to the reflecting surface and to the planes of the waves. Let it cut the reflecting surface along AB; and let MN, PQ, RS, lying in the plane of the paper, be three normals to the incident waves, representing therefore the courses of incident rays. If there were no obstacle, the wave at one instant at N would, after the lapse of time required to describe the perpendicular

distance of its plane from S, come into the position represented in section by S$q$$n$, perpendicular to RS, PQq, and MNn. In order to



examine the effect of the interruption, imagine each portion of the wave as it arrives at NS to become a centre of disturbance, from whence diverge hemispherical waves into the two media respectively, with the velocity appropriate to each. Consider for the present the first medium only. The times which have elapsed since the wave, now supposed to be at S, was at the points N, Q, - - -, are those required to describe Nn, Qq, - - -, and therefore the radii Nn', Qq', - - -, of the hemispherical waves which diverged from N, Q - - -, are equal to Nn, Qq - - - -. Through S draw a plane perpendicular to the plane of the paper, touching in n' the hemisphere whose centre is at N. It is evident that the point n' will lie in the plane of the paper, and that the plane Sn' will touch all the secondary waves, and therefore will be the front of the reflected wave. Moreover Nn', which is perpendicular to this plane, will represent the reflected ray corresponding to the incident ray of MN. Hence the reflected ray lies in the plane of incidence; and on account of the equality of the triangles SNn, SNn', the angles SNn, SNn', which are the complements of the angles of incidence and reflection, are equal, and therefore the angles of incidence and reflection are themselves equal.

Consider now the second medium. Everything will be the same as before, except that the radii Nn', Qq', of the secondary waves



diverging from N, Q, instead of being *equal*, will only be *proportional*, to Nn, Qq, bearing to them the ratio of v' to v, where v' is the velocity of propagation in the second medium. The semicircles in which the hemispheres diverging from the various points of NS are cut by the plane of the paper will form a system of curves for which S is a centre of similitude; and it will be readily seen that if through S be drawn a plane perpendicular to the plane of the paper, and touching in n' the hemisphere diverging from N, it will be the envelope of the secondary waves in the second medium, the point n' will lie in the plane of the paper, and Nn' will be the course of the ray refracted at N, which will therefore lie in the plane of incidence. Also the angles NSn, NSn', which are the complements of the angles SNn, SNn', are equal to the angles of incidence and refraction respectively, and sine of incidence : sine of refraction :: Nn÷NS : Nn'÷NS :: Nn : Nn' :: v : v', a ratio which is constant, that is, independent of the angle of incidence; which gives the law of refraction.

These laws may be easily extended to the general case in which the incident waves and the reflecting or refracting surface are of any form. For let PQ in either of the above figures represent a ray incident at Q, and therefore normal to the incident wave, and through Q imagine two tangent planes drawn, one to the incident wave, and the other to the reflecting or refracting surface. Confining our attention to the secondary waves which start in either medium from the immediate neighbourhood of the point Q, if we suppose them to start when a wave coinciding with the tangent plane to the wave, instead of the actual wave itself, arrives at the surface, and again, if we replace the actual surface by the tangent plane to it drawn through Q, we shall only commit an error on the position of the centre and magnitude of the radius of a secondary wave which is a small quantity of the second order, the distance of its centre from the point Q being deemed a small quantity of the first order. Hence the line of intersection of any two such secondary waves will only be rendered erroneous by a small quantity of the first order, which vanishes in the limit, and therefore the point of ultimate intersection of the secondary waves will not be affected. Hence the laws of reflection and refraction will remain the same as before, the normal to the surface at the point of incidence taking the place of the perpendicular to the plane.

This mode of conceiving of reflection and refraction shows at once that if the point of incidence be slightly varied, and a ray starting from a point in the incident, and reaching a point in the reflected or refracted ray, be supposed to follow the varied instead of the actual course, travelling in each medium with the velocity appropriate to it, the time of transit will be ultimately unchanged. This law may be readily extended to any number of reflections and refractions. In a great many cases the time of passage is less along the actual than along the varied course, in which case the proposition becomes equivalent to Fermat's law of swiftest propagation. The time may, however, be a maximum in place of a minimum, or neither a maximum nor a minimum. Thus, if a ray emanate from a point A, and after reflection at the point P reach the point B, the plane APB will be perpendicular to the tangent plane at P, to which AP, BP, will be equally inclined; and if A, B, be made the foci of a prolate spheroid of revolution, the magnitude of which is increased until it passes through the point P, it will there touch the reflecting surface. If now this surface touch the spheroid externally at the point P, the sum AP + PB will be a minimum when the point of incidence is slightly varied along the reflecting surface; but if it touch the spheroid internally, the sum will be a maximum; and if it both touch and cut the spheroid, so as to be external to it in some directions from P and internal in others, the sum will be neither a maximum nor a minimum.

When concentric waves fall on the surface of a concave mirror, the points on the latter which are successively reached by the waves become the centres of spherical reflected waves, the directions of whose motions tend towards the axis of the mirror; and the surfaces which touch all the secondary waves of like phase become those of as many general reflected waves of spherical or approximately spherical forms, having their convexities towards the mirror. These general waves go on contracting till they pass successively through some point in the axis, the form of the mirror being such as to permit the directions of the motions of the reflected waves to concur in a point; from this point, which is the focus of the mirror, they afterwards diverge as from a radiant point. It is easy to conceive that the general front of a wave formed by a surface which touches the secondary waves of like phase refracted in a transparent medium (at a convex surface, for example) may be spherical, and have its convexity towards the refracting surface. These waves will go on contracting, and pass successively through some point in the axis, provided the form of the surface of the medium be such as to permit the directions to concur in one point. This point is the focus, and from it, as from a radiant point, the concentric waves afterwards diverge.

In order that the relation between the sines of incidence and refraction may be conformable to the results of experiment, it is necessary to assume that the velocity of the waves is diminished when they enter a medium more dense than that in which they previously moved; and in this circumstance the undulatory theory is opposed to the theory of emission; for in the latter the velocity of light is supposed to be increased when it passes from any medium into one more dense. This led Arago to an apparently crucial experiment, to decide between the two theories. If a thin plate of mica be interposed in the path of one of two streams of light proceeding to interfere, the effect, according to the theory of emissions, will be to accelerate, according to that of undulations to retard, the stream passing through it. The direction in which the fringes are shifted, shows that the effect of the plate is the same as that of *increasing* the length of path of the stream passing through it, in accordance with the theory of undulations, and in direct contradiction, as it would appear, to the theory of emissions. However, as the decision is only arrived at by referring to another optical effect, depending for its explanation on the view we take of the nature of light, it is satisfactory to be able to refer to Foucault's celebrated experiment, mentioned at the commencement of this article, in which the same result is obtained by direct experiment. (See 'Annales de Chimie,' tom. 41, 1854, p. 129.)

From the demonstration of the law of refraction according to the undulatory theory, it follows that if μ be the refractive index of a substance, $v : v' :: \mu : 1$. Now, for a given substance μ depends upon the kind of light, increasing, though by no great fraction of the whole, in passing from the red to the violet. According to one of our fundamental suppositions, colour depends on the periodic time of the vibrations, and therefore we are obliged to suppose that one at least of the two velocities of propagation v, v', changes with the periodic time. This has to some appeared a formidable difficulty, inasmuch as theory and experiment combine in showing that musical notes of all degrees of pitch are propagated, in air with the same velocity, and calculation shows that this independence of velocity of propagation and periodic time must hold good in any homogeneous elastic medium in which undulations are propagated by virtue of the pressures or tensions called into play by the relative displacements within an indefinitely small element of the medium surrounding the point at which the pressure is estimated. To us the objection, even prior to the consideration of the mode in which the result may be accounted for, does not appear to be at all of this formidable character; for all the phenomena which bear on the subject conspire, as we have seen, to show that the velocity of propagation v in vacuo is the same for all colours, and therefore it is to a variation in v' that we are to look to account for the observed variation of μ. Now, according to our supposition, light is propagated within water, glass, &c., by the vibration of the ether within them. But the motion of one of two mutually interpenetrating media is so utterly different from anything we have to deal with in the theory of sound that we cannot reason from the one case to the other.

But further, a plausible mode of accounting for dispersion on the undulatory theory has been suggested, which not only removes the objection arising from the existence of a phenomenon which to some might appear inexplicable, but has led to the discovery of the approximate law of dispersion. Fresnel, in his memoir on double refraction, refers to a note, to appear at the end of the memoir, in which he explains dispersion by supposing that the forces by which the ethereal particles act on one another are sensible to a distance which is not infinitely small compared with the length of a wave. This appears to be by no means a violent supposition to make, when we consider the extreme smallness of λ. The note appears to have been lost, at least it does not accompany the memoir, but the subject was taken up by Cauchy, who has thus been led to express the square of the refractive index by a series according to inverse even powers of λ, the wave-length in vacuo. Restricting ourselves to the most important term, we thus get, by ordinary algebraic expansion, $\mu = A + B\lambda^{-2}$, A and B being constants depending on the nature of the medium, according to which expression $\Delta\mu$ ought to vary as $\Delta\lambda^{-2}$. And that this expression is no mere formula of interpolation, but contains a law of nature, any one may readily convince himself by taking Fraunhofer's indices for some kind of glass, and the wave-lengths of the fixed lines C, D, E, F, G, H, as determined by him by a diamond-ruled grating, and subtracting the logarithms of $\Delta\lambda^{-2}$ from those of $\Delta\mu$, Δ denoting the increments belonging to intervals such as C to D, D to E, C to E, &c., and then comparing the results with those obtained from a formula of interpolation taken at random, such as $\mu = A + B\lambda^{-1}$, or $\mu = A + B\lambda^{-3}$, similarly treated. The constancy of the differences of the logarithms in all the less refrangible part of the spectrum when the formula resulting from Cauchy's theory is used, cannot leave a moment's hesitation that the formula expresses a natural law. But if, accepting the formula as a true first approximation, we endeavour to ascend from it to the physical circumstances giving rise to it, we see that it merely indicates the existence, in the partial differential equation of motion, of a differential coefficient of the fourth order, without even completely specifying the variable or variables with respect to which the differentiation is taken. A result of such generality might well be obtained from a variety of physical hypotheses, so that we must not lay undue stress on the experimental verification of Cauchy's law in considering the evidence in favour of the physical theory from which he deduced it. Indeed, the fact, as it appears to be, of the absence of a chromatic variation of the velocity of propagation in vacuo, would seem to indicate that the molecules of ponderable matter play a very direct part in the phenomenon of dispersion.

Hitherto we have confined ourselves to the laws of reflection and refraction, which were in fact demonstrated by Huygens long before the principle of interference was known. Our subject naturally leads us, in the next place, to interference, to which a special article has already been devoted. [INTERFERENCE.] In that article the subject has been generally explained, and two fundamental experiments, due to Fresnel, have been mentioned, which show that interference is an essential property of light. We shall here, therefore, proceed to the formula which gives the intensity of the light resulting from the mixture of two interfering streams.

It will be necessary, in the first place, to express analytically the disturbance in a single stream of light. We shall suppose, for the sake of simplicity, that the waves are plane, and that the maximum accession of the particles of ether is the same at one point of space as another. This will be sufficient in any case, provided we confine our attention to a small portion only of the fronts of the waves, and to variations of distance in a direction perpendicular to the front, such that the change of intensity due to convergence or divergence need not be taken into account. Let the ether be referred to the rectangular axes of x, y, z, x being measured in the direction of propagation; let t be the time, and v the velocity of propagation. Since the waves are supposed plane, the disturbance will be independent of y and z, and therefore will depend only on x and t. Moreover, according to the fundamental notion of an undulation, whatever disturbance exists at the time t at the distance x from the origin will, after the lapse of the time δt, be found at a plane further in advance by δx, δx being connected with δt by the relation $\delta x = v\delta t$. Hence the disturbance remains the same, provided the difference between vt and x remains unchanged, and therefore for one value of $vt - x$ the disturbance will have one value, for another value another, and so on. In other words, the disturbance will be some function $\psi(vt - x)$ of $vt - x$, the direction of the motion of the particles being left a perfectly open question. The character of the undulations will depend on the form of the function ψ. Now we have seen reason to believe that in light we always have to deal with a succession of a great number of similar periodic disturbances, and, further, that the colour depends upon the periodic time. But in all optical phenomena the effects of lights of different colours are simply superposed, and therefore as regards the form of ψ we are justified in restricting ourselves to the consideration of a single regularly periodic function. Among such functions there is one which claims our special attention, namely, that which is expressed by a sine or cosine, or a mixture of the two, that is, $C \sin m w + C' \cos m w$, (w being written for $v t - x$), which again may be put under the form $a \sin (m w + \alpha)$. For in the first place, any dynamical system in a position of stable equilibrium, and therefore capable, on being disturbed, of performing small vibrations, has for its most general small motion a motion compounded of a finite or infinite number of motions, expressed, so far as the time is concerned, by a sine or cosine. If, therefore, we suppose the vibration of the molecules of the self-luminous body in the first instance to have been of this character, the same would have been impressed on the ether to which these vibrations were communicated. In the second place, by a known theorem any periodic function of w, going through its period when w is altered by $2 \pi m^{-1}$, may be expressed by an infinite series of the form $A_0 + A_1 \cos m x + A_2 \cos 2 m x + \cdots + B_1 \sin m x + B_2 \sin 2 m x + \cdots$, where the first term vanishes if the mean value of the function be zero. By virtue of this theorem, and of the principle of the superposition of small motions, we should have a right to resolve the function ψ, supposing it merely to be periodic, into such a series of circular functions, and consider separately the disturbance due to each. Whether this be a *judicious* as well as a *legitimate* course to pursue, depends partly on whether any such resolution takes place *physically*, or whether, on the other hand, there are physical phenomena which we can refer to the *form* of the periodic function expressing the disturbance. In sound we have a sensible phenomenon, *quality*, which is referable to the form of the function expressing the disturbance, while vibrations of different periods are not, under ordinary circumstances, physically separated. But in light we have nothing answering to quality, and disturbances of different periods *are* physically separated, as in the phenomena of interference and diffraction as well as in dispersion. That disturbances expressed by a sine or cosine, rather than by some other periodic function, should be those which are propagated within a refracting medium with a unique velocity, and should not consequently be separated by prismatic refraction, follows from the general laws regulating the small motions of a system slightly disturbed from a position of stable equilibrium. We are led, therefore, by the phenomena with which we have to deal, to express the function ψ by means of a simple sine or cosine. If λ be the length of a wave, $m x$ must change by 2π when x changes by λ, so that $m = 2\pi\lambda^{-1}$. Hence we may take as the standard expression for the disturbance—

$$a \sin \left\{ \frac{2\pi}{\lambda} (vt - x) + A \right\}$$

Suppose, now, that the ether at the same part of space is simultaneously agitated by a second series of undulations, which came originally from the same source. Suppose the directions of propagation to be so nearly the same that in considering, as above, a small portion only of the ether, we may treat them as the same, or the wave-fronts as parallel in the two series; and suppose the directions of vibration to be likewise the same in the two series, except as to a small angle depending upon and comparable with the small angle between the directions of propagation. Suppose, however, that the amplitude of excursion of the particles is different in the second series from what it is in the first, and further, that from having had to describe a longer or shorter path, or from any other cause, the undulations in the second series are ahead of or behind those in the first. Then we may represent the disturbance in the second series by

$$b \sin \left\{ \frac{2\pi}{\lambda} (vt - x) + B \right\}$$

And compounding the disturbances belonging to the two series, we shall have for the result

$$(a \cos A + b \cos B) \sin \frac{2\pi}{\lambda} (vt - x) + (a \sin A + b \sin B) \cos \frac{2\pi}{\lambda} (vt - x),$$

which may be transformed into

$$c \sin \left\{ \frac{2\pi}{\lambda} (vt - x) + C \right\}$$

c and C being given by the equations

$$(1.)\ c^2 = a^2 + b^2 + 2ab \cos (A - B)\,; \quad (2.)\ \tan C = \frac{a \sin A + b \sin B}{a \cos A + b \cos B}.$$

We learn, therefore, that the resultant of the two series is an undulation of the same character as the component undulations, differing from them only in the magnitude of the coefficient of vibration, c, and in the state or *phase* of vibration at a given point of space and at a given instant, as determined by the value of C compared with those of A and B.

It is with c that we are chiefly concerned; the value of C does not enter into account unless when we have a third stream interfering with the two former. Now we see from the formula (1), that according to the value of $A - B$, c varies between two extreme limits, which are the sum and the difference of a and b. These are, the one greater, the other less, than the greater of the two a, b. Hence we see that two streams of light from the same source reinforce each other, or else give an effect less than that of the stronger stream alone, according to their difference of phase.

The question now arises, what precise function of the coefficient of vibration ought we to take as a measure of the intensity? Various considerations tend independently of each other to the same conclusion,—that we must take the *square* of the coefficient of vibration as a measure of the intensity. It will be sufficient here to mention one or two.

Suppose that we have two streams of light just as before, only that in this case they come from *independent* sources. The theoretical difference between the present case and the former consists in this, that in the former, whatever may affect the constant A equally affects B, and therefore leaves the difference $A - B$ unchanged; and whatever affects a affects b in the same proportion, which is not the case when the streams are independent. In the case of streams from the same source, we may, for example, suppose that the actual disturbance consists of a series of regular periodic disturbances followed by a distinct series, and that by another, and so on, there being a great number of such changes in one second. The mode of interference will not thus be affected. But in the case of independent streams, $A - B$, though constant, it may be, during a great number of successive undulations, will go through all sorts of values a great number of times in one second, and the mean value of the term $+2ab \cos. (A - B)$ in the expression for c^2 will be zero. If now we take the square of the coefficient of vibration for the measure of the intensity, we shall have for the intensity of the mixture of independent streams the mean value of $a^2 + b^2 + 2ab \cos (A - B)$, or $a^2 + b^2$; or the intensity will be the sum of the intensities of the separate streams, as it ought to be; whereas if we were to take some different function as a measure of the intensity that would not be the case. Again, all mathematical investigations relative to the propagation of small vibrations in a medium disturbed at one place show that at a great distance from the centre of disturbance the coefficient of vibration varies inversely as the distance. But experiment shows that the intensity of light varies inversely as the square of the distance, and we are thus led in a perfectly independent manner to the same conclusion.

If the interfering streams are of equal brightness, $b = a$, and the limits of the coefficient of vibration c of the resultant stream are o and $2a$, and those of the brightness o and $4a^2$, that is absolute darkness, and four times the brightness of either stream alone.

We shall apply these formulæ to express the intensity at any point of the field of view in the case of the mixture of two streams of light coming originally from a luminous point, and afterwards reflected from two slightly inclined mirrors. [INTERFERENCE.] Supposing, for simplicity, the light to be reflected in a plane perpendicular to the line of intersection of the planes of the mirrors, let a be the distance of the luminous point, and therefore that of either virtual image, from that line, b the distance from the same line to the focus of the lens with which the fringes are viewed, d the distance of the two images. Since the length of path of either stream is the same as if it had started from the virtual instead of the actual image, if we denote these images by I, I', and the point of the focal plane at which the brightness is sought by M, and if we take $c \sin \frac{2\pi}{\lambda} (v t - x)$ to denote the disturbance coming from I, that coming from I' must be denoted by $c \sin \frac{2\pi}{\lambda} \left\{ v t - x - (I'M - IM) \right\}$. Let O be the middle point of the line II'. It will be readily seen that the plane drawn through O and through the line of intersection of the planes of the mirrors will be perpendicular to II'. Let p, q be the co-ordinates of M, measured in the focal plane of the eye-lens, the first perpendicular, the second parallel, to the plane through O just mentioned, the origin being at the intersection of that plane with a plane through IOI' perpendicular to the mirrors. We shall suppose, in conformity with the experimental circumstances of the case, that d, p, q are small compared with a and b. Let $a' = \sqrt{(a^2 - \frac{1}{4} d^2)}$ be the distance of O from the intersection of the mirrors. Then $IM^2 = (a' + b)^2 + (p - \frac{1}{2}d)^2 + q^2$, $I'M^2 = (a' + b)^2 + (p + \frac{1}{2}d)^2 + q^2$, and $I'M - IM = (I'M^2 - IM^2) \div (I'M + IM) = 2pd \div (I'M + IM) = \frac{pd}{a' + b}$ nearly. We have therefore for the intensity (L) of the mixture—

$$L = 2c^2 + 2c^2 \cos \frac{2\pi p d}{\lambda(a' + b)} = 4c^2 \cos^2 \frac{\pi p d}{\lambda(a' + b)}.$$

Since L does not involve q, the illumination will be arranged in bars parallel to the axis of q, and it will be sufficient to discuss its variation along the axis of p. At a series of equidistant points, for which $p = o$ or a multiple of $\frac{\lambda(a' + b)}{d}$, L is a maximum, and equal to $4c^2$. At points midway between these, where therefore p is an odd multiple of half that quantity, L vanishes altogether. Hence we have a series of alternately bright and dark bars, extending on each side of the central plane, or that bisecting II' at right angles, which is in the middle of a bright bar. The scale of the system is found to depend upon the colour, decreasing from the red to the violet, from whence we infer that the wave length also decreases from the red to the violet. The obliteration of the bars at a moderate distance from the centre when white light is used has already been explained. [INTERFERENCE.]

From the expression for L we see that the mean illumination, or the value of $(p'+p'')^{-1}\int_{-p'}^{p''} \mathrm{L}\,dp$ for a large value of $p'+p''$, is $2c^2$, which would be the uniform illumination, if the streams mixed without interfering. This is a particular example of a general principle from which inferences have already been drawn [ABSORPTION], that when two or more distinct streams of light interfere, no light is *destroyed* by interference, which merely causes a different distribution of the illumination.

If β be the breadth of a fringe, which may be measured by a micrometer, $\beta = \frac{\lambda(a'+b)}{d}$, whence $\lambda = \frac{\beta d}{a'+b}$. The distances a, b, to the former of which a' may be deemed equal, are not small, and can be measured without difficulty. The distance d was measured by Fresnel by placing a screen with a small round hole at a known distance from the mirrors, so that a slender beam of light from each of the images I, I′ passed through the hole, and measuring by a micrometer the distance between the centres of the beams at a known distance on the other side of the hole whence d is obtained from the measured distance by similar triangles. This is one method of measuring the length of a wave of light.

The excessive smallness of λ, indicated by this or any similar phenomenon of interference, leads to a complete explanation of one of the oldest difficulties belonging to the undulatory theory, the existence of rays and shadows. Conceive a broad beam of light to fall perpendicularly on a screen containing a moderately small aperture, and let us examine the disturbance produced at a point M, situated at a considerable distance on the other side of the screen. For greater simplicity we shall suppose the incident beam to come from a very distant point, so that the incident waves may be regarded as plane. By Huygens's principle each element of the front of a wave, as it arrives at the plane of the aperture, may be considered as the centre of an elementary disturbance which diverges into the space behind the screen, and in due time reaches M. But the disturbance at M will be by no means proportional to the size of the aperture, since the various secondary waves which at a given instant reach M, and which arise from incident waves which reach in succession the plane of the aperture, are in a condition to interfere. First, suppose M situated at some distance outside the geometrical projection of the aperture. Make M the centre of a number of spheres with radii increasing by $\frac{1}{2}\lambda$, and of which as many are drawn as cut the aperture. These spheres will cut the aperture into numerous narrow slips, of the form of portions of circular annuli, having for their common centre the projection N of the point M on the plane of the aperture. It will be readily seen that the aggregate effect of the secondary waves starting from the various elements of one slip will be as nearly as possible neutralised by that of the waves coming from the next slip. For the squares of the radii of the annuli increase in arithmetical progression, and therefore the areas of consecutive slips are equal, except as to the trifling difference due to the change in the angle subtended at N. Neglecting for the moment this small change, we readily see that to each element of the first slip corresponds an equal element of the second, at a distance from M different from that of the former element by $\frac{1}{2}\lambda$, and therefore the secondary waves belonging to these two elements will, as nearly as possible, neutralise each other's effect. Hence the joint effect of two consecutive slips as compared with that of either of them is a small quantity of the order λ, that is the ratio of λ to the other quantities involved, such as the difference of distance from M of opposite sides of the aperture. But as the number of slips is a large quantity of the order λ^{-1}, it might be supposed that the total effect was comparable with that of one slip. This however is not the case. For the effect of any slip taken along with half the effects of the two adjacent slips is a small quantity of the order λ^2, and the sum of all such, when we group the slips so as to take every alternate slip along with half the effect of its two neighbours, is only a small quantity of the order λ, unless it be in consequence of the want of compensation at the beginning and end of the series. But at the two ends, that is at the parts of the aperture nearest to and farthest from the point N, the length of the slips dwindles down to zero. The peculiar case in which a part of the boundary of the aperture is exactly circular, having its centre in N, which attaches itself to the theory of the bright point in the centre of the shadow of a circular disc, is supposed to be excluded from consideration. We infer therefore that the disturbance at a point M, situated as above described, is insensible.

Next suppose M to lie at some distance *inside* the geometrical projection of the boundary of the aperture. Imagine a series of spheres drawn as before around M, beginning with that which touches the plane of the aperture in the point N. The aperture will now be cut up as before, only that now for some distance round N the annuli will be complete, after which they will become incomplete, and will finally dwindle away to nothing. The neutralisation will in this case take place just as before, except as regards half the effect of the first annulus, or central circle of the system, and the disturbance will therefore be sensibly the same as if the screen were removed.

If the point M be situated near the geometrical projection of the boundary of the aperture, whether inside or outside, or if the aperture be so small that a few only of the spheres above mentioned cut it, the determination of the disturbance at M becomes a more difficult problem, and belongs to diffraction. The explanation of the existence of rays and shadows when the light is divergent, or the intercepting screen is not perpendicular to its course, is nearly the same as before.

We come now to the colours of thin plates, one of the first phenomena to the explanation of which the principle of interference was applied. As, however, the whole subject has been referred to the present article, we shall commence with a description of the phenomenon itself, and of its laws, as discovered by Newton. The colours of thin transparent laminæ had previously been studied to a certain extent, by Boyle and by Hooke, and the latter of these philosophers produced the phenomena in the instructive form in which their laws have since been studied, namely, by placing two object-glasses in contact. It was in this form chiefly that they were studied by Newton, and from him the coloured rings formed by such glasses have been called Newton's rings.

In order to observe these rings conveniently, Newton placed two convex lenses of long foci (14 and 50 feet) in contact with each other at their vertices, keeping them together by means of three clamps at intervals on their circumferences, so that there was between them a very thin plate of air, concave on its upper and lower sides. On bringing the pair of lenses to an open window, and receiving the rays of light from the sky by reflection from them, there were observed, the plates being gently pressed together, seven series of coloured rings or bands about a black spot in the centre: beyond the seventh band the colours could scarcely be distinguished. The diameters of the bands being measured, where the colour in each was the brightest, Newton found that those diameters were proportional to the square roots of the series of odd numbers 1, 3, 5, 7, &c.; at the places where the colours were the least bright, the diameters were found to be proportional to the square roots of the series of even numbers 2, 4, 6, 8, &c. The radii of curvature of the lenses being known, Newton computed the thicknesses of the plate of air at the circumferences in which the colours of the bands had the greatest and least degrees of brightness; and he found ('Optices,' lib. ii.) that, at the most luminous part of the ring nearest to the centre, the thickness was equal to $\frac{1}{178000}$ inch; the thickness at the most obscure part of that ring was equal to $\frac{1}{178000}$ inch. Hence, from the law above mentioned, the thicknesses of the air at the most and least luminous parts of the succeeding rings may be obtained; those thicknesses being considered as proportional to the squares of the semidiameters of the rings.

If lenses whose surfaces have different curvatures are employed, it is always found that like tints are produced in the circumferences of circles at places where the intervals between the surfaces are equal, the eye being similarly situated, or a line supposed to be drawn to it from the centre making equal angles with a plane passing through all the rings; and this circumstance serves to show that the tints depend wholly on the distances between the lenses. If the angle made by the line drawn to the eye be diminished, the diameters of the rings will be increased, the tints remaining the same. Newton found that for moderate obliquities the same ring was formed where the distance between the lenses, or the thickness of the interposed plate of air, varied as the secant of the angle of incidence on the first surface of the lens, which in estimating this angle may be deemed a plate bounded by parallel surfaces. To include great obliquities he has given an empirical rule not sensibly differing from the simple rule of the secant except at great obliquities. It has since, however, been found by careful measures of the diameters of the rings at great obliquities, that the thickness where a given ring is formed is regulated by the simple law of the secant, and not by the more complicated formula given by Newton.

When the rings are formed by homogeneous light they are found to be more numerous than when the light is mixed, indeed they are almost countless when the homogeneity is sufficiently perfect; they are also of the same colour as the light, and are separated from one another by narrow spaces which are quite black. The diameters of the rings in the corresponding bands, at the places where the colours are the brightest, are different when the bands are formed by homogeneous lights of different colours, being least when the light is violet, and greatest when red; and Newton computed, from the measured diameters of the rings of different colours, the intervals between the lenses at the places where the brightest parts of the first rings from the centre are formed: these distances are found to be equal to [illegible] inch for extreme red rays, and [illegible] inch for extreme violet rays, which it may be observed are half the lengths of an undulation for those kinds of light.

The order and the dimensions of the coloured rings are the same, whether air occupy the space between the lenses or whether the latter be in the exhausted receiver of an air-pump: but when a transparent medium, as water, of greater refractive power than air, is interposed between them, the tints are fainter and the diameters of the rings are less; or smaller distances between the lenses are requisite in order to produce the same tints: it is ascertained that, with different media, these distances, in the case of a perpendicular incident ray, are inversely proportional to the refractive indices.

Corresponding rings of colour were observed by Newton in thin plates surrounded by media less dense than the plates: thus a bubble of soap-water exhibits, by the gradual subsidence of the fluid, rings of colour exactly conformable to those between glass lenses; and, before the bubble bursts, a dark spot about half an inch in diameter, is formed at its upper part. The like phenomena have been observed in thin plates of mica and in bubbles of glass blown so thin as to burst.

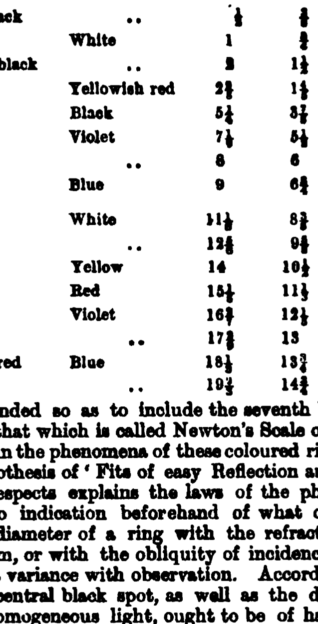
Newton also examined and described the phenomena of the coloured rings or bands between lenses when the light is transmitted through the latter. These rings are less bright than those which are formed by reflection; but when the obliquity of the transmitted rays to the plane of the rings is considerable they are sufficiently distinct: in the centre is a white spot, and the colours of all the rings are exactly complementary to those of the corresponding rings which are seen by the reflected rays. Newton's arrangement of the coloured tints in the first and second rings or bands, reckoning from the centre, is given in the following table, with the thicknesses of the plates of air, water, and glass, at the places where the tints are produced. The unit of measure is one millionth part of an inch.

Number of the Band.	Reflected Tints.	Transmitted Tints.	Air.	Water.	Glass.
I.	Very black	..	$\frac{1}{2}$	$\frac{3}{8}$	$\frac{10}{31}$
	Black	White	1	$\frac{3}{4}$	$\frac{20}{31}$
	Nearly black	..	2	$1\frac{1}{2}$	$1\frac{2}{7}$
	Blue	Yellowish red	$2\frac{2}{5}$	$1\frac{4}{5}$	$1\frac{11}{20}$
	White	Black	$5\frac{1}{4}$	$3\frac{7}{8}$	$3\frac{2}{5}$
	Yellow	Violet	$7\frac{1}{9}$	$5\frac{1}{3}$	$4\frac{3}{5}$
	Orange	..	8	6	$5\frac{1}{6}$
	Red	Blue	9	$6\frac{3}{4}$	$5\frac{4}{5}$
II.	Violet	White	$11\frac{1}{6}$	$8\frac{3}{8}$	$7\frac{1}{5}$
	Indigo	..	$12\frac{5}{6}$	$9\frac{5}{8}$	$8\frac{2}{11}$
	Blue	Yellow	14	$10\frac{1}{2}$	9
	Green	Red	$15\frac{1}{8}$	$11\frac{2}{3}$	$9\frac{5}{7}$
	Yellow	Violet	$16\frac{2}{7}$	$12\frac{1}{5}$	$10\frac{2}{5}$
	Orange	..	$17\frac{2}{9}$	13	$11\frac{1}{9}$
	Bright red	Blue	$18\frac{1}{3}$	$13\frac{3}{4}$	$11\frac{5}{6}$
	Scarlet	..	$19\frac{2}{3}$	$14\frac{3}{4}$	$12\frac{2}{3}$

This table, extended so as to include the seventh band of reflected tints, constitutes that which is called Newton's Scale of Colours.

It was to explain the phenomena of these coloured rings that Newton proposed the hypothesis of 'Fits of easy Reflection and Transmission,' which in many respects explains the laws of the phenomenon. But besides giving no indication beforehand of what ought to be the variation of the diameter of a ring with the refractive index of the interposed medium, or with the obliquity of incidence, it tends to at least one result at variance with observation. According to the hypothesis of fits, the central black spot, as well as the dark parts of the rings seen with homogeneous light, ought to be of half the brightness of the brightest parts; according to the theory of undulations, they ought to be perfectly black. Observation shows, that at least the central spot (which is most easily observed, and does not require homogeneous light) is perfectly black.

A general explanation of the rings according to the principles of the undulatory theory may readily be given. Let M N P Q be two plates or



spherical lenses, which we may suppose plano-convex (though all that is essential is, that the more curved of the adjacent surfaces should be convex), in contact with each other at Z; and let A B be the direction of a pencil, or of a wave of light incident upon the first or upper plate: this will be refracted in some direction as B C, and at the point C part of the pencil will emerge and fall on the other plate in some point E, where it will be partly transmitted through that plate in the direction E R, and partly reflected in the direction E F. Another part of the refracted pencil B C will be reflected at C in the direction C D, some of it emerging at D, and the rest being reflected back into the plate. The reflected pencil E F will also be, in part, transmitted through the upper plate in some direction as F G, and, in part, reflected in the direction F H: at the point H a portion will be transmitted in the direction H S, while another is reflected in the direction H K, and so on. The two principal reflected pencils are those of which the courses are A B C D and A B C E F G; and these being each once reflected will be of nearly equal intensity. The other pencils in the general reflected beam, having been reflected 3, 5, 7, &c. times, will be comparatively weak, except at very

great incidences. The two principal transmitted pencils, A B C E R and A B C E F H S will be of very unequal intensity, the latter having been twice reflected, and the former not reflected at all. These will be accompanied by pencils reflected 4, 6, 8, &c. times, which will be comparatively insignificant.

Supposing, therefore, for the sake of simplicity, that the light is incident perpendicularly, restricting ourselves to the two most important pencils, and considering first the reflected light, we see that the light reflected from the under surface of the thin plate of air has had to travel a distance 2D in air more than the other stream, D being the distance between the lenses at the point under consideration, or the thickness of the plate of air. We might, therefore, perhaps, expect that the vibrations in the two streams would be in perfect accordance when D was equal to zero, or a multiple of $\frac{1}{2}\lambda$, and in opposition when D was an odd multiple of $\frac{1}{4}\lambda$. This would give correctly the law of the variation of the radii of the rings, since D varies as the square of the radius drawn from the point of contact of the lenses, with the single but important exception, that the places of the bright and dark rings are interchanged. But we must remark, that the two reflections take place under opposite circumstances, one at the surface of a rarer, the other at the surface of a denser medium. Various dynamical analogies, such as the reflection of sound from the end of a tube, according as it is closed or open, the reflection of sound at the common surface of two gases which are supposed not to mix, would make it more probable than the contrary supposition that in one of these two reflections there should be a change of sign, in the other not. A change of sign is equivalent to a change in the length of the path of one of the streams amounting to half an undulation. This change being admitted, theory assigns correctly the law of the variation of the radii of the bright and dark rings. And not only the *law of variation*, but the *absolute magnitude* of the rings may be assigned *à priori*, since the length of a wave of light is known by other observations; and the magnitude so assigned is in conformity with experiment. The explanation of the variation of the scale of the rings with the colour, and of the obliteration of the rings beyond the seventh or thereabouts by overlapping, when the incident light is white, is the same as in other cases of interference. Moreover, if a liquid such as water be interposed between the lenses in place of air, since light travels more slowly in water than in air, in the proportion of 1 to μ, the same kind of ring which with air is found at a spot where the distance between the lenses is D, is found with water where it is only $D\mu^{-1}$, which explains the law of variation of the radii of the rings with the refractive index of the interposed medium.

The explanation of the transmitted rings is perfectly similar, the chief differences being, first, that as the interfering streams have been refracted alike, and one of them in addition twice reflected, there is no change of sign, or the interference is determined simply by the difference of path, without the addition of the half undulation; and secondly, that the interfering streams are very unequal in intensity, and therefore with homogeneous light the minima are very far from being absolutely black. Thus when light is incident perpendicularly, whether externally or internally, at the common surface of crown glass and air, only about the $\frac{1}{25}$th part of the incident light is reflected, the remaining $\frac{24}{25}$ths being transmitted. Hence by two such reflections the intensity is reduced in the proportion of 625 to 1; and if we represent by unity the intensity of the light transmitted across the thin plate without reflection, the intensity of the twice reflected light must be represented by $\frac{1}{625}$. The question may naturally be asked, How can such feeble light by interfering with the former give rise to any sensible rings? The explanation of this paradox is derived from the consideration that in interference we must compound not *intensities* but *vibrations*, and thence deduce the intensity by taking the square of the coefficient of vibration. Thus, taking the above numbers as correct, we learn that the coefficient of vibration will be reduced by one reflection in the proportion of 5 to 1 only, and by two in the proportion of 25 to 1. Hence if we take the coefficient of vibration in the simply transmitted stream as unity, that in the twice reflected stream will be $\frac{1}{25}$, and therefore that in the resultant stream will vary between the limits $1 \pm \frac{1}{25}$, and the intensity will vary between the limits $(1 \pm \frac{1}{25})^2$, or $1 \pm \frac{2}{25}$, nearly; so that the difference between the limits is as much as $\frac{4}{25}$ths, or nearly $\frac{1}{6}$th of the mean intensity.

Next, suppose the light incident obliquely. If β be the angle of incidence on the first surface of the upper lens, or which is the same (the lens for this purpose being treated as a plate bounded by parallel surfaces), the angle of refraction into the thin plate of air, it may be shown, as in Airy's 'Tracts' ('Undulatory Theory,' art 64), or still more simply by referring everything to sections of the fronts of the waves by the plane of incidence instead of to rays, that the retardation due to the double transit across the plate is $2\,D\cos\beta$, in place of $2\,D$, as at a perpendicular incidence. This explains the law of the variation of the rings with the obliquity.

From the explanation hitherto given it might seem that in the case of the reflected rings the minima, though nearly, ought not to be perfectly black. For the stream reflected at the second surface of the thin plate has to undergo two more refractions than that reflected at the first surface, and at each refraction a small portion of the incident light would be lost to it by reflection. Fresnel first showed ('Annales de Chimie,' tom. 23, p. 129), by taking account of the infinite number of reflections, as Poisson had previously done in the case of a perpendicular incidence, that the minima in the reflected rings ought at any incidence to be perfectly black, and that, without assuming anything relative to the law of intensity in reflection beyond a law discovered experimentally by Arago, that at any obliquity light is reflected in the same proportion at the first and second surfaces of a transparent plate. For a very simple demonstration at the same time of Arago's law, and of the loss of a half undulation, on the assumption merely that the forces acting depend only on the positions of the particles, the reader is referred to a paper in the 'Cambridge and Dublin Mathematical Journal' (vol. iv. p. 1). A complete investigation of the intensities of the reflected and transmitted rings, in which account is taken of the infinite number of reflections, will be found in Airy's 'Tract,' arts. 64–67. The result is—

For the reflected system $$\frac{4a^2e^2\sin^2\frac{\pi}{\lambda}V}{(1-e^2)^2+4e^2\sin^2\frac{\pi}{\lambda}V},$$

For the transmitted system $$\frac{a^2(1-e^2)^2}{(1-e^2)^2+4e^2\sin^2\frac{\pi}{\lambda}V},$$

where a denotes the coefficient of vibration for the incident light, V the retardation, $2D\cos\beta$, and $1:e$ the ratio in which the coefficient of vibration is altered by one reflection. The sum of the two expressions is always equal to a^2, which shows that the reflected and refracted systems are complementary to each other, conformably to observation.

Sir Isaac Newton also discovered that when the sun's light is reflected into a darkened room, and allowed to fall on a screen with a moderately small hole, and the beam so passing is received perpendicularly on a concave mirror, made of glass quicksilvered at the back, which is placed at such a distance from the screen that the hole coincides with the centre of curvature of its surfaces, so that the regularly reflected light goes back through the same small hole by which it entered, a system of coloured rings is seen depicted on the screen, on the face towards the mirror, surrounding the hole. The order of colours, and the law of the diameters of the rings, agree with the transmitted system of the rings formed between two object-glasses. A metallic speculum exhibits no such rings. If the amalgam be removed from a mirror of quicksilvered glass, the rings are seen as before, but much fainter. With different mirrors the diameter of a given ring varies directly as the radius of curvature of the surfaces, and inversely as the square root of the thickness of the glass.

Although Newton expressly refers to the defect of polish of the first surface in relation to these rings, he does not seem to have purposely tarnished his mirrors. In repeating Newton's experiments, the Duke de Chaulnes observed that the brilliancy of the rings was very greatly increased by tarnishing the surface, for which milk much diluted with water is very convenient. It is advantageous to form a diverging beam by transmitting a beam of sunlight through a pretty large lens, at the focus of which is to be placed the small hole of the screen. In this way of operating the experiment is one of remarkable beauty. On slightly inclining the mirror, the phenomenon changes in a very remarkable way, a set of coloured rings continually opening out from a point midway between the luminous point, or image of the sun in the focus of the lens, and its image formed by regular reflection. The experiment may be varied in a very beautiful way by dispensing with screen and sunlight, and simply placing a small taper-flame in front of the tarnished mirror, in such a position as to coincide with its inverted image. On viewing the coincident flame and image, they are seen surrounded by a splendid series of coloured rings, which appear to have a determinate position in the air like an actual object.

These phenomena are known as the *colours of thick* plates. They have been shown to arise from the interference of two streams of light, whereof one is scattered on entering the glass, and then regularly reflected at the back and refracted out; and the other enters the glass by regular refraction, and after regular reflection at the back is scattered in emerging. At a point coinciding with the luminous point and its image, the two scattered streams follow the course of the regular light, and therefore their difference of path is nothing, and the difference of path of the two scattered streams, which reach a point at no great distance from the former, will accordingly be sufficiently small to allow the streams to manifest the ordinary phenomena of interference. The theory of the rings for the most important case, that in which the luminous point is in the centre of curvature of the mirror, is given in Sir John Herschel's 'Treatise on Light,' arts. 679, &c.

Dr. Whewell and M. Quetelet observed a system of coloured bands, which are seen when the flame of a candle held near the eye is viewed by reflection in a common looking-glass, several feet off, with a tarnished surface. To see them distinctly, the image of the flame must be seen distinctly, so that an eye-glass must be used if required. They change with every change of position of the candle or of the eye, and with both eyes a double system is seen, one with each eye. Their explanation depends on the same principles as that of the rings formed by concave mirrors of quicksilvered glass, and the theory of both kinds will be found treated with great detail in a paper published in the 'Cambridge Philosophical Transactions,' vol. ix., part 2, p. 147.

The subject of diffraction has been already briefly considered in a special article. [DIFFRACTION OF LIGHT.] The full comparison of theory and experiment with reference to this curious and interesting class of phenomena, requires far too much mathematical calculation to be here introduced, and reference must be made to Airy's Tract on the Undulatory Theory, or other works in which the question is treated. Suffice it to remark, that the undulatory theory has led to a most complete explanation of the phenomena, qualitatively and quantitatively, in their minutest details.

There is one phenomenon, the astronomical phenomenon of aberration, the explanation of which on the corpuscular theory is so simple as to attract little notice, but which presents a serious difficulty on the theory of undulations. To account for it, it has been supposed by Dr. Young and others, that the earth in its motion round the sun passes through the ether without disturbing it, allowing it to pass between its own particles like the wind through a grove of trees. Startling as this hypothesis is, we ought not to reject it on the strength merely of previous notions respecting such a mysteriously subtle medium as the luminiferous ether, if we were fairly led to it. But we are not obliged to have recourse to it, for the phenomenon admits of explanation by attributing to the ether a motion, due to bodies passing through it, which is of a kind with which we have a great deal to do in hydrodynamics. (See 'Philosophical Magazine,' vol. xxvii. (1845), p. 9, and several subsequent articles.)

In the explanation of the phenomena which we have hitherto considered, nothing depends upon the direction of vibration of the particles of ether which transmit the waves, but the phenomena of polarisation lead us to suppose that the vibrations are transverse to the direction of propagation. [POLARISATION OF LIGHT.] This supposition being admitted, the curious and complicated phenomena of the interference of polarised light are explained with beautiful simplicity. We have in this article to consider how far the same hypothesis of transverse vibrations helps us towards an explanation of double refraction.

We shall commence by briefly adverting to the facts of double refraction, and to its laws so far as they were ascertained before Fresnel's researches on the subject. It was in Iceland spar that the phenomenon was first discovered, and this crystal, from the great power of its double refraction was well suited for a study of the subject, especially at a time when the instrumental means of examination were far inferior to what we at present possess. Of the two rays into which Iceland spar divides in general a single ray incident upon it, the more refracted was found to obey the ordinary law of refraction, but the less refracted was found to obey a more complicated law, not even lying in the plane of incidence, except in particular cases. On measuring the refractive index of the spar with respect to the latter or extraordinary ray by methods applicable to ordinary media, different values were obtained, varying from a maximum equal to the refractive index for the ordinary ray, and obtained when the course of the ray within the crystal was parallel to the axis, to a minimum, which was obtained in any direction perpendicular to the axis, around which everything relating to the optical properties was symmetrical. Since there are here two rays, we must, if we adopt the undulatory theory at all, assume that a disturbance excited at any point of the crystal would give rise not to one wave, but to two waves, diverging from that point, or what comes to the same, to a wave represented by a surface of two sheets. As the more refracted ray in Iceland spar obeys the ordinary law of refraction, the inner sheet of this surface must be supposed to be a sphere. The facts which have been mentioned respecting the refraction of the extraordinary ray, show that the outer sheet must be a surface of revolution around the axis of the crystal, along which it touches the inner sheet, and must be most protuberant at the equator. Apparently as being next in simplicity to a sphere, Huygens assumed this surface or sheet to be an oblate spheroid of revolution, and found the calculations thence resulting as to the course of the extraordinary ray confirmed by the result of his experiments.

The demonstration of the laws of reflection and refraction in the case of ordinary media, require but a slight modification to adapt them to the case of a crystal for which we are supposed to know the form of the wave surface. In fact, if we suppose, for simplicity, the incident waves and the surface of the crystal to be both plane, we have only to replace the hemispheres within the media by the corresponding wave surfaces, which will form a system of similar and similarly situated curved surfaces with two plane envelopes, one for each sheet. Hence results the following construction. Draw a line perpendicular to the incident waves in air, and therefore representing the course of an incident ray. With the point of incidence for centre, describe a sphere representing the velocity of propagation in air, and likewise within the refracting medium draw the wave surface on a corresponding scale, so that its radius in any direction represents the velocity of a ray propagated in that direction. Produce the incident ray to meet the sphere within the refracting medium which is a continuation of the hemisphere described in air, and at the point of meeting draw a tangent plane to the sphere, or, in other words, a plane perpendicular to the ray. Through the line of intersection of this tangent plane with the plane of the surface, draw tangent planes to the two sheets respectively of the wave surface, and join the point of incidence with the points of contact. The two tangent planes will give the directions of the fronts of the two refracted waves, while the two joining-lines will give in direction the courses, and in magnitude the velocities, of propagation, of the two refracted rays; and if from the point of incidence we let fall perpendiculars on the two tangent planes, they will represent in magnitude and direction the velocities of propagation of the refracted waves, estimated in directions perpendicular to their planes. If the incident waves and the surface of the medium be curved, the same construction will hold good on substituting tangent planes for these curved surfaces, just as in the case of ordinary media, but the front of either refracted wave will of course no longer be plane but curved. A construction based on the same principles gives the courses of internally reflected rays; and it may be remarked that a single incident ray in general gives rise to two internally reflected rays.

The accuracy of Huygens's construction, as has been already observed, was confirmed by the observations of Wollaston and Malus, and it was for some time supposed that other doubly refracting crystals resembled Iceland spar, except as to the energy of their double refraction. But Biot discovered that in quartz and several other doubly refracting crystals it is the *less* refracted instead of the *more* refracted of the two rays which obeys the ordinary law of refraction, so that in the application of Huygens's construction the oblate must be replaced by a prolate spheroid. This difference does not entail any difference in the state of polarisation: it is still the ordinary ray that is polarised in a principal plane. Crystals in which, as in Iceland spar, the ordinary ray is the more refracted, have been called negative, and those of the other class positive; terms derived from certain views relating to the corpuscular theory.

If a plate of Iceland spar cut in a direction perpendicular to the axis be interposed between the polariser and the analyser of a polarising apparatus, a most splendid series of coloured rings make their appearance. If the analyser had been turned till the field was dark, the rings are seen to be interrupted by a black cross, the arms of which are parallel and perpendicular to the plane of primitive polarisation, and the order of the tints, beginning from the centre, agrees with that of the reflected system of Newton's rings. If the analyser be turned through 90°, the black cross is replaced by a white one in the same position, and the tints now agree with the transmitted system of Newton's rings, but are much more vivid. In intermediate positions of the analyser, the rings are less vivid, and are interrupted by a double cross containing white light of mean intensity, or, in other words, by eight radii, of which every alternate pair are at right angles. The arms of the crosses are parallel and perpendicular to the planes of polarisation of the polariser and the analyser. Similar rings are seen in the case of other doubly refracting crystals of the class now known as uniaxal; but sometimes, in consequence of a great chromatic variation in the doubly refracting power of the crystal, the succession of tints deviates materially from that of Newton's rings.

In quartz, the phenomena manifested by polarised light passing nearly along the axis appeared peculiar, resembling a combination of those belonging to an ordinary uniaxal crystal with those belonging to syrup of sugar; but the same have recently been discovered in some other uniaxal crystals.

In investigating the colours exhibited by crystalline plates, Sir David Brewster was led to the discovery that in many—in fact, in the greater number—of crystals, there exist not *one*, but *two*, directions about which coloured rings are seen in polarised light. Such crystals are called *biaxal*, and the two directions in question are called the *optic axes*. Sometimes, as in sulphate of lime, sugar, &c., the optic axes are widely separated; and in this case, if a crystal cut perpendicularly to either axis be introduced into the previously dark field of a polarising apparatus, a series of nearly circular coloured rings is seen interrupted by *a single* dark brush, in place of the pair of brushes forming a cross which are seen in uniaxal crystals. If the crystal be turned round an axis coinciding with the optic axis, the black brush turns round in a contrary direction at an equal rate relatively to space, or a double rate relatively to the crystal, whereas in a uniaxal crystal similarly treated the black cross remains stationary. The rings are ordinarily nearly equidistant, whereas in a uniaxal crystal they obey the law of increase of Newton's rings, the squares of their radii increasing in arithmetical progression. In other crystals, like nitre, the optic axes are near each other, and may be seen together, especially if the plate be cut in a direction perpendicular to their middle line. In this case, on introducing the crystal into the dark field a set of coloured curves are seen resembling lemniscates, having the optic axes for poles; and each optic axis is traversed by a dark hyperbolic brush; and at certain azimuths of the crystal, 90° apart, the two brushes unite and form a cross, one arm of which passes through the optic axes.

Sir David Brewster also discovered the relation between the optical characters of crystals and their crystallographic forms. It was found that the system of rectangular axes formed by lines bisecting the acute and obtuse angle between the optic axes, and a line perpendicular to their plane, were intimately connected with the crystalline form, so that whenever there existed a plane of crystalline symmetry, two of these axes lay in it. It is found that crystals of the cubic system are singly refracting, those of the rhombohedral and pyramidal systems uniaxal, and those of the prismatic, oblique, and anorthic systems

biaxal. No account is here taken of properties like those of syrup of sugar, nor of what Biot has termed lamellar polarisation.

The explanation of these beautiful coloured rings and curves follows at once from combining the observed laws of double refraction, including therein the polarisation of the refracted rays, with the laws of the interference of polarised light. The latter, as we have seen, admit of a perfectly simple explanation on the hypothesis of transverse vibrations; it remains to be seen what account that hypothesis can give of the former.

For some time after the discovery of biaxal crystals, it was supposed that one of the refracted rays followed the law of ordinary refraction, while the other followed some unknown law more complicated than the Huygenian. It was theory which first pointed out to Fresnel, that neither ray followed the ordinary law, an anticipation which he found to be confirmed by experiment.

Our limits would not permit us to enter into the theory of double refraction as given by Fresnel; we shall content ourselves with a brief notice of the principles of the investigation, and a statement of the results to which it conducted him.

In any theory of double refraction, there are two kinds of laws which have to be accounted for; those which regulate the velocity of propagation, and those which regulate the state of polarisation. For the two are evidently so bound up together, that any true theory ought to explain both at the same time.

With regard to the former, if we only knew the form of the wave-surface, all the rest would follow from Huygens's construction. To determine, however, the propagation of a disturbance spreading out on all sides, is a problem presenting many difficulties, some of which may be evaded by the following consideration. Imagine an infinite number of plane waves, the effect of which, severally, is infinitely small, to pass initially through the point from which the disturbance is supposed to emanate. These will serve to represent initially the disturbance in the neighbourhood of that point, and their effect will elsewhere be insensible. As the time progresses, they will travel along with the velocities belonging to plane waves in their respective directions, and their effect will be insensible except along the surface of their ultimate intersections, which, therefore, will be the wave-surface required. Hence, everything is reduced to the determination of the mode of propagation of a plane wave in an arbitrary direction.

This problem Fresnel endeavoured to solve by regarding the ether within a crystal as made up of distinct particles acting on one another with forces which are functions of the distances, and considering in the first instance the motion of a single particle supposed to be alone disturbed. The result is, however, meant to be applied to a whole plane of particles constituting a wave, and this application is kept in view throughout the investigation. The force of restitution called into play by the displacement is accordingly resolved in a direction parallel and perpendicular to the front of the wave, and it is assumed that the latter component produces no effect, because although a single particle would be as free to move in that as in any other direction if impelled, a plane of particles could not so move without compression, whereas vibrations which are strictly transversal take place without compression, to which Fresnel supposes the ether would oppose an immense resistance. Accordingly account is taken only of that component of the force of restitution which lies in the plane of the wave, and which therefore the particle, considered as one of a plane of particles, would be free to obey. It is shown that for either of two rectangular displacements parallel to the front of the wave, the component of the force of restitution which is parallel to the front is also in the direction of displacement, but for a given displacement the force of restitution is different in these two directions. If now the initial displacement be parallel to the front of the wave, but otherwise arbitrary, and if it be resolved in these two directions, the components will be propagated independently of each other, but with different velocities. This accounts both for the double velocity of propagation and for the polarisation, in rectangular planes, of the disturbance propagated with the two velocities respectively.

These results were mainly deduced from a consideration of the force of restitution called into play by an *absolute* displacement, whereas it belongs to the fundamental conception of the mechanism of an undulation that it is propagated by forces called into play by *relative* displacements. This difficulty by no means escaped Fresnel, who endeavoured to show, by probable reasoning, that the general results would still be the same.

The actual results which follow from Fresnel's theory may be enunciated in the following laws:—

(1.) In every crystal there exists a system of three rectangular axes (axes of elasticity), with respect to which the optical phenomena are symmetrical. (2.) Let a, b, c, be three parameters belonging to these axes respectively, and representing certain velocities of propagation; construct the ellipsoid $a^2x^2 + b^2y^2 + c^2z^2 = 1$, and cut it by a diametral plane parallel to the front of a wave, the reciprocals of the semi-axes of the elliptic section will represent the two normal velocities of the waves which can travel independently in the given direction, and planes perpendicular to the wave front and to the respective semi-axes will be the corresponding planes of polarisation.

These laws are of a nature to admit of comparison with experiment, either directly or by the consequences which mathematically flow from them. The direction of vibration in polarised light is not itself cognisable by the senses. In the theory from which Fresnel deduced the above laws, it is supposed that the direction of vibration is *perpendicular* to the plane of polarisation.

The deduction of the form of the wave-surface becomes now a mere geometrical problem of envelopes. Fresnel did not succeed in solving the problem directly on account of the difficulty of the elimination, but he gave a very elegant construction by points of a surface which he afterwards proved to be the wave-surface required, by showing that it satisfied the requisite condition as to tangent planes, and he thus obtained its equation. The construction is as follows. Construct the ellipsoid $a^{-2}x^2+b^{-2}y^2+c^{-2}z^2=1$, cut it by a diametral plane, and from the centre perpendicular to this plane draw lines equal respectively to the semi-axes of the elliptic section: the locus of their extremities will be the wave-surface. In the 'Cambridge Philosophical Transactions,' vol. vi., p. 85, Mr. A. Smith has very simply obtained the equation of the surface, regarded as an envelope, by direct elimination. The equation is—

$$\frac{a^2x^2}{r^2-a^2}+\frac{b^2y^2}{r^2-b^2}+\frac{c^2z^2}{r^2-c^2}=0,$$

where $r^2=x^2+y^2+z^2$. It is readily seen that when two of the parameters, a, b, c, become equal, the wave-surface of Fresnel becomes the sphere and spheroid of Huygens. For an admirable dynamical investigation of the problem of double refraction, the reader is referred to a paper by Green, in the 7th vol. of the 'Cambridge Philosophical Transactions.'

The length to which this article has already run, compels us to omit the subjects of conical refraction, the application of the undulatory theory to the determination of the intensities of reflected and refracted polarised light, and of the change of phase which accompanies total internal reflection, the properties of metals in relation to the reflection of light, the optical properties of syrup of sugar and other active liquids, and those of transparent uncrystallised media subject to the action of a powerful magnet. For these, reference must be made either to the original memoirs of those who have investigated these subjects, or to some of the extensive treatises which have been written on the undulatory theory.

UNGUENTS, or ointments, are unctuous substances, for external application, and intended to answer a variety of purposes, according to their composition. They are variously designated according to their nature and consistence. At one stage of surgery they were of a very complicated kind, as may still be seen in the so-called balsams (artificial) of the continental pharmacopœias; but the progress of modern science leading to greater simplicity, their numbers are much reduced, and their ingredients fewer. If they are composed chiefly of wax, without resin, and of oil, with or without other more active materials, and have a consistence nearly as great as that of plasters, they are termed *cerates*; when fats or resin are used, so that the consistence is scarcely greater than that of butter, they are termed *ointments*; if distilled fragrant waters or essential oils are used, they are termed *pomatums*, or *pomades*; and occasionally, if the appearance correspond, some are termed *butters*, or *pastes*, such as *almond paste*, which, being bland and emollient, must be carefully distinguished from some other compounds also called butters [BUTTERS, in Pharmacy], which are acrid and corrosive, such as butter of antimony, or violent poisons, such as butter of arsenic. Most ointments are formed by melting together the ingredients, and in doing this the heat should never exceed that of the boiling-point of water. To ensure uniformity and smoothness, the ingredients should be carefully stirred while on the fire, and strained through a cloth while yet in the liquid state; if essential oils are used, these must be added afterwards. Some are made by merely triturating the materials together, as in the case of mercurial ointment. No great quantity of any ointment should be prepared at one time, as they are apt to undergo changes, sometimes very detrimental, either by the ingredients acting on each other, or by absorbing oxygen from the air. Many should be prepared only when wanted, such as the ointment of the nitrate of silver.

The chief use of ointments is either by their emollient qualities to soften tense or hardened parts, or to sheath excoriated parts from acrid secretions or the irritation of the air. Applied to ulcers, they may, according to their nature, besides excluding the air, promote the healing, if judiciously used, or hinder it if improperly used. For chapped hands or rough skins, one of the mildest and safest applications is almond-paste.

UNGULA. The hoof of a horse looks like the part of a cone which is separated from the part containing the vertex by an oblique plane. Hence such a solid is called an ungula, and rules for the determination of its content are given in books of mensuration.

UNIAXAL CRYSTALS. [OPTIC AXIS.]

UNICORN. "Concerning the Unicorn, different opinions prevail among authors," says the author of 'Thaumatographia Naturalis' (1683), and he adds that some doubt, others deny, and a third class affirm its existence.

Ctesias, the author probably whom Aristotle followed, describes the Wild Asses of India (ὄνοι ἄγριοι) as equal to the horse in size, and even larger, with white bodies, red heads, bluish eyes, and a horn on the forehead a cubit in length. For the space of two palms from the forehead this horn is entirely white, the middle part is black, and the extremity is red and pointed. Drinking-vessels are made of it, and those who use them are subject neither to convulsions, epilepsy, nor poison, provided that before taking the poison, or after, they drink from these cups water, wine, or any other liquor. After some other particulars, Ctesias describes these animals as very swift and very strong. (Ctesias, ed. Bähr, pp. 255, 329, 363.)

Aristotle notices the Indian Ass as a solipede which has a horn, and the only one of the solipedes possessing an astragalus. ('Hist. Anim.,' ii. 1.) He adds, in the third book, on the parts of animals, that those beasts which have only a single horn have it in the middle of their head; and evidently speaks of the Indian Ass from the accounts of others.

Herodotus (iv. 191) mentions asses (ὄνοι) having horns; and Strabo (xv., p. 1009, Oxford, folio) refers to Unicorn horses with the heads of deer.

Oppian ('Cyneget.,' ii., line 96) notices the Aonian bulls with undivided hoofs and a single median horn between their temples, whereas the Armenian bulls have two.

Cæsar ('De Bello Gallico,' vi. 26), when referring to the multitude of animals bred in the great Hercynian forest, speaks, probably from hearsay, of an ox with the figure of a deer, from the middle of whose forehead a single horn stands out higher and more direct than any horns known to him. He adds, that from the top of this horn branches like palms are diffused, that the nature of the male and female is the same, and that the form and size of their horns are similar. He then notices the Elk.

Pliny, who, to be sure, places it in the company of the *Mantichora*, the *Catoblepas*, and the *Basilisk*, notices it as a very ferocious beast (asperrimam feram), similar in the rest of its body to a horse, with the head of a deer, the feet of an elephant, the tail of a boar, a deep bellowing voice (mugitu gravi), and a single black horn, two cubits in length, standing out in the middle of its forehead. He adds, "Hanc feram vivam negant capi," "that it cannot be taken alive" ('Nat. Hist.,' viii. 21); and some such excuse may have been necessary in those days for not producing the living animal upon the arena of the amphitheatre.

Out of this passage most of the modern Unicorns have been described and figured. But let us pause to scan it. The body of the horse and the head of the deer appear to be but vague sketches. The feet of the elephant and the tail of a boar point at once to a pachydermatous animal; and the single black horn, allowing for a little exaggeration as to its length, well fits the two last-mentioned conditions, and will apply to one of the species of Rhinoceros. [RHINOCEROS, in NAT. HIST. DIV.]

Our limits will not permit us to follow out in detail the descriptions of the numerous writers who have treated of this subject, among whom are Ælian, Philostratus, and Solinus, Æneas Sylvius, Marco Polo, Gesner, Cardan, Garzias ab Horto, Andreas Marinus, Andreas Baccius, Bartholinus, Aldrovandus, Jonston, &c. Some, however, of the modern descriptions of the Unicorn may be excepted. Garcias noted down a description of this marvellous creature from one who alleged that he had seen it. The seer affirmed that it was endowed with a wonderful horn, which it would sometimes turn to the left and right, at others raise, and then again depress. Ludovicus Vartomanus writes that he saw two sent to the Sultan from Ethiopia, and kept in a repository at Mahomet's tomb in Mecca, and he describes them as "cancellis obseptos, minimè feroces." Cardan describes the Unicorn as a rare animal, of the size of a horse, with hair very like unto that of a weasel, with the head of a deer, on which one horn grows, three cubits in length (a story seldom loses anything in its progress) from the forehead, ample at its lowest part and tapering to a point; with a short neck, a very thin mane, leaning to one side only, and legs thin as those of a young Roe (capreolus). But, not to weary the reader, if he wishes to see what our ancestors thought Unicorns like, let him turn to Jonston's 'Historia Naturalis' (1657). There he will behold the smooth-horned Solipede ("Wald Esel"), and the digitated and clawed smooth-horned "Meer Wolff," the latter with his single horn erect in the foreground, but with it depressed in the background, where he is represented regaling on serpents. Then there are the smooth-horned "Monoceros, Unicornu, Einhorn," with the head, mane, and tail of a horse, and bisulcate feet; and another smooth-horned "Monoceros, Unicornu, Einhorn," with a horse's head and mane, a pig's tail, and camel-like feet; the "Meer Steinbock, Capricornus marinus," with anterior bisulcate feet, posterior webbed feet, and a kind of graduated horn like a modern flat telescope opera-glass pulled out, in the foreground, and charging the fish most valiantly in the water in the distance; then there is the digitated "Wald Esel, Onager Aldrovandi," with a mule's head and two rhinoceros-like horns, one on his forehead and the other on his nose, and a horse's tail, with a collar round his neck; beneath we find the "Monoceros, seu *Unicornu jubatus*—Einhorn mit mahnen," with a neck entirely shaggy, a twisted horn, anterior bisulcate feet, the posterior being webbed, and a deer's tail; and at the bottom of the plate, "Monoceros, seu Unicornu aliud—Einhorn mit mahnen, ein andr' art" with a twisted horn, mane, and shaggy gorget, curly tail, and camel-like feet.

The Unicorn seems to have been a sad puzzle to the hunters, who hardly knew how to come at so valuable a piece of game. It was however at last discovered that it was fond of rarities, and particularly attached to chaste persons; so they took the field with a virgin, who was placed in the unsuspecting admirer's way. When the Unicorn spied her, he approached with all reverence, couched beside her, and, laying his head in her lap, fell asleep. The treacherous virgin then gave a signal, and the hunters made in and captured the simple beast.

Modern zoologists, disgusted, as they well may be, with fables of which we have only given a specimen or two, disbelieve generally the existence of the Unicorn, such at least as we have above referred to; but the result of M. Guettard's dissertation is an opinion that some terrestrial animal bearing a horn on the anterior part of its head exists besides the Rhinoceros. The nearest approach to a horn in the middle of the forehead of any terrestrial mammiferous animal known to us is the bony protuberance on the forehead of the Giraffe [GIRAFFE, in NAT. HIST. DIV.]; and, though it would be presumptuous to deny the existence of a one-horned quadruped other than the Rhinoceros, it may be safely stated that the insertion of a long and solid horn in the living forehead of a horse-like or deer-like cranium is as near an impossibility as anything can be.

The "Monoceros horne" in Tradescant's collection was probably that which ordinarily has passed for the horn of the Unicorn, namely, the tooth of a Narwhal. Old legends assert that the Unicorn, when he goes to drink, first dips his horn in the water to purify it, and that other beasts delay to quench their thirst till the Unicorn has thus sweetened the water. The Narwhal's tooth makes a capital twisted Unicorn's horn, as represented in the old figures. That in the repository of St. Denis, at Paris, was presented by Thevet, and was declared to have been given to him by the king of Monomotapa, who took him out to hunt unicorns, which are frequent in that country. Some have thought that this horn is a carved elephant's tooth. There is one at Strasburg some seven or eight feet in length, and there are several in Venice.

Great medical virtues were attributed to the so-called horn, and the price it once bore outdoes everything except the Tulipomania. A Florentine physician has recorded that a pound of it (sixteen ounces) was sold in the shops for fifteen hundred and thirty-six crowns, when the same weight in gold would only have brought one hundred and forty-eight crowns.

The Unicorn is a national symbol with us, for it is one of the supporters of the royal arms of Great Britain, in that posture termed by heralds "saillant." It was introduced as one of the supporters of the English arms by James I., who having as king of Scotland borne two unicorns, coupled one of them with the English lion on his accession to the throne of England.

UNIFORM. Though this word mean nothing more than "of one form," it has a signification in mathematics which might be better rendered by "of one value" or "of one degree," when we speak to the mathematical proficient. But it is a convenience, though only an accidental one, that the word does not imply the idea of value absolutely; a circumstance which may serve us to elucidate a point of great importance in the differential calculus. The commencement is made in the present article: the continuation will follow in VELOCITY.

In order to understand any application of mathematics, whether to space or matter, it is necessary that a perfect mathematical conception should be formed of the quality of space or matter which is to come under consideration. By a perfect mathematical conception, we mean that it must be distinctly seen, first, that the object under consideration is of the nature of magnitude; secondly, that it is of a measurable kind, that is, is capable of being measured, and can actually have a mode of measuring it assigned. Why do so many persons talk and write vaguely about force, velocity, density, acceleration, &c.? Simply because they are only conversant with the first consideration, and have no precision in their ideas of the second: they feel that they are speaking of magnitudes, of things which they know may be more or less, but they have not that familiarity with the precise way of ascertaining the *how much more* or the *how much less*, without which deduction cannot be made intelligible.

Now we say that in every instance in which measurement is shown to be attainable, there is a notion of uniformity which precedes or ought to precede that of mensurability; and that emphatic mention of this circumstance, and full development of its truth and meaning, ought to be the preliminary step to actual measurement. Moreover, we say that, inasmuch as this idea of uniformity is to be gained previously to that of measurement, we must forego the notion of "uniform" and "of one value" being convertible terms, and illustrate the word by considerations independent of value; for this last term implies measurement, as is easily seen.

If we were to take *velocity* as our instance, most readers would be able to appeal to ideas of measurement and value established in their minds, whether vaguely or precisely: we therefore prefer to choose *curvature*, a term which will be quite new as meaning a measurable magnitude to all except those who have more than an elementary knowledge of mathematics. Curvature is, as the name imports, the bending, the gradual bending, which distinguishes a curve from a straight line. It is a magnitude, that is, it allows of the application of the idea of more and less: one curve may bend more than another, or more in one place than in another. So much every one can be sure of at the first announcement: the next step would be to imagine it possible, that one curve might, say at and about a point A, bend exactly twice as much as another at and about a point B. But here the ordinary reader can only imagine a possibility: no distinct criterion will at once present itself for determining what proportion the bendings or curvatures of two curves are to be stated as having to one another at two given points. If two tangents be drawn at the two given points, it is obvious that, according as the curve bends more or less, there will be more or less deflection from the tangent. Thus the curve A P, at the point A, has as much curvature as A Q, or more; certainly not less. Now as in other cases, if we measure curvature, it must be by curvature, as length by length, weight by weight, &c.: and as a preliminary, it will be desirable to have that curve which has everywhere the same

curvature. This curve is obviously a circle, which is throughout its circumference bent in exactly the same manner. Those who cannot imagine how curvatures are to be measured can always see this much, that a true mode of measurement will give the same result to whatever point of a given circle it may be applied. A method of determining value must be false which gives at one point of the same circle a greater curvature than at another. Here we say that any one may see that a notion of uniformity has a useful existence previously to that of any mode of comparing the values of different cases of this uniformity. The circle A may have a radius twice as large as that of B: are we then to say that the curvature of B is double that of A? That the smaller circle bends most is certain; whence it is equally certain that curvature or bending is a magnitude: it has its more and less. Again, it is obvious that the circle B has the same curvature in all its parts, and that the circle A has the same; though the parts of A have a curvature which is not the same as that of the parts of B. Hence it is certain that uniformity of curvature is perfectly conceivable. Now what we have to enforce is, that all this takes place in the mind, before any mode can be given of answering the question how much the curvature of B exceeds that of A. The greater the radius the less the curvature, and A has twice as great a radius as B. If it be proper to say [VARIATION] that the curvature varies inversely as the radius, then B is twice as much curved as A; but if it be proper to say that the curvature varies inversely as the *square* of the radius, then that of B is four times as great as that of A. Here the object of this article ends, and we have referred to VELOCITY the manner of making the next step. At the risk of undue repetition, we state again, that a perfect idea of a magnitude, as a magnitude, and of its uniformity, or total absence of change of value, may exist in cases in which the accurate comparison of values, or measurement, is not attained, and may even exist in a mind which has not the means of conceiving the possibility of such comparison or measurement being accurately made.

UNIGENITUS, BULL. [BULLS, PAPAL.]

U'NISON, in Music, is a sound which is exactly the same as another, in regard to pitch—that is, to acuteness or gravity.

UNIT or UNITY, the name given to that magnitude which is to be considered or reckoned as one, when other magnitudes of the same kind are to be measured. It is not itself *one*, but is the magnitude which *one* or 1 shall stand for in calculation: it is a length, or a weight, or a time, as the case may be, while 1 is only a numerical symbol. This symbol 1 represents the abstract conception of singleness, as distinguished from multitude, and is the unit of abstract arithmetic; but all concrete quantities must have units of their own kind.

Unity, says Euclid (book vii., def. 1), is that according to which each of existing things is called one: *Μονάς ἐστι, καθ' ἣν ἕκαστον τῶν ὄντων ἓν λέγεται.* And, allowing somewhat for idiom, it would not be easy to mend this definition. Anything may be unity, for things of its own kind.

The common division of units into abstract and concrete is merely the distinction between the unit of numeration and that of measurement: the former implying that reckoning or computation is to be performed, without specific reference to any particular object of reckoning; the latter, that some certain unit of length, of capacity, or whatever it may be, is to be signified by 1. On this point the learner must take pains to see, that of all the fundamental operations of arithmetic, three are wholly independent of this distinction, which cannot be said of the fourth. Addition, subtraction, and division can be physically performed, and without reference to units: two lines may be put together into one line, a line may be cut off from another, or a line may be carried along another time after time, until it is seen how many times the greater contains the less. But multiplication requires that number or magnitude should be taken a number of *times*, and the idea of multiplying a magnitude by a magnitude involves an absurdity. [MULTIPLICATION; RECTANGLE.] Nevertheless some enterprising writers on arithmetic profess to multiply magnitude by magnitude; and, to make their doings more striking, they often choose for their instance to multiply 99*l.* 19*s.* 11¾*d.* by 99*l.* 19*s.* 11¾*d.* To take a humbler case, let us examine the product of 5 shillings and 3 shillings: beginners educated in the common system of arithmetic are generally loth to part with the idea that this must be 15 shillings.

The common rule of three, as generally stated, and given without proof, is the cause of much of the habit which leads to this unwillingness; and for those who cannot see any difference between 5 shillings taken 3 times, and 5 shillings multiplied by 3 shillings, the examination of a question in this rule will be worth while. Let it be as follows:— If 10 apples cost 7 pence, how much will 30 apples cost? The computer proceeds in this manner:—As 10 apples are to 7 pence, so are 30 apples to the answer required. According to the rule, he multiplies together 7 pence and 30 apples, and produces 210—of what he does not say. They can hardly be simple apples, or pence: probably they are 210 chemical compounds of an apple and a penny. The result is to be divided by the first term, 10 apples: here 210 divided by 10 gives 21, and the apples in the divisor decompose this compound, free it of all its fruit, and leave for the final answer 21 pence. The confusion which is caused by the improper use of the concrete unit can hardly be conceived by any but one who has been used to teaching.

UNIT JAR. [ELECTRICITY, COMMON, col. 801.]

UNIT OF WORK. [WORK, UNIT OF.]

UNITARIAN. This term, in its strict and literal interpretation, denotes simply a believer in one God; and, when thus understood, is a generic term, applicable to all Christians, for they all profess to receive the unity of the divine nature; and not only so, but to Jews and Mohammedans also, and even to those unbelievers commonly called Deists, who, on the grounds supplied by natural reason alone, admit the existence, providence, and moral government of one Supreme Being. But it is more commonly understood as opposed to Trinitarian, and is accordingly the received denomination of those Christians who acknowledge one God in one person, as distinguished from those who conceive of him in three persons, characters, or relations, each of which they regard as the proper object of a distinct and separate religious worship. The Unitarian Christian believes the Father to be the only true God, and Jesus his messenger to be the Christ. (John xvii. 3.) This is the leading fundamental principle, which constitutes the true and complete definition of the term; under which are consequently included all those who, receiving the divine authority or commission of Jesus Christ, believe him to be a dependent creature, deriving his existence from the Father, and therefore as the fit object of all the veneration, submission, and obedience which can be offered to a creature, but not of religious worship properly so called. Agreeing in this great and leading principle, Unitarians differ in their opinions as to the origin, nature, and dignity of the author of their religion. Some believe him to have been a celestial spirit of great power and dignity, existing before all worlds, and employed by the Father as his instrument or agent in the creation of the universe, or at least of this portion of it in which we dwell. These are usually called, and call themselves, Arians; though differing in various particulars from the distinguishing tenets of that celebrated heresiarch. Of this class was the late Dr. Price, and many of the principal English Unitarians in the earlier part of the last century. Others believe Jesus to have had no existence previous to his birth, and to have been simply "a man, approved of God by miracles and wonders and signs which God did by him." (Acts ii. 22.) These are not unfrequently styled Socinians: but they themselves, almost universally, reject this appellation; both because it is usually given as a term of reproach (though in fact there is no more reason why it should be so considered than Lutheran, Calvinist, or Arminian), and also because Socinus held certain opinions which they disapprove, particularly the duty of praying to Christ, contrary, as many of them think, to his own express injunction. (John xvi. 23.) Unitarians believe that in Christ dwelt all the fulness of the Godhead, inasmuch as the spirit was not given by measure unto him, and as he was invested with full power to make known to the children of men the will and intentions of God concerning them; and they require no other evidence than his authority for receiving all which he delivered as coming from God. On this authority they believe that there will be a resurrection from the dead, both of the just and of the unjust, when all shall be rewarded according to their works, and when Christ himself shall come in the glory of his Father to judge the living and the dead. They believe that the truth of this declaration was ascertained and exemplified by his own resurrection from the grave. They believe that he was sent to include both Jew and Gentile in the terms of a new and better covenant: and to admit the whole race of mankind to a participation in the privileges of the family of God. For this reason it is that the death of Christ is described by himself as the blood of the new covenant, shed for many for the remission of sins; and hence Unitarians receive him not as God himself, but as the *image* of God (2 Cor. iv. 4), and a ray of his Father's glory—as the one Mediator between God and man.

Unitarians believe in the Atonement; understanding that term in the sense in which it is used in the only place where it occurs in the New Testament, namely, reconciliation. Men were enemies to God by wicked works; they were reconciled by the death of Christ, that is, by the new covenant of grace and mercy ratified by his death, in as far as they have been reclaimed from sin to a life of righteousness. In this sense they think that Christ died *for* us; not in our stead, but on our behalf; to procure for us the benefit of a new and better dispensation. Thus the terms or conditions of salvation are "repentance towards God and faith in the Lord Jesus Christ." And they deny that these views are liable to the charge which is sometimes brought against them, of underrating the evil of sin; considering that by repentance is meant not merely sorrow for past sin, but a change of mind and heart, leading to future amendment, and, when practicable, to restitution.

Unitarians are sometimes charged with relying upon their own merits, but erroneously. They profess to look for everything they have or can expect solely to the free grace and mercy of God, manifested in the gospel of Jesus Christ. This, and this alone, is the *procuring cause* of salvation, of which conversion where necessary, and repentance and better obedience in all cases, are only the prescribed but indispensable condition; a condition, which they believe that all men are competent to fulfil, by a diligent and conscientious exercise of their natural powers. These powers, and the entire constitution which man inherits at his birth, they believe to be such as his Maker intended them to be, not less capable in their own nature of religious and moral improvement than those of his first progenitor, when cultivated with due care, exercised under an influential sense of the Divine presence, and an habitual application for the Divine protection and blessing promised in the Gospel of Jesus Christ.

Unitarians for the most part believe in the doctrine of Universal Restitution; considering punishment, both here and hereafter, not as the expression of what is called *vindictive* justice, but as the instrument of a remedial discipline, destined ultimately to bring back the sinner from the error of his ways. But it should be observed that on this, as on all other points, it is difficult to give any precise statement; because in fact there does not exist any Unitarian *creed* or standard, which the general body have ever formally recognised as of authority. No Unitarian will allow himself to be held responsible for the opinions maintained by any other, let his talents, eminence, or reputation be what they may.

Without touching on the controversies which have arisen respecting the history of Unitarianism in the primitive church, it may be sufficient for our purpose to observe that it quickly made its appearance among the leading reformers of the 16th century. The fate of Servetus, who was burnt at Geneva for the profession of this obnoxious sentiment, is the foulest blot on the character of Calvin. Several of the most eminent of the Italian reformers of that period were anti-Trinitarians of different degrees, some of whom became distinguished lights and founders of Unitarian churches in distant lands. In this country, during the reigns of Edward VI., Elizabeth, and James I., several persons expiated the offence of this form of heresy at the stake; but the first religious society established in England avowedly on this principle was gathered in the time of the Commonwealth by Biddle, who may therefore be styled the father of English Unitarianism. The Unitarians of the present day in this country are chiefly the descendants and representatives of that branch of the early Non-conformists who received the denomination of Presbyterians; and they are still known by that name, though no Presbyterian form of church-government, properly so called, has ever existed either among them or their predecessors. A smaller body are Baptists; and a few societies now Unitarian originally belonged wholly or partially to the Independent denomination. In the proper sense of the word they are all Congregationalists; inasmuch as every society is a distinct religious community, acknowledging no external control upon earth in spiritual concerns. The census of 1851 gave 229 congregations in England and Wales, and 50,061 attendances on Sunday, March 30.

In the United States of America there are at least four distinct religious bodies who profess anti-Trinitarian opinions:—1. A large portion of the Congregationalist churches in Massachusetts, with a few in the adjoining states of New England, to which may be added churches of the same denomination in several of the principal towns in other parts of the Union. 2. The Universalists, whose leading tenet is the doctrine of Universal Restitution; but who have in general adopted some modification of Unitarianism. 3. A considerable majority of the American Quakers, from whom their orthodox brethren seceded and formed a distinct community. 4. A numerous denomination who call themselves *Christians* by way of distinction, refusing to be enrolled as the followers of any other body.

At Geneva, once the fountain-head and stronghold of Calvinism, Unitarianism prevails; and in Transylvania the descendants of the followers of Socinus, Davides, and others, in the 16th century, still form a numerous community.

In this article no attempt has been made to exhibit the scriptural proofs on which Unitarians are accustomed to rely; still less to give any minute critical examination of the texts usually cited in opposition to their doctrines; but merely to state as concisely and distinctly as possible what those doctrines are. Those who wish to obtain further information on the views of Unitarians are referred (among other sources) to Lindsey's *Apology* and *Sequel*; Lardner's *Letter on the Logos*; Belsham's *Calm Inquiry*; Carpenter's *Unitarianism the Doctrine of the Gospel*; Yates's *Replies to Wardlaw*; and the Doctrinal Discourses of the late Dr. Channing.

UNITED BRETHREN. [MORAVIANS.]

UNITED PRESBYTERIAN CHURCH (OF SCOTLAND). The United Secession Church and the Relief Church, which had existed as separate organisations for a considerable period, formed a junction in 1847, under the designation of the *United Presbyterian Church*. The original secession from the Scottish establishment, which took place in the year 1733, was occasioned by two acts of the General Assembly; the first, passed in 1730, for putting an end to the practice of recording the protests, or reasons of dissent, given in by individual members against the decisions of church judicatories; the other, passed in 1732, providing that in cases in which what is called the *jus devolutum*, or right of the presbytery to nominate to vacant livings in consequence of no qualified person being presented by the patron within six months, came into operation, the presbytery should always appoint the person chosen by the heritors and elders. The act of 1732 was not satisfactory to some members of the church because it did not restore (in the cases in which the appointment fell to presbyteries) the more democratic practice which had been established in 1649, placing the election with the elders, or members of the kirk session, alone.

The clergyman who took the lead in the movement against the acts of 1730 and 1732 was Ebenezer Erskine, then one of the ministers of Stirling, who had the co-operation of his brother, Ralph Erskine, minister of the parish of Dunfermline. [ERSKINE, EBENEZER, in BIOG. DIV.] Fifteen members of Assembly protested against the passing of the act of 1732. As the Assembly refused to record this protest, Ebenezer Erskine, in a sermon which he preached a few months later, as moderator of the synod of Perth and Stirling, denounced the proceeding as arbitrary and tyrannical. Upon this sermon the synod passed a resolution of censure, from which Erskine appealed to the General Assembly; but the sentence was confirmed by that supreme court in 1733, and he was rebuked and admonished at the bar of the house. He protested, three other clergymen adhering to him, against this decision, and declared he would continue the conduct for which he had been censured; upon which the Commission of Assembly was authorised to proceed against the four protesters, and they were suspended in August, 1733, and deposed on the 16th of November following. This sentence of the Commission however was removed by the Assembly of 1734, which at the same time repealed both the act of 1730 and that of 1732. But in the meantime the deposed brethren, having been joined by four other clergymen, had constituted themselves into a separate presbytery, under the name of *The Associate Presbytery*; the eight clergymen continuing to officiate in their several churches as usual, till the affair was once more brought before the Assembly of 1739. Even in that house the motion for proceeding to a sentence of deposition was lost; but they were finally deposed, and their parishes declared vacant by an act of the next Assembly, passed 15th May, 1740, by a majority of 140 to 30.

The Seceders, or Associate Synod, as they called themselves, remained a united body till the 9th of April, 1747, when they split into two on a quarrel about a clause in the oath required to be taken by the burgesses or freemen of some of the burghs in Scotland, declaratory of their profession and hearty allowance of "the true religion at present professed within the realm, and authorised by the laws thereof." The larger division, who held that the oath might conscientiously be taken by Seceders, kept the name of the Associate Synod, but were popularly designated Burghers; while those who held that it would be wrong to take the oath took the name of the General Associate Synod, and were known as Anti-burghers. In 1820 the Burghers and Anti-burghers coalesced again into the United Associate Synod of the Secession Church. In 1847, this body, when it united with the Relief Church, consisted of 24 presbyteries, representing about 400 congregations.

The practice of subscribing the Solemn League and Covenant was made imperative upon all members of the Secession by the Associate Synod in 1744; but fell into desuetude after a few years. One chief cause of this was the growth among the Seceders of opinions adverse to the principle of national religious establishments altogether, a principle strongly maintained, and placed on very high ground, in the Covenant. But this change of sentiment subsequently gave rise to the separation of small sections from both divisions of the body who, adhering to the principle of an established church, called themselves Original Seceders, on the ground that the first Seceders from the Established Church held that principle. The members of these sections were known as Old Light Burghers, and Old Light Anti-burghers. [SECEDERS.]

The *Relief Church* originated in the secession of a clergyman, Mr. Gillespie, from the Established Church in 1752, on a question of church patronage. Mr. Gillespie did not, for a considerable time, attempt to form any separate ecclesiastical organisation, but kept on friendly terms with many ministers and members of the establishment who sympathised with his views. Others who left the establishment for similar reasons erected places of worship, which were known as Relief Churches, because affording relief from the grievances of lay patronage in the Established Church. From these scattered congregations at length arose several Presbyteries, constituting the Relief Synod. This body, in 1847, at the time of its junction with the United Secession Synod, comprised nine presbyteries, representing 114 congregations.

The United Presbyterian Church now consists of about 550 congregations, constituting 31 presbyteries. The Synod meets annually in May, usually at Edinburgh.

UNIVERSAL; UNIVERSAL AND PARTICULAR (Logic). By a *universal*, in old logic, is meant a term which stands for more things than one: that is, any word which means more than an individual, which applies to a class of objects. In this manner it was applied to the five PREDICABLES, which were also called universals. For the dispute about the character of universals, see NOMINALISTS; but this dispute belongs to metaphysics, not to logic.

The distinction of universal and particular, as applied to propositions, uses the word universal in a different sense. A proposition is *universal* when it makes its assertion or denial about every one of the things spoken of; and *particular* when it makes such an assertion or denial of some as implies that others are, or may be, left unspoken of. Thus "all men are mortal" is universal, and also "no man is perfect." But "some men are born in England" and "some animals cannot live in this climate" are particular. These are the direct logical forms, but it happens commonly that the universal and particular characters are expressed by a great variety of idiomatic turns, and even that forms of expression which, literally speaking, imply universality, are used in a particular sense. Thus "men do not willingly abandon life" strictly means that all men are unwilling to quit life: nevertheless it would be generally understood to speak of most men—all but a few. Except when speaking of laws of nature or necessary conditions of the mind, few writers have much occasion for universal propositions, and consequently the forms of speech which belong to *all*, pass into use when the proposition is intended to be predicated only of *most*.

The particular proposition, in its pure logical form, is of no very common occurrence. The reader must understand that all which is not mentioned is, in the science of logic, considered as unspoken of: now the particular proposition of common life generally denies of the rest what it affirms of some, or affirms of the rest what it denies of some. Thus he who should say "some men are mortal" would be held to utter an untruth, because he would be thought to imply that the rest are not; and a naturalist, wishing to state that some species of a certain animal have fur, in order to state just what his argument requires, would think it necessary to say "some at least," or to use some other form of speech which would signify that, for anything he said to the contrary, all the other species might have fur also. But the logical proposition is always understood to make all possible admission or allowance as to every matter which is not directly spoken of; and "some men are mortal" means that nothing whatever is either said or implied about the rest.

The most common form of speech perhaps is the one compounded of the two particular propositions, the affirmative and the negative, of which the emphatic part is expressed, and the rest implied. Thus, two men going into a company, the first expecting to see all dressed in mourning, and the second thinking none would be so, would come away expressing the same fact in sentences of very different meaning. The first would say "some were not in mourning," the second would say "some were in mourning," both meaning to say "some were and some were not," but each giving only that part of the assertion which contained the (to him) unexpected fact. It would be desirable that writers on logic should make a closer analysis of the common forms of speech, and a comparison of them with the strict and true logical forms.

The universal proposition includes all cases in which there is nothing left unspoken of, and therefore contains all propositions in which the subject is an individual, or cannot be divided into parts. Thus, "Milton was an Englishman" is as much a universal proposition as "all men are mortal." It was at one time a matter of discussion whether propositions asserting matter of individuals could be properly called universal; but whether this term were applicable or not, it was always seen that the rules of deduction applying to such propositions were precisely those which obtain in propositions about the appellation of which no doubt could exist. But the preceding proposition is not universal because it includes *all* Milton, but because it includes all *Miltons*: that is, all Miltons who can answer to a description which is implied in the word as there used. And if, by the closeness of the implied definition, and the number of conditions which are to be fulfilled, there be left but one of men alive or dead whom it is possible to mean, the proposition is not the less true. Thus, when every A is shown to be B, and every B to be C, it follows that every A is C, even though the description given of A be so close that there can be found but one object answering to it in the world.

And just in the same manner as *all* may, logically speaking, be only one, so *some*, or those which are spoken of as some, may be one only, or several, or nearly all, or even all. Some As are Bs is logically true (such is the convention of the formal part of that science) when there is only one A which is B; and also when every A is B.

If we look at the specific elements of propositions, we find that, while the subject is defined, as to whether it be universal or particular, by the express addition of words, or by an implication which has the same effect, the character of the predicate follows the nature of the proposition, and depends solely upon whether it be affirmative or negative. In all affirmative propositions the predicate is spoken of particularly; in all negative propositions, universally. Thus, "As are Bs" in itself does not describe the manner in which A is used: it may be some As or all As; but it does particularise the predicate, B. Here As (so many as are spoken of, be it some or all) are Bs; each one of these As is a B, but other Bs may or may not exist, about which consequently nothing is affirmed. "All horses are animals;" all the horses make up as many of the animals as there are horses: under this form the particular character of the predicate is expressed. But if we say "As are not Bs," even though only one A should be here spoken of, yet every B is compared with it and rejected. What is meant is, that "this one A is not any one whatsoever of all possible Bs."

Formal logic, though an excellent exercise, is in some respects a dead letter unless the student take pains to trace the numerous idioms of language in which the affirmative or negative proposition is conveyed. So very nice are the circumstances, frequently of mere position or of context, by which the universal form is distinguished from the particular, that it would be easy to lay down an isolated sentence, of which no one should be able to say which of the two it is. For example, "homicides are justifiable which are committed in self-defence," and "homicides which are committed in self-defence are justifiable." Though probably the leaning of a grammatical critic would be to the supposition that the first should stand for "All justifiable homicides are those which are committed in self-defence," and the second for "Among the justifiable homicides are," &c., yet no person would be sure of an author's meaning, whichever of the preceding forms he might use, until he had examined the context.

UNIVERSAL DISCHARGER. [ELECTRICAL BATTERY; ELECTRICITY, COMMON.]

UNIVERSAL JOINT. [HOOKE'S JOINT.]

UNIVERSE. This name is generally used, as the word *world* once was, to signify the collection of all created things. In modern language, "the world" generally refers to the earth only, and the universe to all stars and planets. Before the reception of the Copernican theory, "the world," which signifies what we now call the universe, was naturally a synonyme for "the earth," which was supposed to be the principal part of the universe, all the other celestial bodies being only satellites. But since the time when other planets have been advanced to the dignity of being separate "worlds," the term universe has been gradually introduced into common language.

By the technical term *Theory of the Universe* is always understood what is known of the general arrangement of planets, stars, &c., and of their connection with one another.

UNIVERSITIES, lay corporations to which, since the 12th century, the charge of educating the members of what are called the learned professions has in a great measure been confided throughout Europe and the colonies founded by European states. [UNIVERSITY.]

The three oldest learned institutions to which the name University can with propriety be applied are those of Paris, Bologna and Salerno.

It is impossible to fix a precise date at which the educational institutions of Paris can be said to have assumed the form and name of a university. As for the name (*universitas*), it was not confined in the middle ages to scientific bodies; it was used in a sense equivalent to our word *corporation*. There were "universities of tailors" in those days. It was long before the name settled down into its present acceptation. The school of Bologna was a "universitas scholarium," that of Paris a "universitas magistrorum," because the former was a corporation of students, the latter of teachers. The oldest printed statutes of the university of Bologna are called "Statuta et privilegia almae Universitatis Juristarum Gymnasii Bononiensis;" and in not a few universities we find an "universitas juristarum" and an "universitas artistarum" side by side: from this it appears that "universitas" at one time approached nearly to the meaning of our word "faculty." What we now term a university was long designated indifferently "schola," "studium generale," or "gymnasium." The occasion of this vacillating nomenclature is explained by the history of universities.

The oldest document in which the designation "universitas" is applied to the university of Paris, is a decretal of Innocent III., about the beginning of the 13th century. But as early as 1180 two decretals had been issued by Alexander III., the first of which ordained that in France no person should receive money for permission to teach. The glossa of Vicentinus says expressly, that this prohibition was directed against the chancellor of the university of Paris; and the second decretal alluded to exempts the then rector, Petrus Comestor, from the operation of the first; and much earlier than any legislative provisions of popes or kings we find the foundations of the university laid.

To almost every cathedral and monastery of Europe there had been, from a very early period, attached a school, in which all aspirants to priestly ordination, and such laymen as wished and could afford it, were instructed in the *Trivium* and *Quadrivium*. It appears from the letters of Abelard (died 1142), and from other contemporary sources, that the poorer establishments intrusted the conduct of this school to one of their number called the Scholasticus; and that the wealthier bodies maintained a Scholasticus to instruct the junior pupils in grammar and philosophy, and a Theologus to instruct the more advanced in theology. About the time of Abelard the great concourse of students who flocked to the episcopal school of Paris appears to have rendered it necessary to assemble the two classes of pupils in different localities; the juniors were sent to the church of St. Julian, while the theologians remained in that of Notre Dame. All who had studied a certain time, and undergone certain trials were entitled to be raised by the rector of the schools to the grade of teachers. This was done by three successive steps. The candidate was first raised to the rank of master, in which he acted for a year as assistant to a doctor (or teacher); then to the rank of baccalaureus, in which he taught for a year, under the superintendence of his doctor, pupils of his own; lastly, to the grade of independent doctor. The number of students rendered the profession of a teacher at Paris lucrative, and many from all nations embraced it. According to the custom of those unsettled times, they gradually formed themselves into a corporation for mutual support. The corporation consisted of the teachers of all the three grades, and stood under a rector elected by themselves. According to an agreement entered into in 1206, the rector was elected by the residents of the four nations—French, English or German, Picards, and Normans. Before this time, in 1200, Philip Augustus had confirmed the exclusive control of the rector over all students and teachers. The local separation of the artists from the theologians would have been of little consequence, but for the rapid progress which the Aristotelian philosophy made during and immediately after the life of Abelard. The speculations into which studious men were led by the writings of Aristotle necessarily brought them to deal with topics which had hitherto been conceived to lie within the exclusive domain of theology. The consequences were frequent and bold attempts by individuals to modify the received doctrines of the church, clamours about heresy, persecutions, and counter-persecutions. All these contributed to bring about a tacit compromise between the professional theologians and the admirers of speculative philosophy: the former were left in possession of the pulpit and chairs of theology; the latter confined themselves ostensibly to literature and philosophy, and sought to avoid occasioning scandal by rarely overstepping the bounds of abstract inquiry. The progress of this tacit agreement may be traced in the writings of the learned from the time of Abelard down to that of Erasmus; under it grew up a class of literati, who may be called, although many of them took orders, secular scholars. It was the same incompatibility of the free spirit of speculative inquiry with the stability of a dogmatic theology which led to this compromise, that embittered the dispute about the claim of the mendicant orders to establish chairs of theology in the University of Paris about the middle of the 13th century. This controversy ended in the secession of the doctors of theology from the university, as it had for some time been called, and their incorporating themselves into a separate college or faculty. Their example was followed not long after by the doctors of canon law and medicine, who formed themselves into separate faculties. These faculties consisted exclusively of the actually teaching doctors (doctores regentes) of these three branches of knowledge. The masters and bachelors remained members of the university proper, which, from the secession of the theologians, canonists, and doctors of medicine, came in time to be called the Faculty of the Artists. From this period the university consisted of seven bodies or sub-incorporations—the four nations under their procurators, and the three faculties under their deans. The rector was the head of the university; he was elected by the procurators of the old university; no doctor of theology, canon law, or medicine could be elected or take part in the election. At first the rector was chosen by the procurators, but latterly by four electors, specially elected by each nation for that purpose. The Prevôt of Paris (so long as that officer retained any authority) was the conservator of the royal privileges in the university; the bishops of Meaux, Beauvais, and Senlis, of the papal privileges. In respect of criminal jurisdiction, the university stood immediately under the king, till A.D. 1200, when its members were transferred to the episcopal court of Paris: about the middle of the 15th century they were transferred to the Parliament of Paris. In regard to civil jurisdiction the University was originally under the bishop; in 1340 it was transferred to the court of the Prevôt of Paris; when the Chatelet succeeded to the judicial functions of the prevôt, the university was transferred to that court. The rector, with the procurators and deans, formed a court, which had jurisdiction in all complaints against teachers for incompetency or neglect of duty; and against students for disobedience to their teachers, the rector, or the discipline of the university, and in all cases between students, lodging-keepers, booksellers, stationers, &c. From the decisions of the rectorial court there was an appeal to the university, and from it to the Parliament of Paris. Each faculty (that of the artists included), had its own common school. In the faculty of canonists, there were six professors (or doctores regentes); the number in the other faculties varied. At an early period colleges were established within the University of Paris by private families or religious orders. Originally they were intended exclusively for poor scholars, who were to live in them subject to certain rules of discipline. By degrees, however, as more numerous and able teachers were employed in these colleges, they assumed the character of boarding-houses for all classes of students. In the 15th century the students who did not reside in any college had come to be regarded as exceptions from the general custom, and were nicknamed "martinets." The college of the Sorbonne (founded in 1250) was commonly regarded as identical with the theological faculty, because the members of the one were most frequently members of the other also. The promotions however continued to be made by the officers of the university, although the charge of education had been in a great measure engrossed by the colleges. Degrees were conferred in the faculties of theology, canon law, and medicine, by the deans, with the concurrence of the chancellor of the Cathedral of Notre Dame; in the faculty of artists, by the rector, with the concurrence either of the chancellor of Notre Dame or the chancellor of St. Geneviève.

The oldest authentic document bearing upon the University of Bologna is the privilege granted by the emperor Frederic I., at Roncaglia, in November, 1158, to all who travel in pursuit of learning, in which the professors of law are mentioned in terms of high encomium. Bologna is not named in this instrument, but history mentions no other law-school as existing at that early period. The contents of this privilege are twofold; foreign scholars are declared to stand under the emperor's immediate protection, and a special jurisdiction (their teachers, or the bishop of the city) is constituted to judge in all complaints against them. It seems universally admitted that the earliest teacher of civil law at Bologna was Irnerius: he is said to have been originally a teacher of philosophy, but to have acquired such a knowledge of Justinian's compilations that he was invited by the Countess Matilda to expound its doctrines from the professorial chair. Matilda died in 1115: between 1113 and 1115 the name of Irnerius appears in a legal document as "causidicus" for the countess. From 1116 to 1118 he appears to have been employed in weighty missions by the emperor Henry V. Under the emperor Frederic "the four doctors" of Bologna were selected to investigate the rights of the crown, in order to determine how far those claimed by the Lombard towns were usurpations. These circumstances show that the reputation for legal knowledge acquired by the law-teachers of Bologna had proved an introduction to state employments, honours, and emoluments; and this attracted to the city in which they taught a large concourse of the most intelligent and aspiring minds of Europe. The reputation of having studied at Bologna was a passport to office throughout Christendom. The earliest statutes and charters of the University of Bologna are compacts entered into by the students for mutual support and assistance, and immunities granted them by the popes and emperors. The University of Paris was originally an association of teachers: it was a corporation of graduates. The University of Bologna was originally an association of students who had repaired from distant lands to avail themselves of the instruction of a few celebrated teachers: it was a corporation of students. Disputes between the magistrates of the city, and between the students and professors, which occurred about 1214, are the first occasions on which we hear of a rector. From the history of these controversies it appears that the students had previously been in the habit of electing the rector, and that the right was confirmed to them for the future. At first there was merely a school of law in Bologna, and the jurists constituted the university, or rather the two universities of the Citramontani and Ultramontani. In course of time teachers of philosophy and medicine settled in Bologna, and the scholars of each class attempted to form a university: their right to do so was successfully contested by the jurists in 1295, but in 1316 they were allowed to elect a rector of their own. They called themselves "philosophi et medici," or "artistæ." In 1362 Innocent VI. founded a school of theology at Bologna. From this time therefore there were four universities in Bologna: two of law (which, however, were so intimately connected, that they are generally spoken of as one), one of medicine and philosophy, and one of theology. Each of these had its own independent constitution. That of the law university is best known, and agrees in its leading features with the others. The "universities" consisted of the foreign students, who were admitted upon the payment of twelve soldi entry-money, and obliged to renew annually their oath of obedience to the rector and the statutes of the university. The Bolognese students could neither hold offices in the university nor vote in its assemblies. The foreign students were divided into Citramontani and Ultramontani: the former were divided into seventeen nations, the latter into eighteen. The rector was chosen annually from among the students by his predecessor in office, the rector's council, and a number of electors chosen by the nations. A rector was taken from each nation in rotation. The council consisted of at least one representative of each nation: some had two. The university also elected annually a syndic, to act for them in courts of law; a notary; a massarius, or treasurer (chosen from among the town bankers); and two bidelli. The rector claimed exclusive jurisdiction in all civil cases in which one or both of the parties were students, and in criminal cases in which both were students. The professors were elected by the students, to whose body they were reckoned, and all whose privileges they enjoyed, except a vote at elections. They stood under the jurisdiction of the rector, who could fine or suspend them. The degree of Doctor was conferred by those who had previously obtained it: it was held to confer the privilege of teaching everywhere, the power of discipline over the doctor's own pupils, the right to take part in the conferring of all the degrees. At first there were only doctors of civil law: the doctors of canon law appear later, and were long less respected. In the 13th century the university began to create doctors of medicine, of grammar, of philosophy and arts, and even of the notarial art. Any student who had studied five years might be licensed by the rector to expound a single title, or, if he had studied six years, to expound a whole book of the Pandects. He was termed a licentiate; and after he had performed his task, he was declared a baccalaureus. Salaried professors appear in Bologna for the first time about 1279. The doctors taught in their own houses or in halls hired for the purpose: their method of tuition was by lectures, examinations, and disputations.

The history of the University of Salerno is much more obscure than the histories of the Universities of Paris and Bologna. Ordericus Vitalis, whose annals close with the year 1141, speaks of Salerno as a place long eminent for its medical schools. Its most celebrated teacher, Constantine of Carthage (died 1087), was a privy councillor of Louis Guiscard. This school was still flourishing in 1224, when the University of Naples was established. All that can be inferred from these scanty notices of the school of Salerno is, that the scientific study of medicine was making rapid strides about the same time that law began to be more systematically studied, and philosophical and literary pursuits to be regarded as the profession of a class whose members might or might not be priests. [SALERNITANA SCHOLA, in BIOG. DIV.]

A sense of the advantages of general knowledge had led to the foundation of cathedral and cloister schools; a sense of the use of accomplished professional men led to the encouragement of the philosophical and theological schools of Paris, the law school of Bologna, and the medical school of Salerno. The peculiar constitution of society and government at the period led to the peculiar form of incorporation adopted by the schools of Paris and Bologna. The same social necessities were working under the influence of similar social organisation in many different places, and must necessarily have led, even without communication, to similar results. But quarrels which broke out repeatedly between the universities of Paris and Bologna and the civil authorities of these cities, induced the teachers and students at different times to emigrate in a body and settle in other towns. After the breach was healed, they returned; but in some instances celebrated teachers preferred remaining in their new place of settlement, and in others the government created a new university after their temporary visitors had left them. Other universities owed their foundation to the desire of princes, ecclesiastics, or municipal authorities to disseminate learning; and others to a desire on the part of these authorities to procure for their territories a share in the wealth diffused by the resort of numerous foreigners to any celebrated school. Under the influence of motives so various, the growth of universities throughout Europe was rapid. Before the Reformation they were established in many of the principal cities of Italy, France, the Germanic Empire, the Peninsula, Great Britain, and even among the Slavonic nations east of the Germans. In Great Britain the dates of foundation were:—Oxford, before 1149; Cambridge, uncertain; St. Andrews, 1412; Glasgow, 1454; Aberdeen, 1494; Edinburgh, 1582; and Dublin, 1591, are of subsequent foundation.

In all of these institutions we recognise the leading features of Paris or Bologna. All of them, apart from the consideration of their academic character, were privileged corporations, with an independent jurisdiction more or less limited, and the power of making bye-laws. In most of them the division of the members of the corporation into nations prevailed. In all of them the faculties of philosophy (or arts), theology, law (civil and canon), and medicine were more or less fully developed. Some contained within them all the faculties; some only two or more. Almost all had a faculty of arts, which, even where it was politically the most powerful (as in the university of Paris), was regarded as in a great measure preparatory to, and therefore in its scientific character inferior to the others. In the universities of spontaneous growth the privilege of conferring degrees appears to have been claimed only in those faculties which were completely organised; in the factitious universities created by governments the right of bestowing degrees in all faculties appears to have been claimed, even where some of them only were completely organised. In some of these bodies the students constituted the corporation; in others, the masters or teachers: the former appear to have assimilated themselves to the model-university of Bologna; the latter, to that of Paris. The Italian universities, and the greater part, if not all, of the French universities, except Paris, were corporations of students. The Parisian institutions were adopted in England, the Germanic Empire, and the states on the Baltic. Spanish universities have the appearance of being a compromise between the two principles: in Salamanca the rector was elected by the scholasticus of the cathedral from among the students, and the rector appointed the professors and fixed their salaries. This division of the old universities into two classes appears, like everything about those institutions, to have had its origin in the social necessities of the time and countries. The legal faculty predominated in the Italian universities, and the French universities were called "universités des loix." The universities of this type will be found to predominate in those countries in which the Roman law prevailed, as contradistinguished from Teutonic Germany and England, and the "pays coutumiers" of France—in the countries in which the old Roman civilisation had never been entirely extirpated, as contradistinguished from those in which the Teutonic invaders formed the majority of the population. In the former there was a civilisation apart from the church; in the latter there was no civilisation but what came through the church. In the former a secular and independent spirit prevailed: the universities were incorporations of grown men seeking secular learning. In the latter a spirit of clerical domination prevailed: the universities were corporations of teachers seeking to exercise the functions of missionaries.

The universities founded after the beginning of the Reformation adopted the great outlines of the organisation of their predecessors:

the political incorporation, the privileged jurisdiction and power of making bye-laws, the faculties and modes of conferring degrees which custom had established. But the altered circumstances of society modified considerably their external relations. The territorial divisions of Europe had come to be more sharply defined, and the authority of the sovereign to be more energetically enforced by more perfect civil and military organisation. The day of feudal lords, of municipalities and other privileged corporations, each standing upon his or its defence, and acknowledging a limited and precarious subjection to the nominal liege, was past; the day of great states, of territorial governments, had come. The same political power could not and would not be conceded to universities that had formerly been given to them. The old were restricted in their privileges; the new never received them. The protracted strife between the Romish and Protestant churches also had its effect: universities, though no longer allowed to lay down the law, were cherished as advocates of a party. Roman Catholic and Protestant universities were erected to do battle for their respective creeds. Lastly, other sciences had had their practical utility recognised, in the same way as the sciences of law and medicine had had theirs at an earlier period. The application of mathematical science to the purposes of war and navigation had given an impetus to their cultivation: these new practical pursuits never produced a new faculty, but they lent greater importance to the miscellaneous faculty known as the faculty of arts.

The number of universities founded in Europe from the time of the Reformation down to the French Revolution was considerable. But many events occurred during this period to lower universities in the public estimation. The extension of elementary and secondary schools had raised the standard of education among the classes which did not receive a university education. The invention of printing, increasing the facilities of private study, had operated in the same direction. The diminished privileges and restricted jurisdiction of universities had brought them to be regarded merely as schools of a higher order. The increasing number of learned societies raised up a body of non-academical literati, hostile in many instances to the academical; and the public, looking only to the transactions of these societies, forgot that their members were indebted for their training to the universities. Amateur dabblers in science undervalued these institutions; and, in the feverish spirit of innovation which occasioned or accompanied the French Revolution, they too were denounced. In France the old universities have entirely disappeared. In the rest of Europe, as soon as the storms of the Revolution were passed over, they revived; and adapting themselves more to the social necessities of the age, have in many instances started with increased energy on a fresh career of utility. In England two new universities, London and Durham, have been constituted, great improvements have been made in those of Oxford and Cambridge, and further reforms are about to be introduced, as well as into the universities of Scotland.

In the United States of North America the medical and legal professions are educated principally in distinct schools; and this is in the latter country the case also in a great measure with the students of theology. The colleges or universities contain therefore in general only a faculty of arts.

UNIVERSITY. This word is the English form of the Latin *universitas*, which is often used by the best Latin writers. The adjective "universus" signifies the whole of anything, as contrasted with its parts; the plural "universi" also is often used to express an entire number of persons or things, as opposed to individual persons or things. The uses of the word universitas may be derived from the meaning of universus. The word universitas applies either to a number of things, or of persons, or of rights, viewed as a whole. The Roman jurists expressed by the term "universitas bonorum" the whole of a property as contrasted with the parts (singulæ res) which composed it. Such a universitas might be the object of a universal succession, a term which signified the immediate passing from one person to another of all that could be comprehended under such a universitas of property. The Roman hereditas is an instance of such universal succession.

Rights and duties are properly attached to individuals as their subjects: but a number of individuals may be viewed for certain legal purposes as one person or as a unity. Thus the notion of a number of persons forming a juristical person, or a universitas, obtained among the Romans, and universitas was a general name for various associations of individuals, who were also indicated by the names of collegia and corpora. The essential character of these universitates of persons, viewed as juristical persons, was the capacity of having and acquiring property. The property, when had or acquired, might be applied to any purposes which the nature of the association required: but it was the capacity of the association to have and acquire, like an individual, that was the essential characteristic of the body as a universitas; and the purposes for which the property might be had or acquired were no more a part of the notion of a universitas, than the purposes for which an individual has or acquires property are part of his capacity to have or acquire.

The universities or corporate bodies at Rome were very numerous. There were corporations of bakers, publicani or farmers of the revenue, of scribæ, and others. The name was also applied in the sense above explained to civitates, municipia, and respublicæ; and also to the component parts of them, as curiæ, vici, fora, conciliabula, and castella.

From the Roman words universitas, collegium, corpus, are derived the terms university, college, and corporation of modern languages; and though these words have obtained modified significations in modern times, so as not to be indifferently applicable to the same things, they all agree in retaining the fundamental signification of the terms, whatever may have been superadded to them. There is now no university, college, or corporation which is not a juristical person in the sense above explained: wherever these words are applied to any association of persons not stamped with this mark, it is an abuse of terms which requires no further comment.

The word university, in its modern acceptation, has often been misunderstood. Its proper meaning is explained in this article; and the application of the term to associations of teachers or pupils is explained in the article UNIVERSITIES.

UNLAWFUL ASSEMBLY. [RIOT.]

UNLIMITED. This term is frequently used by mathematical writers, in the same manner as INDEFINITE, to avoid the entrance of the word INFINITE. It is also used to describe a problem which may have an infinite number of answers, and which is called an unlimited problem.

UNSTABLE EQUILIBRIUM. [STABLE AND UNSTABLE; STABILITY.]

UPAS POISON. [ANTIARIN.]

URAMIL. [URIC GROUP.]

URAMILIC ACID. [URIC GROUP.]

URANIC ACID. [URANIUM.]

URANIUM (U), a metal discovered by Klaproth, in 1789, who named it after the planet Uranus, the discovery of which had occurred in 1781: the mineral from which it was first obtained is called *pechblende*, which contains about 80 per cent. of the black oxide of uranium ($2UO, U_2O_3$). This and other minerals from which uranium is extracted are described in the NATURAL HISTORY DIVISION of this Cyclopædia.

M. Péligot obtains this metal by decomposing its chloride by means of potassium or sodium, a process which has been successfully adopted for procuring aluminum and magnesium: the metal so separated is partly in the state of a black powder, and partly agglomerated; by carefully detaching the portions which adhere to the sides of the crucible, plates of a metallic lustre comparable to that of silver, are obtained; these are susceptible of being filed, but possess a certain degree of malleability, and have evidently undergone incipient fusion. Uranium is very combustible; at a moderate degree of heat, in contact with the air, it burns with a remarkably white and shining light; the combustion occurs at so low a temperature, that it may take place on paper without causing it to burn. If small particles be shaken from the filter on which the metal in powder has been collected, portions so minute as to be scarcely visible burn with brilliant sparks on coming near the flame of a candle. When heated in a capsule, uranium burns brilliantly, and is converted into a deep green-coloured oxide, the bulk of which is considerably greater than that of the metal employed.

Uranium does not appear to suffer any alteration by exposure to the air, nor does it decompose water at common temperatures, but when put into diluted acids it dissolves in them with the evolution of hydrogen gas. It somewhat resembles iron and manganese in its chemical character. Its equivalent number is 60.

Having now described the properties of uranium we proceed to consider the compounds which it forms with other bodies.

Oxygen and Uranium.—According to M. Péligot, there exist, or may be formed, three oxides of uranium: the protoxide, formerly considered as metallic uranium; that prepared by calcining the nitrate, known by the name of deutoxide of uranium, or uranous acid; lastly, the peroxide, uranic acid, which enters into the composition of the yellow salts. Besides these oxides, it is stated, by the chemist above named, that there are two suboxides of uranium produced by the decomposition of the subchloride by ammonia, and an oxide intermediate between protoxide and peroxide of uranium, which is formed when the oxide obtained by calcining the nitrate is submitted to the action of oxygen.

Suboxide of Uranium (U_4O_3). When ammonia is added to a solution of subchloride of uranium a brown precipitate is formed, which undergoes various changes of colour and composition by absorbing oxygen. Its extreme instability renders its analysis very difficult. It decomposes water, to combine with its oxygen to form the apple-green suboxide, the analysis of which is equally difficult.

Protoxide of Uranium (U O), formerly regarded as metallic uranium. This may be prepared by several processes; one of the best consists in decomposing the yellow oxalate of uranium by hydrogen: the process requires several precautions. Prepared in this manner the protoxide is extreme pyrophoric, the access of air causing it to burn with feeble incandescence and converting it into black peroxide: it is of a cinnamon-brown colour. When the protoxide of uranium is obtained by reducing the double chloride of potassium and uranium, not by means of hydrogen, it is obtained in crystalline scales possessing a high degree of lustre, and being then in a higher state of aggregation it is not pyrophoric; and when procured by decomposing the nitrate, the protoxide is of a maroon colour. When thus prepared in the dry way, it is not acted upon either by hydrochloric or sulphuric acid when diluted; but dissolves in the latter, when concentrated: nitric acid also dissolves it, but nitrate of peroxide of uranium is obtained.

This oxide may likewise be obtained in the moist way, and then it is soluble in dilute acids: it is precipitated in the state of hydrate, by adding ammonia to the green solution of chloride of uranium; the precipitate is of a reddish-brown colour, which by ebullition becomes black and dense, probably because it is dehydrated. It may also be procured by putting fragments of marble into the green solution of chloride of uranium.

Black Oxide of Uranium ($2UO, U_2O_3$) is obtained by calcining the nitrate at a high temperature. It is not decomposable by heat; when added to acids they do not directly combine with it, but a mixture of salts of the protoxide and peroxide is formed.

Olive Oxide of Uranium (UO, U_2O_3).—When any of the preceding oxides are submitted at a low red heat to the action of oxygen, the olive-coloured oxide is formed. It has a velvety appearance, and when strongly heated it loses oxygen and is converted into the black oxide, and when acted upon by acids there is formed a mixture of yellow and green salts, in which the salts of the peroxide exist in the larger proportion, and this is an advantageous process for preparing them.

Peroxide of Uranium, or Oxide of the Yellow Salts (U_2O_3).—This oxide, which is of all the most important, is obtained with difficulty in a separate state: when nitrate of uranium is decomposed with a gentle heat, an orange-coloured subsalt remains, which by the application of a stronger heat becomes olive and then black oxide; when an alkali is poured into a saline solution of this oxide, the yellow precipitate formed retains alkali in combination; even uranate of ammonia resists the prolonged action of boiling water and also of a vacuum; by heat the ammonia and water are not expelled till peroxide itself undergoes decomposition.

Chlorine and Uranium.—The protochloride (UCl) is obtained by passing a current of dry chlorine gas over an intimate mixture of equal parts of any oxide of uranium and charcoal submitted in a glass tube to a high temperature. The chloride of uranium formed appears in the state of a red vapour, and condenses in the cool part of the tube in very regular octohedrons of a metallic lustre, and of a black or green colour according to their size.

Chloride of uranium is volatile, and attracts water so strongly that it very soon becomes fluid by exposure to the air, the moisture of which also decomposes it.

Subchloride of Uranium (U_4Cl_3).—This compound is obtained by passing a current of dry hydrogen gas over the chloride of uranium moderately heated in a glass tube. The residue of this operation is of a deep brown colour, in fine filaments which are but slightly volatile at the temperature at which it is formed: it is very soluble in water; the solution is purple at first, but in a few seconds it becomes green; it gives out hydrogen gas, and at the same time deposits a red powder, which is very probably oxide of uranium, yielded in consequence of the transformation of this substance into chloride of uranium.

Sulphide of Uranium of a black colour may be obtained by adding the alkaline sulphides to solutions of uranium, or by passing the vapour of sulphide of carbon over the oxide at a high temperature.

We shall now briefly notice some of the oxysalts of uranium.

Sulphate of Protoxide of Uranium.—This salt is obtained by adding sulphuric acid to the protochloride of uranium, and heating the mixture, by which hydrochloric acid is expelled, and sulphate of uranium remains; by dissolving the residue in water, and evaporating the solution, green prismatic crystals of the sulphate are formed.

It frequently happens that the crystals possess a silky lustre, are greenish, and but slightly soluble in water; in this case they contain excess of base. This salt yielded by analysis:—

Sulphuric acid	28·0
Protoxide of uranium	46·1
Water	25·9
	100·

Oxalate of Protoxide of Uranium.—This salt is of a greenish-white colour, and very slightly soluble in water either cold or hot. It may be prepared by mixing solutions of oxalic acid and chloride of uranium; the precipitate formed is to be repeatedly washed with boiling water, in order to dissolve the yellow oxalate of the peroxide, which is more soluble, and which is first precipitated. The protoxalate of uranium, after being dried, may be exposed to the air without undergoing any perceptible change.

Nitrate of Peroxide of Uranium ($U_2O_3,NO_5+6Aq.$).—This salt is easily obtained in fine regular crystals. It is of a yellowish colour, effloresces in vacuo, and loses half its water of crystallisation.

Uranium forms a considerable number of double salts, which we have not thought it requisite to describe.

Peroxide of uranium is employed in colouring glass, to which it imparts a fine lemon yellow.

URANUS, the next planet beyond Saturn, counting outwards from the sun. This important member of the planetary system was discovered by Sir William Herschel in the year 1781. On the evening of the 13th of March of that year, while examining certain small stars in the constellation Gemini, the attention of the astronomer was drawn to a small star which appeared sensibly larger than those in its vicinity. With the view of testing the object he applied different magnifying powers to his telescope, whereupon he found that the apparent magnitude of the star in question varied in the direct ratio of the magnifying power, while the stars around it when similarly surveyed by him exhibited only a slightly perceptible change of apparent diameter. Suspecting from this circumstance that the object was a comet, he proceeded to make careful observations of its position by measuring its distance from the stars near to it. A few nights only elapsed before he obtained undoubted evidence of the star being in a state of motion. It appeared to be travelling slowly in the order of the signs, in an orbit inclined at a small angle to the plane of the ecliptic. Having continued his observations down to the 19th of April, he then drew up an account of them, and communicated it to the Royal Society in a paper which was read before that body on the 26th of the same month. He appears to have been under the impression that the object discovered by him was no other than a comet.

Attempts were made by various astronomers on the Continent to determine the orbit of the supposed comet, on the hypothesis of its revolving in a parabola with a comparatively small perihelion distance; but it was found impossible to represent the observed motion of the body in this manner, except for a very small arc of the orbit. At length Lexell, in a paper which he communicated to the Academy of Sciences of St. Petersburg, announced certain facts, which seemed to indicate that the object discovered by Herschel was in reality a planet. In the first place, it differed from a comet in being well defined. On the other hand, it did not exhibit the bright piercing light of the fixed stars. But while thus unlike a comet or a star, it exhibited several features which tended to support the idea of its being a planet. It was to be remarked that, like all the planets, it travelled in the celestial sphere in the order of the signs. Again, while it was actually situate near the ecliptic, its motion in latitude was exceedingly small, a circumstance which seemed to indicate that like the planets it revolved in an orbit, confined within the limits of the zodiac. But Lexell obtained still more convincing evidence in support of his suspicion that the object was a planet. Taking two extreme observations of its position, one of them by Herschel, dated March 17, 1781, and the other by Maskelyne, dated May 11, of the same year, he found that they might be well represented by supposing the body to revolve in a circular orbit, the radius of which amounted to 18·93, the radius of the earth's orbit being assumed equal to unity. Astronomers henceforward agreed in supposing that the object discovered by Herschel was in reality a planet revolving around the sun in the region beyond Saturn. It was soon found, however, that a circular orbit was incapable of satisfying the observations, and that the real orbit must be an ellipse of slight excentricity. Laplace, in 1783, first determined the elliptic elements of the planet's orbit, which he communicated to the Academy of Sciences in the same year.

The right of naming the new planet belonged to the discoverer, who proposed to call it the *Georgium Sidus*, as a mark of gratitude to his munificent patron George III., under whose auspices he was enabled to prosecute his astronomical labours. This designation, however, was at variance with the nomenclature hitherto employed in the planetary system, and the name of Uranus, suggested by the German astronomer, Bode, is that by which it is usually designated.

Herschel found by micrometric measures that the apparent diameter of the new planet, when viewed at its mean distance from the earth, amounted to 3″·91. This gave 34,217 miles for the value of its absolute diameter. It was, therefore, after Jupiter and Saturn, by far the most considerable of the planetary bodies hitherto recognised as revolving around the sun.

It appeared from an examination of the recorded observations of Flamsteed and several succeeding astronomers, that Uranus had been observed on several occasions, previous to its actual discovery as a planet in 1781, under the impression of its being a fixed star. These early positions proved exceedingly valuable in enabling astronomers speedily to determine the elements of the orbit with a degree of precision which, from the slow motion of the planet, could otherwise have been expected to result only after the lapse of a considerable number of years. In 1790 Delambre obtained the prize of the Academy of Sciences of Paris for the construction of tables of the planet. These tables were founded on the observations made subsequently to the discovery of the planet in 1781, and on certain earlier determinations of its position. For several years they sufficed to represent the observed motion of the planet with tolerable precision, but eventually discordances became apparent, which continued to increase in magnitude from year to year. In 1821 Bouvard published new tables of the planet. They were based exclusively on the observations made after the discovery of the planet by Herschel, their author having found it impossible to satisfy by means of the same orbit both the earlier and the more modern observations. These tables continued for a few years to represent the motion of the planet with all desirable precision; but they, in their turn, soon began to deviate from the results of observation, and the discordances continued steadily to increase in magnitude. The reader is aware that the study of these irregularities led to the discovery of a new planet beyond Uranus. In a preceding article [NEPTUNE] a detailed account has been given of the circumstances connected with this memorable triumph of science.

The following are the elements of the orbit of Uranus :—

Mean longitude, Jan. 1, 1800	173° 30′ 37″
Longitude of the perihelion	167° 30′ 24″
Longitude of the ascending node	72° 59′ 21″
Excentricity of the orbit	0.0466794
Inclination of the orbit to the ecliptic	46′28″
Mean distance from the sun	19·18239
Time of a sidereal revolution	30,686·8 days
Mass in terms of the sun's mass as the unit	$\frac{1}{17,918}$

There exists some uncertainty with respect to the mass of the planet. The foregoing value was deduced by Bouvard from the observed perturbations of Saturn. Lamont, from the observed elongations of the satellites, has determined the value of the mass to be $\frac{1}{24,605}$. No tables of Uranus have been published subsequently to the discovery of Neptune in 1846. A correct theory of the planet, with tables founded thereon, is still a desideratum in astronomy. It is to be presumed that M. Le Verrier, who is at present engaged in a systematic investigation of the theory of the various bodies of the planetary system, will in due time accomplish this important object.

URANUS, SATELLITES OF. In the beginning of the year 1787 Sir William Herschel discovered two satellites around Uranus. Having made a series of careful observations of their position with respect to the primary, he next proceeded to determine the elements of their orbits. The results of this investigation are contained in a paper which he communicated to the Royal Society in the following year. He obtained for the times of revolution of the two satellites these values :—

	d.	h.	m.	s.
Period of first satellite	8	17	1	19·3
Period of second satellite	13	11	5	1·5

He also determined the apparent distance of the second satellite from the centre of the planet to be 44″·23. The first satellite, that is, the satellite next to the planet, was an object of such faintness that he was unable to arrive at a definite conclusion with respect to the apparent distance. He however deduced the value of this element from the periodic times of the two satellites, and the apparent distance of the second, by the aid of Kepler's third law. In this way he found the apparent distance of the satellite to be 33″·09. In a paper which he communicated to the Royal Society in the year 1797, he announced two interesting facts with respect to the movements of those minute bodies. The first was that their motions are retrograde, or, in other words, that their revolutions are effected in a direction contrary to the order of the signs; the second consisted in this, that the orbits of the satellites are nearly perpendicular to the plane of the ecliptic.

In the same paper Herschel announced his discovery of four additional satellites around the planet. This made the aggregate number of satellites revolving around the planet to amount to six. The following values of the periodic time and distance of each satellite were given by him. The distances are expressed in terms of the semi-diameter of the planet :—

Order of Distance from the Planet.	Periodic time. d.	h.	m.	Distance from the Planet.
1st satellite	5	21	25	13·120
2nd "	8	17	1	17·022
3rd "	10	23	4	19·845
4th "	13	11	5	22·752
5th "	38	1	49	45·507
6th "	107	16	40	91·008

It will be seen from this table that the two satellites originally discovered by Herschel are the second and fourth, counting in the order of distance from the primary. The periodic times and distances of these satellites were satisfactorily determined by an investigation founded on their observed positions. The case, however, was different with respect to the other satellites. The distance of the first satellite was indeed the result of micrometrical measures, but the distances of the other satellites were mere estimations. The orbit of the third satellite was supposed to bisect the linear interval between the second and fourth satellites; the fifth satellite was supposed to be twice as distant from the planet as the fourth; and the sixth satellite to be twice the distance of the fifth. The periodic times of the four satellites were deduced from these data, and the elements of the second and fourth satellites by the aid of Kepler's third law.

A paper which Herschel communicated to the Royal Society in the year 1815, contains his final researches on the motions of the satellites of Uranus. It appeared from his observations that the planet passed through the common ascending node of the satellites on the 12th of March, 1798. He hence determined the longitude of the node to be 165° 30′. He also obtained 78° 58′ for the inclination of the orbits of the satellites to the ecliptic. On the same occasion he determined anew the synodic revolutions of the second and fourth satellites, which he found to be $8^d\ 16^h\ 56^m\ 5{\cdot}2^s$, and $13^d\ 11^h\ 8^m\ 59^s$ respectively. He still retained his belief with respect to the existence of four additional satellites, and, although he was unable to assign any further proof of a positive nature in support of his opinion, he communicated a series of rough notes of their observed positions which might aid the labours of future inquirers.

In 1828, Sir John Herschel, having directed one of his 20-foot reflectors towards Uranus, succeeded in obtaining a view of the two satellites originally discovered by his father. Having subsequently executed a series of micrometric measures of their observed positions, he instituted a comparison between them and the corresponding results of his father's observations, and in this way he was enabled to deduce new values of the periodic times of the two satellites. He found the period of the second satellite to be $8^d\ 16^h\ 56^m\ 31{\cdot}3^s$, and that of the fourth to be $13^d\ 11^h\ 7^m\ 12{\cdot}6^s$. It will be seen that these results do not differ materially from the corresponding numbers which the elder Herschel derived from his researches. M. Lamont, Director of the Munich Observatory, having in the year 1837 made a series of observations of the same satellites with a refractor of 11 inches aperture, obtained, by a comparison of his own measures with those of the two Herschels, values of the periodic times agreeing very closely with those deduced by Sir John Herschel.

Recently, Mr. Lassell has discovered two satellites revolving within the orbit of Herschel's second satellite, but neither of which appears to coincide with Herschel's first satellite. He has applied to them the names Ariel and Umbriel, designating at the same time the second and fourth satellites of Herschel by the names Titania and Oberon. He does not recognise the existence of any other satellites around the planet except the four to which he has applied these names. The following synopsis may be useful :—

Order of Distance from Primary.	Name of Satellite.	Time of Revolution. d.	h.	m.	s.
1	Ariel	2	12	28	48
2	Umbriel	4	3	27	22
3	Titania	8	16	56	31
4	Oberon	13	11	7	12

URATES. [URIC GROUP.]

UREA ($C_2H_4N_2O_2$). The essential solid constituent of urine. Containing nearly half its weight of nitrogen, it forms the chief vehicle for the final concentration and elimination of that element from the animal organism. Produced in the blood by the oxidising action of inspired air on albumen and other nitrogenous forms of assimilated food and exhausted tissue, it is removed from the blood by the kidneys, and is finally excreted in the urine.

Urea was first separated from urine in 1773, by Rouelle; in 1779, Fourcroy and Vauquelin isolated it in the pure state. Though now usually prepared for experimental purposes by an artifical process presently to be described, it may readily be procured from urine by the following method. A solution of ammoniacal nitrate of copper is added to urine until no farther precipitation of albumenoid and colouring matter occurs; the mixture is then filtered, the colourless filtrate evaporated to a thin syrupy consistence, and about an equal bulk of strong nitric acid added to it. The mass of crystals of nitrate of urea, thus obtained, are gently pressed between blotting paper which frees them from mother liquor, are suspended in water, carbonate of baryta added so long as effervescence of carbonic acid occurs, the mixture evaporated to dryness, the residue treated with boiling alcohol and filtered, and the filtrate set aside to cool and spontaneously concentrate, when long, slender, colourless, striated prisms of urea crystallise out.

Urea is formed artificially in many reactions. By the action of oxidising agents on uric acid; by the influence of alkalies on kreatine or alloxan; on treating fulminate of mercury or silver with sulphuretted hydrogen; from ammonia and carbonic ether, or ammonia and oxychloride of carbon. A method of greater interest than any of the preceding, inasmuch as it gives experimental demonstration of its mode of formation in the human system, is that by M. Bechamp, who produced it from albumen and other azotised compounds, by the oxidising action of a solution of permanganate of potash at a temperature of 176° Fahr.

But the most convenient and economical process for producing urea artificially, is that in which an aqueous solution of cyanate of ammonia has simply to be heated to near the boiling point, when transformation into urea at once occurs :—

$$\underbrace{NH_4O,\ NC_2O}_{\text{Cyanate of ammonia.}} = \underbrace{C_2H_4N_2O_2}_{\text{Urea.}}$$

This close relationship of cyanate of ammonia to urea was first noticed by Wöhler and Liebig in a research on the cyanates. The following are the details of the process by which the cyanate of ammonia, and ultimately urea, is obtained. Twenty-eight parts of well-dried ferrocyanide of potassium and fourteen of binoxide of manganese are finely powdered and intimately incorporated; the mixture is then spread out on an iron plate, and exposed over a furnace containing a dull red fire. The mass soon undergoes a smouldering combustion, absorbing oxygen from the binoxide and, especially if frequently stirred, from the air. When combustion has ceased the mixture is removed, allowed to become quite cold, is then treated with cold water, filtered, and the residue washed. To the washings twenty and a half parts of sulphate of ammonia are added, and the first filtrate then stirred in. Much sulphate of potash will now go out of solution as a granular precipitate, the potassium of the ferrocyanide having been oxidised during the roasting operation: the cyanogen of the ferrocyanide was, however, also oxidised at the same time and by the same means to cyanic acid, which remains in solution combined with ammonia. Evaporated to dryness over a water-bath the solution of cyanate of ammonia yields dry urea, which is separated from residual sulphate of potash by digesting in hot alcohol, containing not more than 10 or 15 per cent. of water. The alcoholic solution yields, on cooling, colourless crystals of urea to the extent of 33 per cent. of the ferrocyanide of potassium used. Should the solution of sulphate of potash have a yellow colour, it will be due to undecomposed ferrocyanide of potassium. In that case sulphate of iron must be added till prussian blue no longer precipitates, and any excess of iron got rid of by carbonate of ammonia.

Pure urea crystallises in colourless, inodorous, transparent, four-sided prisms. It has a saline taste somewhat like that of nitrate of potash. It is soluble in its own weight of water, and requires five parts of cold alcohol, but only one part of boiling alcohol, to dissolve it: it is less soluble in ether, and insoluble in oil of turpentine. Exposed to the air it becomes somewhat moist; melts when heated to near 250° Fahr., and at higher temperatures yields ammonia, carbonate of ammonia, BIURET and MELANURIC ACID. Solution of urea is stable if pure, but in urine, or in the presence of any decomposing organic matter, the urea rapidly changes into carbonate of ammonia:—

$$\underbrace{C_2H_4N_2O_2}_{\text{Urea.}} + 4HO = \underbrace{2(NH_4O, CO_2)}_{\text{Carbonate of ammonia.}}$$

The same change occurs if solution of urea be heated to 284° Fahr. in a sealed tube. Chlorine produces cyanuric acid from fused urea, but quite breaks up urea in solution: nitrous acid also oxidises it to carbonic acid, nitrogen and water.

Urea combines with acids to form definite salts. The formation of *nitrate of urea* ($C_2H_4N_2O_2$, HO, NO_5) has already been described; it crystallises in bright transparent rhombic plates or leaflets, only slightly soluble in water, alcohol, or nitric acid. *Hydrochlorate of urea* ($C_2H_4N_2O_2$, HCl) is a deliquescent unstable salt, formed when hydrochloric acid is passed into urea. A *subhydrochlorate* ($2C_2H_4N_2O_2$, HCl) crystallises in long transparent blades from a solution containing the proper equivalents of each compound. *Oxalate of urea* ($C_2H_4N_2O_2$, HO, C_2O_3) falls as a crystalline, almost insoluble, precipitate when excess of strong solution of oxalic acid is added to solution of urea; it may be obtained in long, thin, colourless, transparent prisms. It is probable that ALLOPHANIC ACID is *carbonate of urea.*

Urea also combines with metallic protoxides. If freshly precipitated oxide of silver be digested in a strong solution of urea, a yellowish crystalline powder is formed containing (3 AgO, $C_2H_4N_2O_2$). With the red oxide of mercury urea forms compounds containing respectively two, three, and four atoms of mercuric oxide to one of urea. The first (2 HgO, $C_2H_4N_2O_2$) separates out as a white powder from a solution of moist mercuric oxide in urea; the second (3 HgO, $C_2H_4N_2O_2$) is a gelatinous precipitate produced when solution of mercuric chloride is added to solution of urea kept alkaline by potash: it becomes granular and of a pale yellow colour on boiling; the third (4 HgO, $C_2H_4N_2O_2$) is prepared in the same manner as the second, mercuric nitrate being used instead of chloride.

Urea forms compounds with metallic salts. Solutions of urea and nitrate of silver, mixed and evaporated in vacuo over sulphuric acid, yield crystals containing (AgO, NO_5, $C_2H_4N_2O_2$) and ((2 AgO, NO_5), $C_2H_4N_2O_2$). A dilute and warm solution of mercuric nitrate added to a warm solution of urea, gives a granular precipitate containing (4 HgO, NO_5, $C_2H_4N_2O_2$); if the mercuric nitrate be added in excess, and the whole maintained at a temperature ranging from 104° to 122° Fahr., the precipitate occurs in six-sided prisms, and has the composition (3 HgO, NO_5, $C_2H_4N_2O_2$); if the mercuric nitrate be acidulated with nitric acid, and solution of nitrate of urea be added until a precipitate occurs, the filtered solution deposits shining rectangular tables of (2 HgO, NO_5, $C_2H_4N_2O_2$). Double nitrates of urea and soda, baryta, lime, and magnesia have also been obtained.

Compound ureas. As already indicated, urea is formed by combination of ammonia (NH_3) and cyanic acid (C_2HNO_2):—

$$\underbrace{NH_3}_{\text{Ammonia.}} + \underbrace{C_2(H)NO_2}_{\substack{\text{Cyanic acid} \\ \text{(cyanate of hydrogen).}}} = \underbrace{C_2(H_4)N_2O_2}_{\text{Urea (ordinary).}}$$

If in the place of cyanic acid—or cyanate of hydrogen as, for the sake of analogy, it may be more conveniently termed—the cyanate of some radical, other than hydrogen, be taken, an urea will be obtained containing the radical of the cyanate used, in the place of one of the four equivalents of hydrogen in common urea. Thus:—

$$NH_3 + \underbrace{C_2(C_2H_3)NO_2}_{\text{Cyanate of methyl.}} = \underbrace{C_2(C_2H_3, H_3)N_2O_2}_{\text{Methyl-urea.}}$$

$$NH_3 + \underbrace{C_2(C_6H_5)NO_2}_{\text{Cyanate of allyl.}} = \underbrace{C_2(C_6H_5, H_3)N_2O_2}_{\text{Allyl-urea.}}$$

$$NH_3 + \underbrace{C_2(C_{12}H_5)NO_2}_{\text{Cyanate of phenyl.}} = \underbrace{C_2(C_{12}H_5, H_3)N_2O_2}_{\substack{\text{Phenyl-urea} \\ \text{(carbanilamide).}}}$$

If a sulphocyanate be used, a sulpho-urea will of course be produced:—

$$NH_3 + \underbrace{C_2(C_6H_5)NS_2}_{\substack{\text{Sulphocyanate} \\ \text{of allyl.}}} = \underbrace{C_2(C_6H_5, H_3)N_2S_2}_{\substack{\text{Sulphallyl-urea} \\ \text{(thiosinnamine).}}}$$

$$NH_3 + \underbrace{C_2(C_{12}H_5)NS_2}_{\substack{\text{Sulphocyanate} \\ \text{of phenyl.}}} = \underbrace{C_2(C_{12}H_5, H_3)N_2S_2}_{\text{Sulpho-phenyl-urea.}}$$

And if now in the place of ammonia itself, a derivative of ammonia (monamines, &c.) be acted upon by the cyanate, ureas are formed in which two, three, or even the four equivalents of hydrogen in common urea, are replaced by compound radicals. Thus:—

$$\underbrace{NH_2, C_4H_5}_{\text{Ethylamine.}} + \underbrace{C_2(C_4H_5)NO_2}_{\text{Cyanate of ethyl.}} = \underbrace{C_2(2C_4H_5, H_2)N_2O_2}_{\text{Diethyl-urea.}}$$

$$\underbrace{NH_2, C_{12}H_5}_{\text{Phenylamine.}} + \underbrace{C_2(C_{12}H_5)NO_2}_{\text{Cyanate of phenyl.}} = \underbrace{C_2(2C_{12}H_5, H_2)N_2O_2}_{\text{Diphenyl-urea (flavin).}}$$

$$\underbrace{NH_2, C_2H_3}_{\text{Methylamine.}} + \underbrace{C_2(C_4H_5)NO_2}_{\text{Cyanate of ethyl.}} = \underbrace{C_2(C_2H_3, C_4H_5, H_2)N_2O_2}_{\text{Methyl-ethyl-urea.}}$$

$$\underbrace{NH_2, C_4H_5}_{\text{Ethylamine.}} + \underbrace{C_2(C_6H_5)NO_2}_{\text{Cyanate of allyl.}} = \underbrace{C_2(C_4H_5, C_6H_5, H_2)N_2O_2}_{\text{Ethyl-allyl-urea.}}$$

$$\underbrace{NH_2, C_{12}H_5}_{\text{Phenylamine.}} + \underbrace{C_2(C_4H_5)NO_2}_{\text{Cyanate of ethyl.}} = \underbrace{C_2(C_{12}H_5, C_4H_5, H_2)N_2O_2}_{\text{Phenyl-ethyl-urea.}}$$

$$\underbrace{NH_2, C_4H_5}_{\text{Ethylamine.}} + \underbrace{C_2(C_6H_5)NS_2}_{\substack{\text{Sulphocyanate} \\ \text{of allyl.}}} = \underbrace{C_2(C_4H_5, C_6H_5, H_2)N_2S_2}_{\text{Sulphethylallyl-urea.}}$$

$$\underbrace{NH_2, C_{12}H_5}_{\text{Phenylamine.}} + \underbrace{C_2(C_6H_5)NS_2}_{\substack{\text{Sulphocyanate} \\ \text{of allyl.}}} = \underbrace{C_2(C_6H_5, C_{12}H_5, H_2)N_2S_2}_{\text{Sulphallyl-phenyl-urea.}}$$

$$\underbrace{NH, C_{10}H_{10}''}_{\text{Piperidine.}} + \underbrace{C_2(C_4H_5)NO_2}_{\text{Cyanate of ethyl.}} = \underbrace{C_2(C_4H_5, C_{10}H_{10}'', H)N_2O_2}_{\text{Ethyl-piperyl-urea.}}$$

$$\underbrace{N(C_4H_5)_3}_{\text{Triethylamine.}} + \underbrace{C_2(C_4H_5)NO_2}_{\text{Cyanate of ethyl.}} = \underbrace{C_2(C_4H_5)_4N_2O_2}_{\text{Tetrethyl-urea.}}$$

Compound ureas are also prepared by the action of water on cyanates of radicals. Thus:—

$$\underbrace{2C_2(C_2H_3)NO_2}_{\text{Cyanate of methyl.}} + \underbrace{2HO}_{\text{Water.}} = \underbrace{2CO_2}_{\text{Carbonic acid.}} + \underbrace{C_2(2C_2H_3, H_2)N_2O_2}_{\text{Dimethyl-urea.}}$$

$$\underbrace{2C_2(C_6H_5)NO_2}_{\text{Cyanate of allyl.}} + 2HO = 2CO_2 + \underbrace{C_2(2C_6H_5, H_2)N_2O_2}_{\text{Diallyl-urea (sinapoline).}}$$

The hydrogen in urea, at least one equivalent of it, may also be replaced by negative radicals. The general method of formation of these *ureides*, so called in allusion to their amidic analogy, is the reaction of urea on the chloride of the negative radical, hydrochloric acid being eliminated. Thus are obtained:—

Acetyl-urea or acetureide . .	$C_2(C_4H_3O_2, H_3)N_2O_2$
Butyryl-urea or butyrureide . .	$C_2(C_8H_7O_2, H_3)N_2O_2$
Valeryl-urea or valerureide . .	$C_2(C_{10}H_9O_2, H_3)N_2O_2$
Benzoyl-urea or benzureide . .	$C_2(C_{14}H_5O_2, H_3)N_2O_2$

Constitution of urea. Urea is now generally considered to be a diamine; that is, diammonia, in which two equivalents of hydrogen are replaced by the diatomic radical carbonyl (C_2O_2''):—

$$C_2H_4N_2O_2 = N_2\left\{\begin{matrix} C_2O_2'' \\ H_2 \\ H_2 \end{matrix}\right.$$

Obviously, any of the compounds already described in this article could be formulated on the typical diagram $N_2\left\{\begin{matrix} C_2O_2'' \\ R\ R \\ R\ R \end{matrix}\right.$, R being any radical; the formula of several ureas will, in fact, be found so written in the article ORGANIC BASES.

Estimation of urea. The amount of urea in a specimen of urine is often required to be known by the physiologist and pathologist. It was originally determined in the state of nitrate or oxalate, a known quantity of urine being taken and treated in the manner already indicated; results so obtained, however, have been shown to be very inaccurate. Ragsky and Heintz proposed to take advantage of the facts, that urea is decomposed into ammonia and carbonic acid when boiled with strong acids, and that ammonia may be estimated by bichloride of platinum, the weight of which would indicate the urea present in the quantity of urine acted upon; this method, however, is not universally applicable. Bunsen takes a weighed quantity of urine, mixes it with an ammoniacal solution of chloride of barium, seals it hermetically in a glass tube, and heats it to a temperature of from 250° to 460° Fahr. for several hours; carbonate of baryta is thus produced, the weight of which indicates the amount of urea originally present, inasmuch as urea is under these circumstances always split up into ammonia and carbonic acid: this process gives accurate results, but requires too much chemical skill and experience to be very generally applicable. Liebig's process for the estimation of urea (and chloride of sodium) in urine is the one now always used. It is a volumetric method, and depends upon the facts already mentioned concerning the combinations of urea with nitrate of peroxide of mercury.

From the following details it will be found that certain standard solutions have to be made; these require time and care, but, when once obtained, the actual analytical operation is one requiring a few minutes only and is very easy of execution. Solution of mercuric nitrate occasions a white precipitate in pure solutions of urea, but not in such impure solutions as urine; this is because chloride of sodium is present in the urine, and the chlorides of the metals of either the first or second groups decompose mercuric nitrate, mercuric chloride, which does not precipitate urea, being formed. But on adding mercuric nitrate to urine until the whole of the chloride of sodium is converted into nitrate of soda, further addition will cause a precipitate because nitrate instead of chloride of mercury will then come in contact with the urea. Obviously now if the strength of the mercuric nitrate solution—which may be distinguished as No. 1—be known, the amount of chloride of sodium in the urine will be at once indicated. The means by which the No. 1 solution is standardised will be given presently. It might be thought that the further addition of the same mercuric nitrate until no more precipitate falls, a point easily ascertained, would afford the means of determining the amount of urea present; but it is not so, probably because the mercuric chloride formed would keep some of the urea in solution, a definite compound of the two having, in fact, been produced. The exact amount of chlorine in the urine therefore having been thus determined, it must now be got rid of by adding to a fresh portion of urine the requisite quantity of a solution of nitrate of silver of known strength. The chloride of silver having been separated by filtration, the filtrate is treated with mercuric nitrate solution (No. 2) until the whole of the urea is precipitated, a point that is ascertained by the yellow colour produced, on putting a drop of the mixture containing the precipitate on to a drop of carbonate of soda solution placed on a white plate; the yellow colour (mercuric oxide) simply showing that mercuric nitrate is then in solution, a state of things that obviously cannot occur so long as urea exists in the liquid.

The only remaining fact to be noticed in connection with this process, before describing the method of preparation of the standard solutions, is that phosphoric acid and phosphates must be removed from the urine before commencing the analysis; this is readily accomplished by adding to any portion of the urine half its bulk of a mixture of two parts of cold saturated baryta water, and one part of cold saturated aqueous solution of nitrate of baryta, and filtering; remembering, of course, that only two-thirds of the filtrate is urine. The filtrate will probably be alkaline from excess of baryta, if so, nitric acid must be added till it is exactly neutral to test paper, and the determination of chloride of sodium and urea then proceeded with. The quantity of the filtrate most convenient for manipulation is 225 grains (=150 grains of urine) for determining the chloride of sodium; and 450 grains (=300 grains of urine) for determining the urea. The indicated number of grains of nitrate of silver solution having been added to the 450 grains just mentioned, exactly one-half of the filtered product (=150 grains of urine), is the quantity recommended to be used for estimating the urea by the No. 2 mercuric nitrate solution.

Solution of mercuric nitrate is obtained on dissolving pure mercury in nitric acid, and boiling until the solution gives no indication of mercurous nitrate on the addition of alkaline chloride. It is then evaporated to dryness over a water-bath and redissolved in seven or eight times its bulk of water. For the No. 1 solution above described, the strong liquid just mentioned is standardised by pure chloride of sodium; and for No. 2 by pure urea. Pure chloride of sodium solution is procured by digesting excess of pure rock-salt in distilled water for one or two days, the whole being occasionally well agitated: 100 water grain measures of such a solution contain, at all ordinary temperatures, 31·84 grains of chloride of sodium: 150 grain measures of this solution of salt are mixed with 45 grain measures of a solution of pure urea containing about 4 per cent. of that substance, and also with 75 grain measures of a cold saturated solution of pure sulphate of soda; the solution of mercuric nitrate is then to be added to the mixture until a distinct permanent precipitate is formed. The number of grain measures of mercuric nitrate solution added corresponds, of course, to 47·76 grains of chloride of sodium: it must then be so diluted that 100 water grain measures may correspond to one grain of chloride of sodium, the resulting liquid being mercuric nitrate solution No. 1. The No. 2 solution is prepared by adding the strong mercuric nitrate solution to 150 grain measures of distilled water containing exactly 2 per cent. of pure urea until a yellow colour is produced, with carbonate of soda in the manner already indicated; the strong solution must then be diluted until 100 water grain measures exactly correspond to one grain of urea. Finally, the nitrate of silver solution, employed for removing the chlorine of the chloride of sodium in urine after the amount of the latter has been indicated by the No. 1 solution, is prepared by dissolving 174·36 grains of fused nitrate of silver in water, and diluting till the whole amounts to 6000 grain measures; 100 water grain measures of the resulting liquid will correspond to one grain of chloride of sodium.

UREA, ESTIMATION OF. [UREA.]

UREAS. [UREA.]

URETHANE. [CARBAMIC ACID.]

URETHRA. [BLADDER, DISEASES OF THE.]

URETHYLANE. [CARBAMIC ACID.]

URIC ACID. [URIC GROUP.]

URIC GROUP, a cluster of chemical compounds, derivatives, or congeners of uric acid. Next to uric acid itself, the products of its artificial oxidation claim chief interest, inasmuch as they illustrate some of the changes which oxygen effects upon the exhausted tissues of the human frame prior to their elimination as urea. Thus uric acid plus moisture and oxygen yields urea and a body termed alloxan. Alloxan plus moisture furnishes urea and mesoxalic acid; and mesoxalic acid contains no nitrogen, the latter element having thus artificially been thrown out from uric acid as urea. It is probable that this change, or a similar one, occurs naturally in animals; for although uric acid is nearly always present in human urine, its quantity is much modified by diet. It does not occur in the urine, but does in the spleen, of the dog; and Professor Haughton, who has paid considerable attention to the physiology of this body, says that "no uric acid whatever should occur in the urine of man in perfect health, but all the nitrogen of the urine should pass off in the form of urea,—a more highly oxidated product than uric acid."

The following list includes nearly all the members of the uric group. The consideration of those of them derived from uric acid is supposed to be simplified by assuming that body to contain the radical *uril* (*uryl*) or *cyanoxalic acid* ($C_8N_2O_4 = C_4O_4Cy_2$); that is, oxalic anhydride, in which two equivalents of oxygen are replaced by two of cyanogen: but uril has not been isolated, and its usefulness is very slight.

Uric (lithic) acid	$2HO, C_{10}H_2N_4O_4$
Uroxanic acid	$2HO, C_{10}H_8N_4O_{12}$
Alloxan	$C_8H_2N_2O_8$, 2 aq.
Dialuric acid	$HO, C_8H_3N_2O_7$
Uramilic acid	$C_{16}H_{10}N_5O_{15}$
Alloxantin	$C_8H_2N_2O_8 + C_8H_3N_2O_7$, 5 aq.
Allituric acid	$C_6H_3N_2O_4$
Dilituric acid	
Amalic acid (dimethyl-alloxantin)	$C_{16}(C_2H_3)_4N_4O_{14}$
Alloxanic acid	$2HO, C_8H_2N_2O_8$
Leucoturic acid	$C_6H_3N_2O_6$?
Difluan	$C_6H_4N_2O_5$?
Mycomelic acid	$HO, C_8H_3N_4O_3$, aq.
Mesoxalic acid	$2HO, C_6O_8$
Parabanic acid	$2HO, C_6N_2O_4$
Oxaluric acid	$HO, C_6H_3N_2O_7$
Uranil (murexan or dialuramide)	$H_2N, C_8H_3N_2O_6$
Thionuric acid	$2HO, C_8H_3N_3O_6, 2SO_2$
Murexid (purpurate of ammonia)	$C_{24}H_{12}N_{10}O_{16}$
Allantoin	$C_8H_6N_4O_6$
Hidantoic acid	$HO, C_6H_5N_4O_5$
Allanturic acid	$HO, C_{10}H_6N_2O_8$
Lantanuric acid	$HO, C_6H_4N_2O_6$
Xanthic (uric) oxide or urous acid	$C_{10}H_4N_4O_4$
Hypoxanthin	$C_{10}H_4N_4O_2$
Guanine	$C_{10}H_5N_5O_2$
Cystin	$C_6H_6NO_4S_2$

Uric Acid ($2HO, C_{10}H_2N_4O_4$).—This substance, sometimes called *lithic acid*, was discovered by Scheele; Vauquelin afterwards found it in the excrements of serpents, Brugnatelli in that of silkworms, and Roubiquet in cantharides.

Uric acid is secreted by carnivorous animals, birds, and by several insects. When in excess, it is deposited from human urine as a brownish-yellow powder, which is usually a compound of uric acid and ammonia. It occurs, in combination with soda or ammonia, in those gouty concretions commonly called *chalk-stones*, and it constitutes the principal portion of the calculi deposited in the human bladder. The semi-solid urine of serpents and birds is chiefly composed of urate of ammonia; and *guano*, the decomposed excrement of aquatic birds, and which is imported from some islands in the South Sea and extensively used as a manure, contains a large quantity of urate of ammonia.

This acid is conveniently obtained by dissolving the excrement of serpents—the boa constrictor, for example—in a solution of potash, and decomposing the clear solution by the addition of hydrochloric acid. It may also be obtained from the excrement of pigeons and other birds by the same process. According to Liebig, it is better to employ borax as a solvent than a caustic alkali, it dissolving less of the animal matter. On the large scale, as a source of murexia as a pigment, uric acid is obtained from guano, which is treated first with hydrochloric acid to remove carbonates and phosphates of lime, magnesia, and ammonia, then with boiling caustic soda, which dissolves the uric acid from sand, clay, gypsum, &c.; and the alkaline solution is finally treated with hydrochloric acid, which precipitates the uric acid, in a state sufficiently pure for conversion into murexia.

Uric acid occurs in small, fine, white, silky, crystalline scales; it is inodorous and insipid, heavier than water, and nearly insoluble in it when cold, and only slightly dissolved by it when hot; the solution reddens litmus-paper, but feebly. It is insoluble in alcohol or ether.

Nitric acid, even diluted, dissolves uric acid with brisk effervescence; the gases evolved consist of equal volumes of nitrogen and carbonic acid. The solution contains alloxan, alloxantin, urea, parabanic acid, ammonia, and other variable products. When the solution is evaporated to dryness, the residue is of a fine purple colour: the formation of this residue is a test of the presence of uric acid, its colour is much intensified on the addition of ammonia.

Sulphuric acid when concentrated dissolves uric acid, and forms a crystalline compound with it; it is decomposed on the addition of water; concentrated hydrochloric acid dissolves it in greater quantity than water.

Uric acid, when submitted to destructive distillation, yields the same products as urea, namely, cyamelide, cyanic acid, cyanuric acid, hydrocyanic acid, a little carbonate of ammonia, and a brown carbonaceous residue containing much nitrogen. In this decomposition the hydrated cyanic acid and ammonia combine in the neck of the retort and form urea. The cyamelide dissolves in potash, and yields cyanurate of potash.

When uric acid is heated with a little water to 392° Fahr. in a closed tube, it is converted, without any disengagement of gas, into a yellow transparent liquor, which becomes a yellow gelatinous mass when it cools; this is soluble both in cold and hot water: the alkalies evolve ammonia from it, and with the acids it produces gelatinous precipitates; with hot nitric acid it effervesces, and the solution by evaporation yields a reddish yellow mass, which ammonia renders purple.

Hydrate of potash when fused with uric acid produces carbonate of potash, cyanate of potash, and cyanide of potassium. When boiled in water with peroxide of lead, it is converted into allantoin and oxalic acid, urea being set free.

Saline combinations of Uric Acid.—Uric acid is dibasic, and forms neutral and acid *urates*. The urates of the alkaline metals and of the alkaline earths are but slightly soluble in cold water, but very soluble in boiling water; an excess of alkali increases the solubility; the urates are generally colourless, and are all decomposed by acids, even by the acetic acid; the uric acid, which is set free, is at first gelatinous, but soon assumes the form of fine brilliant laminæ.

Urate of Ammonia ($NH_4O, HO, C_{10}H_2N_4O_4$).—The acid salt is the only one known. Urinary calculi occasionally consist of this compound. [CALCULI.]

Urates of Potash.—The neutral salt ($2KO, C_{10}H_2N_4O_4$) is prepared by dissolving the excrements of serpents in a weak boiling solution of potash; the insoluble portion being separated by filtration, urate of potash is obtained as a white crystalline mass by evaporating and cooling the solution; this, after washing with cold water, is converted by drying into a brilliant powder, composed of very fine needles. This salt is very slightly soluble in cold water; the solution has an alkaline reaction. On passing carbonic acid through its solution, *acid urate of potash* ($KO, HO, C_{10}H_2N_4O_4$) is deposited.

Urates of Soda.—According to Dr. Wollaston, gouty concretions consist principally of these salts. They may be prepared in the same way as the urates of potash; the reactions are similar. Urate of soda is also formed when uric acid is boiled with borax.

Uroxanic acid ($2HO, C_{10}H_8N_4O_{10}$). When uric acid is boiled for a long time with caustic potash a small quantity of it, by assimilation of six equivalents of water, is converted into a new acid termed uroxanic. *Uroxante of potash* ($2KO, C_{10}H_8N_4O_{10} + 6$ Aq.) is very soluble in water, but may be obtained in rhombic tables; from its solution hydrochloric acid precipitates uroxanic acid in microscopic tetrahedra; boiling water decomposes it, carbonic acid being evolved.

Alloxan ($C_8H_2N_2O_8 + 2$ and 8 Aq.) This is the chief product of the action of cold nitric on uric acid. The latter is added to the former in small quantities at a time, carbonic acid and nitrogen escape, producing brisk effervescence, heat is evolved, so that it is sometimes necessary to artificially prevent undue elevation of temperature, 120° Fahr. being the maximum point to which the mixture should rise. After a time crystals begin to form in the liquid and, on repose, octohedra of alloxan separate out. They contain two equivalents of water, but from resolution in water crystallise in prisms containing eight equivalents of water.

Alloxan is colourless, of faint odour, unpleasant astringent taste, stains the skin pink, is very soluble in water, and has an acid reaction. By the action of sulphuretted hydrogen and similar reducing agents it yields *dialuric acid* ($C_8H_4N_2O_8$) and free sulphur:—

$$\underbrace{C_8H_2N_2O_8}_{\text{Alloxan.}} + 2HS = \underbrace{C_8H_4N_2O_8}_{\text{Dialuric acid.}} + S_2$$

The dialuric acid is crystalline, and forms crystallisable salts. Gregory's *uramilic acid* ($C_{16}H_{10}N_5O_{15}$) seems to be the bidialurate of ammonia.

Alloxantin ($C_{16}H_4N_4O_{14} + 6$ Aq.) is formed on adding together solutions of equivalent proportions of alloxan and dialuric acid, and would seem to be a compound of those substances. It may also be formed by the action of several reducing agents on alloxan. It occurs in small colourless rhomboidal prisms, slightly soluble in cold water, rather more so in boiling water; oxidising agents reconvert it into alloxan. Boiled with hydrochloric acid it yields white, pulverulent, *allituric acid* ($C_6H_3N_2O_4$) and *dilituric acid*, which has not been fully examined. The dimethyl derivative of alloxantin is identical with *amalic acid.* [CAFFEINE.]

Alloxanic Acid ($C_8H_4N_2O_{10}$) may be considered as alloxan plus two equivalents of water. It is a product of the action of bases upon alloxan, and may be isolated on treating an alloxanate with a stronger acid. By evaporation it is obtained as a semi-crystalline mass, of unstable character. Its aqueous solution, by ebullition and evaporation to near dryness, splits up into *leucoturic acid* ($C_6H_3N_2O_6$?) which dissolves on rediluting with water, and a white, insoluble, slightly acid powder termed *difluan*. Some of the *alloxanates* crystallise readily.

Mycomelic Acid ($HO, C_8H_3N_4O_3$, Aq.), or *alloxanamide*, is formed when a solution of alloxan in ammonia is boiled and cooled slowly.

$$\underbrace{C_8H_2N_2O_8}_{\text{Alloxan.}} + 2NH_3 = \underbrace{HO, C_8H_3N_4O_3}_{\text{Mycomelic acid.}} + 4HO$$

Mesoxalic Acid ($2HO, C_6O_8$). Where solutions of alloxanates are boiled for some time, they break up into urea and mesoxalic acid:—

$$\underbrace{2BaO, C_8H_2N_2O_8}_{\text{Alloxanate of baryta.}} + 2HO = \underbrace{2BaO, C_6O_8}_{\text{Mesoxalate of baryta.}} + \underbrace{C_2H_4N_2O_2}_{\text{Urea.}}$$

Mesoxalic acid may be isolated from the baryta salt by sulphuric acid or from the lead salt by sulphuretted hydrogen. It is very soluble in water, but may be obtained in crystals. The silver salt is decomposed when heated, brisk effervescence of carbonic acid and carbonic oxide occurring.

Parabanic Acid ($C_6H_2N_2O_6$) may be obtained in flat colourless prisms on evaporating the nitric acid with mother liquor of alloxan. It is permanent itself, but forms unstable compounds with bases. The parabanate of ammonia, for example, decomposes during evaporation the ammonia salt of *oxaluric acid* ($NH_4O, C_6H_3N_2O_7$) being formed. The latter occurs in brilliant crystals, and is interesting from the fact that dumb-bell crystals of oxaluric acid—at first mistaken for oxalate of lime—are sometimes met with in urinary deposits.

Phenyl-oxaluramide or *oxaluranilide*, ($C_{18}H_9N_3O_6$) is a white crystalline powder.

Thionuric Acid ($2HO, C_8H_5N_3O_6, 2SO_2$). Solutions of alloxan, sulphite of ammonia, and ammonia, combine together when boiled, thionurate of ammonia crystallising out on cooling in brilliant leaflets. The lead salt decomposed by sulphide of hydrogen furnishes an acicular mass of thionuric acid.

Uramil ($NH_2, C_8H_2N_2O_6$) *murexan* or *dialuramide*. When a hot saturated solution of thionurate of ammonia is treated with hydrochloric acid in excess, the mixture is converted into a semifluid mass. The uramil thus obtained is in the form of plumose acicular crystals, which are permanent in the air, and become of a pink colour when heated; they are insoluble in cold and but slightly soluble in boiling water. The alkalies dissolve uramil, and acids precipitate it from them unchanged. The solutions in ammonia and potash become of a purple colour by exposure to the air, and deposit green acicular crystals of a brilliant metallic lustre. If the potash solution be boiled, ammonia is evolved and *uramilic acid* is formed; dilute acids produce similar decomposition. It is soluble in concentrated sulphuric acid, and is precipitated from it by water; by concentrated nitric acid it is resolved into alloxan, with the evolution of hyponitrous acid, and the formation of nitrate of ammonia.

Murexid ($C_{24}H_{12}N_{10}O_{16}$?), *purpurate of ammonia* of Dr. Prout. This substance may be obtained by several processes. The least operose is probably that of dissolving uric acid in dilute nitric acid, evaporating the solution till it assumes a reddish colour; after the liquor has cooled to 158° Fahr., add excess of ammonia; then dilute it with half its volume of boiling water, and allow it to cool. Care must be taken not to employ too much or too little nitric acid. Whilst ammonia continues to give a red precipitate, when added to small portions, the nitric acid is insufficient. If, on the contrary, ammonia produces a glairy yellow precipitate, murexide cannot be obtained without passing a current of hydrosulphuric acid into the liquor.

Murexide crystallises in short four-sided prisms, which exhibit a green metallic reflection. They are garnet-red by transmitted light. It is very little soluble in cold water, and gives it a magnificent purplish red colour. It dissolves readily in water at 158°, and crystallises from the solution unaltered. It is insoluble in alcohol and in ether. It is insoluble also in solution of carbonate of ammonia, but dissolves in a solution of potash, producing a superb indigo-blue colour, which disappears by heat, with the evolution of ammonia.

Purpurate of Potash.—According to Fritzche, this is best obtained by decomposing a boiling solution of purpurate of ammonia by means of excess of nitrate of potash. This purpurate consists of very small reddish-brown crystals; it may however be obtained in large crystals, which have the colour and lustre of the ammoniacal salt. It is difficultly soluble in water, and much less so in saline solutions, and hence the advantage of using excess of nitre in preparing it. It appears to be a neutral salt.

Purpurate of Soda is of a dark brick-red colour, and may be obtained in crystals; it is much less soluble in water than the potash salt, requiring 3000 times its weight for solution, or even more at 60°. The *purpurates of lime, baryta*, and *strontia* are still less soluble than those above described; they are of a deep greenish colour, but when dissolved in water they impart a purple colour to it. There are two salts of lime; one of which is a bulky red crystalline powder, and the other, which is greenish-black, appears to be a subsalt. The *purpurate of magnesia* is very soluble.

When purpurate of ammonia is added to a solution of metallic salts, the effects produced are as follows:—Cobalt, a granular reddish precipitate; zinc, a fine yellow; tin, a scarlet precipitate; mercury, protosalts, a purple precipitate; persalts, a pale rose precipitate; silver, a deep purple one; the salts of lead, iron, nickel, and copper, the chlorides of gold and platina, alter their colour by the addition of purpurate of ammonia, but are not precipitated by it. The pink sediment which generally appears in the urine of those labouring under febrile affections, appears to owe its colour to the purpurate of ammonia.

Allantoin ($C_8H_6N_4O_6$); *allantoic* or *anniotic acid.* A product of the oxidation of uric acid by peroxide of lead in a boiling solution; the hot filtered solution deposits colourless brilliant crystals of allantoin. Allantoin also occurs in the urine of the fœtal calf, and in the allantoic fluid of the cow. It is a neutral body, tasteless, inodorous, tolerably soluble in boiling water, but only slightly so in cold water. Left in contact with strong caustic potash for a few days it appears to assimilate two equivalents of water and become *hydantoic acid* ($C_8H_5N_4O_8$). Solution of allantoin, heated in a closed tube to 280° Fahr., gives white deliquescent *allanturic acid* ($HO,C_{10}H_6N_4O_5$) insoluble in alcohol. *Lantanuric acid*, a product of the action of ferrocyanide of potassium upon uric acid, is probably identical with allanturic acid.

Xanthic, or *uric oxide* ($C_{10}H_4N_4O_4$) or *urous acid*, forms the chief constituent of a rare form of urinary calculus. It is also contained in the intestinal concretions of animals or BEZOARS. It is soluble in alkalies, but is reprecipitated as a white powder by acids, and is insoluble in water, alcohol, or ether.

HYPOXANTHIN, GUANINE, and CYSTIN are treated of in separate articles.

URIC OXIDE. [URIC GROUP.]

URIL. [URIC GROUP.]

URINARY CALCULI. [CALCULI.]

URINE, PATHOLOGY OF, AND MORBID STATES OF. The normal constituents of urine are treated of in the article URINE, in the NATURAL HISTORY DIVISION of this Cyclopædia. We shall here speak of the urine in states of disease, and more particularly of its abnormal constituents. These latter may be divided, first, into those substances which are dissolved in the urine; and, second, those substances which are thrown down as sediments.

1. Substances which are dissolved in the urine, or precipitated only under special conditions.

Hæmatin, or blood-pigment, appears in the urine in two states, either in the blood-cells or independent of them. When the latter occurs, the blood is of a more or less brown or black colour. Such a condition does not indicate the rupture of blood-vessels, but a state of the blood produced by such diseases as typhus fever, yellow fever, scarlatina maligna, scurvy, pyæmia, and other diseases in which the blood-cells are, as it were, broken up.

Albumen is frequently present in the blood, but is not characterised by any particular physical appearance: it often is of a natural colour, sometimes a little paler, at other times it is obviously tinged with blood. For the most part albuminous urine is transparent at the instant it is voided, but on cooling it becomes turbid: its odour is ordinarily less urinous than the urine of health. The tests for detecting albumen are various. Nitric acid is one of the best; for if a few drops be added to the urine containing albumen, a precipitate is formed, which we cannot re-dissolve by an excess of the acid, but which is readily dissolved by the addition of a sufficient quantity of alkali. Heat, from its property of quickly coagulating albumen, is an excellent test for recognising this principle, as it has the advantage of not coagulating the other elements of urine. Albuminous urine, on being exposed to a temperature of about 150°, becomes opaque, and deposits the principle in a coagulated state. The precipitate varies considerably in appearance in different instances, being sometimes firm and similar to that formed by the serum of the blood, from which it may then be supposed to be derived; while at other times it is delicate, fragile, and somewhat resembling curd, when it may be supposed to be of chylous origin.

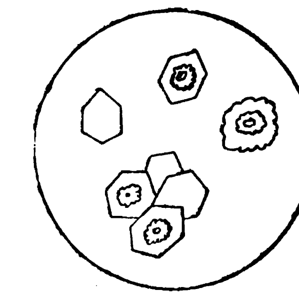
Albumen is generally indicative of disease of the kidneys. [KIDNEYS, DISEASES OF.] This form of disease may come on in many diseases, such as intermittent fever, typhoid fever, measles, small pox, inflammation of the lungs, phthisis, rheumatism, chlorosis, and disease of the heart. It has also been observed in temporary derangement of the digestive organs, and even in health after eating albuminous food, such as eggs. Dr. Parkes found, on examining indiscriminately all cases admitted under his care, that about 25 per cent. had albumen in the urine, and that of these 12 per cent. were temporary, and 13 per cent. were permanent.

In some cases the albumen in the urine is of a modified character, so that although not precipitated by heat or nitric acid alone, nitric acid will cause a precipitate when it is heated.

Xanthic (*Uric*) *Oxide* was first described by Dr. Marcet, and subsequently by Professor Stromeyer. It is said by Liebig to differ from uric acid by containing one proportion less of oxygen. The characters of urine containing this substance are not known, as the urine of the persons from whom the xanthic oxide calculi hitherto met with were taken was not analysed.

Cystic Oxide does not exist in healthy urine, but is occasionally found in certain states of disease. It contains a considerable proportion of sulphur, no less than two atoms being present in each equivalent of the oxide. This substance, when present in the urine, is always in a white crystallised state, never being found amorphous. When urine which contains a deposit of this kind is mixed with hydrochloric acid it is not rendered clear; on the application of heat, however, the cystine slowly dissolves.

Dr. Bird says that when a deposit suspected to contain cystine is examined, it should be washed with boiling water to remove the urates and any crystals of common salts which might be present, and then placed in a drop of water on a slip of glass under the microscope. Crystals of cystic oxide will then be readily distinguished, by their presenting one or other of two forms under which it occurs. In the first of these it appears under the form of tolerably regular six-sided tables, sometimes transparent throughout, but more generally opaque in the centre. In the second it occurs as roundish tables, opaque in the centre, and often quite so, somewhat crenate at the edges.



Cystic Oxide Crystals.

Cystic oxide may be distinguished by its solubility in alkalines and most acids, and by the characteristic odour it yields when burnt. It is however very little soluble in acetic acid; hence when cystic oxide exists in the urine, it may be readily precipitated from that fluid by vinegar.

Leucin has also been found in the urine. This substance exists normally in the spleen, liver, pancreas, and thymus gland. It has been found present in the urine in disease of the liver.

Tyrosin, *Hypoxanthin*, and tannin have been also found in the urine.

Sugar does not exist in healthy urine, but in certain states of disease it is found in large quantities. Sugar of diabetic urine differs in appearance from common sugar, and approaches in its properties to the sugar of grapes, with which it is identical in composition. Urine containing sugar is generally pale-coloured, of specific gravity above 1·030, and its natural ingredients are often relatively much diminished in quantity. This substance is present in the disease called diabetes. [DIABETES.]

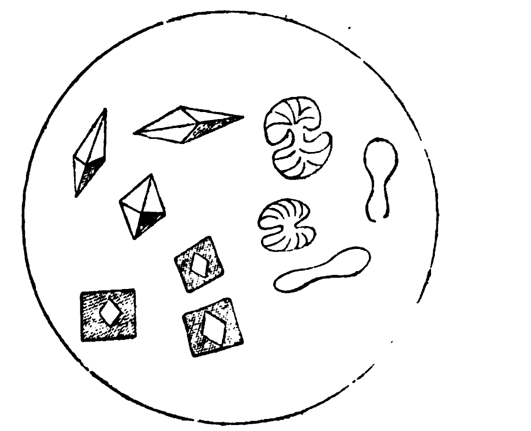
Sugar is found temporarily present in the urine, and is supposed to be produced by a casual absence of oxidation. Thus it has been observed in the urine after temporary injuries of the head. It has also been said to occur in all cases in which respiration is impeded, emphysema, hooping-cough, epilepsy, hysterics, &c.

Colouring matters of various kinds have been found in the blood. Prout first observed indigo in the urine. Hassall examined this subject, and found indigo present in several kinds of urine. Heller has also discovered a blue colouring matter in urine, which he calls moxanthin. This substance is closely related to indigo, and probably both are produced by the same series of changes. A green pigment and a pink pigment, called euroerythrin, have also been found in urine in various forms of disease. Bile pigments are not unfrequently present in the urine of even healthy persons, and are constantly present in those affected with jaundice.

Various acids besides the normal acids have been found in urine. Such are the bile acids, taurocholic and glycocholic, acetic, lactic, butyric, and nitric acids. Sulphuretted hydrogen is also occasionally detected in the urine when first passed.

Of the abnormal sediments in the urine, the most frequent and interesting is the salt of lime with:—

Oxalic Acid—Oxalate of Lime. Oxalic acid is never found in healthy urine, although, according to the important investigations of Dr. Golding Bird, deposits of oxalate of lime are of common occurrence. Where the acid does not result from the peculiar character of the ingesta containing it, as rhubarb or sorrel, the occasion of this morbid deposit is the formation of oxalic acid in the living body, possibly from some undue oxidation of carbon within the kidney. So strong is the affinity between lime and oxalic acid, and so great the insolubility of the resulting compound, that the addition of a very minute quantity of oxalic acid occasions in the urine a precipitate of oxalate of lime, because the oxalate, unlike the phosphate of this earth, is not at all soluble in the natural acid of the secreted fluid. Dr. G. Bird says, that when deposits of oxalate of lime exist, the urine is acid; in tint varying from a pale straw colour to deep amber, sometimes nearly limpid, much more generally containing a copious deposit of urate of ammonia of a very pale colour, rarely being tinged with pink; and frequently mixed with uric acid and numerous fragments of epithelium; the specific gravity generally exceeds the average density of healthy urine, but sometimes is below it, varying from 1·016 to 1·029. An excess of urea is frequently present, so that when the urine is above the density of 1·020, it crystallises very quickly after the addition of an equal bulk of nitric acid. When the urine contains no urate of ammonia the deposit of oxalate of lime, on account of its



Oxalate of Lime Crystals.

transparency, is generally nearly imperceptible; but on decanting the superabundant fluid, after a few hours' repose, and placing a few drops of the lowermost layers in a capsule, a white crystalline sediment is very readily distinguishable, and this, when examined under the microscope, presents a very beautiful appearance. The crystals are of three forms, octahedra, hour-glass or dumb-bell bodies, and small flattened disc-like bodies sometimes round but more frequently elongated, which may be the beginning of the dumb-bell crystals. The octahedral crystals are the most common. Bird and others have attributed a variety of symptoms to the presence of oxalic acid in the system, but Lehmann and Scherer have denied that any connection whatever can be traced between the symptoms described and the appearance of oxalate of lime in the urine. Such a view is also supported by those writers who maintain that the oxalic acid is not formed in the blood at all, but is the result of changes in other constituents of the urine after it has passed from the bladder.

Carbonic Acid; Carbonate of Lime.—Carbonic acid was long ago supposed to exist in urine, although its existence in this fluid is doubted by Berzelius. Dr. Prout says that he has frequently met with this acid in urine, and is most frequently derived from the decomposition of urea, which with water is readily converted into carbonate of ammonia. Carbonate of lime is occasionally found in the urine, and is probably formed by the reaction of carbonate of ammonia on the phosphatic salts: the urine in these cases is alkaline. Carbonate of lime dissolves with effervescence in dilute acid.

Uric Acid frequently exists in larger quantities than natural, and is then precipitated in the urine, either with or without bases. When combined with bases it forms what is called the "calculous sediment" of urine. The exact composition of the sediments of uric acid with bases has been the cause of much dispute. At one time all uric acid deposits were considered as combinations of the acid with ammonia. Subsequent analysis has shown that urate of soda is a very common sediment. These deposits occur either directly after the urine has cooled down to the temperature of the external atmosphere, or some hours after. In the latter case the production of some other acid by decomposition is the cause of the precipitate. These deposits may not alone occur from increase of uric acid in the urine, but also from a decrease of water in the urine and a relative increase of uric acid. The formation of other acids may also cause this. Sometimes the uric acid is deposited without any base, and then assumes its characteristic forms. This may arise from excess of uric acid, but it may also arise from the formation of such acids as the sulphuric, phosphoric, hippuric, lactic, oxalic, or other acids.

Phosphoric acid forms sediments of the ammoniaco-magnesian phosphate, the phosphate of lime, and the phosphate of magnesia. The cause of the deposit of the ammoniaco-magnesian phosphate is the decomposition of the urea. The carbonate of ammonia thus produced lessens the acidity of the urine, and the ammonia partly combines with the phosphate of magnesia. As soon as the acidity declines the ammoniaco-magnesian phosphate is deposited with phosphate of lime.

If the urine become alkaline from potash or soda, and not from ammonia, then the phosphates of lime and magnesia are thrown down. This occurs after eating much vegetable food, or after the carbonates or the mixed alkalies have been used for a length of time as medicines. This group of deposits often become the source of stone in the bladder. [CALCULUS.]

The next group of abnormal deposits in the urine are those which have never been dissolved in the urine, and which fall when the urine is allowed to stand. These are mostly organic, and are detected chiefly by the aid of the microscope.

Blood is often poured out in abundance from the mucous membrane lining the urinary passages, and is generally diffused through the urine, or is passed entire. In other cases small quantities of blood are passed mixed with pus or mucus, or alone, after the urine has been voided. When large quantities of blood are passed, especially without pain, it is probably a simple exudation from some part of the mucous surface of the urinary organs; on the other hand, when the blood is mixed with pus or mucus, and passed with pain, it denotes ulceration of the kidney or bladder, and may be combined with the existence of a foreign body in the bladder. Dr. Willis, and other writers, quote several authorities to show that hæmaturia is endemic in some countries. M. Chapotain, for instance, informs us that in the Isle of France children from their infancy are liable to hæmaturia without suffering any pain from it, or its appearing to prejudice their general health. M. Salesse, a native of the Isle of France, and now a practitioner of medicine there, states that three-fourths of the children are affected with hæmaturia at one time or another. In these cases the bloody urine is generally observed to alternate with that which is chylous or oleo-albuminous. During the invasion of Upper Egypt by the French, many of the men suffered from an epidemic hæmaturia.

When blood corpuscles are present in the urine, of course albumen is also there. It is sometimes a question whether the albumen is greater in amount than can be accounted for by the blood or not.

Pus is often found in great abundance in the urine. Upon standing, the pus subsides to the bottom of the vessel, in a state more or less pulverulent, and the fluid resumes its transparent character. If pus be present as well as mucus, the former is found lying on the latter, and presents a much yellower tint; it is also quite opaque, whereas mucus is more or less transparent. A ready test for determining whether the deposit from the urine be of a purulent nature, is to add liquor potassæ to the sediment collected in a phial or test tube. If it be purulent, it will, on agitation, form with the alkali a transparent viscid compound.

Fat may be either dissolved in the form of a soap, or free in the urine. It is more frequently free. The urine has a turbid emulsion-like appearance. What is called chylous urine depends on the presence of fat globules. This state of the urine sometimes comes on from fatty food, and at other times from some defect in the assimilative functions. It is not at all a dangerous symptom. The administration of gallic acid is said to arrest its development.

Epithelial cells are very frequently present in abnormal numbers in urine. In all urine, after standing, a slight cloud will be seen forming, which, when examined by the microscope, is found to consist of ill-defined granular cells from the mucous membrance of the urinary passages. In many diseases this becomes increased. The shape of these cells will indicate their source. The epithelial cells of the urethra, bladder, and kidney are of different forms. The cells of the urethra are flattened, those of the bladder ovate, whilst those of the renal epithelium are caudate.

Cancer cells are also found when cancerous disease of the kidneys or bladder is present. It is very difficult to distinguish between the caudate cells of cancer and the cells of the renal epithelium. The latter are not often in such abundance as the former, but general symptoms must assist in the diagnosis.

Renal casts are frequent in the urine in disease. They vary in breadth from the $\frac{1}{500}$th to the $\frac{1}{1000}$th of an inch, and are from the $\frac{1}{50}$th to the $\frac{1}{300}$th of an inch in length. They vary, however, in size and transparency, according to the materials of which they are composed. It is, however, impossible to diagnose the nature of the disease of the kidneys by the composition of the renal cast. Large bodies are often found, called cylinders, which are not found in the kidneys, but in the bladder, prostate, or ureter. The casts have been thus named according to their composition by Dr. George Johnson: epithelial casts, large and small waxy casts, granular casts, oily casts, bloody casts, purulent casts.

Other bodies are less frequently found in the urine, as fibrine, starch, spermatozoa, hydatids, hair, and entozoa, the sources of which are indicated by their nature.

Urine sometimes, after standing, presents the mycelium of lower fungi as the *Penicilium glaucum*, cells of the feculent fungus, and vibriones and monads. These and similar growths are evidently introduced from without.

The following tables, from Dr. Golding Bird's work on urinary deposits, give the characters of the various kinds of deposits found in the urine.

TABLE FOR DISCOVERING THE NATURE OF URINARY DEPOSITS BY CHEMICAL REAGENTS.

	It consists of
If the deposit be white, and soluble by heat	Urates.
" " insoluble by heat, but soluble in ammonia	Cystine.
" " insoluble by heat and ammonia, but soluble in acetic acid .	Earthy phosphates.
" " soluble in ammonia and acetic acid	Oxalate, or oxalurate of lime.
" be coloured, and visibly crystalline . .	Uric acid.
" " amorphous, but pale and readily soluble by heat .	Urates.
" be deeply coloured, amorphous, and slowly soluble by heat	Urates stained by purpurine.

TABLE FOR THE MICROSCOPIC EXAMINATION OF URINARY DEPOSITS.

	It consists of
If the deposit be amorphous, and disappear on the addition of liquor potassæ	Urates.
If the deposit be visibly crystalline, and the crystals octohedral	Oxalate of lime.
If the deposit be visibly crystalline, and the crystals hexagonal tables, soluble in ammonia	Cystine.
If the deposit be visibly crystalline, and the crystals radiated or foliaceous, not soluble in ammonia, but soluble in acetic acid with effervescence	Carbonate of lime.
If the deposit be visibly crystalline, and the crystals radiated or foliaceous, not soluble in ammonia, but soluble in acetic acid, without effervescence	Bibasic triple phosphate.
If the deposit be visibly crystalline, and the crystals be dumb-bells, not soluble in ammonia, but soluble in acetic acid with effervescence	Carbonate of lime.
If the deposit be visibly crystalline, and the crystals be dumb-bells, soluble by heat, but not in ammonia nor acetic acid	Urate of soda.
If the deposit be visibly crystalline, and the crystals be dumb-bells, insoluble by heat, ammonia, and acetic acid . .	Oxalurate of lime.
If the deposit be visibly crystalline, and the crystals be dumb-bells with fringed edges, insoluble in alcohol and acetic acid, but soluble in liquor potassæ	Uric acid.
If the deposit be visibly crystalline, and the crystals lozenge-shaped or compound, insoluble in acetic acid and ammonia	Uric acid.
If the deposit be visibly crystalline, and the crystals spherical, with or without spicules, soluble by heat . . .	Urate of soda.

As a summary of the courses and treatment of diseases indicated by a disordered state of the urine, we give the following table, drawn up by Dr. Marshall Hall, premising that considerable advance has been made in our knowledge of urinary deposits since the table was drawn up.

CAUSES.				TREATMENT.
1. Errors in diet. 2. Fatigue. 3. Dyspepsia. 4. Arthritis. 5. Dentition.	I. The Lithic.	I. Diathesis.	Urine Acid, from the Superlithate of Ammonia.	1. Wholesome Diet. 2. Mild Aperients, especially Rochelle Salt. 3. Mild Mercurials. 4. The Alkalies. 5. Magnesia. 6. The Gum Lancet.
		II. Amorphous Deposits.	I. Lithate of Ammonia, frequently mixed with the II. Lithates of Soda and Lime.	
		III. Crystals or Gravel.	Lithic Acid, nearly pure.	
		IV. Concretions or Calculi.*	I. The Lithic Acid. II. The Lithate of Ammonia.	
	tend to			
	An intermediate station is to be allotted to the Oxalate of Lime—	I. Diathesis. II. Amorphous Deposit. III. Crystals or Gravel. IV. Calculus.	Urine nearly natural. The Mulberry, or Hempseed.	1. Antiphlogistics. 2. Mild Aperients, *not* the Rochelle Salts. 3. Mild, wholesome Diet. 4. The muriatic Acid.
	pass into			
1. Irritability } of the 2. Debility } System. 3. Sickly Childhood. 4. 'Breaking up' of the System. 5. Injuries of the Spine.	II. The Phosphatic—	I. Diathesis.	Urine Alkaline and abounding in the Phosphates.	1. Strict Regimen. 2. Mild Aperients—as Rhubarb. 3. Opium; Hyoscyamus, &c. 4. The Uva Ursi; the Alchemilla arvensis, &c. 5. Rhenish or French Wines, Cider, Perry, Lemonade, &c.
		II. Amorphous Deposits.	I. Triple Phosphate (of Magnesia and Ammonia), mixed with II. Phosphate of Lime.	
		III. Crystals or Gravel.	Triple Phosphate.	
		IV. Concretions or Calculi.*	I. The *Triple* Phosphate. II. The *Mixed* { 1. Triple Phosphate with 2. Phosphate of Lime; } or the Fusible Calculus.	*Avoiding.* 1. Alkalis. 2. Salts, with a vegetable Acid, as Rochelle Salt. 3. Mercury.

* To these must be added— I. The *Alternating*; generally consisting of { A Lithic acid, or Mulberry *Nucleus*; An *External Crust* or the *Mixed* Phosphates. II. The *Mixed*; generally consisting of { The Lithate of Ammonia; The Phosphates.

A special place is to be allotted to } The Prostatic Calculi. { These consist of Phosphate of Lime alone.

Lastly—The Cystic Oxide; the Xanthic oxide; the Carbonate of Lime; the Fibrine Calculi, are all extremely rare.

Principles *dissolved* in the Urine.	Urea in excess.	Diabetes insipidus;	Urine of high Specific Gravity; as 1·020.	Blood-letting. Mild Animal Diet. Opium. Dover's Powder. Warm Baths. Carbonate of Iron.
	Sugar.	Diabetes.	Urine profuse; sp. gr. *very* high; as 1·050. Saccharine.	
	Albumen.	Frequently Disease of the Kidney.	Urine coagulates by heat.	

Principles *mixed* with the Urine.	Mucus.	Scanty when from the Kidney Profuse when from the Bladder.
	Pus. Blood.	From Calculus, or Disease, of the Kidney or Bladder.

Those who wish to master the subject of urinary pathology should study the work of Dr. Edmund Parks, 'On the Composition of the Urine in Health and Disease,' 1860. It is one of the most masterly works hitherto published on the urine. Dr. Golding Bird's work 'On Urinary Deposits;' Dr. Beale's 'Treatise on the Microscope in Medicine,' and his 'Illustrations of Urine, and Urinary Deposits,' should also be consulted. Dr. Beale's 'Tables for the Practical, Chemical, and Microscopical Examination of Urine, Urinary Deposits, and Calculi,' will be found of great service.

URINO'METER, an instrument for ascertaining the weight of urine. It is constructed on the principle of a common hydrometer, and consists of a glass tube, which at its lower extremity has two bulbs, the lower one very small, containing a heavy substance, such as mercury, and the other immediately above it much larger, and filled with air. The tubular portion contains a scale denoting with certain figures the specific gravity, the use of which will be illustrated by the following example:—Suppose the water's edge cut the scale at figure 25, then add that number to 1000, and the specific gravity will be 1·025.

URN. [VASES.]

UROERYTHRIN. A red pigment in urine.

UROGLAUCIN. [UROXANTHIN.]

UROUS ACID. [URIC GROUP.]

UROXANIC ACID. [URIC GROUP.]

UROXANTHIN. A yellow colouring matter in urine, which by oxidation is said to be converted into ruby-red, *Urrhoidin*, and blue *Uroglaucin*.

URRHOIDIN. [UROXANTHIN.]

URSA MAJOR and URSA MINOR (the Greater and Lesser Bear), two of the most remarkable constellations of the northern hemisphere: the latter as containing the pole star, or the visible star which is nearest to the northern pole of the heavens; the former from its well known seven stars, by two of which the pole star is always readily found. These seven stars, which are α, β, γ, δ, ϵ, ζ, and η of the constellation Ursa Major, are disposed in the form of a quadrangle joined by one of its corners to a triangle, and with this description it would be difficult to avoid finding them out. A line drawn from β to α, the two pointers, as they are called, passes through the Pole star when continued: these two pointers being the stars of the quadrangle which are farthest from the triangle. This Pole star (α Ursæ Minoris) is the principal star in Ursa Minor, which has seven stars placed together in a manner very much resembling Ursa Major, the Pole star being the corner of the triangle which is farthest from the quadrangle.

The common people of most countries call the seven stars of the Great Bear by the name of "the waggon," sometimes by that of "the plough." Aratus says that both the bears were called waggons by the Greeks; and 'Charles's Wain' is familiar to all our readers. The later stories of Grecian mythology are hardly worth recording: the nymph Calisto was transformed by Diana into the Great Bear for an amour with Jupiter; while the Lesser Bear is Cynosura [CYNOSURE], one of the nymphs who nursed Jupiter.

The following are the principal stars in these constellations:—

URSULINES, an order of nuns in the Roman Catholic church, founded about the year 1537, by Angela Merici, commonly called Angela of Brescia, who was born in 1511, at Desenzano, on the Lago di Garda, and died at Brescia, March 21, 1540. The institution was formally approved of and confirmed by Pope Paul III., in 1544, and it was upon this occasion that the name of Ursulines was given to the order, after the famous British Saint Ursula. The order of the Ursulines was designed mainly for the succour of poverty and sickness, and for the education of the young; and wherever it was established the nuns principally devoted themselves to these services, in rendering which they mixed freely with the world, much in the same manner as the members of the various orders of charity have always been accustomed to do. At first indeed they neither bound themselves by the usual irrevocable vows, nor even lived together in communities; and there appear to have been always some members of the order who continued to reside with their families or by themselves at their own houses. In course of time, however, the Ursulines, like the other religious orders, came for the most part to be distributed in monasteries, especially in France, where they chiefly flourished.

URYLE. [URIL.]

USANCE. [BILL OF EXCHANGE.]

USE. A use at common law was a beneficial interest in land, distinct from the legal property therein. The origin of uses is derived by Gilbert ('Law of Uses,' 3) from a title under the civil law, which allows of an usufructuary interest, distinct from the substance of the thing itself, and which was called in that law the *fidei commissio*. He says it was introduced by the clergy, who were masters of the civil law, and who, "when they were prohibited from taking anything in mortmain, after several evasions by purchasing lands of their own tenants, suffering recoveries, purchasing lands round the church, and making them churchyards by bull from the pope, at last invented this way of conveying lands to others to their own use; and this being properly matter of equity, it met with a very favourable construction from the judges of the chancery court, who were in those days commonly clergymen. Thus this way of settlement began; but it more generally prevailed among all ranks and conditions of men by reason of the civil commotions between the houses of York and Lancaster, to secrete their possessions, and to preserve them to their issue, notwithstanding attainders; and hence began the limitation of uses with power of revocation." But whatever may have been the origin of uses, it is certain that the desire of effecting frequent and secret transfers of property without resorting to the simple and public modes of conveyance of the common law, as well as the natural desire to dispose of property by devise, which the common law did not allow, led to an early adoption of the system.

The system of uses having been found to produce many inconveniences, notwithstanding the statutes which had been passed from time to time to modify them, it was thought a remedy would be found by joining the possession to the use, or, as it is usually termed, transferring uses into possession. With this view the statute of 27 Hen. VIII., c. 10, commonly called the Statute of Uses, was passed, which enacted, that where any person or persons stood or were seised, or at anytime thereafter should happen to be seised of any honours or other hereditaments to the use, confidence, or trust, of any other person or persons, or of any body politic, by any manner of means whatsoever it should be, that in every such case all such person and persons, and bodies politic, that had or thereafter should have any such use, confidence, or trust in fee simple, fee tail for term of life, or for years or otherwise, or any use, confidence, or trust in remainder or reverter, should from thenceforth stand and be seised, deemed, and adjudged in lawful seisin, estate, and possession of, and in the same honours and hereditaments with their appurtenances, to all intents, constructions, and purposes in the law, and in all such like estates as they had or should have in use, trust, or confidence of or in the same; and that the estate, title, right, and possession that was in such person or persons that were or thereafter should be seised of any lands, tenements, or hereditaments, to the use, confidence, or trust of any such person or persons, or of any body politic, should be from thenceforth clearly deemed and adjudged to be in him or them that had or should have such use, confidence, or trust, after such quality, manner, form, and condition as they had before in or to the use, confidence, or trust, that was in them.

It has been questioned whether or not the legislature intended by this act to put an end to the system of uses; nevertheless it was soon settled that it had not that effect, but that uses might still as formerly be raised, upon which the statute would instantly operate. However, some modifications of the system were introduced. Before the statute a mere agreement for sale, without words of inheritance, was sufficient to pass the equitable fee to the vendee; but by the 27 Hen. VIII., c. 16, it was enacted that no contract should transfer the legal estate in the fee, unless it were made by deed enrolled. And it was resolved by the judges that words of inheritance were necessary to pass the fee at law. Indeed no contract importing a future conveyance, even though made by deed enrolled, and containing words of inheritance, would now be held to transfer the legal estate under the Statute of Uses, though it would entitle the vendee in equity to call for a regular conveyance. A further modification of the system of uses was introduced by the seventh section of the Statute of Frauds (29 Car. II., c. 3), which required that all declarations of trusts or confidences of lands, tenements, or hereditaments (which might formerly have been created by parol), should be manifested and proved by writing, signed by the party by whom it is declared.

In order to raise a use which the statute will turn into a possession, it is necessary that there should be, 1st, one person seised to the use of another, *in esse*; 2nd, a use *in esse*, limited in possession, reversion, or remainder. The use may be either *express*, as where lands are conveyed to A and his heirs, in trust for B and his heirs, or in confidence that he and they shall take the profits, or where a vendee, for a valuable consideration, conveys by bargain and sale enrolled, in both which cases the legal estate vests in the grantee or bargainee by the statute; or it may be *implied*, as where a feoffment is made without consideration or declaration of the use, in which case the use results, and the estate returns to the grantor.

It was settled by the courts of law that the statute could not operate except upon an estate of freehold, and that therefore copyhold and leasehold estates are not affected by it. A term of years may of course be created out of a freehold estate by way of use, but when once subsisting cannot be conveyed to uses. If, therefore, a term were assigned to A to the use of B, the legal estate would remain in A, who however would be considered in equity as a trustee for B.

By the operation of the Statute of Uses, a man may, through the medium of a feoffee or releasee, make a conveyance to his wife, which he could not do at common law (Litt., s. 168; Co. Litt., 112 a.). In like manner a married woman, having a power, namely, a right to limit a use, may appoint to her husband.

At common law a man could not limit a remainder to himself, nor could he limit it to his heirs so as to make them take as purchasers, without departing with the whole fee simple out of his person (Dyer, 156 a, fol. 24; Co. Litt., 22 b.), but he may do so by means of a conveyance operating under the statute.

It is a rule of the common law that joint tenants cannot take at different periods. (1 Co., 100, b. 2.) Again, by its rules, a fee could not be limited upon a fee; a freehold could not be made to commence *in futuro*, and an estate could not be made to cease by matter *ex post facto*, so as to let in another limitation before the expiration of the former. [REMAINDER.] But limitations of the above kinds may be made to take effect under the Statute of Uses. Such limitations are called *shifting or secondary* and *springing uses*; and *future or contingent uses*.

Shifting or Secondary Uses are properly such as take effect in derogation of some other estate, and are either limited expressly by the deed, or are authorised to be created by some person named in the deed: as if an estate were limited to the use of A and his heirs, with a proviso that if B pay 10*l*. the estate shall go to B and his heirs. Shifting uses seem to have existed before the statute, when, as the legal estate remained in the feoffees, the rule of the common law, which did not allow the fee to change from one to another except upon breach of a condition annexed to the estate at its creation, was not violated. They are now of constant occurrence in settlements of property. [SETTLEMENT.] The rules against perpetuities in settlements of property are applicable to shifting uses, which must be limited to take effect within the same period, namely, that of a life or lives in being, and twenty-one years afterwards, unless where they are to take effect after an estate tail, in which case, as the tenant in tail may defeat the use by barring the estate tail, such a limitation has no tendency to a perpetuity.

Springing Uses, though often confounded with shifting uses, are more properly such as are limited to arise in a future event where no previous use is limited; as in the case of a bargain and sale to take effect ten years hence, where the use in the mean time remains in the grantor. They are subject to the same limits as shifting uses.

Future or Contingent Uses are properly such as are limited to take effect as remainders; such as a use to the first unborn son of A, after a limitation to him for life or for years determinable with his life. The rule of law, that a vested freehold must precede a contingent remainder, did not apply before the statute to contingent uses, because the freehold remained in the feoffees; but, since the statute, they are subject in this respect to the rules of contingent remainders. [REMAINDER.]

As the Statute of Uses was made previously to the Statute of Wills (32 & 34 Hen. VIII.), it has been questioned whether the former can be held to apply to the latter; but as, before the statute, devises of the use were permitted, so, since the statute, the courts have uniformly held that, where a devise is made to a use, the intention of the testator must be taken to be that the devisee of the use should have the legal estate.

By a construction of the Statute of Uses, adopted soon after it was passed, the grounds of which it is not easy to understand, it was settled that a use could not be limited on a use, that is, that the statute would operate on the first declaration of use only: so that if, by bargain and sale, a use in lands were limited to A and his heirs in trust, or to the use of B and his heirs, the statute would vest the legal estate in A without adverting to the use declared in favour of B. The Court of Chancery availed itself of this construction to revive Uses under the name of Trusts; and it was determined that A was, in the case above mentioned, a trustee for B of the beneficial interest in the land. It is not true, however, as has been said by Lord Hardwicke, that the Statute of Uses "has had no other effect than to add at most three words to a conveyance;" for the Court of Chancery, availing itself of its exclusive jurisdiction over trusts, and aware of the mischiefs attendant upon uses before the statute, has gradually established a system well adapted to answer the exigencies of family settlements and provisions, without producing any of those evils which the statute of Henry VIII. was intended to remedy. [TRUSTS.]

USES, CHARITABLE AND SUPERSTITIOUS. The term "Charitable Use," as understood in law, is of very extensive application, and includes dispositions of property which cannot with any propriety be described as charitable, but which are so called with reference to the purposes enumerated in the statute 43 Eliz., c. 4, or such as are considered analogous to them. That statute enacted that the Commissioners thereby empowered should inquire as to the lands, &c. given by well-disposed people "for relief of aged, impotent, and poor people; for maintenance of sick and maimed soldiers and mariners; schools of learning, free-schools, and scholars in universities; for repair of bridges, ports, havens, causeways, churches, sea-banks, and highways; for education and preferment of orphans; for or towards the relief, stock, or maintenance of houses of correction; for marriage of poor maids; for supportation, aid, and help of young tradesmen, handicraftsmen, and persons decayed; and for relief or redemption of prisoners and captives, and for aid or ease of any poor inhabitants concerning payment of fifteens, setting out of soldiers, and other taxes." Many gifts not within the letter have been held to be within the equitable construction of this statute; and when the gift is to charity in general, without any particular purpose being specified, it will be carried into effect either by the Crown or the Court of Chancery, upon principles which the determinations of that court have established. The term "Charitable Use," in law, is applied exclusively to gifts for what are called public charities, the objects of which are not particular individuals, but a class or the public in general.

A superstitious use, in its original sense, was where lands, tenements, rents, goods, or chattels were given, secured, or appointed for or towards any of the following purposes, namely: the maintenance of a priest or chaplain to say mass; for the maintenance of a priest or other man to pray for the soul of any dead man in such a church or elsewhere; to have or maintain perpetual obits, lamps, torches, &c., to be used at certain times, to help to save the souls of men out of purgatory. (See the 15 Rich. II., c. 5; 23 Hen. VIII., c. 10; and 1 Edw. VI., c. 14.) The statute of Richard II. was passed for the purpose of subjecting lands conveyed to uses to the law of mortmain. The statute of Henry VIII. relates only to assurances of lands to churches and chapels, which, if for a longer term than twenty years, it declares to be absolutely void. By the 1st of Edward VI. certain superstitious uses then existing were forfeited to the king, but the statute has no prospective operation. There is no statute making superstitious uses void generally, but the king, as head of the commonwealth, and as intrusted by the common law to see that nothing is done in maintenance or propagation of a false religion, was considered entitled to pray a discovery of a trust to a superstitious use, and to order the property to be applied to a proper use. The same principle has been applied to many cases of gifts of property for purposes which cannot properly be classed as superstitious uses, but are either expressly prohibited by the law of the country or contrary to its policy. A change in the doctrine of superstitious uses has been made by the 2 & 3 Wm. IV., c. 115, which puts persons professing the Roman Catholic religion upon the same footing, with respect to their schools, places for religious worship, education and charitable purposes, as Protestant Dissenters; with respect to whom the doctrine of the court is, that it will administer a fund to maintain a society of Protestant Dissenters promoting no doctrine contrary to law, though at variance with that of the Established Church. The 2 & 3 Wm. IV., c. 115, is retrospective. (2 M. & K. 225.)

The Court of Chancery has a general jurisdiction over property given for charitable purposes, and the regular mode in which matters relating to charities are brought before it is by information by the attorney-general on behalf of the crown.

The Court of Chancery adopts a very liberal construction of gifts for charitable purposes; and there are numerous cases of gifts for objects not within the letter of the statute of Elizabeth, which have been considered to be within the equitable meaning of the word charity as understood in that court, and have been administered accordingly. And when a gift is made for charity generally, without any purpose specified, if the gift be to trustees, the court will order a scheme to be prepared for the direction of the trustees in the administration of the trust; and where the declared object is charity, but no trust has been interposed, the right to dispose of the property, and to declare the particular charitable purposes to which it is to be applied, belongs to the crown by sign-manual. Where the particular objects which the donor had in view fail, either wholly or in part, the court adopts what is called the principle of administration *cy-pres*, that is, it directs the property to be applied to worthy objects in its judgment most nearly resembling those which have failed, or when more than one charity has been named by the donor, to such of the others as are still subsisting. When the revenue of the property increases from any cause, the increase goes to the charity, if it appear to have been the intention of the donor that the whole should be disposed of in that manner; otherwise the increase will go to the legal representative of the donor. In cases where the revenue of the property was distributable among several charities, the question has been, in what manner the increase of income was to be disposed of among them. The principle established by the cases seems to be, that a charity to which a fixed annual sum has been given has no right to participate in the increase, but that one entitled with the other charities to a proportionate part of the original income will have a right to a similar proportion of the increase.

When property is given to a superstitious use, or for a charitable purpose which the law will not allow to be carried into effect, the court, upon the not very satisfactory ground that the property was meant for a charity, will apply it to some other charity of which it approves. In the words of Sir William Grant, "Whenever a testator is disposed to be charitable in his own way and upon his own principles, we are not content with disappointing his intention, if disapproved by us: but we make him charitable in our way and on our principles. If once we discover in him any charitable intention, that is supposed to be so liberal as to take in objects not only not within his intention, but wholly adverse to it." (7 Ves., 495.) If the superstitious use be one which the court considers charitable, the fund goes to the king to be disposed of to such charitable uses as he shall direct by sign-manual: if the use be not charitable, the gift is merely void, and the property will go to the donor's representative. (2 M. & K., 684.)

The regular mode of proceeding in cases of abuse of charitable funds was until recently by way of information in the name of the attorney-general on behalf of the crown. But the act 16 & 17 Vict. c. 137, known as the Charitable Trusts Act, has, without abolishing the functions of the attorney-general with respect to charities, provided a regular machinery of commissioners and inspectors, whose duty it is to investigate all cases that may be brought to their notice, and to institute such proceedings as may be necessary for the rectification of abuses.

The jurisdiction of the Court of Chancery over property given to charity must be distinguished from the authority frequently exercised by the lord chancellor or lord keeper as visitor of charities. Charities are either under the management of individual trustees, or are established by charter as eleemosynary corporations. On the institution of a corporate charity, a visitorial jurisdiction arises of common right to the founder and his heirs, whether he be the king or a private person, or to those whom the founder has appointed for that purpose; and the office of visitor is to determine the differences of the members of the society, and to superintend generally the government of the body, in accordance with the statutes originally propounded by the founder. With this visitorial power the Court of Chancery has nothing to do, its right of interference being confined entirely to the administration of the property. When the charity is of royal foundation, the visitorial power of the king is exercised by the lord chancellor as his representative; and even where the founder of the charity was a private person, if he has made no appointment of a visitor, and if his heir cannot be discovered, or has become lunatic, the visitorial power, rather than that the charity should not be visited at all, results to the crown, and, as in the case of royal foundations, is exercised by the lord chancellor. The mode of application in these cases is not by way of information, but by petition addressed to the Great Seal.

Certain restrictions have been put upon the power of making gifts of property to charitable uses by the 9th of Geo. II., c. 36, commonly, though improperly, called the Mortmain Act. By it devises of land and bequests of money to be laid out on land or in any interest in land are declared void. For an explanation of the provisions of this act, see MORTMAIN.

USNEIN. [LICHENS, COLOURING MATTERS OF.]

USNIC ACID. [LICHENS, COLOURING MATTERS OF.]

USUCAPIO. Gaius (ii. 40-42) states that if a Res Mancipi was transferred by bare tradition, without the forms of Mancipatio or in Jure Cessio, the original owner retained the Quiritarian ownership, and the person to whom the thing was transferred had only the right to the enjoyment of the thing until by possession he had acquired the ownership (possidendo usucapiat). For the effect of such enjoyment was to give him the same rights with respect to the thing as if it had been transferred in due legal form. In the case of moveables the Twelve Tables fixed one year as the term of Usucapio; in the case of land and houses, two years. The acquisition of the Quiritarian ownership of a thing by enjoyment of it under the circumstances above stated for these several periods was called Usucapio.

Gaius states that there might also be Usucapio in the case both of things Mancipi and things Nec Mancipi which had been transferred by bare tradition from a person who was not the owner, provided the transferee received them in good faith (bonâ fide), or, in other words, believed that he received them from the owner. It seems probable that this rule of law was established by analogy to the rule of the Twelve Tables as to Res Mancipi which had been transferred by defective modes of conveyance. But the Twelve Tables may have fixed only the time of Usucapio: the origin of Usucapio may be anterior to the Twelve Tables.

When Gaius wrote (in the second century of our æra), Usucapio, as it appears, had become a regular mode of acquiring ownership; for property of all kinds might be so acquired which had been received by tradition and bonâ fide from a person who was not the owner. The case of things stolen, or the possession of which had been acquired by violence (vis), was an exception, for even if received bonâ fide they could never become the property of the receiver by Usucapio. The Res Mancipi of women also, who were in the tutela of their agnati, could not be objects of Usucapio unless they had been received from her by traditio with the proper consent (auctoritas) of her tutor: and the hereditas of a woman who was in tutela legitima could not be an object of Usucapio. As land (fundus) could not, according to the best opinion, be an object of furtum, a bonâ fide purchaser of land from a man who was not the owner, and knew he was not the owner, might acquire the property of it by Usucapio, provided the seller had not acquired the possession by violence, but had either taken possession of land which was vacant through the carelessness of the owner, or from the owner dying without a successor, or having been long absent.

Besides individual objects of property, Usucapio could exist in the case of Servitutes, and marriage, and in the case of an Hereditas. Originally such Servitutes as followed the rule of law as to Res Mancipi could only be transferred like Res Mancipi; and therefore Usucapio could only apply to such servitutes. But by analogy to Res Mancipi, they could be acquired by bare contract, to which Usucapio was superadded; and when Mancipatio at a later period was replaced by bare tradition, they could be acquired by contract simply. In the case of marriage, when there was no co-emptio, the woman might come into the power of her husband by virtue of uninterrupted cohabitation for one year; and she was then said to become a part of his Familia by Usucapio founded on a year's possession. (Gaius, i. 111.) In the case of the Hereditas, when the testator had not disposed of his property by the necessary forms of the Mancipatio and Nuncupatio, the person who was named heres in the will could only acquire his legal title as such by Usucapio.

These various instances will show the original notion of Usucapio. It was a legal effect given to bonâ fide possession and enjoyment for a fixed time, by means of which defects in the transfer of a thing were made good: it was not originally a mode of acquisition. It was founded on a title good in substance, but defective in form; and this defect was supplied by the proper period of enjoyment (usus). When this usus had continued for the legal time, it gave its auctoritas (as the Romans expressed it), its efficiency and completeness to what was in its origin incomplete; and the phrase Usus Auctoritas was older than the expression Usucapio, which was afterwards the ordinary term. But Usus by itself never signified Usucapio; for Usus alone could not give a title to the ownership of a thing. In the case of public land the possessor had the usus, but this was all that he could be entitled to as possessor. Such usus could not from the nature of the case have an auctoritas, for the possessor did not occupy the public land as a bonâ fide purchaser. A man might also have the usus of private land without having a title to anything further: in which case also the usus could never have an auctoritas. In the Roman law, as known to us in the Pandects, Usucapio appears as a mode of acquisition, which must have been owing to the circumstance of Mancipatio ceasing to be regarded as important: for bare tradition in all cases, followed by the proper usus, gave complete ownership. Finally, when the difference between Res Mancipi and Nec Mancipi was abolished, Usucapio in its original sense ceased. But as in the time of Gaius we find Usucapio applicable to the case of things Nec Mancipi, which a person had possessed bonâ fide, this rule of law still continued, and various limitations were in course of time established as to the mode of acquiring the ownership of a thing by the enjoyment of it. Thus Justinian, in his 'Institutes' (ii., tit. 6), after reciting the old law, refers to one of his Constitutions, by which the ownership of moveables might be acquired by use (usucapiantur), provided there was a bonâ fide possession (justa causa possessionis præcedente) for three years, and that of immovable things by the "longi temporis possessio," which he explains to be ten years "inter præsentes," and twenty years "inter absentes;" and the Constitution applied to the whole empire. Usucapio is defined in the 'Digest' (41, 3, 3) to be the "addition of ownership by the uninterrupted possession for a time fixed by law." As it was the addition of ownership, something is here implied to which this addition was to be made; and this something was a bonâ fide possession.

The subject of Usucapio admits and requires a much more complete exposition. The reader may refer to the following works: Engelbach 'Ueber die Usucapion zur Zeit der zwölf Tafeln,' Marburg, 1828; and Mühlenbruch, 'Doctrina Pandectarum.'

USUFRUCTUS, or USUSFRUCTUS, and USUS, belonged to the class of Servitutes Personarum among the Romans. Ususfructus is defined ('Dig.,' 7, 1, 1) to be "the right to use and take the fruits (fruendi) of what belongs to another without impairing its substance." Usus is defined ('Dig.,' 7, 8, 1, 2) to be the right "to use, but not to take the fruits (frui)."

The objects of ususfructus might be land (fundus), houses (ædes), slaves, beasts of burden, and other things. He who was entitled to a Ususfructus was called Usufructuarius, or Fructuarius. A right to a Ususfructus might be given to a person by testament, or it might be established by contract.

Generally, it may be stated that all the "fructus," or produce of a thing that accrued during the time of enjoyment, belonged to the Fructuarius; but his title to fructus was not complete till he had taken them, and it was a general rule that any "fructus" which had not been got in or taken at the time when the Ususfructus ceased did not belong to him. The law as to things that yield an increase, such as fruit-trees and animals, did not present many difficult questions. As to houses and lands, the questions were sometimes more difficult. The Fructuarius was entitled to the rents and profits of houses during his time of enjoyment, and he was bound at least to keep them in sufficient repair, but probably not to rebuild them, if they were in a ruinous condition. He was bound to cultivate land in a proper husbandlike manner. He could work existing mines and quarries for his benefit, and he could also open new mines and work them. The Fructuarius could maintain his rights to the ususfructus by actions and interdicts. The period of ususfructus might either be for a fixed time or for the life of the Fructuarius. At the termination of the period of enjoyment, the thing was to be given up to the owner, who could generally require security for its being properly used and given up in proper condition.

The usus of a thing, as already explained, was a right to the enjoyment of a thing, but not to the produce or profits of it. Yet in some cases the usus of a thing implied a right to a certain amount of produce. Thus the usus of cattle implied that the usuarius was entitled to a moderate allowance of milk; and a man who had the usus of an estate could take wood for his daily use, and could enjoy the orchard and other things in moderation. If a man had the usus of oxen, he could employ them for all purposes for which oxen are properly used. The duties of the usuarius resembled those of the fructuarius.

The rules of law which related to the ususfructus and usus were numerous. Many of them are collected in the 'Digest,' lib. 7; see also 'Fragmenta Vaticana,' 'De Usufructu;' and Mühlenbruch, 'Doctrina Pandectarum.'

USURPATIO is sometimes used by the Roman jurists in the sense of interruption of Usucapio. But the verb "usurpo" and its derivatives are commonly used in the sense of "using," or "employing," in any way that is suitable to the character of the object used or employed. The participle "usurpatus" sometimes signifies the acquisition of a right by use: thus "usurpatam mulierem" (according to the ordinar reading in Gellius, iii. 2) means a woman who had come into the power of her husband by uninterrupted matrimonial cohabitation for one year. (See Savigny, 'System des heutigen Römischen Rechts,' iv., ch. iii., § 183, on the passage of Gellius, which is a quotation from Q. Mucius Scævola, the pontifex.) The word is also used in the sense of taking possession of a thing; and in course of time the notion of wrong was attached to the word. Ammianus Marcellinus (xxvi. 7, ed. Gronov.) uses "usurpator" in a sense somewhat like the modern "usurper," when he says "usurpator indebitæ potestatis."

USURY. Although the legitimacy of interest upon moderate and conscientious terms has long been recognised amongst us, it has, until quite recently, been believed desirable to regulate by law the rate at which it should be taken, and interest beyond this allowed limit has long been stigmatised with the odious appellation of usury. [INTEREST.] It has been reserved for our own time to carry out a principle which political economists had preached for above a century, that of permitting the rate of interest to regulate itself according to the exigencies of the time and the nature of things. The first statute by which some relaxation of the usury laws was made in favour of trade, was the 3 & 4 Will. IV., c. 98, which enacted, that no person taking more than the rate of legal interest for the loan of money on any bill or note not having more than three months to run, should be subject to any penalty or forfeiture. Shortly afterwards the statute 5 & 6 Will. IV., c. 41, enacted that bills or other securities should not be void because a higher rate of interest than was allowed by the statute of 12 Anne had been received thereon. The statute 1 Vict., c. 80, next enacted, that bills payable within twelve months, should not for a limited time be liable to the usury laws, and this statute was followed by six others, extending from time to time the application of the original act. The statute 2 & 3 Vict., c. 37, enacted that no bill or note, payable within twelve months after date, or not having more than twelve months to run, nor any contract for the loan of money above 10*l.*, should by reason of interest taken thereon or secured thereby, or any agreement to buy or receive or allow interest in discounting, negotiating, or transferring any such bill or note, be void, nor any person so lending be liable to the penalties of the usury laws; but it was provided that this relaxation should not extend to the loan or forbearance of any money on the security of land. The public mind having thus slowly advanced in the direction of the policy advocated by Bacon above two centuries ago, at length became prepared for a still wider measure, and the statute 17 & 18 Vict., c. 90, after laconically reciting in the preamble, that "it is expedient to repeal the laws at present in force relating to usury," proceeds to repeal wholly, or in part, eleven English, five Scotch, and four Irish acts, on which the whole penalties of usury previously rested: among these acts are included those relating to annuity transactions. [ANNUITY.] The natural laws which regulate the terms on which money can be borrowed are, therefore, now left to operate freely, and borrowers and lenders are amenable to no other rules than those which govern contracts in general.

(Blackstone's *Commentaries*, Mr. Kerr's edition, vol. ii., p. 475.)

UT. [GAMMUT.]

UTRECHT, TREATY OF. [TREATIES, CHRONOLOGICAL TABLE OF.]

UVA, *Uvæ papæ*. The former is the name of the fruit of the vine, in the natural state of grape, the latter when the grapes have been spread out and dried, and so made *raisins*. Currants are a peculiar kind of grape dried. The chief employment of *raisins in medicine* is to flavour unpleasant mixtures, or for their demulcent properties. In the former point of view they are unimportant; in the latter, of considerable utility. Fresh grapes are cooling, aperient, moderately nutritive, and demulcent. Their use in the south of France is thought to contribute greatly to the amelioration which consumptive persons experience there, and in some instances their effect is so striking as to have given rise to the term *cure de raisins*. The dried fruit is less acid, but more nourishing, and more demulcent. It possesses all the soothing qualities of jujube, and is much cheaper. It may be easily made into a conserve by removing the seeds and beating the pulp into a thick mass. For persons with irritable throats and liable to winter coughs, a portion of this put into the mouth before going into the open air is an excellent protective measure, and often prevents cough, which, when once excited, it is difficult to allay. An excellent demulcent drink is made from a compound of barley and raisins. Currants contain more acid than common raisins, and should be preferred where an aperient action is desired. Much tannin of a very pure kind is also contained in the pits of the seeds. This may render the seeds astringent; but for consumptive persons it is best to remove the seeds from the grapes, at all events not to swallow them, as their very indigestible nature may irritate the bowels and cause diarrhœa, a formidable symptom in consumptive persons.

An oil exists in the seeds of the grape, in the proportion of 12 pounds of oil to 100 pounds of seeds. Though it is not obtained without difficulty, it is extracted in Italy in large quantity. When heat is used, it has a harsh taste, and is mostly used for burning; but when cold-drawn, it may be used for food.

USUS. [USUFRUCTUS.]

V

V, as pronounced by the English, is the pressed or medial labial aspirate, bearing the same relation to *f* that *b* does to *p*. Its form is only a variety of the character by which the vowel *u* is denoted, the latter being in its origin the cursive character employed with soft materials, while *v* is better adapted for writing on stone. The Roman letter *v* was probably pronounced as a *w*, a supposition which would explain the fact that in the alphabet of that language one character is employed for both *u* and *v*. The converse of this appears in the German alphabet, where *w* has nearly the power of *v*, while the latter symbol is used to designate the sound of the English *f*, as is the case also in Welsh.

v is interchangeable with *b* and *m*: see these letters. It is also interchangeable with *f*, and hence the confusion between the characters, as just observed. The changes with *w*, *gu*, *du*, will be considered under the letter W.

VACCINATION. [SMALL POX; JENNER, in BIOG. DIV.]

VACCINIC ACID. This name was applied to an acid substance extracted from butter, but it is now believed to be merely a mixture of butyric and caproic acids.

VACUUM, or VOID, the name given in physics to the idea of space wholly free of matter, or perfectly empty. In the common phrase, space is called empty when, so far as air can fill space, it is full of air; and even in a more scientific form of speech, there is said to be a vacuum when there is only such an approach to a vacuum as the operations of philosophy can procure. Thus in the *vacuum* of the air-pump, however long the attempt at exhaustion may be continued, there is always air left, though in a highly attenuated state; and even in the mercurial vacuum, or in the space which is left over the mercury of the barometer, there is not unfrequently a slight portion of air, and always an atmosphere of the vapour of mercury. Physically speaking, it is perhaps impossible to procure a vacuum: it is most likely that, even if a real vacuum could be procured for an instant, air or other vapour would at once begin to be disseminated from the sides of the vessel in which the vacuum was made and that the vacuum would thus instantly cease to exist.

But the question of the existence of vacuum, in its strict and absolute sense, and as to whether such a thing were possible or not, was a subject of controversy from before Aristotle to after Newton. It was meant, like other questions of physics, to receive its solution from the exercise of the intellect employing itself upon the apparent properties of material bodies. Aristotle and others denied the actual existence of a vacuum, from a want of exact knowledge of the laws of motion. In a vacuum, says Aristotle ('Physic.,' l. iv., c. 8), there would be no reason why motion should be to one part rather than another. He apparently attributes all motion to the pressure of adjacent matter, not only in its commencement, but in its continuance. A modern philosopher would say that, even if the creation of a vacuum destroyed the cause of gravitation, still a body falling downwards into a vacuum would move through it with the velocity which it had at its entrance. Democritus, Epicurus, and others, assert the existence of a vacuum; and most of the different sects among the Greeks seem to admit the possibility of such a thing, though some of them deny its actual existence.

Descartes denied the very possibility of a vacuum, and upon such grounds as will make most persons feel that if Newton had not come, it would have been better to have kept to Aristotle. There is in his writings an absolute and palpable confusion between *space* and *matter*, to the extent of an assertion that the destruction of all the matter in a certain space would be the destruction of the space itself. He places the essence of matter in the occupation of space, and thence infers by a wrong conversion that there cannot be space without substance (by which he means matter). As follows: "Vacuum autem philosophico more sumptum, hoc est, in quo nulla plane sit *substantia*, dari non posse manifestum est ex eo quod extensio spatii vel loci externi, non differat ab extensione *corporis*. Nam cum ex eo solo quod corpus sit extensum, rectè concludamus illud esse substantiam; quia omnino repugnat ut nihili sit aliqua extensio; idem etiam de spatio quod vacuum supponitur, est concludendum: quod nempè cùm in eo sit extensio, necessariò etiam in eo sit substantia." ('Principia Philosophiæ,' part ii., § 16.) "So that," he proceeds (§ 18), "if God were to destroy all the matter (corpus) in a certain vessel, and to permit no other to come into the *place* of it (locum ablati), the sides of the vessel would be contiguous; *for* when nothing (nihil) comes between two bodies, they must touch each other." Matter and space are both things; but Descartes falls into the extraordinary confusion of ideas which is implied in first adopting the common sense of the word nothing, as when we say a vacuum is full of nothing, and then arguing from the strict meaning of the word "nothing," and denying that "nothing" can have extension. It is not true, properly speaking, that there is "nothing" in a vacuum, for the very notion of a vacuum is *space* void of matter.

The idea of Descartes on the essence of matter was carried by his followers to the full extent of using matter as a synonyme for extension. Le Grand says that a vessel filled with gold has not more matter than one filled with water. There is more weight, he says, more hardness, &c., but not therefore more matter; for the essence of matter is not in weight, nor in hardness, &c., but in extension. And he objects to the adage that "Nature abhors a vacuum," because he considers such an assertion merely to amount to saying that Nature abhors a contradiction in terms. Newton ('Principia,' book iii., prop. 6, cor. 4) expresses his opinion of the vacuum question in this way: "If all the solid particles of bodies are of the same density, so that rarefaction cannot take place without the creation of pores, there must be a vacuum." Since matter is of different density in different substances, and since the same substance may be compressed into smaller space or expanded into larger, it must either be that the solid particles are contracted or expanded, or that vacuous pores exist. This alternative does not do much. A person trained in the sciences as they now exist, thinks the idea of *solid* matter (that is, entirely solid, without any vacuum) being compressed into more solid matter, to be most incongruous and improbable; but impressions derived from habits are not arguments. The strong part of the Newtonian argument arises however from the results of the planetary theory. These celestial bodies have moved, during two thousand years of recorded observations, with exactly the same mean motions as at present, which they could not have done if they had moved in a medium of any sensible resistance. If then the celestial spaces be full of matter, it is matter of such a degree of tenuity that two thousand years is not enough to make it show any visible effect in altering the planetary motions. But again, though this argument has, almost up to the present time, induced astronomers to suspect an absolute vacuum, yet very recently the feather has shown a resistance which was not manifest against the guinea. A comet has been strongly suspected—all but proved—to be undergoing precisely the same sort of change in its mean motion which it is known would result from a resisting medium. [COMETS, col. 68.] The undulatory theory of light, moreover, which is now pretty generally received, supposes the whole of the celestial spaces to be filled with the luminiferous ether. The astronomical argument, therefore, in favour of *absolute* vacuum has fallen; but the views of the constitution of matter which have grown with the rise of the molecular sciences of chemistry, light, heat, electricity, &c., have supplied its place with much more effect. We cannot enter into the various probabilities in favour of the molecular theory, which supposes matter to be atomic, the atoms being perhaps separated by distances which are many times their own diameters. If any one were to assert that the densest substance has in it many millions of times more of vacuity than of solid matter, the assertion could not be disproved, nor even shown to be improbable. "There are difficulties," said Dr. Johnson, "about a *plenum*, and there are difficulties about a *vacuum*, but one of them must be true;" that is, either all space is full of matter, or there are parts of space which have no matter. The alternative is undeniable, and the inference to which the modern philosophy would give the greatest probability is, that all space is *full* of matter in the common sense of the word, but really occupied by particles of matter with vacuous interstices; showing all degrees of density, from that of the ether of light, which is wholly unappreciable, to that of hammered platinum, which is twenty-two times as heavy as water.

Probably the manner in which the reader is most familiar with the use of our leading word is in connexion with what he may have seen written on the maxim which we have already quoted—"Nature abhors a vacuum;" a doctrine which, though common among the followers of Aristotle, must not, any more than many others, be therefore taken as emanating from that philosopher himself. This is usually cited as a proof of the puerility of the ancient and middle philosophy—we think, somewhat unjustly. The personification of Nature is common to all times, and we are in the habit of saying that Nature exhibits phenomena, conceals her operations, uses the simplest means, &c. Now Nature may as well abhor, as exhibit, conceal, or employ; and where intelligence is understood, all who use the word Nature mean the God of Nature: while when the mere operations are referred to, Nature is only the personification of the collective body of second causes. As the statement of a fact, it is *true*: Nature *does*, to the best of our knowledge, abhor a vacuum; *she* (if we may personify her) never suffers it to exist to the extent of allowing any space which is perceptible to our senses to be vacuous. But if the adage were meant to supply a reason for the fact, those who used it were deceiving themselves, but not so that the most of those who would laugh at them would have any reason in their mirth. It is the error of every period to use words expressive of a fact observed in the sense of assignment of a reason for that fact; and the centuries which have always been ready with their *fluids* to stand for the causes of heat, electricity, magnetism, &c., should not be too hard upon the preceding ages, which put the feelings of nature in the place which they rather prefer to occupy by hypothetical gases. The very word attraction [ATTRACTION], in the sense generally assigned to it, is precisely of the same nature as the natural *abhorrence* of the Aristotelians: namely, a word invented to supply the place of a cause. Those who can use the former word in a really philosophical sense are precisely those who can see that some of the ancients may have done the same with the latter.

"The question of the existence of vacuum, in its strict and absolute sense," to repeat the designation given in the preceding portion of this article, which is reprinted as it originally appeared, on account of its historical and philosophical value, is inseparable from that of the nature of space. If space, as suggested in a former article [PHYSICAL FORCES, CORRELATION OF, col. 496], be "the extension of material substance, the resultant of its dimensions, and mere consequence of its existence," an absolute vacuum is in the nature of things impossible. But the admission of the existence of space distinct from matter is equivalent to affirming the existence of an absolute vacuum. Space distinct from matter is nothing else. This subject, however, resembles others of what may be termed transcendental natural philosophy, such as the (alleged) infinite divisibility of matter or of space, the absolute zero of heat, &c. The affirmative of each is purely imaginary, being something which is mentally conceived to be abstractedly and intrinsically possible, without any reference to known physical facts, which are gratuitously assumed, not in reality to define and limit the subjects, but to depend altogether, in relation to them, on the necessary imperfections of the senses and of our finite condition. But neither by observation or experiment, nor by mathematical reasoning from either, do we know anything about space distinct from matter, about the infinite division of matter, or about the existence of anything but at some temperature or amount of heat in the state or condition in which it causes expansion. (The calculations which have been made as to the number of thermometric degrees between some known temperature and the supposed absolute zero are entirely nugatory, and unworthy of attention. There is no more reason to believe in the existence of an absolute zero than in absolute rest, or in a limit to space, or than to believe, for philosophical reasons, in the cessation of phenomena, or in the beginning or the end of time.) And these three subjects—the alleged absolute vacuum, infinite division of matter or of space, and absolute zero or its converse—are as inseparably connected in mental conception, as are the physical types of which they are abstractions in observed fact.

To divest the subject of a notion introduced—we think unnecessarily—into modern discussions on the divisibility of matter, we must here premise that absolute vacuum and empty space, or space distinct from matter, being the same thing, it is clear that there can be no infinite division of space; while, by hypothesis, so far as our argument has yet advanced, there may be infinite division of matter. But admitting space to be the property of matter, its divisibility is the same thing as that of matter, and the possibility of that divisibility must depend on that of matter itself.

This being premised, we return to the main union of subjects before us. The mental conception of an absolute vacuum is in reality incompatible with that of the infinite division of matter and of the absolute privation of heat; though, remarkably, some philosophers, and even modern men of science, have affirmed the second and third (the two latter) and denied the first, while others, also, have denied the first and third but admitted the second. If, again, matter be infinitely divisible, there can be no absolute zero, since everything must exist at some temperature, which, in fact, is as inseparable from material existence as space and time themselves. If there were an absolute zero, matter could not be infinitely divisible, for there would be (an inferior) limit to its expansibility.

But, on the other hand, the idea of the only finite divisibility of matter does not imply that of an absolute zero, though it is the only notion of divisibility compatible with it; because the finite particles of matter, like the masses they compose, must be susceptible of indefinite reduction of temperature, if they retain the character of matter.

We must descend, however, from these views to the observed facts from which we believe they are necessary inferences. The sum of our actual knowledge, whether exclusively experimental or also inductive or deductive, is, that something (but not everything) exists everywhere; that everything exists in some place—that is, in, or is, some part of space, is of some magnitude and of some temperature, and that nothing is at rest—that is, that the place of everything is always changing. In absolute truth these are, we believe, if not identical propositions, yet such as involve each other, though to prove this would require greater length than we can now command.

In the present era of physical science, that inaugurated, in certain directions, by the successive labours of Volta, Davy, Oersted, Seebeck, and Faraday, a belief that the intervention of material particles is necessary for the transmission of any kind of force, and therefore that no force does or can operate through unoccupied space or vacuum, has gradually, but, until a comparatively late period, as it were silently, grown up. The force of the evidence which had accumulated, however, appears not to have been recognised until after the appearance (in the 'Philosophical Transactions' for 1835-1838) of Dr. Faraday's experimental researches on electrical induction. We have been of opinion, from the time of their publication, that these in reality involve the demonstration of the impossibility of distant action, and therefore of the necessity of the intervention of particles by which the action may be and is transmitted from one acting body to a distant one; and it is certain that the awakening of the attention of philosophers to the true condition of the subject involved, dates from about that time.* This result is of course fatal to the admission of a true physical vacuum. It is remarkable that this result had been clearly anticipated by Newton himself, who held that the planetary spaces could not really be vacuous because they were traversed by the force of gravity. This remarkable expression of Newton's sagacity and power of thought has had a singular fate. Recorded in 1693, it remained unpublished for nearly a century, when it appeared (in 1783) in Horsley's edition of his works. But it seems to have remained unregarded until it was brought forward by the celebrated Professor Playfair, so late as the year 1819—more than a century and a quarter after its original enunciation—and that merely for the purpose of proving "that Newton did not consider gravity as a property inherent in matter." But even Playfair did not perceive the entire force of the passage, and, indeed, the light which electricity was destined to throw on all branches of molecular physics had not then been received; Faraday had not yet replied to Playfair's question, "it is not quite clear in what manner the interposition of a material substance can convey the action of distant bodies to one another." † A third part more of a century was destined to elapse, when Faraday cited Newton's expression, to the general surprise of the scientific world, in one of his discourses at the Royal Institution, in 1853, in order to show that Newton "was an unhesitating believer in physical lines of gravitating force," and must be ranked "amongst those who sustain the physical nature of the lines of magnetic and electrical force." ‡ The irreconcilability of the conception of lines of physical force with that of an absolute vacuum, identifies the subject now reviewed with that of the present article.

We proceed to notice some modern and comparatively recent experimental investigations, involving the production of nearer and nearer approximations to a physical vacuum, or the more and more complete removal of ponderable matter from an inclosed space. It is matter of this kind only, the quantity of which, in a given space, can at all be diminished; that of the matter of a higher order, the ether which manifests and transmits heat and light and perhaps magnetism, according to our present experimental means, cannot be affected; though apparently acted upon in a certain mannner by the molecules of ordinary matter, it cannot be confined or diminished in amount, any more than it can be measured or weighed. Or,—to express this in terms independent of theory,—a vacuum transmits light and heat, diminished only by the imperfect transparency and transcalescence of the including vessel. In the investigation in question, more or less perfect vacua have been obtained by the air-pump; others on the principle of the space void of air left above the mercury in the barometer, called the Torricellian vacuum; some by the combination of both these means; and others again by the union of one or both with chemical agency, by which apparently the most perfect vacua have been produced.

Dr. Thomas Andrews, F.R.S., Vice-President of Queen's College, Belfast, whose refined physico-chemical researches have required the use of the nearest approach to a perfect vacuum in which certain instruments could be observed, has devised a method of obtaining probably a more perfect air-pump vacuum than had before been produced. He characterises the Torricellian as the nearest approach to a perfect vacuum which at the time when his method was devised had been obtained. "It is true," he remarks, "that it contains a little mercurial vapour at the ordinary temperature of our summers, and probably also at lower temperatures, but the quantity is exceedingly small, and its influence in depressing the barometric column must be altogether inappreciable. Besides the mercurial vapour, a trace of air may generally be detected." Dr. Andrews shows that it is easy to calculate approximatively the depression of the column produced by this; and he finds that if the diameter of the bubble be 0·02 inch, the pressure of mercury under which it has been measured 2 inches, and the volume of the space above the mercury when the tube is vertical 1·2 cubic inch, the depression of the mercurial column is nearly 0·00001; "or the depression of the mercury, in consequence of the vacuum not being absolutely perfect (with respect to air), amounts only to $\frac{1}{100,000}$ of an inch. It is easy in actual practice," Dr. Andrews continues, "to realise this close approximation to a perfect vacuum," and the quantities he stated, he says, apply to a barometric tube employed in an experiment he subsequently describes. Observing, however, that the Torricellian vacuum is unfortunately applicable to very few physical investigations, as no instrument of any kind can be introduced into it, nor even a substance which is acted upon by mercury, and noticing the imperfection of the ordinary air-pump and of M. Regnault's method of pushing the exhaustion further after the valves have ceased to act he proceeds to describe, in the following terms, a process by which, with very little trouble, a vacuum may be obtained in the ordinary receiver of an air-pump, so perfect that the residual air exerts no appreciable elastic force.

"Into the receiver of an ordinary air-pump, which is not required to exhaust further than to 0·3 inch, or even 0·5 inch, but which must retain the exhaustion perfectly for any length of time, two open vessels are introduced, one of which may be conveniently placed above the other; the lower vessel containing concentrated sulphuric acid, the upper a thin layer of a solution of caustic potash, which has been recently concentrated by ebullition. The precise quantities of these liquids is not a matter of importance, provided they are so adjusted that the acid is capable of desiccating completely the potash solution, without becoming itself notably diminished in strength, but at the same time does not expose so large a surface as to convert the potash into a dry mass in less than five or six hours at the least. The pump is in the first place worked till the air in the receiver has an elastic force of 0·3 or 0·4 inch, and the stop-cock below the plate is then closed. A communication is now established between the tube for admitting air below the valves, and a gasholder containing carbonic acid, which has been carefully prepared so as to exclude the presence of atmospheric air. After all the air has been completely removed from the connecting tubes by alternately exhausting and admitting carbonic acid, the stop-cock below the plate is opened. and the carbonic acid allowed to pass into the receiver. The exhaustion is again quickly performed to about the extent of half an inch or less. If a very perfect vacuum is desired, this operation may be again repeated; and if extreme accuracy is required, it may be performed a third time. It is not likely that anything would be gained by carrying the process further. On leaving the apparatus to itself, the carbonic acid which has displaced the residual air is absorbed by the alkaline solution, and the aqueous vapour is afterwards removed by the sulphuric acid. The vacuum thus obtained is so perfect, that even after two operations it exercises no appreciable tension."

Even after this limit has been reached, the exhaustion may be pushed still further, "till it must become at last not less complete than the Torricellian vacuum; while at the same time by suppressing the manometer, the existence of mercurial vapour may be altogether prevented. The manipulation required to arrive at this result will not interfere with the presence of even the most delicate instruments in the receiver." In an experiment which Dr. Andrews describes, the theoretical residue of air would be $\frac{1}{135,000}$ of the entire quantity in the receiver, which would cause a depression of $\frac{1}{4500}$ of an inch only, and this, he says, must have been nearly realised. Such a vacuum has remained without the slightest change for fourteen days. 'Phil. Mag.,' Feb., 1852; 'Quart. Journ. of Chem. Soc.,' vol. v., p. 189-192.

Unless the still more perfect carbonic-acid vacua employed by Mr. Gassiot, and about to be described, should be obtainable in comparatively large vessels adapted for the observation of instruments, &c., —towards which result, indeed, Mr. Gassiot has made some approach, —Dr. Andrews's method appears to be the most eligible for the generality of exact researches for which a vacuum is required.

In a paper 'On the Electrical Phenomena exhibited in Vacuo,' by Sir H. Davy, in the 'Philosophical Transactions' for 1822, he relates some experiments which he made for the purpose of elucidating "the relations of electricity to space, as nearly void of matter as it can be made on the surface of the earth." He repeated the electrical experiments with the Torricellian vacuum of Morgan and Walsh, and instituted others with similar vacua above a difficultly fusible amalgam of mercury and tin, and above fused tin. With the results as bearing on the theory of electricity we are not at present concerned; but these approximations to vacuous space were, of course, in reality, atmospheres of the vapours of the metals employed, though of excessive rarity; and a calculation made by Mr. Babbage for the author may be cited, as indicating how minute must have been the quantity of matter which they contained—how great must have been its "attenuation," in the language of the present day—which is a point of information important to the subject of this article. Considering the elastic force of vapour of water at 52° to be equal to raise by its pressure about ·45 of an inch of mercury; the relative strengths of vapour will be, reckoning the boiling points all from 52°, for mercury at 600°, ·000015615, ... and for tin, at 5000°, 37015, preceded by 48 zeros. The data on the diminution of the density of vapours by diminution of temperature supplied in this case by the chemist to the mathematician were probably in some degree erroneous, and the results would be affected by the limit to vaporisation for every substance at a certain temperature which Faraday, a few years after, rendered so highly probable, if not certain, but the latter would operate to diminish the density of the metallic vapours in question; and we may, all things

† 'Second Dissertation on the Progress of Mathematical and Physical Science;' Supplement to 'Encyclopædia Britannica,' vol. iv., p. 83, note; 'Ency. Brit.,' 8th edit., vol. i., p. 684, note.

‡ How important to the progress of the science of physical forces this calling the attention of philosophers to Newton's views has really been, will appear from the following extract from the 'Theory of the Force of Gravity,' by Professor Challis, published in the 'Philosophical Magazine' for December, 1859, p. 442. "The *actio in distans* has been so long and so extensively regarded as an ultimate principle, and not as a temporary hypothesis admitting eventually of explanation, that it requires some degree of moral courage to maintain a different theory. Science, in my opinion, is much indebted to Professor Faraday for having recently directed attention to the opposite views entertained by Newton on this point, and for giving expression to analogous ideas of his own. (See the Lecture on the Conservation of Force, in the 'Phil. Mag.' for April, 1857, vol. xiii., p. 232.)" The lecture referred to was delivered in the preceding February; but Faraday, as we have seen above, had originally directed attention to Newton's views in 1853; and he regarded their importance as so great, that he had recalled them also in his discourses of the two following years.

considered, accept these numbers as fair expressions of the minute quantities of matter they are intended to represent.

Mr. Grove ('Phil. Trans.' and 'Phil. Mag.,' 1852) having originally observed a peculiar striation in electric discharges taken in a well-exhausted air-pump receiver, apparatus in some respects similar to that employed by Davy has been constructed by Mr. Gassiot, for the further investigation of that phenomenon as observed in Torricellian vacua, and partly by means of a process devised by the late Mr. John Welsh ('Phil. Trans.' 1856, p. 507), he has produced more perfect Torricellian vacua than any before obtained. 'Phil. Trans.,' 1858, pp. 3, 5.

In the continuation of the researches which these experiments of Mr. Grove and Mr. Gassiot initiated, the united science and ingenuity of several physicists, chemists, and mechanicians, have produced vacua still more perfect, that is, still more devoid of ordinary or ponderable matter; more strictly again, spaces in which a smaller amount of such matter existed than in any obtained before, and probably greatly exceeding in this respect the most perfect Torricellian vacua previously experimented with by the old electricians, and by Davy, as well as those first employed by Mr. Gassiot himself. For the purpose of obtaining them, a method has been adopted, often indicated, and to a certain extent employed, in chemical and physical research, but now pursued with much greater care and refinement, and with all the resources to ensure accuracy which the most delicate operations of modern chemistry can supply. The vacuum tubes to which we now allude appear to have been first constructed about 1857, by M. Geissler, of Bonn, and the vacua obtained by an application of the method alluded to, but which, it is understood, he has not precisely explained. Mr. Gassiot, desirous of knowing, during the progress of the experimental research upon which he had entered, the exact conditions under which each particular vacuum had been obtained, and finding that there was some uncertainty in the description of those he had obtained from M. Geissler, employed Mr. Casella to construct above 100 new tubes, each of which, however, was charged and exhausted by himself or in his presence. Each tube was filled, in the first instance, with atmospheric air, hydrogen, oxygen, or nitrogen, then exhausted by a good air-pump; another supply of air or of gas admitted, and the tube again exhausted; after the repetition of this process two or three times, mercury was introduced, and the tube finally exhausted as a Torricellian vacuum, and lastly hermetically sealed; the attenuated medium within thus being mercurial vapour, plus the remains of air or of the gas with which the tube had been originally filled.

Tested by the appearance of the electrical discharge from the Ruhmkorff inductive coil, found by Mr. Gassiot in these researches to be the most delicate of all tests of the presence of ponderable matter, these vacuum-tubes were at length ascertained to be void even of the slightest trace of air or gas, mercurial vapour alone remaining. But the progress of the investigation required that this also should be removed, and a still nearer approach to empty space obtained. This was effected by a refined modification of Dr. Andrews's process already described, suggested by Dr. Frankland; tubes, into which caustic potash had been introduced, being repeatedly filled with carbonic acid and exhausted; finally exhausted to the utmost limit of the capability of the air-pump, and sealed. These were found, on the application of the electrical test, to be far more perfect vacua than the Torricellian, and when the infinitesimally rare included atmosphere of carbonic acid gas was exposed to the action of a large surface of hydrate of potash, the vacuum no longer permitted the electrical discharge to pass, a result first obtained by Mr. Gassiot, and in these researches; when the potash was heated, more ponderable matter being diffused in the tube, the discharge again passed; but on allowing it to cool, the tube resumed its insulating state. These results were given by a tube 40 inches long and 1¼ inch internal diameter. An excellent carbonic-acid vacuum was obtained by the same method in an egg-shaped vessel, 22 inches long and 7 inches in its greatest diameter; but this did not insulate the discharge,—judging from the appearance of which, this vacuum may be inferred to be about equal, though in so large a vessel, to the best Torricellian vacuum in comparatively narrow tubes. The minute fraction of ponderable matter present does not appear to have been calculated in any of these instances. This is the nearest approach to a true physical vacuum that science has yet succeeded in producing. Mr. Gassiot concludes his paper with the remark—adopting a suggestion made by Mr. Brayley—"The fact that a vacuum so perfect can be obtained in a closed vessel containing such a substance as hydrate of potassa, would excite a hope that the limit to vaporation (vaporisation), the existence of which Faraday and others have, if not proved, at least rendered so probable, may be determined, and even its consequences exhibited by direct experiment." ('Phil. Trans.,' 1858, p. 157.)

Such is the present condition of this subject, one of the most interesting and most extensive in its philosophical applications which can claim the attention of the physicist and the chemist. The bearings of Mr. Gassiot's results, and of those obtained by other experimenters with similar apparatus, on the nature and theory of electricity, however important, are foreign to the object of this article. But the terms in which they have been described and the reasoning which has been founded upon them, involve a subject which is strictly within its scope. We conceive that the true and immediate induction from these results, is, in general terms, that in consequence of the diminution in density of the media through which the electricity has to pass—that is, of the diminution of the quantity of matter contained in a given space—certain properties of electricity are exhibited in a manner which a denser medium precludes it from manifesting: that this takes place up to a certain point of rarefaction, through which, if electricity can pass at all, greater intensity is required; or it may even be that a vacuum absolutely free from ponderable matter, which luminous electricity requires for its production and convection, has been temporarily obtained. Considering the nature and circumstances of the vessels and materials by which only it can be obtained, it must necessarily be temporary only. But the results have been described and reasoned from (originally, we believe, on account of certain views respecting the nature of matter entertained by Mr. Grove, to which we have elsewhere adverted), as if they depended, not on the removal of ponderable matter, but on its presence in an increased degree and with increased causation of phenomena. But in proportion to the completeness with which such matter is removed from an inclosed space, the ether which it still contains will be more free to exhibit its peculiar properties, unimpaired by the presence of an inferior and grosser form of matter; and the phenomena which have been attributed to "attenuated (ordinary) matter," ought, we conceive, to be ascribed to the unincumbered ether which remains. The fact that a certain amount of ordinary matter is essential to the manifestation of any sensible effects whatever by the electricity does not militate against this conclusion. It should be so. The conduction, or the convection by induction, of electricity belongs to ordinary matter, while the reception and transmission of impressions from it in the form of light and heat, belong to the higher order of matter, the ether.

VAGABOND. [VAGRANT.]

VAGRANT. This term, which in its etymological meaning simply denotes "a wandering person," is obviously derived from the Latin *vago*. It was probably introduced into our law language from the Norman French; the phrase "*vagerants de lieu en lieu currants per paiis*" occurring in our early statutes in the sense in which the word "vagrant" is used in common language at the present day. (Stat. 7 Ric. II., c. 5.) The persons to whom it is applied in ancient documents are usually classed with "faitours," (a word of doubtful origin, but meaning an idle liver or slothful person: Cowell's 'Interpreter;' Kelham's 'Dictionary,') "travelyng-men," and "vagabonds." The latter expression, "vagabundus," was known throughout Europe in connection with feudal law, and is interpreted to mean "crebro vagans, cui nec certum domicilium, nec constans habitatio est." (Calvini 'Lexic. Jurid.') It was used in this sense in English law as early as the reign of Henry II. (Cowell's 'Interpreter.') Modern laws have however given to the word "vagrant" a much more extended meaning, in the application of which the notion of wandering is entirely lost.

In the course of the transition made by the lower classes of society from the condition of feudal villeins to that of free labourers, vagrancy and mendicity necessarily ensued from the unsettled state of the poor; and in most countries where feuds had prevailed, severe laws were made to repress the evils which sprung from this source. In England various statutes and ordinances passed from time to time to obviate the inconveniences arising from wandering mendicancy. The earliest of these was a statute of ordinance, made in the 23rd year of Edward III. (1349), commonly called the Statute of Labourers, which, after reciting that "many sturdy beggars (validi mendicantes) were enabled by the gains of begging to live, and to devote themselves to pleasures and sins, and sometimes to thefts and other crimes," forbade "all persons, on pain of imprisonment, to give anything under colour of piety or charity to such as were able to labour." In 1366 there is a petition of the Commons complaining of wandering artificers and servants becoming beggars in order to support an idle life, and praying that it might be forbidden under a penalty for any one to give alms or sustenance to any such idle beggars; and that they should be apprehended and put in the stocks or sent to jail until they found surety for their return to their own country. ('Rolls of Parliament,' vol. i., p. 340.) The answer to this petition does not appear: but a few years afterwards a statute was passed making it (almost in the language of the petition) penal for artificers, servants in husbandry, and others, without a special licence, to quit the town, hundred, or wapentake in which they lived, to live and work in another town, hundred, or wapentake; and persons found vagrant (*vagarant*) without such licence might be placed in the stocks and imprisoned by the local authorities, until they found security for their return to the place to which they properly belonged. (Stat. 12 Ric. II., c. 3.) It was also enacted that "those who were able to work and went begging should be dealt with as persons travelling without a licence, and that beggars unable to work, dwelling in cities or towns, should remain in such cities or towns; that if such cities and towns were unable to support them, they should be taken to other places within the same hundred or wapentake, or to the place of their birth, and there remain during their lives." (Stat. 12 Ric. II., c. 7.) And it was probably upon the principle declared by these laws, that in the 15th century it was held to be lawful for any person to arrest and send to jail a man "found wandering (*vagarant*) in such manner that it is unknown how he gets his living." ('Year Book,' 9 Edw. IV., c. 27.) A statute which was passed in 1494 declared that all "vagabonds, idle and suspected persons, should be set in the stocks three days and three nights, and have none other sustenance but bread and water, and then should be put out of the town; and that whosoever should give such idle persons more should forfeit 12 pence; and that every beggar not able to work should resort to the hundred where he last dwelt, was best known, or was born, and there remain, upon the pain aforesaid." (Stat. 11 Hen. VII., c. 2.) This vague enactment was followed by the more definite provisions of the stat. 19 Hen. VII., c. 12, which declared that impotent beggars should go to and abide in the city, town, or hundred where they were born, or else the place where they had made their last abode for three years; and this rule of settlement was adopted in the statutes subsequently passed against vagrancy in the reigns of Henry VIII., Edward VI., Mary, and Elizabeth. (Nolan's 'Poor Law,' chap. xv.) By stat. 22 Hen. VIII., c. 12, the justices of the peace in every county were empowered to grant licences under seal to "poor, aged, and impotent persons," to beg within a certain precinct; and persons begging without licence or out of their precincts were to be whipped or set in the stocks for three days and three nights, with bread and water only. This provision applied to impotent vagrants. On the other hand it was provided that if any person, "being whole and mighty in body," and able to labour, should be found begging or vagrant, he should be taken before a magistrate, who might direct him to be whipped out of the place at the end of a cart, "till his body was bloody," and should then be sworn to return to the place where he was born, or last dwelt by the space of three years, and there to put himself to labour as a true man ought to do. He was to be provided with a certificate of his punishment, stating the place to which he was going and the time allotted for his journey; and during that time he might beg by the way. Another law passed against beggars and vagabonds was the 27 Hen. VIII., c. 25, which, though severe in its terms against such persons, approached more nearly to just principles than previous enactments on the same subject, inasmuch as it provided a legal mode of supporting the poor, and thus took away the common apology for vagrancy. This law directed the governors of shires, cities, towns, hamlets, and parishes, to find and keep every aged, poor, and impotent person, by way of voluntary and charitable alms, with such convenient alms, that none of them should be compelled to go openly in begging: children under fourteen years of age and above five, taken begging, were to be put to work: "a valiant beggar or sturdy vagabond" was to be, for the first offence, whipped and sent to his place of settlement; and if he continued his roguish life, to have the upper part of the gristle of his right ear cut off; and if after that he was taken wandering in idleness, or did not apply to his labour, or was not in service with any master, he was to be indicted and tried as a felon, and if found guilty, to suffer death.

Notwithstanding the above laws, vagrancy appears to have greatly increased at the commencement of the reign of Edward VI., of which effect the abolition of monasteries was one main cause. Previously to the Reformation churches were bound by law, both civil (stat. 15 Rich. II., c. 6) and ecclesiastical, to contribute a portion of their income to the living and sustenance of the poor, and the gates of the religious houses were thronged by beggars, who daily received a donation of food, and sometimes of money. This practice contributed no doubt to increase the number of idle beggars, who, upon the withdrawal of their accustomed means of support by the dissolution of the monasteries, became vagrants. To remove the pressure of the evil thus occasioned, an enactment of unexampled severity was devised. The stat. 1 & 2 Edw. VI., c. 3, after reciting that "the multitude of people given to vagabondrie and idleness had always been within this realm very great, and more in number than in other regions," and that the laws of preceding reigns had been found ineffectual, repealed all statutes previously made for the punishment of vagabonds and sturdy beggars. It then enacted that all able-bodied persons, without property sufficient for their support, who should, "either like serving men wanting masters, or like beggars, or after any other such sort, be lurking in any house, or loitering or idle-wandering by the highway's side," or who in towns should not apply themselves to any service or art, and should so continue for three days without offering to labour for meat and drink (if no man otherwise will take them); or who, having been taken to service, should leave their work or run away, should be taken to be vagabonds; and that it should be lawful for any person having offered or given work to any such idle person, and for any other person espying the same, to bring such idle person before two justices, who should immediately cause him to be marked with a hot iron on the breast with the letter v, and adjudge him to such presenter "*to be his slave; to have and to hold the said slave unto him, his executors, or assigns, for the space of two years then next following*, and to order the said slave as followeth (that is to say), to take such slave with him, and only giving him bread and water, or small drink and such refuse of meat as he shall think meet, cause him to work by beating, chaining, or otherwise in such work and labour (how vile soever it be) as he shall put him unto." The statute also provides that an action of trespass may be maintained for a runaway slave, and that the runaway himself shall, upon his apprehension, be adjudged by two justices to be his master's slave for ever. If he ran away a second time, the slave became a felon, and might be tried and executed as such. This singular enactment further declared that a master might "let, set forth, sell, bequeath or give" the service and labour of such slaves, upon such condition and for such term of years as he might do with any other of his moveable goods or chattels. "Some thought," says Burnet, "this law against vagabonds was too severe, and contrary to that common liberty of which the English nation has always been very sensible. Yet it could not be denied but extreme diseases required extreme remedies; and perhaps there is no punishment too severe for persons that are in health, and yet prefer a loitering course of life to an honest employment." ('History of the Reformation,' vol. ii., p. 45.)

The consequence of the absurd severity of this law was that its provisions were not carried into execution; and being found wholly ineffectual, it was repealed by the statute 3 & 4 Edw. VI., c. 16, which also repealed all former laws upon the same subject excepting the 22 Hen. VIII., c. 12. Another statute of the same reign (5 & 6 Edw. VI., c. 2) slightly modified the preceding laws; but the regulation of vagrants and mendicants stood in effect upon the footing of the three last-mentioned statutes until the latter part of the reign of Elizabeth.

About the beginning of the reign of Elizabeth, a description of persons called *rogues* first appeared in the general class of vagrants. The derivation of this word is variously given by etymologists. Horne Tooke derives it from a Saxon word signifying "cloaked," or covered. ('Diversions of Purley,' vol. ii.) Webster takes it from another Saxon word, and Dr. Johnson admits its derivation to be uncertain. Lambard says "the word is but a late guest in our law; for the ancient statutes call such a one a valiant, strong, or sturdy beggar, or vagabond, and it seemeth to be fetched from the Latin 'rogator,' an asker or beggar." ('Eirenarcha,' book iv., chap. 4.) Dalton also says "a rogue may be so called quia ostiatim rogat." ('Country Justice,' chap. 83.) It is believed that the word does not occur in the English language before the middle of the 16th century; and if so, it is probably one of those numerous cant words by which, at that period, vagrants, in counterfeiting Egyptians or gipsies, began to designate different classes of their own "ungracious rabble," and of which Harrison enumerates twenty-three degrees. (Harrison's 'Description of England,' prefixed to Holinshed's 'Chronicles.')

In the course of the reign of Elizabeth the evils of vagrancy increased to an alarming extent; and although the accounts given by historians of the multitude of vagabonds in England are founded upon rude estimates, and are probably somewhat exaggerated, there is undoubted evidence that the numbers and attitude of these persons at that period constituted an evil of dangerous magnitude. Strype relates that in 1569 circular letters were issued by the privy council to the sheriffs of the different counties, directing them to search for and apprehend "all vagabonds and sturdy beggars, *commonly called rogues or Egyptians*;" and he says that on the search through the nation 13,000 "masterless men" were taken up. (Strype's 'Annals,' vol. i., part 2, pp. 295, 296, 554.) Harrison, who wrote towards the end of Elizabeth's reign, states that the number of vagrants in England in his time amounted to above 10,000 ('Description of England'); and Strype publishes a paper, written, in 1596, by a justice of the peace of Somersetshire, which affirms that there were 300 or 400 wandering idle people in every county, who met at fairs and markets for purposes of theft and rapine, and who sometimes assembled in troops to the number of 60, and completely overawed the magistrates and constables by their audacious threats. (Strype's 'Annals,' vol. iv., p. 405.) The recorder of London, in a letter to Lord Burleigh, written in 1581 (Ellis's 'Letters,' vol. ii., p. 283), gives a remarkable account of the prevalence of vagrants in the metropolis at that period. He says, that being informed that the queen, "in taking of the air in her coach at Islington, had been environed with rogues," he went abroad himself and took seventy-four rogues, "whereof some were blind, and yet great usurers and very rich." A day or two afterwards he says that, in consequence of warrants issued by him, he received "a shoal of forty rogues, men and women, from Southwark, Lambeth, and Newington," and after bestowing them in Bridewell, he "perused" St. Paul's, and took about twenty "cloaked rogues that there used to keep standing." Notwithstanding this zeal and activity, vagrants still increased in the metropolis, both in numbers and audacity; and the efforts of the ordinary magistrates having failed to prevent the frequent and dangerous disorders and tumults occasioned by offenders of this description, they were, in 1595, placed under martial law. The instrument appointing a provost-marshal for this purpose authorises that officer "to repair with a convenient company to all common highways near to the city of London, where he should understand that any vagrant persons did haunt; and calling to his assistance some convenient number of justices and constables, to apprehend all such vagrant and suspected persons, and deliver them to the said justices, to be by them committed and examined of the causes of their wandering." It then directs him that "if such persons should be found notoriously culpable in the unlawful manner of life, as incorrigible, and should be so certified to him by the justices, he should by law-martial cause some of them to be executed upon the gallows or gibbet." (Rymer's 'Fœdera,' vol. xvi., p. 279.)

The means of suppressing or diminishing vagrancy and mendicancy were constant subjects of discussion in the parliaments of Elizabeth. With this view, extraordinary means of relief were devised. Voluntary subscriptions of sums of money, varying in amount according to the rank and supposed ability of the contributors, were made in both

Houses to relieve "the great number of poor people pressing in the streets to beg." (D'Ewes's 'Journals,' pp. 462, 463, 499, 503.) Orders were also made that those who preferred private bills in the House of Commons should pay 10*l.* or 5*l.*, according to the subjects of their bills, to the relief of the poor, to be distributed as the House should appoint. (D'Ewes's 'Journals,' p. 665.) Several statutes were also passed, at one time increasing the punishment for vagrancy, and then repealing it, without any settled principle of legislation. In some of these statutes, however, the notion of a parochial fund for the relief of the poor, and the principle of taxing the parishioners for that purpose, are distinctly recognised. (Stat. 5 Eliz., c. 3; 14 Eliz., c. 5; and 18 Eliz., c. 3.) At length, in 1597, after experience had shown that temporary expedients and ill-directed charity only increased the amount of vagrancy, and that severe punishments and penalties were wholly ineffectual in preventing it, the House of Commons appointed a committee to whom most of the existing laws relating to the condition of the poor, as well as certain bills for their amendment, were referred. (D'Ewes's 'Journals,' p. 561.) This committee, of which Sir Francis Bacon was member, and which was composed of all the practical men of the House, seems to have perceived and to a certain extent acted upon the principle that, in order to justify severity against vagrancy and mendicity, it was necessary to provide the means of relieving that destitution which was the ready and plausible excuse for both. They therefore prepared the stat. 39 Eliz., c. 3, which for the first time organised that machinery for the legal relief of the poor which was a few years afterwards completed and made perpetual by the stat. 43 Eliz., c. 2. The same committee also recommended measures for encouraging the building of "hospitals, or abiding and working houses," for the poor, and for improving and reforming such as were already in existence, but had been misapplied or abused. And at the same time they introduced a more rational enactment for the correction and suppression of fraudulent vagrancy than had previously existed. (Stat. 39 Eliz., c. 4.) "Many statutes," says Sir Edward Coke (2 'Inst.' 728), "have been made for the punishment of rogues, vagabonds, and sturdy beggars, but very few to find them work and to enforce them thereunto." The statute 39 Eliz., c. 4, supplied this deficiency by providing houses of correction, with stocks, and materials for the employment of the inmates, and by enforcing the use of the means thus placed in the hands of the poor by severe penalties against the idle. The provisions of this statute, with some alterations made by the stat. 1 Jac. I., c. 25, continued in force during the whole of the 17th century; and when repealed by the stat. 12 Ann., stat. 2, c. 23, still served as the model and foundation for future acts. It declared that the following persons should be deemed rogues, vagabonds, and sturdy beggars:—1, persons calling themselves scholars going about begging; 2, sea-faring men, pretending losses of their ships or goods, going about begging; 3, idle persons going about the country, either begging or using any subtle craft or unlawful games or plays, or feigning themselves to have knowledge in physiognomy, palmistry, or telling fortunes; 4, persons that were or uttered themselves to be procurers or collectors for jails or hospitals; 5, fencers, bear-wards, common players of interludes and minstrels wandering abroad, other than players of interludes belonging to any baron of the realm, or any other honourable personage of greater degree [THEATRE]; 6, jugglers, tinkers, pedlars, and petty chapmen, wandering abroad; 7, wandering persons and common labourers, able in body, using loitering, and refusing to work for reasonable wages, and having no other means of maintenance; 8, persons delivered out of jail who begged for their fees, or otherwise travelled begging; 9, persons who wandered abroad begging, pretending losses by fire, or otherwise; 10, persons, not being felons (*i.e.*, by a late statute, 5 Eliz., c. 20), wandering and pretending themselves to be Egyptians. A person who committed any of the above offences might, by the appointment of any justice, constable, headborough, or tything-man (the headborough or tything-man being assisted therein by the advice of the minister and another of the parish), be openly whipped till he was bloody, and then sent from parish to parish till he came to the parish where he was born: if that was unknown, to the parish where he last lived for a year; and if that again was unknown, to the parish where he last passed without punishment. He was provided with a testimonial of his punishment, and of the place whereunto he was to go, stating the time limited for that purpose; and if he was found loitering by the way, he might again be whipped. If any rogue appeared to be dangerous to the inferior sort of people, or not likely to be reformed (an expression which seems to have led to the phrase "incorrigible rogues"), two justices might commit him to jail till the next quarter-sessions, and then he might by the justices there be either banished out of the realm, or adjudged perpetually to the galleys of the realm; and any banished rogue returning without leave became a felon.

The several judicious measures which were enacted at this period for the relief and employment of the deserving poor, and the punishment of idle and profligate beggars and vagrants, effectually checked for a time the evil, which had only increased in magnitude under the previous inefficient and inconsistent laws. Sir Edward Coke, whose testimony as a contemporary is valuable, says, that "upon the making of the statute of 39 Elizabeth, and a good space after, whilst justices of peace and other officers were diligent and industrious there was not a rogue to be seen in any part of England; but when justices and other officers became *tepidi* or *trepidi*, rogues, &c. swarmed again." (2 'Inst.' 729.) This disposition on the part of magistrates to neglect or relax the laws relating to vagrants is noticed in a proclamation made soon after the accession of James I., in September, 1603, which, after reciting the stat. 39 Eliz. c. 4, and that great benefit had at first ensued from its due execution, but that, by the remissness, negligence, and connivancy of justices, vagrants again swarmed and abounded everywhere more frequently than in times past, calls upon all justices of peace, mayors, and other officers whatsoever, to see that the said "profitable and necessary law" should be carefully, duly, and exactly executed (Rymer's 'Fœd.,' vol. xvi., p. 554). The continued unwillingness of magistrates to enforce the statute of Elizabeth, notwithstanding the above proclamation, occasioned the passing of the stat. 7 Jac. I. c. 5, which compelled the justices of every county under heavy penalties to erect proper houses of correction for setting rogues, vagabonds, and other idle and wandering persons to work, and also required them to meet twice a year or oftener, if occasion required, for the better execution of the law. The justices were also directed to cause a general privy search to be made before each of their meetings for finding out and apprehending vagrants, who were then to be brought before them for punishment; and all constables and tythingmen were required to make a return on oath to the justices of the number of vagrants apprehended by them. By this statute it was also enacted that persons running away and leaving their families upon the parish should "be deemed and taken to be incorrigible rogues, and endure the pain of incorrigible rogues." This phrase was, therefore, at that time become familiar, though it does not occur in any earlier statute. In all probability, however, it denoted the class of persons mentioned in the stat. 39 Eliz. c. 4, who are there called "dangerous rogues, or rogues not likely to be reformed," and who were liable to be committed to jail until the sessions, and then banished.

The laws relating to vagrants continued substantially upon the footing of the statutes of 39 Eliz. and 7 Jac. I. for more than a century, until, in 1744, they were reconsidered and remodelled by the stat. 17 Geo. II., c. 5. This was the first legislative measure which distributed vagrants into the three classes of idle and disorderly persons, rogues and vagabonds, and incorrigible rogues. Although this statute is now wholly repealed, it continued in force nearly a century; and as its provisions, as well as those of two supplemental statutes on the same subject, are material with respect to the general history of the laws respecting vagrants, it may be desirable briefly to state them. It may be remarked that the several offences comprised in these classes still bore the character of wandering, in conformity with the object of all previous enactments upon this subject.

By the stat. 17 Geo. II., c. 5, and the supplemental statutes passed previously to the new Vagrant Act, 5 Geo. IV., c. 83, idle and disorderly persons were defined to be—1. Those who threatened to run away and leave their families upon the parish. 2. Those who returned to a parish from which they had been removed as paupers. 3. Those who refused to work for usual wages. 4. Those who neglected work or spent their earnings improperly, so that their families became chargeable to the parish (stat. 32 Geo. III., c. 45, s. 8). And all such persons might be summarily convicted by a magistrate, and committed to hard labour in the house of correction for a month.

Rogues and *vagabonds* were defined to be—1. Those who went about as gatherers of alms under pretence of loss by fire or other casualty, or as collectors for prisons or hospitals. 2. Fencers and bear-wards. 3. Common players of interludes, and all actors for hire not authorised by law [THEATRE]. 4. Minstrels and jugglers. 5. Those who pretended to be gipsies, or to have skill in physiognomy, palmistry, or like crafty science, or to tell fortunes, or who used any subtle craft to deceive people, or played at unlawful games. 6. Those who ran away and left their families chargeable to the parish. 7. Petty chapmen and pedlars wandering abroad without licence. 8. Those who wandered abroad and lodged in alehouses, barns, outhouses, or in the open air, not giving a good account of themselves. 9. Those who wandered abroad and begged, pretending to be soldiers or sailors, or pretending to go to work in harvest. 10. All wandering beggars. 11. Those who should be apprehended having upon them any picklock key, crow, jack, bit, or other implement with intent to break into houses, &c.; or any pistol, hanger, cutlass, bludgeon, or other offensive weapon, with intent feloniously to assault any person. 12. Those who should be found in any dwelling-house, warehouse, coach-house, stable, or outhouse, or any inclosed yard or garden, or area belonging to any house with intent to steal. The two classes last enumerated were added by the stat. 23 Geo. III., c. 88.

Incorrigible rogues were defined by the stat. 17 Geo. II., c. 5, to be—1. End-gatherers offending against the stat. 13 Geo. I., c. 23, for the regulation of the woollen manufacture. 2. Those who being apprehended as rogues and vagabonds escape from those who apprehend them, or refuse to go before a magistrate, or to be examined on oath, or to be conveyed by a pass, and those who knowingly give a false account of themselves. 3. Those who escape from the house of correction before the expiration of their term of imprisonment as rogues and vagabonds. 4. Those who after punishment as rogues and vagabonds again commit offences in the same class.

Rogues and vagabonds and incorrigible rogues were, by the stat. 17 Geo. II., c. 5, to be committed by magistrates to the house of correction until the next quarter-sessions, when the justices were empowered to order rogues and vagabonds to be further confined in the house of correction for any time not exceeding six months; and incorrigible rogues for any time not less than six months, nor more than two years, and to be whipped.

The statute 17 Geo. II., c. 5, was by no means a well-considered or a well-expressed law. It has been justly said that "in the long catalogue of actions which it holds up, many are of a dubious nature, and nice legal acumen would often be required to distinguish whether a person had incurred any and what penalty under the statute." (Eden's 'State of the Poor,' vol. i., p. 306.) The courts too complained of the inaccuracy of its expression and the consequent difficulty of understanding its meaning. (Rex *v.* Rhodes, 4 'Term Reports,' 222.) Repeated attempts were made in parliament to modify and improve its provisions. A committee of the House of Commons, appointed in 1775 to review and consider the Poor Laws and the laws relating to vagrants, resolved "that the stat. 17 Geo. II., c. 17, should be explained and amended in such a manner as to enforce the execution thereof, and prevent the practice of begging in the streets and highways, pernicious in its consequences and highly disgraceful to this country." Nevertheless this statute continued in force until the year 1822, when a temporary act, stat. 3 Geo. IV., c. 40, passed, repealing all former laws and re-enacting most of the provisions of the stat. 17 Geo. II., c. 5, with many additions and modifications. The provisions of the stat. 3 Geo. IV., c. 40, were however entirely superseded by the stat. 5 Geo. IV., c. 83, which now constitutes the law respecting vagrants. By the third section of this statute the following persons are declared to be *idle* and *disorderly* persons, and may be committed by a single magistrate to hard labour in the house of correction for any time not exceeding one month:—1. Every person able to maintain himself and his family, refusing or neglecting to do so, whereby he or his family become chargeable to the parish; 2. Every person returning and becoming chargeable to a parish from which he has been legally removed by order of two justices without having a certificate of his settlement in some other parish from the officers of such parish; 3. Petty chapmen or pedlars wandering abroad and trading without licence; 4. Prostitutes wandering in the streets or highways, or in any place of public resort, and behaving riotously or indecently; 5. Every person wandering abroad or placing himself in any public place to beg and gather alms, or procuring any child to do so. To which other statutes have since added:—6. Paupers in workhouses, not doing task-work when required, or injuring their clothes or damaging the property of the guardians; 7. Women neglecting to maintain their illegitimate children; and, 8. Persons applying for relief as paupers, having possession of money, &c., of which they do not make disclosure. These offenders are punishable by a single justice with one month's imprisonment and hard labour.

The 4th section of the 5 Geo. IV., c. 83, declares the following persons to be *rogues* and *vagabonds*, and empowers a single magistrate to commit them to hard labour in the house of correction, for any time not exceeding three months:—1. Every person committing any offence which would constitute him an idle and disorderly person; 2. Every person pretending to tell fortunes, or using any device, by palmistry or otherwise, to deceive and impose upon the people; 3. Every person wandering abroad and lodging in any barn or outhouse, or in any deserted building, or in the open air, or under a tent, or in any cart or waggon, not having any visible means of subsistence, and not giving a good account of himself; 4. Every person wilfully exposing to view in any street, road, highway, or public place, any obscene print, picture, or other indecent exhibition. (By 1 & 2 Vict., c. 38, this provision is declared to extend to exposing such articles in a shop window.) 5. Every person wilfully and obscenely exposing his person in any street or highway, or in the view thereof, with intent to insult any female; 6. Every person wandering abroad and endeavouring by the exposure of wounds or deformities to gather alms; 7. Every person going about as a gatherer or collector of alms, or endeavouring to procure charitable contributions under a false pretence; 8. Every person running away and leaving his wife actually or probably chargeable to the parish; 9. Every person playing or betting in any street, highway, or public place with any table or instrument of gaming, at any game of chance; 10. Every person having in his possession any picklock-key, crow, jack, bit, or other implement, with intent feloniously to break into any house, &c., or being armed with any gun, pistol, hanger, cutlass, bludgeon, or other offensive weapon, or having upon him any instrument with intent to commit any felonious act; 11. Every person, being found in any dwelling-house, warehouse, coach-house, stable or outhouse, or in any inclosed yard, garden, or area for any unlawful purpose; 12. Every suspected person or reputed thief frequenting any river, canal, or navigable stream, dock, basin, or any quay, wharf, or warehouse near or adjoining thereto, or any street, highway, or avenue leading thereto, or any place of public resort, or any avenue leading thereto, or any street, highway, or place adjacent, with intent to commit felony; 13. Every person apprehended as an idle and disorderly person, and violently resisting any peace-officer so apprehending him, and being subsequently convicted of the offence for which he shall have been so apprehended.

Incorrigible rogues are—1. Persons breaking or escaping out of any place of legal confinement before the expiration of the term for which they shall have been committed, or ordered to be confined by virtue of the statute; 2. Persons committing any offence against the statute which subjects them to be dealt with as rogues and vagabonds, such persons having been at some former time adjudged so to be and duly convicted thereof; and, 3. Every person apprehended as a rogue and vagabond, and violently resisting any constable or other peace-officer so apprehending him, and being subsequently convicted of the offence for which he shall have been so apprehended. These offenders are to be committed to the next sessions, and kept to hard labour in the interim; and the sessions may further punish them by imprisonment with hard labour for one year, and if males, with whipping.

The statute, besides the definition of the facts and circumstances which are to constitute offences in the several classes above enumerated, contains various provisions for the prosecution of vagrants and the regulation and disposal of them. Thus it is enacted that any person may apprehend a vagrant and bring him before a magistrate. The persons as well as the carriages or luggage of the several descriptions of vagrants may be searched, and money or goods found upon them may on their conviction be applied towards the costs of apprehending them and maintaining them in prison. If proceedings at the sessions are contemplated, either by reason of an appeal against a summary conviction or the commitment of an incorrigible rogue, the committing magistrate may bind over witnesses to prosecute, and the justices at sessions may order the payment of costs to persons so bound. And an appeal is given to the next sessions to any person aggrieved by an act or determination of any magistrate out of sessions concerning the execution of the act.

VALERENE. [VALERIANIC GROUP.]

VALERIA'NA OFFICINALIS—*Medical Properties of.* The root, or more properly the rhizoma with its root-fibres, of this species, particularly the variety termed *sylvestris*, is used in medicine. It should be collected in spring before it shows flower, or late in autumn. It is best from plants of two or three years old, which grow in elevated stony places, rather than in very moist meadows. It varies considerably in appearance and in its sensible properties, according to the age of the plant, its place of growth, and the length of time it has been kept. The rhizoma is small, short, rounded or oblong, truncated, furnished with very many root-fibres, which are about the thickness of a straw, and from two to six inches long; the colour of the freshly obtained root is a dirty yellowish-white; the consistence fleshy; by drying, which is easily effected, it becomes wrinkled, more yellow or brownish, and in time dark. The root gathered in spring becomes most wrinkled. The odour is heavy, penetrating, and very characteristic. This odour is stronger in the dried than the fresh root, and is scarcely impaired by time, even when the access of the air is freely allowed. The taste is acridly aromatic, camphoraceous, and bitter. The English Valerian is the most esteemed: it is abundant in Hampshire, formerly in Kent and Essex, and the wild plant is to be preferred to that which is cultivated for medical use. It is to be regretted that this root is often confounded or fraudulently adulterated with that of the *Valeriana dioica*, which is smaller and of much feebler odour, and that of the *Geum urbanum* or *avens*, which is pleasantly aromatic. Much more serious is the confusion, probably always accidental or merely from ignorance, of the genuine root with those of several species of ranunculus, or crowfoot, namely, *R. repens*, *acris*, and even *polyanthemos*, also those of *Sium angustifolium* and *S. latifolium*, or more rarely *Helleborus niger* and *Asclepias Vincetoxicum*; but the absence of the peculiar odour of valerian, or the presence of a very repulsive one, may always distinguish them with moderate attention.

According to the analysis of Trommsdorf ('Journal der Pharmacie,' xviii., p. 8), 100 parts of the dried root yield of volatile oil 1·2, peculiar resinous extractive (termed valerianin) 12·5, gummy extractive 9·4, soft resin 6·2, woody fibre 70·7; by distillation a volatile fatty acid termed valerianic acid is obtained, besides the volatile oil. The medicinal action is chiefly due to the volatile oil and extractive. Valerian is considered a *cerebro-spinal* stimulant, large doses of it causing marked excitement of the nervous system, not only of the human race, but also of cats, which are remarkably fond of it. In the slighter forms of nervous diseases not dependent on any change of structure of the brain or spinal cord, valerian is of considerable utility. In several instances, especially if there be much acidity of stomach, its beneficial effects are increased by combination with ammonia. In other instances valerian (in powder) greatly heightens the tonic power of the *disulphate of quinia*, the absence of all aroma from which renders it inferior as a tonic to many of the other forms of administering bark. [CINCHONA.]

Valerianic acid, combined with various bases, such as iron, zinc, quinine, &c., furnishes compounds of great value as antispasmodics—more useful than any of these agents singly.

VALERIANIC ACID ($HO,C_{10}H_9O_3$). *Valeric acid. Delphinic acid. Phocenic acid.* This body exists in valerian root, hence its name; in the oil secreted by several species of phoca (hence *phocenic*) and cetacea, and in the berries of the guelder rose. It is also a product of the action of caustic potash on oil of camomile; of oxidising agents on fats; is often present in decaying cheese; and is formed on passing amylic alcohol (fousel or fusel oil) vapour through a tube containing the hydrates of soda and lime heated to 400 Fahr. In the latter process valerianate of soda is produced, which, when cool, must be plunged rapidly into cold water, or it would take fire spontaneously. The aqueous solution acidified with sulphuric acid and distilled furnishes valerianic acid. Another and more convenient method is to distil a mixture of amylic alcohol, bichromate of potash, and sulphuric acid :—

$$\underbrace{C_{10}H_{11}O,\ HO}_{\text{Amylic alcohol.}} + O_4 = 2HO + \underbrace{HO,\ C_{10}H_9O_3}_{\text{Valerianic acid.}}$$

Some valerianate of amyl also passes over; the distillate should therefore be heated with caustic potash when amylic alcohol is volatilised: the residual valerianate of potash may then be decomposed by sulphuric acid and the mixture distilled, when pure valerianic acid will be obtained.

Valerianic acid forms two hydrates. When it is separated from the aqueous solution of a valerianate by a stronger acid, it contains, according to Liebig, three atoms of water, of which two may be separated, by distillation, in the state of pure water, which afterwards becomes milky, and at last the colourless monohydrate passes over in distillation.

This monohydrate is oleaginous, very fluid, of an acid penetrating odour, like the valerian root; its taste is acrid and sharp, with a sweetish after-taste; it produces a white spot on the tongue. It does not become solid at 0° Fahr. Its density is 0·937, and it boils at 347° Fahr. The terhydrate boils at about 270°. The monohydrate dissolves in 30 parts of water at about 53°: it dissolves in all proportions in alcohol, ether, and crystallisable acetic acid; sulphuric acid when heated carbonises it. It dissolves iodine and camphor.

Valerianic acid combines with bases to form salts, which are called *valerianates*; the potash and soda salts are very soluble, deliquescent, and crystallise with difficulty. The valerianates of lime and baryta are also very soluble, but they are crystallisable and unalterable in the air; the magnesian salt crystallises in efflorescent needles. The pure monohydrate absorbs much ammonia, becoming, after a time, a solid mass of snow-white, non-deliquescent, crystals of valerianate of ammonia. Valerianate of zinc, readily prepared by double decomposition and used to some extent in medicine, is a pearly white salt, having a faint odour of valerianic acid and a metallic astringent taste.

Chlorovalerisic Acid ($HO,C_{10}(H_6Cl_3)O_3$) and *chlorovalerosic acid* ($HO,C_{10}(H_5Cl_4)O_3$) are formed when chlorine gas is passed into valerianic acid. They are heavy colourless, inodorous liquids, and form well-defined, stable monobasic salts. From the amount of chlorine in them, these acids are sometimes termed *trichlorovalerianic* and *tetrachlorovalerianic acid.*

Nitrovalerianic Acid ($HO,C_{10}(H_8NO_4)O_3$) is a volatile, beautifully-crystalline body, resulting from the prolonged action of the strongest boiling nitric acid on valerianic acid. It is sublimable and forms stable salts.

Valerianic anhydride or *anhydrous valerianic acid* $(C_{10}H_9O_3)_2$ is formed when one part of oxychloride of phosphorus is gradually added to six parts of dry valerianate of potash; the product is washed with dilute solution of carbonate of soda, digested in ether, the etherial solution dried with chloride of calcium and evaporated, when valerianic anhydride is left as a colourless liquid of agreeable odour; sp. gr. 0·934; boiling point, 419° Fahr.; vapour density, 6·23.

VALERIANIC GROUP. A cluster of chemical substances, each supposed to contain, or be derived from, the theoretical radical *valeryl* ($C_{10}H_9O_2$).

Valerianic acid is best produced by the action of strong oxidising agents on fusel oil. [VALERIANIC ACID.]

Valeryl-aldehyd or *valeral* ($C_{10}H_9O_2$, H), *hydride of valeryl,* is formed on oxidising fusel oil (amylic alcohol) with less powerful agents than those necessary to form valerianic acid. Thus a mixture of bichromate of potash, sulphuric acid, and fusel oil furnishes valeral. It is purified by mixing with a saturated solution of bisulphite of soda, recrystallising the double salt thus formed, distilling with carbonate of potash, and drying the distillate over chloride of calcium. Valeral is a colourless limpid liquid of powerful penetrating odour, and burning taste; soluble in alcohol, ether, and the volatile oils; insoluble in water; burns with a bright flame; boils at 230° Fahr.; vapour density, 2·96; specific gravity, at 71° Fahr., is 0·820; oxidising agents convert it into valerianic acid, and ammonia combines with it to form crystalline *valeryl-aldehyd-ammonium* or *valerylide of ammonium* ($C_{10}H_9O_2$, NH_4).

Valeraldine ($C_{30}H_{31}NS_4$) results from the action of sulphide of hydrogen on valeryl-ammonium suspended in water containing a small quantity of free ammonia :—

$$3(C_{10}H_9O_2,\ NH_4) + 6HS = C_{30}H_{31}NS_4 + 6HO + 2NH_4S$$

It is an oily, volatile, alkaline liquid of disagreeable odour, and combines with acids to form salts.

Leucin, a body associated with the chemistry of animal substances, appears to be a valeryl derivative, inasmuch as it may be formed by the action of hydrocyanic and hydrochloric acids upon valerylide of ammonium. It is treated of in detail in a separate article. [LEUCIN.]

Chloride of valeryl ($C_{10}H_9O_2$, Cl) is formed on reacting with protochloride of phosphorus and monohydrated valerianic acid. It is a colourless mobile, fuming, liquid; rather heavier than water, and boils at about 240° Fahr.

Bromide of valeryl ($C_{10}H_9O_2$ Br), is obtained in the same manner as the chloride, the bromide instead of the chloride of phosphorus being used. It boils at about 290° Fahr.

Valerone ($C_{18}H_{18}O_2$), the *valerylide of butyl* (C_8H_9, $C_{10}H_9O_2$), is a light colourless liquid of agreeable ethereal odour, produced when valerianic acid is distilled with excess of lime. A mixture of valerate of potash and acetate of soda yields, by distillation, an oil which is probably *valerylide of methyl* (C_2H_3, $C_{10}H_9O_2$).

Valeramide $\left(N \begin{cases} C_{10}H_9O_2 \\ H \\ H \end{cases}\right)$ is formed by boiling valerianic ether (valerate of ethyl) with strong ammonia: on concentrating and cooling the solution, valeramide crystallises out in brilliant plates. It is neutral, fusible, volatile, and soluble in water, alcohol, or ether. Heated with phosphoric anhydride it loses the elements of water and is converted into *cyanide of butyl* (C_8H_9, NC_2) or *valeronitrile* ($C_{10}H_9$, N).

Valeronitrile is also one of the products of the oxidation of gelatin by chromic acid; it is accompanied by another somewhat similar liquid *valeracetonitrile* ($C_{26}H_{21}N_2O_6$). *Valeranilide* or *phenyl-valeramide* $\left(N \begin{cases} C_{10}H_9O_2 \\ C_{12}H_5 \\ H \end{cases}\right)$ is produced on digesting valerianic anhydride and aniline together. It crystallises in long, brilliant needles, slightly soluble in water, but very soluble in alcohol; melts at 239° Fahr., and boils without decomposition at 428° Fahr.

Valerins. Combinations of valerianic acid and glycerin. Three of these have been obtained, namely:—

Monovalerin . .	$C_{16}H_{16}O_8 = C_{10}H_{10}O_4 + C_6H_8O_6 - 2HO$
Divalerin . . .	$C_{26}H_{24}O_{10} = 2C_{10}H_{10}O_4 + C_6H_8O_6 - 4HO$
Trivalerin . .	$C_{36}H_{32}O_{12} = 3C_{10}H_{10}O_4 + C_6H_8O_6 - 6HO$

The proportion of the constituents, the temperature employed and the state of concentration of the mixture, determines which of the three shall be formed. *Valerochlorhydrin* is a valerin containing the elements of hydrochloric acid.

Valeryl-urea or *valerureide* has already been alluded to [UREA].

Oil of valerian, obtained as described under ESSENTIAL OILS, generally contains about 5 per cent. of valerianic acid; 25 per cent. of a neutral volatile hydrocarbon, boiling at 160° Fahr., and termed *valerene* ($C_{20}H_{16}$), identical with the borneene of Borneo camphor; and about 70 per cent. of an oxidised portion containing resin and valerol. *Valerol* ($C_{24}H_{20}O_2$) is a stearopten, and condenses as a crystalline solid in the neck of the retort in which the oil of valerian is fractionated. It is lighter than water, in which it is insoluble; is readily dissolved by alcohol, ether, and essential oils; is resinified slowly in the air, more readily by nitric acid; and with sulphuric acid forms blood-red *sulphovalerolic acid.*

VALLEYS. The term Valley, from the Latin *Vallis* or *Valles,* of the same signification generally, may be applied, in its most comprehensive meaning, to any depression on the surface of the globe. "The largest valleys form the beds of the great oceans. Seas, bays, gulfs, &c., are all valleys below, or partially below, the level of the sea." But in the common acceptation of the term, valleys are those depressions which are observable above the sea-level, separating or intersecting mountain-ridges, and in fact breaking them up into separate mountain-masses, and in which are the basins of inland seas and lakes, the beds of rivers, &c. Mountains and hills, therefore, are the boundaries of valleys. Occasionally a valley is formed by a ridge of elevated land entirely, or almost entirely, surrounding the basin of an inland sea or of a lake. The word *vale,* sometimes employed synonymously, is the diminutive, but is more properly applied to the depressions between eminences of moderate elevation, or hills, which, together with them, form what is called undulating country. Valleys parallel to the mountain-ridges or chains which they separate, or which bound them, are said to be longitudinal; while those the direction of which is transverse are so called. Both may be principal or lateral, the latter designation being usually applied to the smaller transverse valleys uniting the principal. But these epithets admit of innumerable variations, and merge, in fact, into common descriptive language.

The citation above, in which the term valley is applied to the depressions filled by sea, is from an unquestioned authority, the Rev.

C. G. Nicolay, in the 'Manual of Geographical Science.' But though the sea-basins or ocean-hollows may be included within the necessary geometrical definition of valleys, as being depressions below the average level of the external surface of the solid crust of the globe, and continents and islands within that of mountains, as being elevations above it, we conceive that some distinction in this respect should be established in the nomenclature of geology and physical geography. The surface of the globe above which continents and islands are raised, —that is, the bed of the sea, universally,—cannot be considered as identical, as a geographical or geological element, with the surfaces of those masses of land themselves, on which are the minor, and in this sense secondary, elevations and depressions we commonly call mountains and valleys. Many of the phenomena of configuration and physical state presented by the latter could only have been occasioned by causes connected with the agency of an aërial atmosphere; and while many of them also have had a subaqueous origin, yet the configuration of those parts of continents and islands which are below the level of the sea must have been received from operations exclusively subaqueous. The forms of the proper surface of the land were produced originally by its elevation through the surface of the ocean to a subaërial position above it, and have been completed by atmospheric and fluvial erosion.

Many valleys, for example, were first excavated by marine currents during their elevation, and have been reduced to their present figure by the rivers which have flowed through them from the period of the elevation above the sea-level of the eminences which bound them.

But the forms of the masses constituting continents and islands have been produced by the agency of elevatory and marine forces only, except in the cases of the subsidence of land previously fashioned more or less by atmospheric action. However, the chief differences, probably, between the configurations of the surface of the land and those of the more extended surface consisting of the sea-bed and the land regarded as one, depend on their relative magnitude and on the depth of the sea, which, in fact, is merely the measure of the vertical dimensions of the latter. Around the islands of that part of the Indo-Australian archipelago which is physically a portion of Asia, the sea is so shallow that those islands may truly be regarded as the summits of mountain-masses separated by valleys of very inconsiderable depth, inferior indeed to that of many of the terrestrial valleys upon them. Those islands are in fact united by a vast submarine plain, which abruptly terminates westward near the north-eastern coasts of Borneo, in the middle of the Straits of Macassar, and in the Strait of Lombock, in an unfathomable ocean. We then come to the island-masses of Lombock and the chain immediately to the west, the Moluccas, New Guinea, and the other Australian islands, rising abruptly again from the bottom of this ocean, and thus exemplifying one of the peculiar characters of the masses of land which rise from and bound ocean-hollows; and how characteristic of them is the form thus produced will appear in the sequel. Islands fundamentally volcanic—especially if, like Teneriffe, they contain one principal volcano—are probably altogether conoidal, the submarine portion being merely the continuation of the subaërial. [VOLCANOS.]

Another difference, originating in the different process of formation, is this: while mountains proper have characteristically smaller dimensions above than below, and thus approximate more or less nearly to the figure of triangular prisms, of pyramids, or cones, their altitude being their principal dimension, the masses of continents and islands are tabular in form, with sides of every degree of obliquity, and sometimes very nearly vertical, their upper surface being much greater in area than their sides, their altitude being their least dimension, and their form thus approximating to that of a low parallelopiped. Valleys proper, again, are widest at the top, and approach in general to the form of an inverted triangular prism, more or less obtuse or acute, or to that of an inverted pyramid, or to the frustum of such a prism or pyramid, the edge or apex being replaced by a plane—the floor of the valley; while the intervals between continents are almost as tabular in form as the masses of the land, but their lower surface, while its area is much greater than that of the sides, being less than the upper formed by and at the level of the sea. [SOUNDINGS, DEEP SEA.]

The configuration of land above the level of the sea which most nearly resembles the continental masses is that which is called *Table-land*, such as the table-lands of Tibet, Eastern Africa, and Mexico; and the intervals which separate different portions of them most nearly answer to the ocean-hollows between continents. As an example of this may be cited the hollow between the table-land of Tibet on the south, and its recurvature called the Thian-Shan, being a portion of North-Western China, on the north, of which the plain or plateau of Yarkend and Khotan, and what is termed the valley of Lake Lhop, form the base, and which, if we compare the two portions of the table-land to mountains, will answer to a valley, according to the common mode of description. [PLAINS.] This comparison will hold good, and is illustrative in another respect. Colonel Strachey, in his 'Physical Geography of the Himalayas' (not yet published, but quoted in 'Phil. Trans.,' 1859, pp. 774–776), represents that "the summit of the table-land (of Tibet), though deeply corrugated with mountains and valleys in detail, is in its general relief laid out horizontally." This description will accurately apply to the mass of elevated land which forms a continent or great island, of which it may always be said that while its summit is corrugated with valleys and mountains, it is in its general relief horizontal.

We are led by the previous comparison, and on further investigation, to the apparent fact, that some portions of the earth's surface, however, above the sea-level, present us with the essentially unaltered configuration of other portions which are still below it. From the united geographical researches and inductions of Dr. Thomas Thomson, Dr. Joseph D. Hooker ('Himalayan Journals,' vol. ii., p. 399), and Professor James D. Forbes, it has appeared that the structure of Norway very closely resembles, on a small scale, that of Central Asia, particularly of the Himalaya; and that if it were so elevated that the bottom of the deep fiords which penetrate it became dry land, we should have a model of the Himalaya, with its deep valleys and high acute summits; or, conversely, if the latter country were depressed, so that those valleys became ocean-hollows, the land and mountain-peaks remaining above the sea-level would correspond, on the great scale, to the mountain-peaks of Norway, and the submerged valleys to the fiords. Dr. Thomson ('Western Himalaya and Tibet,' p. 492) has extended this comparison to the structure of Scotland, well known to resemble that of Norway, and to be, in fact, a continuation of it. He has also described (pp. 429–438) the remarkable elevated plain of Karakoram, south of the pass of that name, occupying an immense concavity in the great chain of the Kouen-lun, the northern face of the table-land of Tibet. It measures from six to eight miles in diameter, and has a mean altitude of not less than 17,000 feet, being surrounded by great depressions separating it from the mountains. It has the appearance of having formerly been the bed of a lake, but is itself crossed by several ranges of hills, and by a rivulet, and has a water-parting. This is evidently the configuration of an island in the ocean, agreeing, therefore, with the examples above described.

Conversely, a portion of the bed of the Atlantic, from the coast of Ireland westward, has a configuration resembling that of the land of Western Europe; but still further west, the great Atlantic depression, very unlike a terrestrial valley, commences abruptly, the depth of the sea increasing, within a distance of twenty miles only, from 1320 to 9000 feet, forming a sort of marine cliff on a gigantic scale. For at least a thousand miles the whole surface is one vast depressed plateau, which, according to Professor Ansted (in his 'Geological Gossip,' a work deserving of a more appropriate title), is "totally unlike any equal extent of dry land, though more resembling that on the eastern side of the Andes, in South America, than any other known land." On the (North) American side of the Atlantic plateau "there is a second cliff, facing eastward, having a total rise of about 5000 feet, immediately to the west of which the ground slopes gradually upwards at the rate of about forty feet in a mile, till it reaches the American continent."

We thus arrive at the final confluence of the two branches of the subject. The elevations and depressions of certain parts of the globe, of various magnitudes, closely resemble some of the continental masses and ocean-hollows; while the latter more generally have a distinct and peculiar character; and the corrugations of the upper surface of those masses, ordinarily termed mountains and valleys, in their actual condition, usually differ from both, as already represented. In a paper 'On the Lines of Deepest Water around the British Isles,' by the Rev. R. Everest, F.G.S., read before the Geological Society of London, on June 19th, 1861, and which will probably appear in the 'Quarterly Journal' of that Society, the student will find new materials for pursuing this particular subject.

Some geographical observers, because a river-basin (defined in the article RIVERS) is necessarily bounded by high land, except where it declines to the sea, employ the terms "basin" and "valley" of a river indiscriminately and convertibly. Thus, Mr. Alfred R. Wallace begins the chapter of his 'Travels on the Amazon and Rio Negro,' headed "The Physical Geography and Geology of the Amazon Valley," with the statement that "the basin of the Amazon surpasses in dimension that of any other river." Now, although, strictly speaking, the difference between river-valleys and -basins is comparative only, and merges in nature, yet this practice leads to erroneous conceptions of fact; for though a wide valley, through which a river of moderate dimensions having many small tributaries takes its course, may be termed a basin (sometimes called a valley-basin), yet the main stream, as well as its tributaries, must each have its own separate valley, however shallow: such is the Thames, which is described as having a basin, while its valley is often not recognised, though some of its affluents flow through well-characterised valleys. [THAMES, in GEOG. DIV.] On the other hand, the basin of a great river may, and in fact must, include many such wide valleys; and a river-basin, more properly, is the country which is made up of them, and the drainage of which at last finds its way into one stream, and through one principal outlet into the ocean. In this sense, the depression through which the upper course and affluents of the river flow may sometimes be regarded as the basin, while that giving passage to the lower course is properly termed its valley. In the case of the Nile, the depression through which the single stream runs for 1300 miles, from the junction of its last affluent, the Atbara, to the Mediterranean, that is, its lower course, is properly the valley of that river; while its basin comprehends a vast extent of country in Africa, to the eastward, southward, and southwest of that point, made up of many valleys of large dimensions, some giving passage to its great head-streams and tributaries, and almost all to considerable rivers, the affluents of the former respectively.

A form of valley to which the convenient appellation of valley-plain has been given is that which exists when an extensive horizontal surface of land at any elevation, and generally of greater length than width, is surrounded by continuous ranges of mountains rising from and above it. Of this form the so-termed Vale of Tenochtitlan, usually called, after Humboldt, the Valley of Mexico, and the plain, valley, or "Vale" of Cashmere, are examples. The latter is, in fact, the valley of the river Behat or Jelam (by which, however, at least in its present form, it was clearly not excavated), and the inclosed plain, as in many cases of this description, has once been the bed of a lake, and consists, itself, of a lacustrine formation. It depends on the extent of the plain, its degree of unevenness, and the inclination of the slopes, whether or not it shall become and deserve to be called a river-basin.

Another form of valley is the circular spiral, alluded to in the article Rivers, col. 115. This has been noticed, hitherto, in Eastern Africa only, in the basins and valleys of the eastern affluents of the Nile. Though plainly shown, in one instance at least, in the maps of Abyssinia constructed at the beginning of the 17th century by the Portuguese Jesuit missionaries, Dr. Beke appears to have been the first geographer of modern times to call attention to it, and that from his own explorations. In reference to the Mareb, one of the tributaries of the Atbara, already mentioned, he points out "the remarkable peculiarity which it possesses, in common with many of the rivers of the Abyssinian table-land, of returning on itself, so as to perform a sort of spiral course." The river Abai, or the Nile of Bruce, for example, has a circular spiral course round the peninsula of Gódjam; and while forming this curve, or flowing in a valley of the same figure, it is joined by numerous streams, having their sources in the mountains forming the conoidal core of the peninsula. Dr. Beke has recorded his opinion of the probability that the head-stream of the Nile itself has such a circular spiral course, and therefore flows through a valley of that figure, around a lofty mountain-mass, similar in character to the snow-capped mountains of Samien and Kaffa, in Abyssinia, around which some of the rivers alluded to take their own curved course. This remarkable subject will be noticed again in the geological part of the article. ('Sources of the Nile,' pp. 10, 28; 'Journal of Royal Geographical Society,' vol. xvii., pp. 5, 81.)

In the article Rivers, col. 113, the Arabian *wadies* have been noticed as the winter-brooks of the countries of which they are characteristic. But this is a figurative use of the term. A *wady*, the correlative of the Hebrew *nachal* (not *nahar*, with which it is confounded in the authorised version of the Scriptures, but which is a river proper), is originally a valley of a peculiar kind. It is a depression, more or less deep or wide or long, worn or washed by the mountain torrents, or winter rains for a few months or weeks in the year. In the article Deserts, col. 481, the *oases* have been described, after Malte-Brun, as rising in the midst of the sands like islands in the ocean. If we consider the sources of the springs of water which supply them, and to which they owe their existence, to be included in the locality designated an *oasis*, this description is correct. But the oasis itself, like the wady, is properly a species of valley. What the oasis of Ammon, in the western desert of the Nile, "is on a great scale may be seen on a small scale elsewhere; namely, deep depressions of the high table-land, which thus became the receptacles of all the rain and torrents, and, consequently, of the vegetation and the life of the whole of that portion of the desert. These oases, therefore, are to be found wherever the waters from the different wâdys, or hills, whether from winter streams," or from the few living perhaps perennial springs of the country, "converge to a common reservoir." We are indebted for these explicit characters of geographical features much oftener alluded to than understood, to the Rev. A. P. Stanley, who, in his 'Sinai and Palestine,' has so well described the details of the physical geography of those countries.

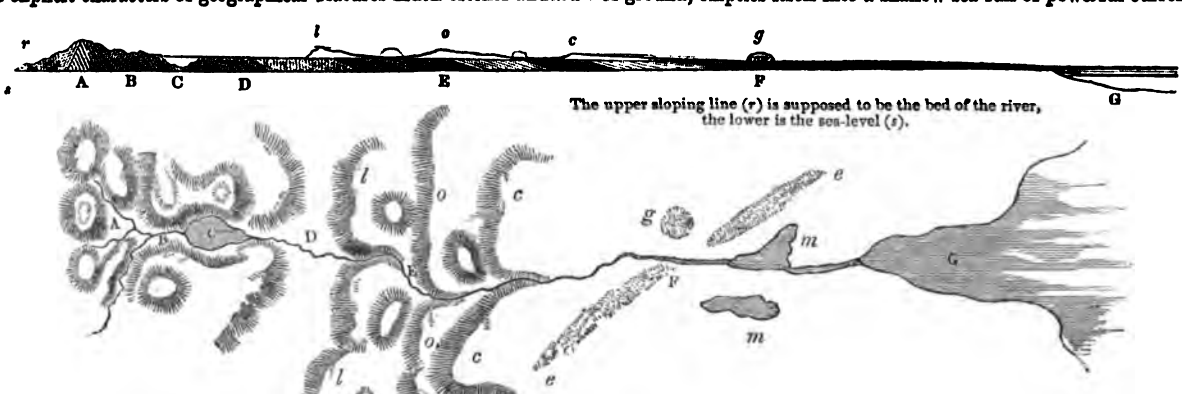
The preceding statements and views relate principally to the subject of valleys geographically considered: their geological history is discussed in the following essay, which originally constituted the article. We have now appended to it some facts and considerations disclosed by and arising from the subsequent progress of geology.

"Why has the earth any mountains?" is the question from which De Luc, writing in 1792, sets out to expound his whole geological system; and to answer at the present time the corresponding question, Why has the earth any Valleys? requires reference to almost the entire series of general truths which have been established by investigation into the structure of the crust of the globe. For in these hollows on the surfaces of plains, hilly slopes, and steep mountains, we behold not only the results of atmospheric agencies, both chemical and mechanical, and of the flowing of streams, operating under the actual conditions of nature on materials of unequal induration, but also the earlier effects of other watery agencies, under other physical conditions, on materials differently circumstanced, both as to their consolidation and their position in reference to the general curve of surface of the globe and the relative level of the sea. The origin of valleys ascends to the earliest geological eras, but their completion includes the latest phenomena produced in our own days.

To discuss the literary history of this celebrated question, and estimate the degrees of truth attained in the conflicting hypotheses of Dr. Hutton and De Luc—which may stand as the types of two great classes of rival speculations, not yet completely reconciled—would be a long, intricate, and unfruitful labour. The problem to be solved has seldom been seized by any but the most modern writers in all its generality; and the partial solutions, really arrived at in particular cases, were not permitted to have even the value which limited truths often do possess, because they were unwisely made the basis of what was called a general theory. Though De Luc could prove that valleys on whose line were deep lakes could not have been excavated by the streams now running in them, he was scarcely entitled to say that "all the notions of the great ravages produced by the rain-waters upon our continents since their existence have been mere illusions." (Letter I. 'On Geology.') And Dr. Hutton might have carried his pupils beyond the mechanical effects of "rivulets that run only in time of rain," before he required them to admit "the great fact, that rivers have in general hollowed out their valleys." (Playfair's 'Illustrations of Huttonian Theory,' Note xvi.)

Theories thus supported were only successful in destroying each other: modern geology has been advanced by a very different process. Mr. Lyell, M. D'Halloy, Mr. Scrope, and other modern writers, have contributed similar partial solutions of particular cases, by careful investigation of the features of the valleys of Auvergne, Belgium, and the Rhenish provinces (see cols. 541–2); but to obtain a general view of the theory of valleys, we must add to these many other equally established local results. This necessity is indeed virtually acknowledged by the eloquent writer to whom the Huttonian hypothesis owes its celebrity, for even while he declares the great hollow of the Valais to be the work of the Rhône, he adds, this tract, when the Alps rose out of the sea, may have included many depressions of the surface which the river joined together, and, from being a series of lakes, became one great valley.

To take the problem of the formation of valleys in all its extent, let us trace in imagination the course of a considerable river, which, commencing in a mountain-ridge, runs to the eastward, namely, in the direction of the dip of the strata, and, after traversing the usual variety of ground, empties itself into a shallow sea full of powerful currents.



The upper sloping line (r) is supposed to be the bed of the river, the lower is the sea-level (s).

A. The summit of drainage between one river area and another being supposed to be below the level of perpetual snows, we find, above the permanent sources of many rivers, occasional feeders, which depend on particular falls of rain, becoming dangerous torrents or appearing as mere lines of pebbles according to the state of the weather. After heavy rains the hill-sides of the highland districts of Scotland, Wales, and Cumberland are whitened by abundance of short-lived torrents, which hurry down considerable heaps of the loosened materials of the hills, and spread them into little deltas on the margin of the valley below. Similar effects on a particular slope follow the bursting of a waterspout (High Pike, in Cumberland) [WATERSPOUT], or the intumescence of a wet peat-bog (above Keighley, Yorkshire). Frost and the sun's heat are felt in extreme in the high regions which give birth to rivers, and by their alternation the rocks are broken and disintegrated. To these regions Hutton and Playfair rightly propose to carry their pupils for the purpose of impressing upon their minds the extensive waste produced on the earth's surface by modern causes in action. Examples are everywhere abundant: Glen Coe, Borrowdale, Snowdonia, may be cited. (N.B. The *general* features of the higher parts of mountain-valleys are nearly the same around glaciers, and these features are liable to change by the violent alternations of temperature.)

B. The second stage of valleys is that which admits of the union of permanent natural springs to the occasional hill-side floods, and of the gathering of these streamlets into a rapid and agitated river. The now augmented water is often confined in a narrower glen than any of its tributaries, and rushes and cascades among rocks and mounds, which are so disposed as to show proof that the course of the stream has varied from time to time, as the levels changed, in consequence of eroding action.

C. At length the glen opens in a pebbly plain, or sinks into a broad and quiet lake. Such lakes, or plains which seem to have been lakes, are of very general occurrence along the line of rivers, while they are engaged in the midst of their parent mountains (Derwent Water, Llanberis, Loch Tay). They even appear at the foot of particular mountains, receiving only occasional streams (Red Tarn, under Helvellyn), and in a very great variety of cases appear to be irregular hollows left after great disturbances of the stratification amongst the angularly posited masses of broken ground. Their depth is from a few feet to a thousand feet (Lake of Geneva) below the level of the valley; and as the rivers which enter the upper ends there lose their force in the expansion of water, and drop their transported sediments, the *growth of new land* in that part of such lakes is proportioned to, and is in truth a measure of, the whole effects of those rivers in transporting away the detritus of the mountains round their source. Such lakes then are ***natural dynamometers***, which may with proper caution be used to determine the amount of transported materials delivered into them in given times by rivers; they also give the sum of all the effects of this kind performed by such rivers; and thus finally they are ***natural chronometers;*** for by dividing, in any particular case, the integral effect or mass of deposited materials by the rate of annual progress, an approximate answer in years is given to the question of the length of time which has elapsed since that river began to flow. By this argument De Luc arrived at the conclusion that the desiccation of our continents by elevation above the sea is a phenomenon of no very great antiquity, belonging to an epoch only a few thousand years removed from our own. Though geologists cannot, from the evidence of particular lakes in certain districts, adopt this conclusion for other districts where quite different phenomena appear, Professor Sedgwick and other eminent persons have declared the argument of De Luc, within its proper limits, to be unanswered and unanswerable. In all cases then where lakes are so interposed in the path of a river that they must be believed to have received all the sediments which that river has brought, the cubic volume of these accumulations in the lake may be compared with the cubic space of the concavities between the hills along the line of the rivers and rivulets above the lake; and if found to be inferior in a noteable degree, we may positively conclude that these concavities have not been produced, though doubtless they have been enlarged and modified, by the atmospheric agencies belonging to that particular area of drainage. Now this comparison has been often made, and generally with the positive result, that the excavation of the valleys above the lakes is not the effect of those watery agencies now exerted within them. Excavated however some of them have been by watery agency, and in all of them the surface slopes have been adjusted by this power, both in level and in direction, to the boundaries of the present lake; but we must avoid the error of assuming that no other currents having a different origin may have operated in those valleys before the existence of the lakes.

D. Beyond the region of the lakes, the rivers, flowing away from the rugged mountains, encounter ranges of stratified rocks, often very regularly inclined at a moderate angle, in parallel ridges and hollows which correspond to alternately hard and soft portions of the series of strata. If there were no gaps across these ridges, so as to connect their intervening hollows, each of these hollows would include one or many lakes, and the river whose course we are tracing could not pass over the first of the ridges until the hollow space between it and the lake district (C) was filled with water, generally at a high level. If such a circumstance were supposed ever to have happened, the waters might be imagined to make themselves a passage across this ridge, and, by like reasoning, across any lower ridges lying beyond. (See the figures above, and in art. GEOLOGY, in NAT. HIST. DIV.)

It sometimes happens that more than one group of such parallel ridges and hollows—as the mountain limestone group (*l*), followed by the oolitic ridges (*o*), or those by the chalk-hills (*c*)—lie on the course of even one river, and require the repetition of such phenomena to account for the course of the valley. But a greater difficulty must be encountered. The very hollows themselves in which these sheets of water are imagined to have spread are valleys, and yield as plain proof that they also have been excavated and modified by watery action, as the river-channels which cross them. For in the midst of such hollows, insulated hills (the unremoved portions of the same or the nearest superjacent strata) remain variously distributed, to mark the ancient height of the land therein, and attest the enormous degradation which has been there occasioned. If, then, the supposed lake gave the force to break over and cut through the inclosing barrier of rock beyond, so as to shape a course and descent to the river, the excavation of the space in which the lake was gathered was the fruit of earlier and different watery action. This conclusion is again and again forced upon our attention as we proceed along the line of the valley.

E. In crossing through the parallel ridges and hollows of hard and soft strata, the river is confined to steep, narrow, angularly bent passages among the hard rocks; but in the softer strata between them it flows and winds more at liberty, through wider spaces, which open far on each side, and bring additional supplies of water. In these hollows the velocity of the stream dies away, and the sediments derived from wasting of the adjoining high grounds fall on fertile meadows in floods or silt up their own channels in times of slack-water, while around appear insulated hills, left by the ancient water-currents which swept away the materials around them.

F. The river, on emerging from these ranges of secondary strata, enters a wide region of plains and low hills of gravel (*g*), rising irregularly amidst alluvial plains and marshes (*m*), amongst which, for a certain distance, the tide flows up the expanded river-channel.

Wherever these marshy plains and gravelly ridges are locally related by geographical situation and distribution to the main stream or smaller branches, so as to allow of the possibility of referring their formation to the action of the existing fluviatile and tidal currents, it would be false philosophy to look for a more remote or more general cause. This is often the case, perhaps generally so, with the alluvial sediments, for they contain often freshwater shells and other marks of limited lacustrine or fluviatile action; but it is seldom the case with the gravel beds and ridges. These often lie across the path of the river (*e e*), and often rise to a great height above it; often consist of stones not only beyond the present power of the river to transport, but such as do not occur *in situ* in any part of the area drained by its main stream or tributary waters.

Yet, from their form, distribution, and composition, there is no doubt that some have been wholly accumulated and all modified by water-currents; so that here again we have proof of the waste and remodelling of the surface of the earth by other forces than the existing atmospheric agencies.

G. On reaching the sea, we find the influence of the river prolonged into the salt-water, augmenting the mass of sediments drifted coastwise by the tide, and feebly assisting in the distribution of them. But the bed of the sea is unequal, soft, or rocky, excavated into hollows, and varied by sand-banks and gravel-beds, not unlike those on the neighbouring land, and even yielding, as they do, bones of gigantic extinct mammalia (Happisburgh coast [and in fact the eastern coast of England from Bridlington to beyond the mouth of the Thames]). These points of agreement between the actual sea-bed and the neighbouring lands mark some community of origin: the land has been raised out of the sea, and owes some of its irregularities to marine currents (as Buffon thought), or the sea's bed is subsided land. Each of these may be partially and locally true, but there can be no doubt of the sea-currents having power to alter the distribution of sand-banks and gravel-banks to some considerable, though not precisely known, depth; and as all the stratified crust of the earth has been once the bed of the sea, it is evident that the action of marine currents is a cause of universal application to the theory of the inequalities of the earth's surface, as well as of extraordinary power.

The slight sketch here presented includes phenomena which may be seen on the English rivers, though not all on one and the same stream: the description may be verified in every one of its stages a hundred times, and augmented with additional phenomena by any intelligent reader personally acquainted with the physical geography of Britain. Exactly similar phenomena, either all in the same order or variously associated, may be paralleled by instances selected from other parts of the world, and it only remains to apply a plain course of reasoning to them.

The action of atmospheric agencies, river-streamlets, and rivers, with or without lakes, with or without glaciers, is always one and the same: to degrade the high lands and to raise the low, and thus to equalise the levels, and to diminish the irregularities of the surface of the globe; and this because of the universal action of gravity, wherever there are weighty masses and inequality of level. The sea's action is similar, and though complicated by tidal fluctuations, as rivers and lakes are by drought and inundations, and by the variable influence of wind and temperature, its final results are of the same character.

This is indisputable. It is equally true that the direction of the existing watery agencies on the land is determined by the present relation of levels between the different parts of the land, and between the land and the sea. Moreover the effects of these agencies are perfectly adjusted to these levels. It follows inevitably that the sum of the effects of these existing agencies has been to diminish the original inequalities of the earth's surface, that is to say, to lower the hills, to smooth and level the valleys, to fill up the lakes, which are a part of the valleys; in a word, to change gulfs into lakes, and chasms into vales, by a mere surface action on forms which had been more boldly marked in earlier eras of nature.

We must therefore believe that immediately after the desiccation of the land, its grand chains of mountains and long continuous vales were more firmly outlined, more roughly and strongly modelled, deeper and higher than they now appear, and it only remains to inquire to what known geological causes this can be justly ascribed.

We must remember, first, that the surfaces of stratification on the sea's bed were once continuous, but on the land they are now interrupted by excavated valleys and left dismembered on residual hills: secondly, that these surfaces were plains or nearly so, and horizontal or nearly so; but now they are found contorted, ruptured, placed in angular positions, vertical, or even reversed in particular regions. The latter class of effects depends on the violent nature of the elevating movements to which the land was subject; the former is often independent of local disturbance, and seems to be due to the mere action of powerful currents of water. But it is often seen that the line of these valleys is the line of a fault, of a synclinal basin, or anticlinal ridge, that is to say, *a line of weakness*, a line of least resistance, determined by causes anterior to the current of water which, flowing up or down the line, or both up and down, has worn it into a valley.

Now if we remember that the most powerful mechanical action of water takes place on the seacoast; if we remember that, by the continual or the periodical rising of the land, this littoral action has been transferred from point to point over every part of the area of the land, beginning among the mountains at the source of the present rivers, and successively washing and wasting every part; we shall readily admit in this one universal and powerful agency the principal cause which broke the continuity of the planes of strata, washed away the least resisting and left the hardest parts, and, by successively retiring lines of action, gradually completed the main features of the valleys and hills which had not been previously impressed by violent subterranean movements.

Atmospheric agencies must be admitted to have greatly co-operated in this result, especially if, as geologists suppose, there were grounds for believing these to have been more powerful in the earlier [or in some past] eras of the world, when the temperature was perhaps higher and the atmosphere in consequence more highly vaporous. Nor must we undervalue the eroding power of modern streams, or the volume of the disintegrated earthy masses which they transport away. It is past a question that modern rivers have cut their own channels through lava (Lyell, 'Principles of Geol.'), through diluvial gravel and clay drifted from other regions (Phillips, 'Sections of the Yorkshire Coast'), and through trap thrown up by the Eifel volcanoes ([Phillips], MS., 1829). But in each of these latter instances the valley of diluvial gravel and clay lies in and conceals in part an *older valley* of ruder aspect, excavated in the stratified rocks of sandstone or limestone or argillaceous slate; and we may often contemplate in the course of one stream the fragmentary state of the rocks as left by elevatory forces, the wasting of these when they formed part of an ancient shore, the obliteration of the old valleys by some yet ill-understood cause of local accumulation, and the final adjustment of levels and slopes by causes which are still continuing this beneficent process, enlarging and enriching our meadows, contracting the areas of our lakes, and softening for the future wants of mankind the rugged features of hills which will not always defy the hand of industry.

(The reader who desires to follow out this large subject may consult with great advantage De Luc's works—as, 'Letters on Geology,' 'Lettres sur l'Hist. de la Terre et de l'Homme;' Playfair, 'Illustrations of Huttonian Theory;' Buckland's 'Reliquiæ Diluvianæ;' Lyell, 'Principles' and 'Manual of Geology;' Murchison; Darwin; [John Phillips, 'Rivers, Mountains, and Seacoast of Yorkshire']; and other modern writers. The article PARALLEL ROADS [NAT. HIST. DIV., with addition in the present article], may also be read. M. Agassiz's 'Speculations on Glaciers,' have several points of important bearing on the subject of Valleys.)

Allusion has been made in the article SURFACE OF THE EARTH, of which subject valleys constitute so important a feature, to the researches on the subject of their excavation of Mr. G. Poulett Scrope, V.P.G.S., a not less philosophical, if less popular advocate of the sufficiency of existing causes in geological dynamics than Sir C. Lyell, and to the views which his inductions from their results have led him to form. In the first volume of the 'Proceedings of the Geological Society of London,' p. 170, the reading (now above thirty years since) is recorded of a paper by that geologist, hitherto, we think, unappreciated, in which attention is drawn to the value which would attach to a test by which any one valley could be ascertained to be the result either of a rapid and violent, or of a slow and gradual excavatory process; since the forces of aqueous erosion are of a general nature, and while in activity in one river channel, were probably not idle in others. Such a test was previously pointed out by Mr. Scrope, in his work on the 'Geology of Central France,' where lava-currents which have flowed into valleys at intervals of time appear now at different heights above the actual river bed, marking the successive steps of the progress of excavation. In the paper here cited he finds another, and an equally valuable test in the extreme sinuosities of some valleys. Any sudden, violent, and transient rush of water of a diluvial character, that is, a flood of wide area, could only produce straight trough-shaped channels in the direction of the current, and could never wear out a series of tortuous flexures, through which some rivers now twist about, and often flow for a time in an exactly opposite direction to the general straight line of descent, which a deluge or débâcle would naturally have taken. Curvatures of this extreme kind are frequent in the channels of rivers flowing lazily through flat alluvial plains; these curves are gradually deepened and extended, till the extreme of aberration is corrected, and the direct line of descent restored, by the river cutting through the isthmus which separates two neighbouring curves. There are occasional instances, where the bias of the river, or direction of its lateral force of excavation has remained so constant, as to give the valley itself the utmost degree of sinuosity. But such examples must be immensely rarer than those of the configuration previously described; because the frequent shiftings of the channels of streams tend to obliterate their windings, and reduce the sum of the several successive excavations—that is, the valley—to a more or less straight form.

The valley of the Moselle, between Berncastle and Roarn, excavated to a depth of from 600 to 800 feet through an elevated platform of later palæozoic—formerly termed transition—rocks, constitutes a striking instance of the former class. Its windings are often so extreme, that the river returns after a course of seventeen miles in one instance, and nearly as much in two others, to within a distance of a few hundred yards of the spot it passed before: wearing away on either side the base of the ridge-shaped isthmus separating the curves, and enclosing a peninsula of elevated land five or six hundred feet high; but sloping *towards* the bottom of the curves, where it is strewed with boulders, left there, it may be presumed, by the river, as it gradually deepened its channel and extended its lateral curvature. The valley of the Meuse near Givet offers, through a great distance, a number of similar windings, and the same character is seen at intervals in many of the other rivers of the same physical district of Europe. Parts of the Seine below Paris, and the valley of the Wye between Hereford and Chepstow, are examples nearer home.

Valleys which like these twist about in the same regular curves as the channel of a brook meandering through a meadow, can only be accounted for by the slow and long continued erosion of the streams that still flow in them, increased at intervals by wintry floods. To attribute them to a transient and tremendous rush of water in the main direction of the valley appears to be impossible. Whilst these valleys were slowly excavated, other rivers, during the same protracted period, will have produced likewise an amount of excavation proportioned to their volume and velocity, and the nature of the rocks they flowed over. In the examples cited above, the rocks are mostly hard strata, yet the valleys are wide and deep. Where softer strata, as sands, clays, and marls, were the materials worked upon, the valleys excavated may be expected, as they are found to be, far wider in proportion to the volume of water flowing through them. The comparative softness of the materials also, by accelerating the lateral erosion of the stream, will have multiplied the shiftings of its channel, and reduced their sum with greater certainty to one average direction. Hence the deeply sinuous valleys, such as those particularised, are only found penetrating the more solid rock formations. Mr. Scrope concludes by a confirmation of his opinion that extreme curvature of channel can only be produced by a slow and comparatively tranquil process of excavation, by a reference to mountainous districts, in which, where the torrents and rivers are most rapid, their course is nearly straight; from which a legitimate converse induction arises, that a certain subdued velocity in the stream is necessary to produce the former result.

It may deserve investigation, whether the spiral course of the rivers and valleys of eastern Africa, noticed in the geographical portion of this article, may not have originated in the windings of the rivers in a former and very different geological condition of the country, of which the actual curves are the remains, after the elevation of the land into its present form.

In a paper on the elevation and denudation of the lake district of Cumberland and Westmoreland ('Quart. Journ. of Geol. Soc.,' vol. iv., pp. 70–98), Mr. Hopkins has investigated and apparently solved the problem of the origin and process of formation of the lake valleys; throwing great light on the history of similar valleys in other countries. The probable origin of the lakes, it may be remarked, that is, in the first instance, of their valleys, in diverging dislocations, was first suggested by Professor Sedgwick, but Mr. Hopkins has placed the argument in its favour, for the first time, in a determinate and demonstrative form.

It would appear impossible not to ascribe the origin of the lakes of Coniston and Windermere, for example, to the dislocations of strata, with which they are so immediately associated. Mr. Hopkins has described an enormous dislocation of the band of limestone interstratified with the older palæozoic rocks seen just above Coniston Water, producing a horizontal displacement of about a mile. The direction of the fault, as determined by a line joining the extremities of the dislocated portion of the limestone band, passes exactly down the lake. Another fault ranges down the valley of Troutbeck, as indicated by a dislocation of the limestone band, and a great horizontal displacement. It ranges accurately with that part of the lake of Windermere which lies to the south of the embouchure of the valley. On the east of Troutbeck also, there are dislocations evidently connected with the formation of the two striking valleys of Troutbeck and Kentmere. The line of dislocation would seem to pass exactly along that part of the latter valley in which the mere is situated. Indeed, according to the geologist whose views we are reciting, the existence of any of the larger lakes cannot be accounted for independently of similar dislocations. Taking Wastwater, for instance, its depth is found to be forty-five fathoms, so that its bottom is probably almost a hundred feet lower than the level of the sea. It is evident that such a basin could not be scooped out by the action of water; nor is its depth increased by an accumulation of detritus at the mouth of the valley, for the river by which its surplus water is discharged cuts into the solid rock. The lake (and its including valley), could only be formed, therefore, by a relative subsidence of its bottom, the strata being relatively displaced on opposite sides of the fault. If, in any such case, this relative subsidence do not extend to the mouth of the valley, or be less there than in the upper part of it, a lake will necessarily be formed. This general explanation will apply to all the lakes of the district.

The lakes, Mr. Hopkins concludes, are thus only "the secondary and accidental consequences of the faults with which they are associated, the primary effects being the valleys in which those lakes are situated; for, whatever may have been the agency by which the masses once occupying those valleys have been removed, it is easy to see that it would act more efficiently along lines of dislocation than elsewhere; and since the existence of dislocations along the lake valleys may be considered as established, it would seem impossible to avoid the conclusion, that those valleys must themselves have originated in such dislocations. We are thus led to conclude that a dislocation was produced before the valley began to be formed; that this led to the formation of the valley by denuding causes; and that the subsidence which caused the lake was one of the last of that series of repeated disturbances which might occur during the long interval of time which was probably necessary for the completion of the valley. . . . . This view of the origin of valleys of this kind must be considered as applicable principally in places nearest the centres or axes of elevation. In other cases they may have arisen altogether from aqueous action; or, when they originated in dislocations, they may have had their directions so altered, and their character so modified by denuding causes, as to retain no distinct traces of their origin."

From these illustrations, derived from local phenomena, we return to a part of the general history of the subject, in which again physical geography and geology are united, but remain distinct.

Whatever influence the geological constitution and lithological nature of the strata and rock-masses in which a valley has been excavated, may have upon its form, that form is still independent of what may be termed the geometrical disposition and configuration of those strata and rock-masses. This is equally true of mountains as of valleys. It seems natural to suppose that when a group of strata inclining upwards towards the same line from opposite points form what is denominated an anticlinal, a hill or a mountain should be produced; and that when a synclinal is formed by the similar meeting in one line of a group of strata inclining downwards from opposite points, a valley should be the result; and in many cases such is the fact. But in many cases also the reverse occurs, valleys being situated on anticlinal arches, and mountains consisting geologically of synclinal troughs of strata. (Lyell, 'Manual,' p. 57.) Thus it has been recently shown by Sir R. I. Murchison and Mr. Geikie ('Quart. Journ. of Geol. Soc.,' May, 1861), that the enormous mass of Ben Lawers, "like many other mountains in Scotland, as well as elsewhere," actually occupies a synclinal trough, while the deep valley of Loch Tay, like that of the Great Glen through which the Caledonian canal extends, runs along an anticlinal arch. In this manner the geographical configuration of the land is often quite different from its geological configuration, or that of its geological elements. In connection with this subject, it may be useful to advert to the manner in which the terms in question have come to be employed in modern physical geography,* and which has already led to erroneous inferences. When a geographer speaks of an anticlinal line, ridge, or axis, he simply means the ridge formed by the meeting of an upward slope and counterslope, or the imaginary line drawn through or along it; and by a synclinal, in like manner, he merely understands a linear depression or valley, formed by the meeting of a downward slope and counterslope; without reference to the geological constitution of the land having such figures. Thus geographical anticlination and synclination (derivatives employed, we believe, for the first time by Mr. Brayley), are quite different things from the disposition of groups of strata, designated by the geologists as anticlinal and synclinal. Thus, also, the slope and counterslope may consist of strata, either meeting or sloping away from each other; a difference quite unimportant in geography, but of great moment in geology. Geographers are often not geologists, and borrow appellations from the science of the latter, which they use in a sense, quite correct, of their own, but at the same time quite different from its original one.

* The term anticlinal seems to have been first adopted in geography in Dr. Beke's 'Origines Biblicæ,' Lond., 1834, p. 316, where it is remarked, that the range of mountains called the Karadjeh Dagh, "forms the geographical anticlinal line between the two great rivers Tigris and Euphrates, and their respective tributary streams."

Another and frequently occurring case of the position of a valley on an anticlinal axis is the following. In certain dome-shaped hills, or elevated regions, which all consider as having been thrust up by a force from below, there is often an elliptical cavity at the summit, due partly to the fracture of the upraised rocks, but still more to aqueous denudation, as they rose out of the sea. The central cavity is called a *valley of elevation*. It exposes to view the subjacent strata or rocks, and the incumbent stratified mass, the central portion of which has thus been removed, dips away on all sides from the axis. The structure and the theory of the production of such valleys were first recognised, and the appellation given to them, by the late Rev. Dr. Buckland, who described a remarkable instance in the valley of Kingsclere, in Berkshire, together with others, all presenting the same features of a valley, circumscribed on all sides by an escarpment, whose component strata dip outwards from an anticlinal line, running along the central axis of the valley. The most symmetrical valley of elevation in the British isles occurs in the Woolhope district in Herefordshire, consisting of two concentric narrow ranges of hills, almost continuously surrounding a broad, nearly elliptical dome; the lowest and most ancient strata forming the dome, the incumbent strata the including hills. (Buckland, 'Trans. Geol. Soc.,' series II., vol. ii.; Murchison, 'Siluria;' J. Phillips, in 'Mem. of Geol. Survey,' vol. ii.; Lyell, 'Principles,' 1853, p. 421.)

The perusal of the article Parallel Roads in the Natural History Division of this work is referred to above (col. 541), as desirable for the student of the history of valleys. Subsequently to the investigations of the eminent observers referred to in that article, and also to those of Professor Agassiz, Sir G. S. Mackenzie, Mr. R. Chambers, and others, the structure of the parallel roads of Lochaber has been carefully studied by a distinguished American geologist, Professor Henry D. Rogers, F.R.S., who occupies, greatly to the advantage of science, the chair of Natural History in the University of Glasgow. The results of this study he stated in a discourse delivered at the Royal Institution, in London, on March 22nd of the present year (1861), of which an abstract appears in the 'Proceedings;' and in which he states that he has been led by it to reject all the hypotheses hitherto offered in explanation of the terraces, as inadequate, and to recognise in certain phenomena discovered by him, but not before noticed or theoretically considered, a key to the solution of the problem. Of these we will briefly notice the principal, omitting the details, and subjoin the conclusion at which Professor Rogers has arrived.

These parallel roads are apparently level, and therefore parallel, "but further instrumental measurements," Professor Rogers remarks, "are necessary before the question of their absolute horizontality can be regarded as satisfactorily settled;" on which point, therefore, he seems to be at variance with Mr. Darwin, as well as with Sir T. L. Dick and Mr. Maclean, by whom, as stated in the former article, they were carefully levelled.

Each "road," "shelf," or "terrace," according to Professor Rogers, is a nearly level, wide, deep groove, in the easily eroded boulder-drift or diluvium [Surface of the Earth] which, to a greater or less thickness, everywhere clothes the sides of the mountains exhibiting them. They vary greatly in their relative distinctness. With scarcely an exception, each terrace or shelf is most deeply imprinted in the hill-side, and is broadest, where the surface thus grooved has its aspect *down the glen*, or towards the Atlantic; and is faintest where the ground fronts towards the head of the valley, or the German Ocean. While conspicuous on the open sides and the westward sloping shoulders of the hills, the terraces *disappear altogether* in the recesses or deeper corries which scollop the flanks of the mountains. Each grows usually more and more distinct as it approaches the head of its own special glen, until those of the two opposite sides meet in a round spoon-like point. Each again coincides accurately in level with some "water-shed" (?) or notch in the hills leading out from its glen into some other glen or valley adjoining.

The internal structure of the matter composing each terrace consists in an "oblique lamination" or slant bedding of the layers of gravel, sand, and other sediment which constitute it, such as geologists familiarly recognise as the result of a strong *current* pushing forward the fragmentary material which it is depositing, and which is held by them to indicate, in the direction towards which the laminæ dip, the direction towards which the current has moved. The "dip," or downward slant, is almost invariably *up* the glen, or towards its *head*, and *not down the glen*, or towards the Atlantic.

In all previous hypotheses, the agency of *standing* water is assumed, either the ocean in its ordinary state of repose, or lakes pent within the glens, as explained in the former article. But to these Professor Rogers opposes the facts, that these level shelves are not true marine beaches, exhibiting not a vestige of any marine organic remains, no rippled sands, no shingle, and no sea-cliffs; that they display, in like manner, a total absence of the distinctive marks of lake-sides, not one lacustrine organism, neither fresh-water plant nor animal having ever been discovered imbedded in them. Nor has any feasible cause of blockage of the glens at different stations above their mouths, to pond the waters to the respective heights of the terraces, been assigned;

there are no traces of former barriers in any of those localities where alone we can assume them to have existed, to produce the required embaying of the waters. The hypothesis of successive "sea-margins," or sea-levels, is stated to be overthrown by the now well-established deduction from the recent measurements of Professor Rogers himself, that none of the several shelves, or "roads" of Glen Roy correspond in level with any of those seen in the adjacent valley, Glen Gluoi, a marked discrepancy separating the two groups of terraces into two independently produced systems.

After adducing further objections, both of fact and reasoning, to former hypotheses on the origin of the parallel roads, Professor Rogers concludes by sketching, in the following terms, the action to which he ascribes their formation :—"He supposes the several terraces to have been cut or grooved in the sides of the hills by a great inundation from the Atlantic, engendered by some wide earthquake disturbance of the ocean's bed, and forced against the western slope of Scotland. The features of the country indicate that, while a portion of such a vast sea-tide entering the Frith of Linnhe rushed straight across the island through the deep natural trench, Glen Mor or the great Caledonian valley, a branch current was deflected from this, and turned by the Spean valley and its tributary glens, Glen Roy and Glen Gluoi, into the valley of the Spey, and so across to the German Ocean. In this transit, the deflected waters first embayed in these glens, and then filling and pouring through them, would, upon rising to the levels of the successive water-sheds, or low passes, which open away to the eastern slope of the island, take on a swift current through each notch, and as long as the outpour nearly balanced the influx, this current, temporarily stationary in height, would carve or groove the soft "drift" of the hill-side. But the influx increasing, the stationary level and grooving power of the surface-stream would cease, and would only recommence when the flood rising to the brim of another natural dam, a new equilibrium would be established, a new horizontal superficial current set in motion, and a second shelf or terrace begin to be eroded at the higher level. So each of the parallel roads is conceived to have been produced in the successive stages of the rising of one vast steady incursion of the sea. The lapsing back of the waters, unaccompanied by any sharp localised surface-currents through the passes, could imprint no such defined marks on the surface, nor accomplish more than a faint and partial obliteration of the terraces just previously excavated during their incursion."

A succinct view of the controversy respecting the formation of the parallel roads, showing the position of the subject prior to Professor Rogers's investigation, will be found in Sir C. Lyell's 'Manual of Elementary Geology,' 5th ed., 1855, pp. 86–89.

VALUE signifies, in political economy, the quantity of labour, or of the product of labour, which will exchange for a given quantity of labour or of some other product thereof. It is necessary in the outset to distinguish utility from value, or, as Adam Smith expresses the distinction, "*value in use*" from "*value in exchange*." The utility of an article causes it to be an object of demand; and without some real or imaginary utility an article will not have value; or, in other words, no one will give other articles in exchange for it: but utility alone does not constitute value, except when there is a limited and exclusive possession, which enables one man to refuse to others the enjoyment of any natural product without the payment of an equivalent or price. It is the labour of man alone which in ordinary circumstances creates value. What all may enjoy alike without labour may indeed be most useful and necessary, but cannot be an object of exchange, and therefore is destitute of value. "The real price of every thing," says Adam Smith, "what everything really costs to the man who wants to acquire it, is the toil and trouble of acquiring it. What everything is really worth to the man who has acquired it, and who wants to dispose of it or exchange it for something else, is the toil and trouble which it can save to himself, and which it can impose upon other people." Hence the labour of man becomes the real measure of the exchangeable value of all commodities.

To illustrate the distinctive character of utility, and the effects of labour and of exclusive possession respectively upon value, suppose a party of settlers to occupy a tract of land, and to divide it amongst them in equal portions by lot. Suppose also that each settler has upon his own land timber, lime, and stone. They all need houses, and have the materials to build them with; but the unaided labour of each man is unable to appropriate and apply the materials in the manner he desires. One man calls in the assistance of his neighbour, and by their joint labour a house is built; and this service he repays by helping his neighbour also to build a house. He can only repay him by labour, because the materials, though of the highest utility, are common to both, but need labour to make them available. It is clear that the timber, the lime, and the stone are in this case without value, and could not be offered by one man in exchange for the labour of another. But suppose it should happen that all the timber, lime, and stone in the whole district should be found in the portion of land allotted to one of the party. Here the materials would not only be objects of utility, but the limited and exclusive possession of them would endow them with value. The fortunate owner of them might say to his neighbours, "You shall not have any of my materials until you have first built me a house; but when you have each worked for me a day, instead of repaying each of you with a day's labour myself, I will permit you to take the materials for building from my estate." Here the power of withholding the products of nature from others is productive of value, being equivalent to a certain quantity of labour. But even in this case it is labour which creates the value, and is the measure of exchange between the parties.

The great mass of commodities which are made the subject of exchange amongst men are produced by labour only, and are not affected by any exclusive possession whatever. With these therefore the quantity of labour used in their production is the measure of their real value. They will ordinarily exchange for other commodities upon which an equal quantity of labour has been expended; but there are circumstances which may affect their exchangeable value, while their real value or cost of production may remain the same. If a larger quantity of any article has been produced than there is an effective demand for, its exchangeable value is reduced; if on the contrary, its supply is unequal to the demand, its value is raised. But these variations cannot be of long duration. Articles which do not repay the cost of production will soon cease to be produced, until the diminished supply has again raised their value; and when articles bear a market value much higher than their cost, production will be encouraged until the supply is not very wide of the demand. Any permanent alteration, therefore, in the exchangeable value of one commodity as compared with another, cannot be referred to these fluctuating and accidental causes, but must be the result of a change in the real value of one or the other, that is to say, in the quantity of labour required to produce it. The value of labour is always the same, but the value of the products of labour changes with circumstances.

The real value of a commodity having been shown to be dependent solely upon the quantity of labour necessary for its production, and the exchangeable value, for the causes stated, never varying materially either above or below the real value, it follows that the price paid for labour does not affect the exchangeable value of articles produced under similar circumstances. If the labourer gains a larger share, the profits of his employer are proportionately diminished; and if his share is less, then profits are increased: while both are generally preserved by competition from any great disproportion.

Equal quantities of labour however are not always equivalent; the skill of one labourer, or the severity of his employment, may render the time for which he is engaged more than equivalent to the same time occupied in labour by another. But this circumstance, though it originally affects the comparative value of commodities produced by different descriptions of labour, is no cause of subsequent variation in their relative value. The relations of different qualities of labour are soon practically adjusted, and are not afterwards liable to much variation.

Every reduction in the quantity of labour required to produce a commodity diminishes its real value, and therefore, for the causes already explained, its value in exchange. Improvements in tools and machinery, by saving the labour of man, reduce the value of commodities; but in estimating their influence, we must not omit to calculate the quantity of labour bestowed upon the article, directly and indirectly—from the growth of the raw material to its finished state—throughout the whole process of manufacture—upon the tools, machinery, buildings, and other appliances by which labour is assisted. Upon the same principles every increase in the quantity of labour directly or indirectly applied adds to the value of a commodity.

The amount of capital employed also enters into the computation of value. Capital is only accumulated labour. Where it is abundant a small interest is accepted, but where it is scarce a larger portion of interest has to be added. Labour can hardly ever be profitably exerted without the intervention of capital, as the labourer must be provided with subsistence until his labour has realised a profit. All improvident attacks, therefore, of the labourer upon the labour fund by lessening the amount of capital to be advanced for his support in view of prospective realisation, must inevitably react upon himself to his own disadvantage.

The effects of labour upon price become further complicated by the durability of the machinery employed to assist it. If two commodities are produced by machinery at an equal cost of labour, and if the same quantity of labour has also been bestowed, in each case, upon the machinery—the value of such commodities would appear to be the same; but if one machine wears out in two years or needs much labour to keep it in repair, while the other lasts for ten years requiring but little repair—the relative quantities of labour expended indirectly upon the two commodities become so unequal, that a considerable disproportion must be found in their respective degrees of value.

Disturbances of the relative value of different commodities apparently produced by the same amount of labour, are also caused by the comparative quantities of fixed and circulating capital employed, and by the length of time over which the labour is spread, and before the products are brought to market. Under these varying circumstances in the production of articles, the price of labour becomes an element in their relative value, which is not the case when commodities are produced under precisely similar circumstances. If all commodities were produced by an equal proportion of fixed and circulating capital, any rise or fall of wages would affect them all equally, and would not therefore disturb their relations to each other. If a yard of woollen cloth, for instance, exchanged for a yard of silk, and wages rose, the value of each would rise in an equal proportion, and the articles would continue to exchange for each other as before. But if the cloth were produced almost entirely by machinery and the silk entirely by manual labour, a rise of wages would scarcely affect the former at all, while it would add materially to the cost of producing the latter. They would therefore no longer exchange for each other, or, in other words, their relative value would be altered. The general law of such variations is thus stated by Mr. Ricardo, namely, that in the event of a rise in the price of labour, "only those commodities would rise which had less fixed capital employed upon them than the medium in which price was estimated, and that all those which had more would positively fall in price when wages rose. On the contrary, if wages fall, those commodities only would fall which had a less proportion of fixed capital employed on them than the medium in which price was estimated; all those which had more would positively rise in price."

With all these causes of disturbance in the relations which the different products of labour bear to each other, it is obvious that no commodity can be a perfect standard by which to compare the variations in the value of other commodities; but as, in an advanced stage of society, labour cannot be the ordinary measure of value, some representative of labour must be selected, by which to carry on the exchanges of trade, and the more nearly it represents the amount of labour expended upon it, and the less that amount varies, the fitter will it be for a common standard of value.

The precious metals, or paper convertible into them, are the standards usually adopted. They are however articles of commerce varying in supply and demand, and in the quantity of labour required, at different times, to produce them. They cannot therefore be invariable standards, but must fluctuate more or less like other commodities. Practically, this variation is not, upon the whole, so great as in the case of other articles, but in the degree in which it prevails it makes gold and silver imperfect standards of value. The circumstances and results of this imperfection and the means of obviating them are among the most important speculations of the political economist, but are more fitly treated of in other parts of this work. VALVASOR. [VAVASOR.]

VALVE. A moveable partition introduced in machinery for the purpose of alternately opening and closing a passage through which steam or water may be intended to pass, is called a *valve;* and this generic name receives many specific designations according to the position, or the function, the valve may be required to occupy, or to perform. Thus there are head, or feet valves; suction valves; delivery, discharge, air-pump, steam, safety, blow-off valves; spindle, clack, flap, slide, cup, crown valves; stop, expansion, distribution, equilibrium, and countless other varieties of valves, which can only be described in the detailed notices of the machinery of which they form part. It may suffice, then, to state here briefly, that the conditions a valve is required to fulfil are, that it shall open freely in the required direction; that it offer no obstruction to the passage of the fluid it is designed to pass when it is open; that when it is closed it shall not allow the fluid to return. Valves must, therefore, fit closely on their seats; be sufficiently strong to resist the pressure to which they are to be exposed; they must be composed of materials which should not be likely to suffer deterioration or wear; they must be accessible at any time for examination and repair. In the exceptional forms of throttle-valves, the majority of the last-named conditions apply; though, of course, as those valves are not intended effectually to close the passage of the fluids they intercept, they do not require the same amount of strength, or the same perfection in the seating, as the ordinary valves do.

It follows, from the nature of the work performed by ordinary valves, that great mechanical perfection is necessary in their execution. The bearing surfaces are, therefore, carefully planed, turned, and fitted; and the face of the valve itself is frequently covered with a semi-elastic material, for the purpose of more effectually excluding the passage of the fluids; or it may be kept close against the seating by means of springs. These contrivances, however, necessarily give rise to considerable friction on the opening and shutting of the valves, and it thence becomes necessary, in designing machinery, to diminish the weight and the number of the valves as much as possible. Moreover, as valves only open when the pressure on one side exceeds that upon the other, the effort required to open them may become a question of serious importance, and the reaction which may ensue upon their being suddenly closed may frequently exercise a powerful effect upon the solidity of the machinery; as for instance, in the cases of a valve upon the rising main of a large pump, or of the expansion gear of a steam-engine. It is for the purpose of obviating these sources of inconvenience and danger, that the cup-valves and the equilibrium-valves, before alluded to, under PUMP and STEAM-ENGINE, are introduced; for ordinary purposes it may be considered that *lifting*-valves are adapted for rough work and for dense fluids; that *hinged*-valves present some mechanical advantages over the lifting-valves; and that when there is a necessity for gradually closing a passage, or for preventing the escape of a rare fluid, the *sliding*-valves should be resorted to.

Flap-valves, and screw-valves, are occasionally used in hydraulic engineering; the former, for the purpose of securing an autonomic discharge of drainage waters whenever the internal pressure on the valve shall exceed the external pressure; and the latter, for the purpose of intercepting the flow of water, or even of gas, in pipes. Self-acting balance-valves are often used for ventilation, and occasionally for the purpose of regulating the draught in furnaces, chimnies, &c. A very ingenious system of self-acting balance valves was introduced by Mr. Thom in the Greenock Water Works, to ensure the uniformity of flow of the mill streams he had there to deal with: a full account of these contrivances is to be found in the 'Annales des Ponts et Chaussées' for 1831.

VALYL. [BUTYL.]

VAMPIRE. According to Dom Calmet's 'Dissertation sur les Vampires,' the vampire is a dead man, who returns in body and soul from the other world, and wanders about the earth, doing every kind of mischief to the living. Generally he sucks the blood of persons asleep, and thus causes their death. Those who are destroyed in this way become vampires. The only manner of getting rid of such unwelcome visitors is, according to the same author, to disinter their bodies, to pierce them with a stake cut from a green tree, to cut off their heads, and to burn their hearts.

The belief that the dead sometimes return to this world, in order to annoy the living, was prevalent in very early times. Eastern nations have a similar superstition about malicious ghosts, called "gouls," &c. The belief in these apparitions was not destroyed by the introduction of Christianity, but remained, like many other superstitions bequeathed by paganism, in full force during the middle ages. The laws of Charlemagne ('Capitularium pro Partibus Saxoniæ') contain certain enactments respecting apparitions called Striga or Masca (this last word signifies a shapeless being). This circumstance proves the generality of this belief during that period.

The advance of civilisation in modern times was unable to destroy a superstition founded upon a feeling by which the great mass of mankind is so frequently actuated—fear; and many authors wrote books on the subject. Besides Dom Calmet, whom we have quoted, we may mention—Philip Rerius, an author of the 17th century; Michael Rauft, who published in the last century a treatise 'De Masticatione Mortuorum in Tumulis;' Ferdinand von Schers, 'In Magia Posthuma,' Olmütz, 1706, &c.

The superstition about the vampires is chiefly prevalent in some parts of Eastern Europe. These apparitions are known in Poland under the name of "Upior;" in the Ukraine, "Upeer;" in Russia, "Googooka;" in Hungary, Servia, Greece, &c., "Vroucolackas," "Vardoulacka," "Broncolucka," &c.

Of all those countries, Hungary and its dependencies may be considered as the principal seat of vampirism, and little more than a century has elapsed since all Europe was filled with reports about the exploits of vampires in Hungary and Servia. It was during the five years from 1730 to 1735 that vampirism reached its height. It was so general, that Louis XV. of France commissioned his ambassador at Vienna, the Duc de Richelieu, personally to ascertain, in Hungary and other Austrian dominions, the reality of vampirism. The French diplomatist denied in his report to the king the existence of the vampires, and he informed him at the same time that the anecdotes about them were inserted in the contemporary records of the Austrian tribunals. This superstition gained ground so much that the chief periodicals of that time contain accounts of cases of vampirism in Hungary; such as, for instance, the 'Mercure Historique et Politique,' for October, 1736, pp. 403, 411; and the Dutch paper, 'Le Glaneur,' No. ix., for 1733.

A great number of anecdotes, many of which had been officially registered, are related by contemporary writers; some of them even described the manners and customs of those vampires; as for instance, that lying in their graves they suck and chew their winding-sheets, and that it was therefore necessary to place under their chins a piece of green turf in order that they might not be able to reach the sheets with their teeth, and to bind their hands, that they might not turn about in their coffins. Many believe that the vampires, notwithstanding all the means used to destroy their bodies, will resume their shape, and recommence their mischievous wanderings as soon as the rays of moonlight fall on their graves. This superstition is chiefly prevalent in Greece, and the tale of 'The Vampire,' written by Dr. Polidori, was founded upon it.

It may be supposed that the superstition about the vampire has derived considerable strength from cases where men, supposed to be dead, have been buried alive. Such cases have happened in many countries, as has been shown by the altered position of the body in the coffin, spots of blood on the torn winding-sheets, bites on the hands, and other marks of the struggle and despair before life became extinct. It is probable that such signs have been sometimes interpreted as the marks of vampirism.

VANADIC ACID. [VANADIUM.]

VANADIUM (V). A rare metal. It was discovered in 1801 by Del Rio, and in 1830 named, by Sefström, Vanadium, from *Vanadis*, a cognomen of the Scandinavian goddess *Freia*. In exceedingly minute quantity it exists in nearly all clays, but occurs in abundance in a lead ore (vanadiate of lead) found at Wanlockhead in Scotland, Zimapan in Mexico, and recently in Chili.

By reducing vanadic anhydride with potassium, and digesting the product in water, vanadium is obtained as a brilliant, metallic powder; soluble in nitric acid or aqua regia, but unacted upon by boiling sulphuric, hydrochloric, or nitric acids.

The equivalent of vanadium is 68·46.

Vanadium and *oxygen* combine in three proportions. The *protoxide* (VO) has the appearance of graphite, and is formed when hydrogen is passed over heated vanadic acid. The *binoxide* (VO_2) is a black powder produced when the protoxide is heated in the air; it combines with acids to form salts, which have a blue colour. The *teroxide* or *vanadic anhydride* (VO_3) is a brownish-red powder that remains on heating bivanadiate of ammonia. It fuses at a red heat, and is slightly soluble in water, to which it communicates a yellow tint and an acid reaction. *Vanadic acid* (2 HO, VO_3) falls as a precipitate when nitric acid is added to a hot solution of a bivanadiate; in appearance it much resembles hydrated oxide of iron. Dried over sulphuric acid it loses an equivalent of water, and *protohydrate* (HO, VO_3) remains.

Vanadiates are obtained on decomposing bivanadiate of ammonia by a chloride. They contain—

Bivanadiate of soda	NaO, $2VO_3 + 9HO$
„ strontia	SrO, $2VO_3 + 9HO$
„ lime	CaO, $2VO_3 + 9HO$
„ magnesia	MgO, $2VO_3 + 8HO$
Baryta salt	3BaO, $5VO_3 + 19HO$

To produce bivanadiate of ammonia Hauer recommends that the crude vanadium compound be calcined, the residue digested in water, the insoluble portion fused with nitrate of potash, the resulting mass digested in water, the solution concentrated, and vanadiate of ammonia precipitated by adding excess of chloride of ammonium; it is purified by repeated crystallisations from water containing acetic acid.

Two *chlorides* (VCl_2 and VCl_3), as well as sulphides, bromides, iodides, and fluorides of vanadium, have been obtained.

Tests for Vanadium. By reducing agents, such as sulphide of hydrogen, or a boiling mixture of sulphuric acid with alcohol or sugar, vanadiates yield beautiful blue solutions. This reaction distinguishes them from chromates, which under the same circumstances give green liquids.

VANDALS. [TEUTONIC NATIONS.]

VANILLA, [VANILLA, *Aromatica*, in NAT. HIST. DIV.] is a native of Brazil. The fruit is the only part of the plant that is used. It has a balsamic odour, and a warm agreeable flavour. For these properties it is indebted to a peculiar volatile oil, and to a considerable quantity of benzoic acid. The fruit is gathered when it gets yellow, and it is first allowed to ferment for two or three days: it is then laid in the sun to dry, and when about half dried it is rubbed over with the oil of cocoa: it is again exposed to the sun to dry, and oiled again a second time. The fruit is then collected in small bundles, and wrapped up in the leaves of the Indian reed, and sold to the Europeans. It is used to flavour chocolate.

VANISH (Mathematics). A quantity is said to vanish, or to become evanescent, when its arithmetical value is nothing, or denoted by 0. When the evanescent quantity is only a part of another, there is seldom or never any more difficulty about the case in which it vanishes than about that in which it takes any other specified value: but when the whole of what is under consideration vanishes, any or all of those views may be required to render this case intelligible which are explained in NOTHING; INFINITE; LIMITS; RATIOS, PRIME AND ULTIMATE; &c. And in particular the phrase of two quantities vanishing in a certain ratio is to be referred to the last of the articles cited. When a value given to a letter makes an expression vanish, or reduces it to 0, it would be very convenient to say that the given value *nullifies*, and is a *nullifier* of the expression: but this language is not used.

VANISHING FRACTIONS. [FRACTIONS, VANISHING.]

VANISHING POINT, LINE, &c. [PERSPECTIVE.]

VAPORISATION is the process by which a liquid on being sufficiently heated passes off in the form of vapour. It differs from EVAPORATION in being generally an artificial and a quicker process, while the latter is spontaneous.

VAPOUR. There are many substances, both fluid and solid, which when exposed to the air, or to the more powerful agency of heat, are gradually but totally dissipated, owing to their particles assuming the state of vapour by what is termed *spontaneous evaporation.* A vapour, then, consists of ponderable matter combined with sufficient specific heat to enable it to retain its aëriform existence: we have already [GAS] given a similar definition of a gas. The question, then, naturally arises, In what do vapours differ from gases? The answer is, that the difference is a conventional one, being of degree only, and not of kind: thus, when atmospheric air containing, as it always does, the vapour of water, is suddenly cooled by exposure to a colder substance, the water which it contained in the state of invisible vapour is deposited in the state of palpable water on the colder body; we say then aqueous vapour or the vapour of water, and not aqueous gas. No similar change is produced, by this abstraction of heat, in the form of the constituents of the air, and they are therefore termed gaseous bodies or gases. The difference, however, we repeat, is one of degree only; for many gaseous bodies which had been, not many years since, considered as permanently elastic as atmospheric air, have been shown by the important investigations of Dr. Faraday to be reducible to liquids [GASES, LIQUEFACTION OF]; and additional experiments have even shown that carbonic acid gas, which requires a pressure of 35 atmospheres to render it fluid, may by particular management be converted into a solid. [CARBONIC ACID.]

A practical difference between a vapour and a gas is illustrated by the use of the vapour of water, and its subsequent condensation, as a motive-power in the steam-engine. [STEAM and STEAM-ENGINE.] No known gaseous body could be employed with the same advantage, owing to the great degree of pressure and cold required for its condensation. Nor could the vapour of any other liquid than water be so profitably employed as a prime mover, for the reason given under LATENT HEAT.

It was formerly supposed that the air dissolved vapour and held it in solution as water holds sugar or salt. This was the theory of Le Roi, propounded in some otherwise ingenious papers, 'Sur l'Elévation et la Suspension de l'Eau dans l'Air et sur la Rosée.' ('Mem. Acad. Royale des Sciences,' 1752; and also in a separate volume, 'Mélanges de Physique et de Medicine,' 1771.) This theory, however, was completely demolished by Dalton at the commencement of the present century ('Manchester Memoirs'), who showed that a vapour forms much more easily in a vacuum, and that the pressure of air retards and obstructs the evaporation of a liquid. Dalton's apparatus consisted chiefly of two barometers placed side by side. A drop of a given liquid was sent up into the vacuum of one of them, when it became converted into a transparent vapour, and, exerting a pressure on the mercurial column, lowered the mercury in the tube. The amount of this depression was measured by comparison with the adjacent barometer, and the elasticity of the vapour was expressed not by that depression, but by an equal quantity of mercury which the vapour would support. Thus, if the summit of the column of the mercury containing the vapour stood half an inch below the mercury in the adjacent barometer, the pressure of the vapour would be such as would support a column of mercury half an inch in height. In estimating this pressure, sufficient liquid must be sent into the vacuum to saturate it, and it is then found that the elasticity of the vapour is directly as the temperature. By surrounding the tube with some vessel capable of containing hot water, with a thermometer for indicating temperature, the temperature of the vapour can be known, and the relation between its temperature, pressure, and density ascertained. [EVAPORATION.] Various forms of apparatus have been contrived by Dalton, Gay-Lussac, Arago, and Dulong, and by Regnault, for determining the pressures and densities of vapours, and obtaining such results as are given in the table under STEAM and STEAM-ENGINE.

The specific gravities of vapours, like those of gases, are referred to air as a standard at the temperature of 32° and a pressure of 30 inches; or the density of a vapour may merely express the ratio of a given volume to an equal volume of air of the same temperature and pressure. In the case of steam above 250° this ratio is invariable, and indeed the ratio of the densities is constant for the vapour of most liquids above their boiling points. These ratios have been thus determined by Gay-Lussac:—

Air	10,000
Vapour of water	6,235
„ alcohol	16,138
„ sulphuric ether	25,860
„ sulphuret of carbon	26,447
„ essence of turpentine	50,130
„ mercury	6,976
„ iodine	8,716

When a gas and a vapour which do not act chemically on each other are inclosed in the same space, they will exert separately on the sides of the vessel the same pressures that each would produce if it occupied the same space in the absence of the other, so that the total pressure of the mixture is equal to the sum of the separate pressures.

When vapour receives a supply of heat after it has been separated from the liquid it is called super-heated vapour. Such vapour, unlike ordinary vapour, may lose a portion of its heat, and still the whole of it continue to be vapour. If, after a vapour has been raised from a liquid, it be compressed into a smaller space, its temperature will rise, and if expanded it will fall; but the temperature, pressure, and volume will always be such as the vapour would have had if it had been raised directly from the liquid at such temperature and pressure. Thus, vapour raised from water at 68° has a volume 58·224 times greater than the water that produced it. If this vapour be separated from the water, and its volume be compressed until it is only 1696 times that of the water, its temperature will rise to 212°, or that which it would have had if directly raised from the water under the increased pressure.

Evaporation, both spontaneous and artificial, and especially the latter, is employed in numerous manufacturing and chemical processes. When, for example, common salt is prepared from sea-water, it is exposed in the first instance to the air in shallow clay pits, by which spontaneous evaporation takes place; and this occurs to the greatest extent in hot weather, and when the surface of the brine is agitated by the wind. It is found, however, that spontaneous evaporation can be carried on with advantage to a certain extent only; and when this point is arrived at, the operation of salt-making is finished by removing the concentrated brine to iron vessels, in which the evaporation is artificially conducted by the application of heat, the vaporisation being greater as the temperature is higher, till the boiling-point is arrived at, when it is greatest.

Evaporation is used for numerous purposes and processes, and in different modes, according to the substances operated on and the objects to be attained. When contrivances are adopted for condensing the whole or any portion of an evaporated liquid, the process is termed DISTILLATION, and the ends accomplished by it are various. When, for example, water is distilled, it is for the purpose of separating the saline and earthy impurities, which, not being vaporisable, remain in the body of the still, while the pure vapour of the water is condensed by cooling in the worm: so, again, when wine is submitted to distillation, it is for the purpose of evaporating and subsequently condensing the spirit or brandy from the water and the colouring-matter. When herbs, as lavender, peppermint, &c., are heated with water in a still, the oil and water rise in vapour and are condensed; when turpentine is similarly treated, a volatile oil rises in vapour, while the resin or rosin, not being volatile, remains in the still. Vaporisation in the form of distillation is also largely employed in the preparation of various acids, such as the nitric acid, hydrochloric acid, &c.

When solid bodies are vaporised and subsequently condensed, the operation is termed *sublimation*, and it is resorted to with different intentions, as for the purification of camphor and the preparation of corrosive sublimate and calomel.

It will be evident on slight consideration that vessels of very different materials and construction must be employed in evaporation, distillation, and sublimation, and according to the nature of the substance operated on. Thus the first stage of the concentration of sulphuric acid is conducted in lead, the concluding one in glass or platinum; saline solutions are evaporated to the crystallising point in lead or copper; the caustic alkalies in iron or silver; the distillation of spirits in copper; that of acids in iron, earthenware, or glass; while the preparation of common salt is completed in vessels of iron.

For further information we refer to EVAPORATION; DEW; HYGROMETRY; BOILING OF LIQUIDS; EBULLITION; DISTILLATION; STEAM and STEAM-ENGINE; LATENT HEAT; SPECIFIC HEAT; TRANSPIRATION.

VAPOUR-BATH. [BATH; BATHING.]

VAPOUR, OPALESCENT. This appears to be the most convenient appellation for what has sometimes been termed red or orange steam. It is a condition of condensed and condensing aqueous vapour which was first distinctly recognised, and its optical properties investigated by Dr. James D. Forbes, F.R.S., when Professor of Natural Philosophy in the University of Edinburgh. Its effects in nature have been observed from time immemorial, though ascribed to other causes; and there can be no doubt that it would long ago have been recognised and described by those practically conversant with steam and steam-engines, had not its effect on luminous bodies been confounded with that of smoke, from which it is in fact undistinguishable by the eye. In the year 1838, Professor Forbes, standing near a locomotive engine which was discharging a large quantity of high-pressure steam by its safety-valve, chanced to look at the sun through the ascending column of vapour, and was struck by seeing it of a very deep orange colour, exactly similar to dense smoke, or to the colour imparted to the sun when viewed through a common smoked glass. The same he found might be observed during the ordinary progress of the engine in the steam thrown into the chimney, but the presence of smoke itself rendered the experiment less satisfactory. He afterwards observed that while for some feet or yards from the safety-valve at which the steam blows, its colour for transmitted light is the deep orange red, at a greater distance, the steam being more fully condensed, the effect entirely ceases. Even at moderate thicknesses the steam cloud is absolutely opaque to the direct solar rays, the shadow it throws being as black as that of a dense body; and when the thickness is very small it is translucent, but absolutely colourless, just like thin clouds passing over the sun, which indeed, according to Professor Forbes, have a perfect analogy of structure. When the steam is in this state no indication of colour is perceptible in passing from the thickness corresponding to translucency to that which is absolutely opaque.

Professor Forbes proceeded to investigate this novel subject by means of a high-pressure steam-boiler, and a theodolite with a good prism placed in front of the telescope, and from the experiments he made deduced the following conclusions:—"1. Steam in its purely gaseous form is, as commonly supposed, colourless, at least in small thicknesses. 2. The orange-red colour of steam by transmitted light appears to be due to a particular stage of the condensing process. Before condensation steam is colourless and transparent; it is next transparent and smoke-coloured; finally it becomes colourless at small thicknesses, and absolutely opaque at greater. 3. The state of tension of the steam seems only to affect the phenomena so far as it renders the critical colorific stage of condensation more or less completely observable. 4. The absorptive action of steam on the spectrum is not exerted in the same way as that of other gaseous coloured bodies, such as nitrous acid gas, and iodine vapour. It cuts off, however, totally the same part of the spectrum as nitrous acid does. Its phenomena perhaps have a greater analogy to those of opalescence than any other." 'Phil. Mag.,' series 2, vol. xiv., p. 121-126; the paper having been read before the Royal Society of Edinburgh, on January 21, 1839.

The combination of a variety of other facts with those thus made known by Professor Forbes, relating to the nature and properties of condensing steam with respect to light, have subsequently led other men of science to unite in the conclusion, that the structure of orange steam is in reality that of opalescent bodies, with the phenomena of which, as we have seen, he recognised the analogy of those presented by it. Innumerable globules of water are formed throughout the still gaseous vapour, by the joint action of which on light the colour of the aggregate mass is produced. It is on this account that its absorptive action on the spectrum is not exerted in the same way as nitrous acid gas and iodine vapour, which themselves possess true colour. The other results obtained by Professor Forbes also harmonise with this conclusion.

But though we are thus obliged to relinquish the idea that aqueous vapour in any state is itself truly coloured, the observation of the existence of this particular condition of a condensing volume of steam is of great value; especially in its application to the phenomena of nature. Professor Forbes at once inferred from his investigation of it, that the condition of watery vapour he had observed "is the principal or only cause of the red colour observed in clouds;" and he is entitled to the credit of being, in fact, the discoverer of the true cause of the colours of dawn and sunset. In a subsequent elaborate communication 'On the Colours of the Atmosphere,' he investigated the history of science on this subject, refuting the fallacious inferences which had prevailed, and applied to it his own observations. "Soon after the maximum temperature of the day, and before sunset," he remarks, "the surface of the ground, and likewise the strata at different heights in the atmosphere, begin to lose heat by radiation; this is the cause of the deposition of dew, and consequently in severe weather we have vast tracts of air containing moisture in that critical state which precedes condensation,"—in other words, in the red opalescent condition, by which the rays of the setting sun are coloured accordingly. For the details of this subject we must refer to Professor Forbes's paper in the 'Trans. of the Royal Society of Edinburgh,' vol. xiv. But we cannot wholly agree with him as to the colours of the morning sky, the phenomena of which appear to us to be the same with those of the evening, but in the reverse order. Mr. Luke Howard had long before observed the connection of the presence in the sky of a stratum of vapour having the peculiar red colour, with the coming or actual formation of dew, and had given to it the name of the *dew-band*, of which many observations will be found in his 'Climate of London.'

VAPOUR-PLANE. This term, which was probably adopted by Luke Howard from De Luc, denotes a region of the atmosphere horizontal in its general direction, though subject to elevations and depressions, at or on and above which clouds form by the condensation of aqueous vapour, and on which, therefore, they appear to float. Its position is most readily recognised by the eye, by observing the modification of cloud called *cumulus*, the various aggregations of which, or distinct clouds, have a common base-line, or have their inferior surfaces at the same height. The subject has already been noticed in the articles CLOUD (col. 981) and DEW-POINT; but in the latter the vapour-plane is erroneously stated to be the superior, instead of the inferior, limit of a certain stratum of the atmosphere, and also that cloud forms below instead of above it, when it is regarded as a mathematical plane. But there are in fact as many vapour-planes in the atmosphere of any locality on the earth's surface, and at any time, as there are strata of clouds at different elevations; and in each case the plane becomes itself a physical plane, or stratum, throughout which cloud is produced. These successive strata originate, of course, in alternations of temperature and in the amount of aqueous vapour present in a given volume of air.

The following statement, founded upon the principal results deduced by the late Mr. J. Welsh from experiments made by him and described in his account of meteorological observations in four balloon ascents made in 1852 ('Phil. Trans.,' 1853, pp. 311-346), already cited under CLOUD, gives a general view of the nature of the alternations in question, which may be compared with the particulars of the height of the several strata of cloud passed through in those ascents, and stated in that article, col. 983.

The temperature of the air decreases uniformly with the height above the earth's surface, until, at a certain elevation, varying on different days, the decrease is arrested, and for a space of from 2000 to 3000 feet the temperature remains nearly constant, or even increases by a small amount, the regular diminution being afterwards resumed and generally maintained, at a rate slightly less rapid than in the lower part of the atmosphere, and commencing from a higher temperature than would have existed but for the interruption noticed. This interruption in the decrease of temperature is accompanied by a large and abrupt fall in the temperature of the dew-point, or by actual condensation of vapour, from which it may be inferred that the disturbance in the progression of temperature arises from a development of heat in the neighbourhood of the plane of condensation, or *vapour-plane*. The subsequent falls in the temperature of the dew-point are generally of an abrupt character, and productive of as many vapour-planes; corresponding interruptions in the decreasing progression of temperature are sometimes distinguishable, but in a less degree, as might indeed be expected from the fact that at greater elevations, and consequently lower temperatures, the variations in the absolute amount of aqueous vapour are necessarily smaller, and their thermic effects consequently diminished.

VAREC. An obsolete name for crude carbonate of soda.

VARIABLE. A quantity is said to vary when it changes value, whether gradually, or by jumps or starts. The notion of a variable quantity is the first which must be established in teaching the Differential Calculus, and requires a little explanation.

One magnitude at least is hardly conceivable without the notion of variation; we mean time or duration. Reckoning from a fixed epoch, the idea of *the present time* is nothing but that of the other extremity of a variable quantity, the variation of which we cannot suspend, even in thought. Again, in space-magnitudes, though we are not obliged to consider them as formed by variation, yet it is in our power to do so, and we are constantly learning the variation of length, area, or solidity consequent upon motion. And we can even consider this variation as arising from no act of our own, as independent of us, and out of our power to stop: though even when this is physically true, namely, that the variation is out of our power, we can conceive or imagine that it does stop, and trace the consequences of such stoppage. Variable *magnitude*, then, presents natural ideas, such as we not only easily acquire, but such as it would be difficult, if not impossible, to suppose that we could help acquiring.

But when we come to speak of *number*, the case is much altered. The constant phrase of an algebraist, "let x be a variable quantity," clear as it may be when quantity means magnitude, is not quite so plain when quantity means number as the representative of magnitude. There is something to be said as to how number is imagined to vary at all: and still more as to its *gradual* variation.

Number is an abstraction of the mind; it is not magnitude, but a mode of reference of one magnitude to another. If we might dare to say it, number is more of the nature of an opinion about magnitude than of magnitude itself. When we speak of a symbol representing a variable number, we know that, though we say the symbol changes its values, it is we ourselves who arbitrarily change the meaning of the symbol. We can imagine (waving all question about the possibility of our imagination, or its metaphysical truth) everything annihilated except two material points, one or both of which are in motion with respect to the other: but we cannot in such a case imagine x to be a symbol of a variable number. Unless some intellect be in existence to mean something by x, or to make a symbol of x, there can be no such thing as a variable number, or as the abstract idea of number at all. When we say, let x be a variable number, we must always be understood to mean, let x be a symbol which at one time we may be allowed to make to stand for one number, and at another time for another.

Now as to *gradual* variation. A point never changes its distance from another by, say a foot, without making every assignable lesser change in the interval. Or, a line which is lengthened from AB to AC by the motion of a point, must at some period of the change be equal to AD, if AD be anything between AB and AC. At least it is a necessary condition of *our* existence to believe this to be as evident as that two straight lines cannot inclose a space, though [SPACE AND TIME] we believe some would be found to deny it. But in the case of number, we cannot form anything but an approximation to this idea of gradual variation. We can pass from 1 to 2 by successive steps, by millions of millions of steps if we please: that is, h representing a small fraction, we can proceed from 1 to 2 by the steps $1+h$, $1+2h$, $1+3h$, &c., in such manner that we shall not arrive at 2 till a million of million of steps have been made. But this is not gradual variation, such as is in our ideas when we think of a line increasing in length by the recession of one extremity from the other. Nor, if we subdivide our steps ever so far, can we, in counting, cease to make steps; that is, we cannot imagine gradual variation of number. When, therefore, we talk of x standing for a number, which is also to represent the number of units in a variable length, we can only mean that our numerical progression can be made, if we please, by steps so small, that whatever length AD may represent, the linear representatives of some or other of the numerical steps by which we pass from the number in AB to the number in AC, may be made as near to AD as we please. It is, no doubt, in this essential distinction between the ideas involved in the variation of number and in that of magnitude, that the existence of INCOMMENSURABLE quantities takes its rise.

The first steps of the Differential Calculus are often embarrassed by a mode of speaking which appears as if two different symbols were used for the same thing. "Thus," it is said, "let x be a variable, and y a function of that variable, such that y is always $=x^2$. Then let x be changed into $x+h$, in consequence of which y becomes $y+k$; so that $y+k=(x+h)^2$." Now if x be the symbol of the *variable* quantity, which can only mean this, that both before the quantity has changed, and after, it is represented by x, how can it be allowed both to let x, as it were, imply its own variation in its very meaning and yet alter x into $x+h$ to denote that x changes? The truth is that the language is incorrect; it should be as follows:—Let there be two variable quantities, one of which is always the square of the other; let x be the value first given to one of the variables, and y to the other, so that $y=x^2$. Then let a new value $x+h$ be given to the first variable, in consequence of which the second becomes $y+k$, so that $y+k=(x+h)^2$. In fact, x does not represent a variable quantity, but a certain value given to a variable quantity.

VARIABLE STARS. This term has been applied to a class of stars which exhibit variations of brightness when observed from time to time. The branch of astronomy which takes cognisance of such objects is entirely of modern origin. The first star of which the light was found to be variable is a small star in the constellation of the Whale, usually designated in the catalogues of astronomers as *o* Ceti, or omicron Ceti. This star was observed by Daniel Fabricius, on the 13th of August, 1596, and noted by him as a star of the third magnitude. In the month of October of the same year, the star had vanished from observation, as if it had been extinguished, and for some time afterwards it does not seem to have attracted the notice of observers. Bayer, in his 'Uranometria,' published in 1603, has inserted the star, but he makes no allusion to its previous disappearance. The discovery of the variability of its light is due to Holwarda, a Dutch astronomer. In the month of December, 1638, Holwarda perceived the star during an eclipse of the moon, when it exceeded in brightness a star of the third magnitude. About the middle of the following summer he was unable to discover the slightest trace of it. However, on the 7th of November, 1639, he again detected it in its original position.

The star was now carefully observed by several individuals, among the rest, by the famous Hevelius. The discovery of the period of its variations is due to Bouillaud, who found that an interval of 333 days elapsed between two successive disappearances or reappearances. The results of modern observation indicate the exact period to be $331^d\ 15^h\ 7^m$.

In addition to the star to which we have just been referring a great many other stars have been found to be variable, and the number is rapidly increasing every year. This important result is due in a great degree to the practice of carefully scrutinising small stars in connection with the search for asteroids which has been so assiduously prosecuted in recent years by a number of individuals in different countries. We shall now allude briefly to the peculiarities of two or three other examples of variable stars.

β Persei. This star, usually termed Algol, which is situate in the head of Medusa, was found by Montanari and Maraldi to exhibit strange fluctuations of brightness, but the period of its variations was first established by Goodricke in 1782. It generally appears as a star of the second magnitude. In the short space of three hours and a half it descends to the fourth magnitude, and then in an equal interval of time regains its usual brightness. It shines as a star of the second magnitude during the space of two days, thirteen hours, and three-quarters, and it consequently passes through the complete cycle of its changes in two days, twenty hours, and three quarters. According to Argelander, the exact period is $2^d\ 20^h\ 48^m\ 52^s$.

β Lyræ. This star was first found to be variable by Goodricke in 1784. It is an object of great interest, inasmuch as it possesses a double maximum and a double minimum. When it arrives at its maximum brightness, it resembles a star of the third magnitude. At one of its minima it appears between the third and fourth magnitude, and at the other, between the fourth and fifth magnitude. Argelander has found that it passes through its variations in $12^d\ 21^h\ 53^m\ 10^s$.

δ Cephei. This interesting star was also first discovered to be variable by Goodricke in 1784. Argelander determined its period to be $5^d\ 8^h\ 47^m\ 39{\cdot}5^s$; but the late Mr. Johnson, director of the Radcliffe Observatory, Oxford, fixed the period at $5^d\ 6^h\ 42^m\ 18{\cdot}4^s$. At its minimum it is equal to a star of the fifth magnitude, and it hence increases until it resembles a star between the third and fourth magnitude at its maximum. The interval which elapses between the maximum and the minimum is $3^d\ 19^h$, while between the minimum and the maximum the interval is only $1^d\ 14^h$.

Some stars have been discovered to be variable, but their fluctuations are so irregular that it has been hitherto found impossible to reduce them to any fixed law. A remarkable example of this kind is furnished by the bright star in the southern hemisphere, denominated *η* Argûs. In 1677, Halley, during his residence at St. Helena, classed it among the stars of the fourth magnitude. In 1751, Lacaille estimated it to be of the second magnitude; however Burchell, who resided in South Africa from 1811 to 1815, again ranked it among the stars of the second magnitude. From 1822 to 1826, it was estimated to be of the second magnitude by Brisbane and Fallows, who observed it, the former at New South Wales, and the latter at the Cape of Good Hope. In 1827, Burchell, while residing at St Paul's, Brazil, estimated it to be of the first magnitude, and almost equal to *α* Crucis; but in the following year he found from observations made at Goyer, that it had again descended to the second magnitude. Johnson, who observed the star at St. Helena between 1829 and 1833, estimates it to be of the second magnitude; and Taylor's observations at Madras during the same period indicate the same fact. Sir John Herschel also, from the time of his arrival at the Cape of Good Hope in 1834 till 1837, estimated it invariably to be between the first and second magnitude. But on the 16th of December, 1837, while engaged in making photometric observations of the small stars in its vicinity, he was surprised to find that it had rapidly increased in brightness. It was now equal to α Centauri, and far surpassed in brightness all the other fixed stars except Canopus and Sirius. It attained its maximum brightness on the 2nd of January, 1838. Shortly afterwards it grew fainter, and it continued to diminish in brightness till March, 1843. In the following month it again rapidly increased in brightness. According to the observations of Maclear at the Cape of Good Hope, and of Mackay at Calcutta, it now surpassed Canopus in brightness, and almost rivalled Sirius. It continued for several years to exhibit this great degree of brightness, when it began to fluctuate as before.

The new stars which have appeared in the heavens, and of which several instances are recorded in history, probably belong to the class of variable stars. The most notable objects of this description are the new star which appeared in 1572, of which Tycho Brahe has given a detailed account, and the new star of 1604, which was observed by Galileo and Kepler.

The following table of variable stars, drawn up by Mr. Pogson, is extracted from vol. xvii. of the 'Observations made at the Radcliffe Observatory,' Oxford. Mr. Pogson is known as one of the most successful explorers of this interesting field of astronomy.

Name.	Discoverer of Variability.	Observed Variation of Magnitude.		Elements.		Authority.
				Epoch.	Period.	
		Max.	Min.			
α Cassiopeiæ	Birt	2·0	2·5	Uncertain	79·1 days	Argelander.
ο Ceti	Holwarda	2·0	Under 12	1861, June 16·45	331·3363 days	Argelander.
β Persei	Montanari	2·3	4·0	†1854, Oct. 8·22355	2·86727 days	Argelander.
λ Tauri	Baxendell	4·0	4·5	†1858, June 2·633	3·953 days	Baxendell.
R Tauri	Hind	8·0	Under 13·5	1856, Feb. 2	330 days	Winnecke.
ε Aurigæ	Heis	3·5	4·5	Uncertain	Unknown	
R Leporis	Schmidt	7	..	Uncertain	Unknown	
α Orionis	Herschel	1	1·5	1852, Nov. 26	196 days	
ζ Geminorum	Schmidt	3·8	4·5	†1857, Feb. 7·3000	10·15833 days	Argelander.

The epochs marked thus † are epochs of minimum.

No satisfactory explanation of the phenomena of variable stars has hitherto been advanced by any inquirer. Some astronomers have suggested that the variations of light may be due to dark bodies circulating around the stars. According to others, the fluctuations of brightness may arise from the presence of dark tracts on the surfaces of the stars, which are periodically turned towards the earth by the revolution of the stars on their axes. The phenomena, however, are in general so irregular, that neither of these hypotheses is capable of satisfactorily accounting for them.

VARIATION. Under this head comes the explanation of a part of the language of proportion which is much used, and which was once very prominent in English mathematical writings. We refer to such phrases as the following:—A varies as B—A varies inversely as B—the gravitation of particles varies inversely as the squares of their distances—the time of oscillation of a pendulum varies as the square root of its length, &c.

When we say that one thing varies as another, we mean that there are two variable magnitudes which have this property, that if when the first changes from A to B the second change from a to b, then A is to B in the same proportion as a to b. And when we say that one thing varies inversely as another, we mean that if when the first changes from A to B the second changes from a to b, then—

$$A : B :: \frac{1}{a} : \frac{1}{b} \text{ or } :: b : a.$$

The modes of denoting these laws of connection used to be, in English works—

$$A \propto a \qquad\qquad A \propto \frac{1}{a}.$$

These were in fact but modes of writing the equations

$$A = c\,a \qquad\qquad A = \frac{c}{a}$$

in a manner which should recognise their existence without obliging us to think of the particular value of the constant c. According to the preceding equations, if we take the first, and suppose that A changes into B when a changes into b, we see obviously that $A \div B$ is the same as $a \div b$, both being equal to c. And $A \propto a$ informs us that $A \div a$ is always the same quantity, without saying what it is.

When one quantity varies as both of two others jointly, it means that if either of the second and third mentioned remain constant, the first varies as the other. Thus the price of a quantity of goods varies jointly as the number of things and the price of each. At a given price per article, the whole price varies as the number of things; for a given number of things, the whole price varies as the price of one. When x varies as y and z jointly, the equation $x = c\,y\,z$ is implied.

We are rather inclined to regret the complete disappearance of the *notation* of variations which has taken place within the last thirty years, though the *phraseology* is still in some degree of use. It is now usual either to write equations at full length, or to make an equation of the variation itself, which can always be done by a proper choice of units. Thus $A \propto a$, or $A = c\,a$, can always be made $A = a$, if such choice of units be made in which to measure the magnitudes A and a as will make $c = 1$. This must be done by contriving that A and a shall become unity together. But this, however convenient for mere calculation, is likely enough to produce confusion in the mind of the learner, and actually does so in many instances. It is obvious enough that of two different kinds of magnitude one may *vary* as the other:

thus the height of the barometer (a length) varies as the pressure of the atmosphere on a given surface (a weight). But it is just as obvious that one magnitude cannot be *equal* to another, unless the two be of the same kind. When therefore a writer on mechanics, with little or no previous explanation about the units employed, states that the *weight* of a body is its *mass* multiplied by the *force* of gravity, or that the *pressure* on a mass is equal to the *mass* multiplied by its *acceleration*, he writes effectively only for a reader who knows the subject already. The weight of a body varies jointly as its mass and the acceleration which the force of gravity would create in one second. Alter either of these alone, and the weight is altered in the same proportion. Hence, if w, m, g be the numbers of units of their several kinds in the weight, the mass, and the acceleration caused by gravity, the equation $w = c\,m\,g$ must subsist, where c is a numerical constant depending on the units employed. If the weight which is called 10 (pounds, ounces, or whatever they may be) belong to the mass called 5, when acted on by such gravity as produces an acceleration of 4 (feet, yards, or whatever the unit of length may be) in the time called 1 (second, minute, or other unit of time), then $10 = c \times 5 \times 4$, or $c = \frac{1}{2}$. So long as the same units of length, time, mass, and weight are employed, the equation $w = \frac{1}{2} m g$ must subsist: change the units, and the constant c must have another value, to be again determined from an instance. When the writer above mentioned says that $w = m\,g$, he means, or ought to mean, that it is an agreement between him and his reader that whatever mass may be called 1, and whatever may be meant by 1 of length and 1 of time, the weight which is called 1 shall be that of the mass 1 acted on by the force of gravity 1. The older writers, who used variations, needed no specifications of this kind, since the actual concretes themselves were the subjects of reasoning, and the variation asserted was true both of the concrete magnitudes and of any system of units which they might adopt. The introduction of their units was naturally and easily made; and when variations became equations, the student could not help seeing the introduction of all conditions depending on the mode of measurement. In dropping the notation of variations, our writers passed into that want of distinct explanations of primary terms which was the characteristic of many of the French writers.

The beginner must carefully bear in mind that one quantity does not vary *as* another, because it varies *with* that other. A square and its root vary together, but the square does not vary *as* its root: if, for instance, the root be doubled, the square is not doubled, but quadrupled.

It is however most important to remember that when two quantities change together, in any manner whatsoever, the increment of the one varies as the increment of the other very nearly, if both the increments be small, and the more nearly the smaller they are. Thus, if we know that when x has a certain value, the addition of ·01 to x gives an addition of ·001 to its logarithm, we may be sure that the addition of $\cdot 01 \times h$ to x will give an addition of $\cdot 001 \times h$ to the logarithm, very nearly, as long as $\cdot 01 \times h$ is small.

VARIATION OF THE COMPASS. [COMPASS CORRECTION; DECLINATION; MAGNET; TERRESTRIAL MAGNETISM.]

VARIATION OF THE MOON. [MOON.]

VARIATION OF PARAMETERS. A *parameter* was a name originally given to a particular line connected with a conic section: being the third proportional to a diameter and its conjugate. In time the word was applied to any line which serves by its value to distinguish, or to help to distinguish, one individual of a family of curves from another: thus the radius of a circle, the axes of an ellipse, the co-ordinates of the centre of either, were called parameters. When a word gets into the descriptive name of a method, it may happen, as part of a phrase, to outlive its own separate use; and such has been the case with the word *parameter*. As this word is now generally abandoned, *element* is the most frequent substitute for it, and it would be desirable to speak of *variation of elements*.

Whatever phrase we may use, the thing occurs both in physics and mathematics, in modes which are closely connected with each other. A planet moves in a curve which is not an ellipse, but which would change and become an ellipse if the disturbing attractions of the other planets were removed, and that of the sun only continued. The easiest way of calculating the planetary motions is to consider the planet as moving in this ellipse, while during the motion the elements which determine the ellipse are perpetually changing; so that the form and position of the ellipse both vary. This is done in such manner that the ellipse of each moment is that which the planet would go on to move in, if at that moment the disturbing attractions were all removed. The advantage is that in this case the elements will vary very slowly, or it will be long before the disturbing attractions produce much effect. In theory, any curve might be taken. A planet for instance might be supposed to move in a parabola, which varies its dimensions and position in a manner to be determined. In TROCHOIDAL CURVES, all the curves given are produced by a point moving in a circle with variable elements; that is, of variable centre, though given radius. If it were required to investigate trochoidal curves with loops and undulations of different magnitudes, the best way would be to consider them as made in the same manner, with a circle of variable radius also: or else to make both circles variable.

In the differential calculus the variation of elements is introduced thus:—If an algebraical expression containing some variables and some constant elements be proper to answer a certain purpose, it is not impossible that it may answer the same purpose when the constants are made variable, provided they be made to vary in a proper manner. Now, if the purpose which is to be answered involve differentiation, the infinity of the number of suppositions which may be made as to the variation of the (former) constants is equivalent to introducing an arbitrary function instead of each constant, to be determined by the conditions of the question. Two species of cases have frequently arisen.

1. When under certain circumstances a problem is solved by an expression containing certain constants, and the circumstances are then altered; it is often convenient to inquire whether the altered problem might not be solved by the same expression, on the supposition that the constants become variable. And the question then is, how the (former) constants are to be made to vary.

2. Without any alteration of the circumstances, having a solution which contains constants, it may be asked how to substitute variables in place of constants, so that the altered expression may still be a solution.

In both cases it is obvious that so soon as the constants are made variable the differential co-efficients of all expressions into which they enter will receive an accession of terms above what they had before. These new terms, which we may describe as functions of the variations of the elements, must, in the first case above noted, be so taken as to provide for the effect of the altered circumstances. But in the second case they must destroy one another's effects altogether. We shall take a few instances in which the variation of elements is successful or unsuccessful.

1. The equation $y' + \text{P}y = 0$, P being a function of x, is solved by

$$y = \text{C}\epsilon^{-\int P dx}$$

C being a constant. Now alter the equation into $y' + \text{P}y = \text{Q}$, and to meet the alteration, let C become a function of x. On this supposition $y' + \text{P}y$ becomes

$$-\text{CP}\epsilon^{-\int P dx} + \text{C}'\epsilon^{-\int P dx} + \text{CP}\epsilon^{\int P dx}$$

But this ought to be Q: therefore we must have

$$\text{C}'\epsilon^{-\int P dx} = \text{Q}, \quad \text{or } \text{C} = \int(\text{Q}\epsilon^{-\int P dx}) + \text{E}$$

E being another constant. Here $y' + \text{P}y = \text{Q}$ is solved by $y' + \text{P}y = 0$ and subsequent variation of an element.

Now try $y' + y^2 = 0$ and $y' + y^2 = \text{Q}$ in the same manner. The first is solved by $y = (x + \text{C})^{-1}$ and if C be made variable, and y thus altered be introduced into the second, it is found, making $z = x + \text{C}$, to require the solution of

$$z' + \text{Q}z^2 - 1 = 0$$

as difficult an equation as the original. In this case then we are unsuccessful.

2. Let $\frac{du}{dx} + \frac{du}{dy} = x$. One solution of this is $u = \frac{1}{2}x^2 + a(x-y) + b$, a and b being constants. To find a more general solution of this same equation let b be a function of a, a being a function of x and y. We have then

$$\frac{du}{dx} = x + a + \left(x - y + \frac{db}{da}\right)\frac{da}{dx}$$

$$\frac{du}{dy} = -a + \left(x - y + \frac{db}{da}\right)\frac{da}{dy}$$

and the equation will obviously still be satisfied if b and a be so related that

$$x - y + \frac{db}{da} = 0$$

Now as b is what function of a we please, so also is $\frac{db}{da}$: hence it follows that if $b = \phi a$, and $x - y = -\phi' a$, we may make a what function of $x-y$ we please. Let $a = \psi(x-y)$ and let $\chi v = \int v \psi' v\, dv$. We have then

$$u = \frac{1}{2}x^2 + (x-y)\psi(x-y) + \chi(x-y)$$

of which the last two terms merely amount to an arbitrary function of $x-y$, so that the complete solution is

$$u = \frac{1}{2}x^2 + \phi(x-y)$$

ϕ meaning any function whatever.

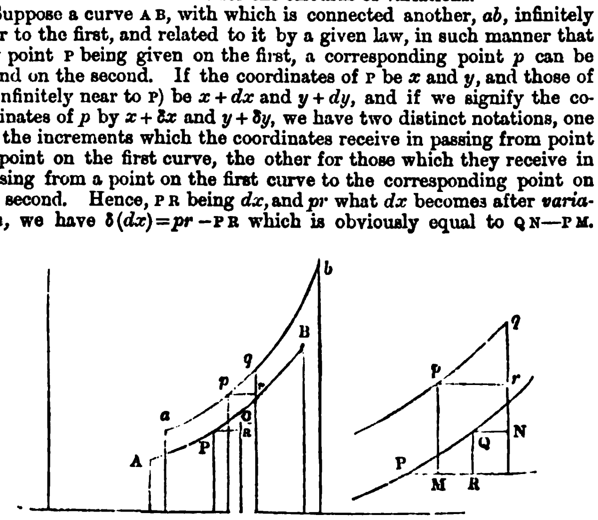
This subject has many developments. We have introduced it here under the idea that some students of the differential calculus may be led to consider it at an earlier period of their reading than books will give it to them.

It is to be remarked that this method does not merely search for *some* solutions of a question: if the number of constants be sufficient, it goes direct to the most general solution. In our first example there is no function of x but what is capable of being represented by

$c\epsilon^{-\int P dx}$; in our third there is no function of x and y but what is capable of being represented even by $\frac{1}{2}x^2+a(x-y)$ or $\frac{1}{2}x^2+b$, and also by $\frac{1}{2}x^2+a(x-y)+b$ with a relation between a and b. Whatever function of x, or of x and y, will solve these equations, is sure to be found, if the method be successful. This point would need a little more development than we have here space to give.

VARIATIONS, CALCULUS OF. The preceding words might seem fit to include every organised mode of dealing with the variations of value which algebraical quantities are made to receive; the differential calculus, for example: but they have a technical meaning, which we proceed to explain. When a quantity is subject to one sort of variation only, the consideration of that variation belongs to the simple differential calculus: but when it is subject to two or more distinct sorts of variation, suppose that of the differential calculus and another, then the mode of dealing with the second sort of variation is said to belong to the calculus of variations. In dynamics, for example [VIRTUAL VELOCITIES], there are two distinct species of motion to consider: one which, at the end of the time t, the system is about to take during the ensuing time dt, in consequence of the velocities acquired by its particles; and another which, without any consideration of the first, must be impressed upon it for the examination of the conditions which express the equivalence of the impressed and effective forces. Here then is a case for the calculus of variations.

Suppose a curve A B, with which is connected another, ab, infinitely near to the first, and related to it by a given law, in such manner that any point P being given on the first, a corresponding point p can be found on the second. If the coordinates of P be x and y, and those of Q (infinitely near to P) be $x+dx$ and $y+dy$, and if we signify the coordinates of p by $x+\delta x$ and $y+\delta y$, we have two distinct notations, one for the increments which the coordinates receive in passing from point to point on the first curve, the other for those which they receive in passing from a point on the first curve to the corresponding point on the second. Hence, P R being dx, and pr what dx becomes after *variation*, we have $\delta(dx)=pr-$P R which is obviously equal to Q N—P M.



But P M is δx, and Q N is what δx becomes when x is changed into $x+dx$, whence Q N$-$P M$=d(\delta x)$; or $\delta dx=d\delta x$, and the same may be proved for y. We shall now recapitulate the results of the further application of this method. It is quite beyond our limits to attempt to prove them; so that, referring to works on the differential calculus for further information, we shall content ourselves with some remarks on the loose manner in which this calculus is nearly always applied to questions of maxima and minima, and to a very few words on its history.

1. The operations of differentiation and variation are interchangeable in order, as in $\delta dx = d\delta x$, $\delta\int \text{V}dx = \int\delta(\text{V}dx)$, &c.

2. If y be a function of x, and if y', y'', &c., stand for successive differential coefficients of y with respect to x, the successive differential coefficients of $\delta y - y'\,\delta x$ are $\delta y'-y''\delta x$, $\delta y''-y'''\delta x$, $\delta y'''-y^{\text{iv}}\delta x$, &c.

3. Let V be a function of x, y, y', y'', &c., and let $\int \text{V}dx$ taken from $x=x_0$ to $x=x_1$ be required, and let y_0, y'_0, y''_0, &c., and y_1, y'_1, y''_1, &c., be the values of y, y', y'', &c., when $x=x_0$ and $x=x_1$: and let moreover $\omega=\delta y-y'\delta x$, which becomes ω_0 and ω_1 at the two limits. Let the differential coefficients of V with respect to x, y, y', y'', &c., separately made variable, be X, Y, P, Q, &c., and let the complete differentiations of these with respect to x be denoted by accentuations, and their limiting values by subscript ciphers and units as before: then we shall have for $\delta\int \text{V}dx$ the following formula:—

$$\begin{aligned}
&\text{V}_1\,\delta x_1 - \text{V}_0\delta x_0 \\
&+ (\text{P}_1 - \text{Q}'_1 + \text{R}''_1 - \&\text{c.})\,\omega_1 - (\text{P}_0 - \text{Q}'_0 + \text{R}''_0 - \&\text{c.})\,\omega_0 \\
&+ (\text{Q}_1 - \text{R}'_1 + \text{S}''_1 - \&\text{c.})\,\omega'_1 - (\text{Q}_0 - \text{R}'_0 + \text{S}''_0 - \&\text{c.})\,\omega'_0 \\
&+ (\text{R}_1 - \text{S}'_1 + \text{T}''_1 - \&\text{c.})\,\omega''_1 - (\text{R}_0 - \text{S}'_0 + \text{T}''_0 - \&\text{c.})\,\omega''_0 \\
&+ \;.\;.\;.\;.\;.\;.\;.\;.\;.\;.\;.\;.\;.\;.\;.\;. \\
&+\int_{x_0}^{x_1} (\text{Y} - \text{P}' + \text{Q}'' - \text{R}''' + \&\text{c.})\,\omega dx.
\end{aligned}$$

The most usual application of the preceding formula, in its most general geometrical form, is as follows:—V being a given function of x, y, y', &c., it is required to draw a curve such that $\int \text{V}dx$ shall be the greatest possible or the least possible, provided that at one limit of integration x_0 and y_0 shall be coordinates of one given curve, and that at the other limit x_1 and y_1 shall be coordinates of another given curve. Such a case arises when it is required to draw the shortest line between two given curves, or to find in what form and position a flexible curve of given length will rest when its ends are supposed to slide upon given curves. We have pointed out (Differential Calculus, 'Library of Useful Knowledge,' ch. xvi.) that the ordinary mode of treating these questions is not sufficiently general, and must in certain cases even lead to positive error. We intend here to enforce this conclusion by showing that even in more ordinary questions of maxima and minima the same want of generality may lead to the same sort of false conclusion.

A maximum, or greatest value, means one which is greater than any neighbouring value; so that when a function is at its maximum, any allowable slight change must be one of diminution. For greater read less, and for diminution increase, and we have the definition of a minimum. Now an ordinary question of maxima and minima is as follows:—ϕx being a function of x, what are the real values of x which make it a maximum or minimum? There is a maximum when $x=a$, provided that $\phi(a+h)$ and $\phi(a-h)$, when both are possible, are both less than ϕa: but if one of the two $\phi(a+h)$ and $\phi(a-h)$ be impossible, there is a maximum if *both values* of the other be less than ϕa. In all these cases it is supposed that h may be as small as we please. Now—

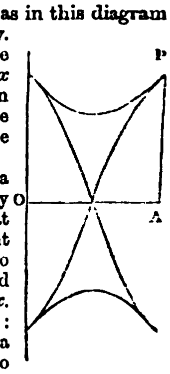
1. When $\phi(a+h)$ and $\phi(a-h)$ are both real, the theory explained in MAXIMA AND MINIMA is perfectly sufficient: there is a maximum when $\phi' x$ changes from positive to negative in passing through $\phi' a$, and there is not a maximum in any other case.

2. When $\phi(a+h)$ is impossible, there is a maximum if both values of $\phi' x$ be positive from $x=a-h$ up to $x=a$: when $\phi(a-h)$ is impossible, there is a maximum if both values of $\phi' x$ be negative from $x=a$ to $x=a+h$.

It is the neglect of the second case which has led to the oversight in the calculus of variations which we shall presently mention. We shall now propose a case as follows:—It is required to find the maximum value of y in the equation

$$y=(1-x)^{\frac{3}{2}}+x^{\frac{3}{2}}=\phi\,x.$$

The form of the curve which has this equation is as in this diagram; O being the origin and O A (= A P) being unity.



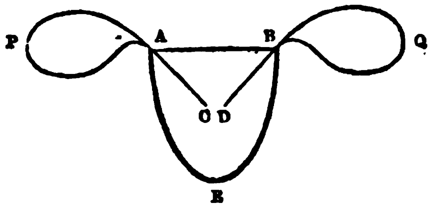
Now it ought certainly to be said that A P is the greatest ordinate of the curve, but neither is $\phi' x$ here equal to nothing, nor does it change sign. In fact when $x=1$, we have $\phi\, x=1$, $\phi' x=1{\cdot}5$. The second criterion shows that A P is a maximum; the first shows nothing of the kind.

Now we can easily imagine it said, that in such a case as the preceding, A P, though unquestionably the greatest ordinate the curve can have, is not what is technically called a maximum: but it is meant that the last term should be restricted solely to denote those values of ϕx in which $\phi\,(x+h)$ and $\phi\,(x-h)$ are *both possible*, and both less than ϕx. To this, *ceteris paribus*, there could be no objection: it often happens that the technical use made of a foreign term will not bear, and is not meant to bear, translation into our own language. The word *maximum*, even in its widest allowable use, and if all we ask for should be granted, will not answer to *greatest*: for there may be several maxima and minima, and some of the minima may be greater than some of the maxima, which cannot be true of the words when translated. Suppose, then, that the word maximum is so restricted as to apply to no value of ϕx except when $\phi\,(x+h)$ and $\phi\,(x-h)$ are both possible: the disadvantage will be twofold. First, in every problem of maxima and minima, or in every problem which is reducible to one of maxima and minima, we shall have to invent an additional term to signify, perhaps, the very greatest or very least value of the function. Secondly, in applying the same limitation to the calculus of variations we shall frequently be obliged to forego the solution of which we are in search, unless we look for the very case, as an answer to a problem of maxima and minima, to which we have previously refused to apply the term maximum or minimum.

In order to make $\int \text{V}dx$, as before described, a maximum, it is generally presumed that $\delta\int \text{V}dx$ must$=0$, and that y must be found in terms of x from this condition. Now the truth is that $\int \text{V}dx$, after the variation, becomes $\int \text{V}dx + \delta\int \text{V}dx$, and all that is absolutely necessary is that $\delta\int \text{V}dx$ should be always negative, for all values of δx and δy between the limits, and for all values which are consistent with the limiting conditions, at the limits. It is easily shown that this requires, as to the indefinite integral part, the following equation:—

$$\text{Y}-\text{P}'+\text{Q}''-\text{R}'''+\ldots\;=0;$$

and if we be resolved not to consider any points of the limiting **curves,** except those at which δx_0, δx_1, δy_0, δy_1, may be either positive **or negative,** as we please, then it is easily proved that the rest of the **expression** for $\delta\int vdx$ must also vanish, and this limitation is generally **made in works** on the subject, by which means solutions are misstated **and may even** be lost sight of. Thus it is generally asserted that the **shortest line** between two curves is always a straight line which is per**pendicular** to the tangents of both; and that a flexible chain, allowed **to slide between** two curves, with an extremity on each, is in equili**brium when** it is in the form of a catenary perpendicular to the **retaining curves** at the points of suspension. On this we need only



direct attention to the accompanying figure. The shortest line that can be drawn between the curves A P A and B Q B is A B, which is perpendicular to neither of the tangents A C, B D; and the flexible chain A E B will hang from the cusps A and B without the slightest tendency to become perpendicular to A C and B D at its extremities.

The fact is, that owing to the very great complexity of the mathematical part of the subject, the part of the calculus of variations which relates to the maxima and minima of integral forms is in a very incomplete state: and it is found impossible to introduce what has been done into elementary works. How long it will be before the mere vanishing of a differential or variation will cease, in elementary works, to be taken as the conclusive evidence of a maximum or minimum, depends on the degree in which mathematics will be studied as a discipline, and not solely as an instrument of physical inquiry.

The history of a large part of the calculus of variations is simply that of dynamics from the time when D'Alembert proposed his celebrated principle (1743). But long before this, the questions of maxima and minima which ultimately came to occupy the greater part of professed works on the calculus of variations, took their rise in the researches of the two Bernoullis, and led to their celebrated quarrel. [BERNOULLI, in BIOG. DIV.] The first problem, namely, to find the curve of shortest descent between two given points, proposed by John Bernoulli, was quickly followed by others of the same kind, proposed by James Bernoulli, in which the curve to be found was required to be of a given length. The prevalence of problems in which this last condition was contained, led to the name of the *Solution of Isoperimetrical* problems, by which the calculus in question was long distinguished. But it must be noted that the first who solved any such problem as has since been referred to the calculus of variations, whatever may have been his method, was Newton, who, in the Scholium to the 34th proposition of his second book, gives, without demonstration, the construction requisite for finding the solid of least resistance. [PRINCIPIA, cols. 739–40.] The subject was successively taken up by Brook Taylor, Euler, Simpson, Emerson, and Maclaurin, the second of whom first gave the general equation which determines the nature of the function required, independently of the limits of integration; and his 'Methodus inveniendi lineas curvas proprietate maximi minimive gaudentes,' published in 1744, being the last of his efforts on this subject which was made before Lagrange came into the field, is an epoch in its history. Lagrange's first change in existing methods was the introduction of the specific symbol δ to stand for the variation of x (which suggested to Euler the name of the *Calculus of Variations*) and of the formation of all that part of $\delta\int vdx$ which is free from the integral sign. Furnished with such an apparatus, he undertook problems of a much more complicated class than any of his predecessors, and stamped upon the subject the form which it has never since lost, at the same time that he gave it an extension which it cannot be said to have since greatly exceeded. Lagrange's memoirs were contained in the first and fourth volumes of the 'Miscellanea Taurinensia,' published in 1760 and 1773. The 'Mécanique Analytique' of Lagrange (first edition, 1788) must also be regarded as the first work in which the calculus of variations was fully applied to problems of statics and dynamics, in the manner since universally followed. A complete and most excellent history of the rise and progress of the branch of this calculus which treats of the maxima and minima of undetermined integrals is contained in, and forms the substance of, Woodhouse's 'Treatise on Isoperimetrical Problems,' Cambridge, 1810. This work carries on the history to the end of the last century, and is worthily succeeded by Mr. Todhunter's recently published 'History of the Calculus of Variations,' Cambridge, 1861, 8vo, which describes what has been done by the successors of Lagrange down to the present time. Accordingly, there is now no branch of mathematics of which *all* the history is so well written as the calculus of variations. The only complete and separate elementary work on the subject is Jellett's 'Calculus of Variations,' Dublin, 1850, an able, elaborate, and, the subject considered, intelligible work.

VARICELLA, or *Varicella lymphatica*, is the eruptive disease commonly called chicken-pox, and which has been described by different writers under the names of *chrystalli, variolæ, pusillæ, variolæ, spuriæ*, &c. It is almost peculiar to infants and young children; and the eruption appears either without premonitory signs, or after two or three days of slight illness. The eruption commences on the shoulders, neck, and breast: on the scalp and back it is usually abundant, but the face is only slightly affected. It consists of vesicles, about as large as a split-pea, full of transparent fluid, and lenticular, conoid, or globular in their form. They are surrounded by a slight superficial redness, and successive crops of them appear for two or three days, the old vesicles shrivelling up as the new ones are formed. Most of the vesicles burst naturally, and the cuticle which covered them falls to the level of the surrounding skin; but some shrink, the fluid within them becoming whey-like, or, if they be much irritated, purulent. After drying they form small scabs, which fall off in grains, and sometimes leave small superficial scars. The whole course of the disease occupies about a week, and is not attended by any important constitutional disturbance. It therefore requires no particular treatment.

The first writers on varicella considered it as only a mild form of variola, or small-pox, and the same view is maintained by some modern authors, especially by Dr. Thomson of Edinburgh. It is however more probable that chicken-pox and small-pox are essentially different, on these grounds: 1. They sometimes prevail in distinct epidemics, no case of genuine small-pox occurring among many of chicken-pox. 2. The characters of the chicken-pox eruption are altogether different from those of small-pox, even in its mildest and most modified form. 3. Chicken-pox is not inoculable, though the mildest small-pox is. 4. Chicken-pox is altogether unaffected by previous vaccination, and does not prevent the action of vaccine matter.

VARICOSE VEINS. [VEINS, DISEASES OF THE.]

VARIOLA. [SMALL POX.]

VARIOLARIN. A substance extracted from lichens. It is supposed to be identical with LECANORIC ACID.

VARIX. [VEINS, DISEASES OF THE.]

VARNISH, a fluid applied to the surfaces of various articles, as wood, &c., and which, by the evaporation or chemical change of a portion, leaves upon them a shining coating, impervious to air and to moisture.

Varnishes may be divided into three classes: alcoholic or spirit varnishes, volatile-oil varnishes, and fixed-oil varnishes.

Spirit or *alcoholic* varnishes are in general prepared very readily, are easily applied, soon become dry, and emit no disagreeable smell: they are, however, liable to crack or scale off, and are incapable of resisting friction or blows. One kind is made as follows:—Mastic 6 ounces, sandarac 3 ounces, reduced to fine powder, and 4 ounces of coarsely-powdered glass; digest in a quart of spirit of wine, contained in a loosely-corked vessel, for three days in a warm room, shaking the mixture frequently; then add 3 ounces of melted Venice turpentine to the warm solution, stirring thoroughly till mixed; let the mixture remain in a warm room for about a week, and then strain it. This is a strong varnish applied to chairs and other articles of furniture. Another consists of copal, which has been liquefied and afterwards very finely powdered, 3 ounces, mastic 2 ounces, and elemi 1 ounce; digest in a warm room in a quart of spirit, and when the solution is complete add 2 ounces of Venice turpentine. This is stated to form a good varnish for violins and other musical instruments. For different purposes the ingredients of spirit-varnishes are considerably varied; seed-lac, benzoin, anime, frankincense, entering into the composition, according to the use to be made of them.

The only *essential* or *volatile oil* largely used in varnishes is oil, or, as it is commonly called, spirit of turpentine; and one of the best varnishes into the composition of which it enters is copal varnish. [COPAL VARNISH.] This is chiefly used for pictures. Another powerful varnish is prepared by adding to highly-rectified oil of turpentine about an eighth of its weight of caoutchouc; this, indeed, is the varnish now generally employed in waterproofing the garments well known by the name of Mackintoshes; sometimes gas-oil, or coal-naphtha, is employed for the same purpose, but its smell is more disagreeable, and longer in going off. The preparation of this varnish does not require the application of heat.

In *fat* or *fixed-oil* varnishes, the solvent undergoes a chemical change, and dries with the substance dissolved: these are sometimes termed fat varnishes. We shall mention two kinds, first the most colourless: this is prepared by mixing 4 ounces of copal, which has been liquefied and finely powdered, with oil of turpentine and drying linseed-oil, of each 10 ounces; digest in a gentle heat till the whole is dissolved; strain it after standing a few days. This forms a solid and nearly colourless glazing, and dries easily at common temperatures. The black varnish used by coachmakers is thus prepared: take of amber 16 ounces, melt it, and add to it half a pint of drying linseed-oil boiling-hot, 3 ounces each of asphalt and rosin, both in fine powder; stir the materials together till they are thoroughly melted and incorporated, add to the mixture a pint of warm oil of turpentine: this varnish is intended to dry to a very hard consistence.

Dr. Cattell, in 1860, proposed to manufacture varnish by dissolving gums in two kinds of liquids, ethylated and methylated. The gums are of the usual kinds; but the varnishes are grouped in one or other of two classes, according to the class of solvent employed. Alcohol, wood spirit, methylated spirit, peat oil, shale oil, benzole, and coal naphtha, are among the solvents named. Various proportions are named between the ingredients, according to the kind of varnish intended to be produced. We may here mention that Mr. Cooley describes no less than sixty-four kinds of varnish, of which the chief are placed under the headings of amber, balloon, black, body, book-binders', carriage, Chinese, copal, crystal, drying, Dutch, etching, flexible, furniture, glass, gun-barrel, hair, india-rubber, Italian, Japan, lac, mahogany, mastic, oak, oil, leather, picture, printers', spirit, toy, transfer, turpentine, and wax varnish.

Two special kinds of varnish are connected with the processes of *French polishing* and *lacquering*.

French polishing depends on the use of a varnish which, from the ingredients in its composition, admits of being rubbed until great smoothness and gloss are produced. The best French polish is made of pale shellac and rectified spirits of wine; in the next best quality, wood-naphtha is substituted for the spirits of wine. Sometimes mastic, gum elemi, or gum sandarac are used instead of shellac; and a little linseed-oil or copal is mixed with the spirit. When intended to modify the colour of the wood to which the French polish is to be applied, small proportions of other ingredients are added, such as dragon's blood, alkanet root, red sandalwood, turmeric, gamboge, &c. French polish is never required to be so limpid as other varnishes. When an article of wood is to be French polished, the surface is brought to a very smooth and clean state. A rubber is made by rolling up a strip of thick woollen cloth, and using the soft elastic edge of the coil. The rubber, being wetted with the French polish, is inclosed in a doubled cloth of soft linen, the outer surface of which is slightly touched with a drop of raw linseed-oil, and the workman rubs it steadily over the wood, until the rubber and linen become nearly dry. He supplies a second time, and again a third, and perhaps a fourth time, rubbing the wood steadily until each portion of polish is worked in. Very little of the composition is actually laid on; the effect being due rather to skilful manipulation than to a thick layer of glossy material.

Lacquer differs from ordinary varnish and from French polish in being applied either to metal or to hard wood; in other respects lacquers may be regarded as spirit-varnishes. One kind of hard wood lacquer is made in the proportion of 2 lbs. of shellac to 1 gallon of spirit of wine; and another, in that of 1 lb. of seed lac and 1 lb. of white resin to 1 gallon of spirit of wine. Among many kinds of lacquer for metal, one consists of 1 lb. of the best pale shellac to 2 gallons of spirit of wine. Hard wood lacquer is mostly used for turned work: it is applied on a wad or rag while the turned article is rotating, with a few drops of linseed-oil to enable it to work smoothly. For flat woodwork, lacquer is applied much in the same way as ordinary spirit-varnish, with camel-hair brushes. Lacquer for metals differs somewhat in its composition from that for wood. The metal, when about to be lacquered, is cleaned from all grease and oil, then heated to about 200° Fahr., at a lacquering stove, or on a plate heated by gas, or over a charcoal fire, or on a red-hot piece of iron, or on a vessel of boiling water or steam; this heating is necessary to enable the lacquer to attach itself firmly to the metal, and to make the spirit evaporate quickly. The lacquer, which is sometimes coloured to give it a rich tint, is applied with a brush.

VARNISH-TREES. This name has been applied to several trees which exude liquid resins naturally or from incisions. These become dry in the air, and are employed for preserving various articles from the influence of the air, water, or insects, as well as for giving them greater brilliancy, and also for varnishing pictures. Most of them are found in India, Burma, and China. Some of these exude an acrid resinous juice, which on drying becomes black, and is used as a varnish, as that of the *Anacardium occidentale*, or cashew-nut tree. The marking-nut, or *Semecarpus anacardium*, has its outer coat covered with cells filled with a similar black, oily-looking, acrid juice, which is much used as a marking-ink. *Augia sinensis* of Loureiro is said to produce the genuine Chinese varnish with which the different fancy articles are lacquered, and which is black when simply dried, but becomes coloured by the admixture of different pigments. The Japan varnish of Kæmpfer and Thunberg is *Rhus vernix*, and that of the Malayan islands *Stagmaria verniciflua*. Dr. Buchanan informs us that the juice of *Holigarna longifolia* is used in Malabar for varnishing shields. The varnish-tree of the Burmese is described under MELANORRHŒA, in NAT. HIST. DIV. A very fine liquid varnish is also yielded by *Vateria indica* and *V. lanceæfolia*.

VASES, derived from the Latin *vas*, analogous to the German *fass*, a word in its widest sense comprising all vessels intended to contain fluids or other substances, and made of various materials. In ancient art the term is applied to all ancient vessels, but in modern it is limited to those used for ornament. The shapes of vases are various, from a cup or saucer to that called vase or urn in the narrower sense of the word. Those of ancient nations are distinguished by their shape, form, and material, and may be classed into vases destined to hold and preserve fluids or other substances, comprising craters, jars, and bowls; jugs and cruets for pouring out liquids, and cups for drinking. In Egypt, from the scenes represented in the tombs and temples, elegant large vases of the precious metals inlaid with lapis-lazuli or enamel, and chased with figures of animals or flowers, seem to have been manufactured; and also by the neighbouring nations of Asia, subdued by the arms of Egypt. Of similar forms were vessels of bronze, used for culinary and other purposes. Serpentine basalt and aragonite, or oriental alabaster, especially the latter, were favourite materials, and enamelled fayence, or porcelain, principally of blue colour, and opaque glass, were used for smaller vases for the toilet. Pottery was employed for all purposes. Peculiar vases, popularly called *canopi*, were used for holding the viscera of the dead. The forms of Egyptian vases are simple, the prevalent being the oval and expanding lotus shape; the decorations are plain and the ornaments few. The Assyrian vases resemble in their form the Egyptian, but are sometimes ornamented with relief subjects. There are no vases of the other oriental races of antiquity, and although Sidon, in the days of Homer, was famous for its silver vases, no specimens have survived time or destruction. Alabaster vases are, however, known to have been used by the Assyrians and Persians, and have also been found in the early sepulchres of Greece and Etruria. Several remarkable vases of alabaster exist, inscribed with the names of Persian monarchs in hieroglyphic and cuneiform writing. In Asia, vases were often made of precious stones, as agate and onyx, and one of the kings of Pontus, Mithridates VI., had a collection of 2000. The anthrax, or carbuncle, and chrysoprase, and especially crystal, were often used for vases of small dimensions. Besides the larger vases of marble, principally urns, amphora, cups, lavers, and labra of large size, and enriched with reliefs, were in use during the latter days of Greece and the Roman empire. In the best days of the Athenian commonwealth, large lecythi of Pentelic marble, frequently embellished with sepulchral reliefs, were placed on the graves of the dead.

One of the most remarkable classes of ancient vases was the myrrhine, *myrrhea*, *myrrhina*, the material of which has been a source of controversy since the revival of letters. It is supposed to have been Chinese porcelain by Scaliger, jade by Hager, sardonyx by Le Blond, alabaster, onyx, soapstone, jade, opal, mother of pearl, a kind of amber, meerschaum, or an indurated resin; but the opinion of Rosière and Thiersch, that it was fluor-spar, is most favourably received. The difficulty, however, of reconciling the description of Pliny with the appearance of the substances supposed to be the true myrrhine, does not appear to have been entirely overcome. According to Pliny, it was first brought to Rome from Asia, by Pompey, and exhibited in his triumph, B.C. 62. The countries where it was found were Parthia and Carmania, and it was dug out of the earth like rock crystal, or, according to popular report, baked in Parthian furnaces, and is often mentioned in connection with glass, as if some variety of that material [Schol. ad Lucan; and Oudendorp, t. i. p. 292; vol. ii. v. 380], as semi-transparent, with an opalescent gloss. The most valuable kind had spots changing into purple and white, or into both these colours, and others which were iridescent, while any translucency diminished its value. The material was exceedingly fragile, and perfumed with myrrh, but this was probably owing to the former contents of the vases. The material did not admit of the making of vessels of large size, it rarely being found larger than small plinths, *abaci*, or thicker than goblets. Pompey indeed dedicated to the Capitoline Jupiter small jugs, *capides*, and cups of this substance, which soon after became fashionable and the most precious of all materials, costly cups of it being used by the wealthy, out of which they drank the warmed Falernian wine (Martial, xiv. 113). The value of cups of large size was immense; one of the capacity of 3 sextarii, or 4½ pints, being sold for 70 sestertia, or 565*l*. 6*s*. 1*d*., and a fragment, in the days of Nero deemed a rarity, although according to the jurists they were not considered gems, *lapilli*; and this emperor gave 10 sestertia, or about 80*l*. 15*s*. for a small jug, *capis*, of this material. Still more precious was the myrrhine bowl, of the value of 300 sestertia, or 24,225*l*., which T. Petronius destroyed, when on the point of death, in order that it should not fall into the hands of Nero. A kind of false myrrhine, of opaque glass, with blue, yellow, white, and purple bands, was manufactured in later times at Alexandria ('Thiersch ueber die Vasa Myrrhina,' Bayer, Akad. Wissensch., t. i. 4to. 1856, 35, p. 443).

Vases of glass of small dimensions were in very early use: amongst the Egyptians small amphoræ and jugs, and toilet phials of opaque glass, dated, as early as B.C. 1450, in the reign of Thothmes III.; while the earliest known dated specimen of transparent glass is a small dicta found at Nimroud, bearing the name of Sargina, B.C. 711. Various vases, cups, phialæ, and jugs, were in extensive use amongst the Greeks and Romans; and in the middle period of the Empire, Alexandria and Sidon supplied Rome with glass vases, especially the makers Irenæus and Artas of Sidon. To this age are to be referred the celebrated Portland and Auldjo vases in the British Museum, made of transparent deep blue glass, with friezes and arabesques of opaque white, exquisitely polished, produced by cutting down the upper strata of white glass in the manner of a cameo. About the 3rd century, A.D., and later, remarkable glass cups with undercut letters in relief, or pateræ engraven with subjects, appear, the so-called *diatreta*. To this and an earlier period belong the remarkable vases of madrepore glass, chiefly pateræ. At a later age glass vessels were ornamented with gilded subjects at the bottom, enclosed by two layers of glass. Glass vases of a remarkable size and fabric, principally deep cups, are found in the Saxon graves, ornamented with undercut projections at the sides, a rude imitation of the more artistic *diatreta*.

In Greece, from the earliest ages, gold and silver vases were used for sacrificial and other purposes, and they abounded amongst the Hellenic and other races of Asia Minor, the most renowned in early times being those dedicated by Crœsus at Delphi, some the works of the Samian Theodorus. After the conquest of Alexander immense numbers of toreutic works, some inlaid with gems, were common all over Greece; and in two remarkable festivals, one of Ptolemy Philadelphus at Alexandria, the other of Antiochus Epiphanes at Antioch, were exhibited immense numbers of these vases; and great services of plate were possessed by the Græco-Asiatic monarchs, which subsequently became the booty of the Romans, and were exhibited in their triumphs, or plundered by their officers. The most celebrated metal vases were those of Boethus, Mys, and Mentor. A few gold vases exist in the museums of Europe, the most remarkable being the ancient Greek *phiale* from Agrigentum, in the British Museum; and that of the age of Severus, discovered at Rennes, in Bretagne, now in the Bibliothéque Impériale of Paris, and the gold vases at Vienna. Silver vases are less rare, and were more often chased by ancient artists, and many specimens of ancient plate, some found in Britain, are preserved in the different museums of Europe. Silver vases were often used for sacred purposes. Bronze vases are still more common and of larger dimensions, and are generally thin and hammered out in *repoussé* work, or else ornamented with elegant cast reliefs, *emblemata*; or detached ornaments, *crustæ*. Etruria and Magna Græcia were celebrated for bronze vases, and highly ornamented specimens from the sepulchres of Greece and Italy are in the principal museums of Europe. They are principally *craters*, pails for holding wine; *oinochoai*, jugs for pouring it out; *cyathi*, for straining it; and *phialai*, saucers; *arytainai*, ladles; and *kylices*, cups; *aryballi*, oil cruets; *lebetes*, pots for boiling; *podaniptra*, foot-baths. Bronze vases, called *echea*, were also used for sounding-boards in the theatres. Etruria was celebrated for its bronze lamps and candelabra; and Pompeii was full of bronze vessels. Considerable taste was shown by the ancients in their bronze vessels, the lips being often decorated with the ovolo ornament, the handles sometimes in shape of the human form, artistically adapted for the purpose, and generally terminating in animal heads, *prokossoi*, at the mouth, while the place of insertion on the body of the vase was ornamented with mythological subjects, or heads in bas-relief. Subjects in outline were sometimes incised on vases, and a magnificent *lebes* from Capua, in the British Museum, has, in addition to the figures in full relief on the mouth, an incised frieze round the body, representing some of the labours of Hercules. These ornaments were often either modelled by artists of merit, or copied from celebrated works of art. In the 4th and 5th centuries, damascened Roman vases were made; enamelled about the same time. The temples of Greece abounded with presents of these vases, along with tripods, statues, and other objects of bronze. Leaden vases were used by the ancients to hold unguents, perfumes, and collyriums.

The most numerous and remarkable ancient vases are those of baked clay, found in recent years all over Greece, Italy and its isles, the north coast of Africa, and the Crimea, in fact throughout the settlements of Greece. Some of them appear to have held the ashes of the dead, and all were made for use or ornament. These vases are painted with a brown or black silicated glaze, and touched up in parts with flat unglazed colours. They were either made on the wheel or moulded, then dried, the subject or ornamentation traced out with a pointed instrument, the black or brown colour, which is a silicated glaze, filled in with a reed pencil, and the muscles and other details incised through the black colour to the ground of the clay with a sharp knife. Their paste varies from a pale straw to a dark red, and is very soft, light, and porous. The vases appear to have been carefully dried, painted, and baked in close furnaces; the colours used in the decoration being all minerals,—black oxide of manganese and iron being used for the black; oxides of iron, copper, and pipeclay for the other colours. The glaze is a fine silicate of soda, perhaps produced by salt. The style, shape, and ornaments of these vases vary in the different localities where they are found. The earliest of large shape, chiefly jugs, amphoræ, and lekane, found on the most ancient sites of Asia Minor, as at Mount Sipylus and the so-called treasury of Atreus at Mycenæ, are ornamented with friezes, mæanders, zigzags, and such simple ornaments, with animal forms of small proportions introduced as friezes, or metopes. These vases of the heroic period of Greece, probably of the 8th or 9th century B.C., were succeeded by another class, which has been extensively found at Athens, Corinth, Italy, and the Isles, distinguished by friezes of animals of larger size, of black or brown colour, with incised lines upon a pale straw-coloured ground, still accompanied by ornaments, and the area of the friezes are of animals, some with flowers. A few vases of this style have human figures, combats, and myths, derived from Homeric poems, with inscriptions as old or older than the 5th century B.C., their art resembling the oldest sculpture of Selinus and Ægina. By degrees the vase art improved, the potters introducing a slightly warm tone into their clay, abandoning the excessive use of ornament and the flowers in the field, and giving more importance to the human figures, although still retaining friezes of animals. The principal shapes of these vases are the *pelike*, *oinochoai*, and *alabastros*. From the shape of the inscribed letters found upon them, and their art, these vases appear to be as old as the 5th century B.C. The great improvement in style consisted in introducing a warmer tint into the paste of the clay, which became of a light bright red, while the colour of the figures became of a jet black, with the same details as those of the previous classes, and occasional use of white accessories. The vases of the so-called old style are distinguished by their superior art and size, and the interesting mythological subjects with which they are painted, and are often of large size. *Hydriæ*, water vases with three handles, *amphoræ*, two handled jars, *oinochoai* wine jugs, *lecythi*, oil cruets, *crateres*, bowls for holding wine, *cylices*, flat shallow cups, and *cyathi*, cups, occur in this style. The eyes of the figures are painted oblique, the hands and feet long, the forms muscular, the attitudes rigid. The subjects are principally derived from the myth of Bacchus, the Gigantomachia, the Amazonomachia, and the war of Troy. The figures are sometimes explained by accompanying inscriptions. Besides the names of figures, the names of beautiful youths and females, and of the artists who painted and the potters who made the vases, are painted on them, while memoranda relative to the proprietors of the vases are often found incised on the foot.

The style with black figures seems to have flourished till the 4th century B.C. The prize vases given in the Panathenæa having on one side a Pallas Athene and on the other the different games, and inscribed "Prizes from Athens," were of the hard black style, which was conventionally retained till the time of Alexander the Great, the vases being then inscribed with the names of the Athenian archons. But this style of painting was by no means keeping pace with the development of art, and the vase painters towards the close of the 4th century B.C., or even earlier, changed the colour of the figures to a bright orange red, and painted the background entirely black. The inner muscles of the figures were indicated by fine lines of a light brown, the coarser ones by black colour, and the principal accessories were in blue and white. The style considerably improved, but still remained "severe," by which it is known; the principal shapes were *amphoræ*, *oinochoai*, *cylices*, especially the last; inscriptions continued to be used; the names of artists are frequently seen. Henceforth the transitions are no longer those of colour, but of art and drawing. The eyes of figures half a century later are not represented oblique but full eyelashes appear, the limbs are broader, the faces grander, and the influence of the school of Zeuxis in painting begins to show itself; the vases are principally *kalpides*, *amphoræ*, *lecythi*, *aryballos*, and large *craters*, often with columnar handles. The subjects represented contain, in addition to those of the preceding classes, many of the exploits of Perseus and Theseus, and others derived from the Tragedians, especially the Oresteid. But this style, about the time of Alexander, or B.C. 330, began to decline, and in the days of Pyrrhus had passed into the florid style, distinguished by considerable artistic differences. The figures are taller and more elegant in their proportions, their hair curiously fine, and the details minute and numerous, the backgrounds being charged with arabesque and floral ornament. The shapes of the vases too are distinguished by narrow necks, thicker bodies, and taller handles: large *craters*, *amphoræ*, and *calpides* are common. Perspective appears in the drawing; gilding is common amongst the accessories. The inscriptions are sometimes incised, but the vases are often without them. Contemporaneous with these vases were the polychromatic, chiefly *lecythi*, made for sepulchral purposes, although *oinochoai* and *cylices* occur. They all have a *leucoma*, or coating of fine stucco, on which the artist drew the subject in red outline, and subsequently filled in the draperies with opaque colour, or else finely traced the subject in a siennic or bistre-coloured outline. The subjects are chiefly from the Oresteid or other sepulchral sources. There are few inscriptions on any of these vases. Towards 200 years B.C. the art was rapidly declining, and the florid gave way for one far inferior in merit, the figures being often coarsely drawn, androgynous in their character, and overladen with white colour, while the subjects are derived from the Bacchanalia, the low comedy and buffooneries of the Athenian stage. On the last vases of this style the drawing degenerates into a scrawl, and these were succeeded by ornaments in opaque white upon a red ground, and these by others with moulded ornaments. The inscriptions on vases are in different dialects, often incorrect, while the number of inscribed vases is much less than those without. From some memoranda inscribed by the potters upon the vases the prices paid for vases of inferior kinds are known. A *cylix*, or flat painted cup, cost a drachma, which at the different value of money in ancient times amounted to about 3*s*.; a *crater* 4 oboli, or 2*s*.; a *lecythus* 1 obolos, or 6*d*.; a small pot ½ an obolos, or 3*d*.; and a saucer ⅛ obolos, or 2*d*. It is curious to contrast this with the sums paid for valuable ancient vases in modern times. The Durand collection alone, principally vases, realised 12,524*l*.; in 1836 a vase, with the subject of the death of Orestes, sold for 264*l*.; and other important vases for as much as 280*l*., 240*l*., and 170*l*. each. Yet, these sums are far inferior to those paid for remarkable vases by the Naples Museum, a vase with the last night of Troy having been acquired for 1000*l*., and the same sum was paid by the late Mr. Edwards for a large vase, now in England. The characteristics of Etruscan and Roman vases have been already mentioned. [POTTERY.]

One of the most difficult portions of the history of vases has been their nomenclature, obscured by the difficulty amongst the ancients themselves of describing or defining vases, and the various names in use at different periods. The names of vases have been classed under their employment, as the *pithos*, *stamnos*, *bikos*, *hyrche*, *lagynos*, *pytine*, *askos*, *oinophoros*, *amphoreus*, *kados*, *hydria*, *kalpis*, *krossos*, for containing liquor; the *kothon* and *rhyton*, *bessa*, *bombylios*, for wine; the *lecythus*, *olpe*, *alabastros*, for oil; the *crater*, *psycter*, and *dinos*, for mixing wine; the *lebes*, *chytra*, *thermanter*, for warming liquids; the *chous*, *oinochoe*, *prochous*, *epichysis*, for pouring out wine; the *arytaina*, *aryballos*, *cotyle*, and *cyathos*, for drawing; the *louterion*, *asaminthos*, *pyelos*, *scaphe*, *lecane*, *podanipter*, *holkaion*, *perirrhanterion*, *ardanion*, for washing; the *depas*, *aleison*, *kissybion*, *kypellon*, *cymbion*, *scyphos*, *cantharus*, *carchesion*, *cylix*, *therikleios*, *phiale*, *acatos*, *keras*, for drinking; and the *canoun*, *discos*, *pinax*, *paropsis*, *tryblion*, *oxybaphon*, and *oxis*, for holding food. A few ancient vases have been identified with their names, but many still remain obscure. The names of the Roman vases, with some exceptions, are equally difficult to determine. The dishes for the table were the *patina* and *patella*, the *catellum* and the *lanx*; pots for cooking, the *olla* and *cacabus*; and drinking vessels, the *calix*, *patera*, *ciborium*, *scutella*, and *concha*; the oil jugs, the *ampulla*, *guttus*, *guttulus*, *gutturinum*, and *concha*; while for mixing and pouring out wine, the *amphora*, *lagena*, *cadus*; and for keeping it in the cellars, the huge *dolia* or vats were in constant use. The *capis*, *capedo*, *simpulum*, and *simpuvium* were sacred vessels, and often of earthenware. The Roman poets indeed often use the Greek names of vases, but these were apparently borrowed from the poets of Greece, whose effusions they imitated. The Roman vases are of metals and earthenware [POTTERY], lead, pewter, and box-wood.

Amongst oriental nations the vases of China are most remarkable for their antiquity, size, and beauty; the principal shapes of the metallic vases are wine-jugs, *tsun*; cups, *e*; pails, *yew*; teapots, *hoo*; incense vases, *tung*; and tripods, *ting*. Some of the metallic vases are of great antiquity, as old as the Emperor Chingtang, of the Shang dynasty, B.C. 1743, and engraved with characters of a hieroglyphic nature. Some were given as honorary rewards, those offered to the emperor being made of gold, while the nobility received vessels of fine copper, and the literati iron. Others were used for ancestral worship, or for holding sticks of incense in the Buddhist and other temples. At an early period honorary vases were buried with the dead, but about B.C. 200, Che-hwang-te, of the Tsin dynasty, exhumed the graves of ancient sages, and many ancient vases were discovered. The vases with three feet are supposed to allude to the stars presiding over the prince, mandarin, and people. Those with four, to those stars presiding over the four civil officers. The device of the eyes of a tiger is supposed to warn against drunkenness or gluttony; the mæander, or 'thunder pattern,' to agriculture; the characters cow, *new*; sheep, *yang*; hog, *she*; to agricultural merit. The inscriptions, generally in ancient seal characters, are the names of the person, the vessel, the date, the object for which it was given, and other details. Many of the Chinese vases of later periods are beautifully enamelled in various colours, and of great value: others are elegantly damascened with gold and silver patterns. The vases dated in the years of Seuentih, A.D. 1426–36, are said to be made of a mixed metal of gold, silver, and brass, accidentally produced at the burning of the palace. Those of porcelain have been already described. [POTTERY.] Other vases are made of jade, soapstone, and the horn of the rhinoceros, which was supposed to be an antidote against poison.

In Europe, during the middle ages, vases of rock crystal continued to be made till the capture of Constantinople by the Turks in the 15th century, when the art was transferred to Western Europe; and rock crystal, heliotrope, and jasper were used by Italian artists for this purpose till the 17th century, when the art was abandoned, although subsequently revived in the 18th century. The goldsmiths indeed, from the 12th century, had introduced vases ornamented with damascene and niello work, and many elegant examples were made in Italy, especially by Cellini. As early as the 12th century glass vases of filagree work, made by a peculiar process, were produced at Venice, and the manufacture was only abandoned in the 18th. Many of these were of fantastic shapes. German vases, of cylindrical shape, with enamelled paintings of armorial bearings and other devices, were invented at a later period.

The Arabian vases of the middle ages are chiefly of metallic or glazed ware. [POTTERY.] The first kind consists chiefly of ewers and basins for washing the hands, and are generally of latten, a mixture of copper and tin, chased or stamped, and embellished with knobs, arabesques, mosaic and damask work slightly tooled out, *champlevé*, or chased out, the ground lowered and pricked or pounced, and the silver pressed upon it. Many were made at Mossoul, in Mesopotamia, as early as the 12th century.

In modern arts vases still continue to play a part, although not so important as those of the ancient world. Russia is probably the country where the largest and costliest specimens are produced, in jasper, malachite, quartz, and other hard rocks, chiefly from stones found at Orsk, in Orenburg, in Siberia, the sites of the manufactures being placed at Perm and Tomsk. The island of Malta also produces small vases in hard stone, carved in the style of the renaissance; and Tuscany is remarkable for its vases of the pure white alabaster of Volterra, very elaborately and tastefully carved, for the purposes of decoration. England, France, and Austria also produce elegant vases of cut and coloured glass, the successors of the old filagree glass vases of the Venetians; and the European nations fabricate ornamental vases in all metals for prizes, presents, or decorations, each in their peculiar style of art and taste. The invention of electrotyping and the increase of luxury have given a new stimulus to this branch of the fine arts.

Vas.*, 8vo, Breslau, 1846; Krause, *Angeiologie*, Halle, 1854.)

VASSAL. [FEUDAL SYSTEM.]

VAUDEVILLE. *Aval*, or *à-vau*, is a phrase among navigators, implying the reverse of *amont*. *Avau de l'eau* is used adverbially to express drifting down a stream:—"Personne ne ramoit, nous nous laissions aller à-vau de l'eau." Vaudeville appears originally to have been applied to designate any song or ballad borne along on the current of town gossip or popularity—*à-vau de ville*. It has been customary among etymologists to maintain that the word was originally *vau-de-vire*, from the valley of Vire in Normandy, "where gay and malicious songs were composed centuries ago, which had great currency." No evidence has ever been adduced in support of this legend, and the kind of rhymes originally designated by the word vaudeville are quite as likely to have originated in populous towns and their gossiping crowds, as in a Norman valley. "Vaudeville," we read in the 'Dictionnaire de l'Académie,' "signifies a popular song, the air of which is easily sung, and the words composed upon some story of the day." From songs the term was extended to pamphlets and theatrical pieces founded on ephemeral gossip. At present the theatrical application of the name has superseded the others. Theatrically speaking, a vaudeville is a short drama, the dialogues of which are interspersed with short songs set to popular airs. The principal charm of the vaudeville consists in its covert allusions, its delicate raillery on the leading characters and events of the time. The plot ought to be simple—rather sketched or indicated, than developed—and the characters presented in the same slight manner. The interest ought never to be sufficiently serious to divert attention from the interchange of playful sarcasm and simple melodies which all can appreciate. The vaudeville charms by its brilliant and easy dialogue, its snatches of apparently impromptu music and song, and its least possible spice of malice: any attempt to give a show of reality to the story and persons of the drama would render the elegant trifle ponderous and stupid. Hitherto French authors alone (with perhaps the exception of Göthe) have succeeded in composing, and French actors in representing, these charming nothings: the graceful levity of the vaudeville can scarcely ever bear translation into the more sinewy languages of Europe. Among all French authors of vaudeville, the palm is undoubtedly due to the late M. Scribe of the thousand dramas.

VAUDOIS (Waldenses, or Valdenses; in Latin *Vallesi*; *Valdési* in Italian; *Vaudés* in their own dialect), a remarkable people, who form a communion separate from the Church of Rome, and who live in three high valleys of Piedmont, on the eastern or Italian side of the Cottian Alps, between Mount Viso and the Col de Sestrieres, in the province of Pignerol. The valleys are—1, that of Lucerna, through which flows the Pelice, an alpine torrent which rises in the Col de la Croix, near Mount Viso, and flowing eastward, falls into the river Clusone; 2, Valley of Perosa, through which passes the Clusone, which rises in the Col de Sestrieres, flows in a south-east direction by Fenestrelle, Perosa, and near Pignerol, and, after receiving the Pelice, joins the Po a few miles further down; 3, Valley of San Martino, which branches out of the valley of the Clusone, along the course of a torrent called Germanasca, which rises in the Col d'Aliries. The Vaudois are distributed in thirteen parishes, each having its pastor, called *barbe* in their dialect. One of the pastors bears the title of moderator, being superior in authority to the rest. In former times, when the Vaudois communion was much more extended than it is now, they had bishops, who are mentioned in several old documents. In every parish there is a Vaudois church and a school, besides a church for the Roman Catholic population. The Vaudois clergy are allowed to marry. They take no fees for burials, baptisms, or marriages. The Liturgy now in use is that of Geneva, in the French language: formerly they made use of a Liturgy in Italian. The spoken dialect of the people resembles the other dialects of Piedmont. The origin of the name Valdenses, or Valdesi, is found in the word *vallis*, and means inhabitants of the valleys. Its derivation from Peter Waldo, or Valdo, of Lyon, a merchant of the 12th century, who was a religious reformer, caused portions of the Bible to be translated into French, and was the founder of the sect called the Poor Men of Lyon, is now abandoned. Waldo, being condemned by the archbishop of that city, A.D. 1172, and afterwards by Pope Alexander III., emigrated to Germany, and is said to have died in Bohemia. The Vaudois of Piedmont however existed as a religious community long before Waldo, whom Beza even suspects of having derived his tenets, if not his name, from them. From him, however, the separatists from Rome in the south of France have been called Waldenses, and this has caused them to be confounded with the Vaudois, or Vaudés, of the Alps, although the doctrines and discipline of some of the former were not always in accordance with those of the Vaudois. The real Vaudois remained in the valleys east and west of the Cottian Alps. The Albigenses properly so called were quite distinct from the Vaudois. [ALBIGENSES.]

This little community is remarkable for having kept itself from time immemorial separate from the Church of Rome, in ages when that church is generally considered as having been the only existing church in the West, and for being the only Italian church which continues to this day separate from Rome. We have memorials of the doctrines of the Vaudois written in the early part of the 12th century: their tenets were then such as they are now. The 'Nobla Leyçon' is a sort of abridgment of the history and doctrine of the Old and New Testaments. It speaks of the mission of the Apostles and of the primitive church, and of certain practices that were introduced afterwards in its bosom: of simony, the institution of masses and prayers for the dead, of absolution, and other tenets of the Church of Rome, which it rejects. It is a poem in the Vaudés dialect, nearly the same as that which is spoken at the present time, and records in the text its having been composed in the early part of the 12th century.

There is also a confession of faith of the Valdenses, bearing date A.D. 1120, acknowledging the Apostles' Creed and the canonical books of the Old and New Testaments, recognising no other mediator and advocate with God the Father but Jesus Christ, denying purgatory, admitting only two sacraments—Baptism and the Lord's Supper—as signs or visible forms of the invisible grace, discarding the feasts and vigils of saints, the abstinence from flesh on certain days, the mass, &c. And another manuscript dated 1100, speaks of the Valdenses as having maintained the same doctrines from time immemorial in continued descent from father to son, even from the times of the Apostles. Besides these, there are two controversial treatises, one entitled 'Of Antichrist,' and the other upon 'The Invocation of Saints,' which seem to bear this internal evidence of their antiquity, that in enumerating the various tenets and practices of the Roman Church which the Valdenses reject, they speak of the doctrine of the real presence, and of the adoration of the Virgin Mary and the Saints, but in so doing they do not use the words transubstantiation and canonisation. Now the term transubstantiation was first introduced under Pope Innocent III., and confirmed in the council of Lateran, A.D. 1215, and the first papal bull in which the word canonisation occurs is dated 1165. Nor do these treatises speak of the devotional exercise of the Rosary introduced by St. Dominic, nor of the Inquisition, which began in the 13th century. Had those institutions existed when the treatises were written, they could hardly have escaped the notice of the writer. Manuscript copies of these and other ancient documents relative to the Vaudois, amounting to twenty-one volumes, were brought to England by Sir Samuel Morland, who was sent by the Protector Cromwell as envoy to the Duke of Savoy in 1655, and were by him presented, in 1658, to the library of the University of Cambridge. Morland wrote a 'History of the Evangelical Churches of the Valleys of Piedmont,' London, 1658, giving a transcript and English translation of the 'Nobla Leyçon.' P. Allix, D.D., who published 'Remarks upon the Ecclesiastical History of the Antient Churches of Piedmont,' in 1690, notices the manuscripts brought by Morland. But now only fourteen out of the twenty-one volumes are existing in the University Library, and nobody can tell what is become of the rest. The 'Nobla Leyçon' is one of those which are missing. In 1669, Jean Leger, a pastor of the Valdenses, published at Leyden, 'Histoire Générale des Eglises Evangéliques des Vallées du Piémont,' in two books, the first of which treats of the early date and continuity of their doctrine, and he gives transcripts of several of the manuscripts brought to England by Morland.

The question about the early date of the 'Nobla Leyçon,' the Vaudois confession, and the other manuscripts above mentioned, is of considerable importance in an historical as well as a religious point of view. There is however further evidence brought forth for the antiquity of the Vaudois doctrines. The name of Valdenses does not appear in historical records till the end of the 12th or early part of the 13th century, but we find allusions as early as the 9th century to the existence of non-conformist churches on the borders of Italy. Jonas, bishop of Orleans, in his work 'De Cultu Imaginum,' addressed to Charles the Bald, A.D. 840, speaks of Italian churches which he accuses of heterodoxy because they refused to worship images, and he charges Claudius, bishop of Turin, with encouraging the people of his diocese in their separation from the Catholic unity.

The fragments existing of the works of Claudius show his opinions concerning faith and merits, prayers after death, the worship of images, the invocation of saints, tradition, and church authority, to have been the same as are expressed in both the old and modern Vaudois catechisms, as well as in the catechisms of the modern reformed churches. And it is worthy of remark, that Claudius in his epistle, 'Ad Theodemirum,' says, in reply to the charge of promulgating novelty in religion, "I teach no new sect, but keep myself to the pure truth, and I will persist in opposing to the uttermost all superstitions and schisms." Claudius died about A.D. 840, and contemporary with him Agobardus, bishop of Lyon, as appears by his 'Treatise against Pictures,' edited by S. Baluze, was also preaching against the worship of images. The valleys of the Cottian Alps must have been under one or the other of these bishops. In the synod held at Arras, A.D. 1025, it was represented to the president, Bishop Gerard, that certain persons had come from the borders of Italy and had introduced heretical dogmas about the nature of justification, the real presence, and against images, relics, altars, &c. About 1140, Bernard of Clairvaux, in his sixty-sixth sermon upon the Canticles, speaking of heretics who then were disturbing the church, mentions, among others, "a sect which calls itself after no man's name, which affects to be in the direct line of apostolical succession, and rustic and unlearned though it is, yet it contends that we are wrong and that it only is right. It must derive its origin from the devil, since there is no other extraction which we can assign to it." The Valdenses have always rejected any distinctive sectarian appellation, and have boasted of adhering from age to age to the primitive faith. In the bull of Pope Lucius, A.D. 1183, four years after the Lateran council, in which the Albigenses were anathematised, several sorts of heretics are mentioned, Cathari, Paterini, the Poor Men of Lyon, and the Passagini, or men of the passes, as lying under a perpetual anathema. And in 1194, Alfonso, king of Aragon and marquis of Provence, issued an edict, "commanding the Valdenses, the Insabbatati, who otherwise are called the Poor Men of Lyon, and all other heretics, to depart out of his dominions." About 1230, Reinerus, a Dominican, who states that he had been himself a heretic, wrote a treatise against heretics, 'Opusculum de Hæreticis,' in which he speaks, among others, of the Leonists, or Poor Men of Lyon ("Secta Pauperum de Lugduno qui etiam Leonistæ dicuntur"), and describes their tenets, which are exactly the same as those contained in the old records of the Valdenses as well as in their modern catechism. The Valdenses and the Poor Men of Lyon (Valdenses sive Lugdunenses) are confounded together in the chronicles of that age; and in the Chronicon of Abbas Ursbergensis (A.D. 1212) the Pauperes de Lugduno are represented as an ancient order which arose in Italy long ago. Reinerus begins by saying, that these Leonists or Pauperes were the most pernicious of all the sects, for three reasons: 1, because they are the most ancient—more ancient than the Manichæans or Arians, dating their origin, according to some, from the time of Pope Sylvester I., and according to others from the time of the Apostles; 2, because they are more universally spread; 3, because they have the character of being pious and virtuous, as they believe in the Apostles' Creed, and are guilty of no other crime than that of blasphemy against the Roman Church and clergy. This book of Reinerus is very important, but we must refer those who wish for further information to the Rev. W. S. Gilly's 'Second Visit to the Vaudois of Piedmont,' section iii., where the author has placed in parallel columns passages from Reiner's text, the corresponding opinions of Italian writers previous to the 12th century, and those of the ancient and modern Valdenses concerning the same topics.

When Marcus Aurelius Rorenco, grand-prior of St. Roch, was sent by Duke Charles Emmanuel, about the middle of the 17th century, to make inquiries concerning the Vaudois, he reported that "these Apostolicals, as they call themselves, were of an origin of which nothing certain could be said, furthermore than that Bishop Claudius might have detached them from the church in the 8th century, and that they were not a new sect in the 9th and 10th centuries." And the monk Belvidere, who went to the valleys of the Cottian Alps on a similar inquiry, reported "that heretics have been found in the valley of Angrogna in all periods of history." Claude Seissel, archbishop of Turin, A.D. 1500, spoke of them as "the Vaudois sect, which originated with one Leon, a devout man, in the time of Constantine the Great." From all the above testimonies it is contended, with considerable show of argument, by the Vaudois, that they are not a sect that sprung up in the 12th century, or was introduced by emigrants from abroad, but that they are an aboriginal Alpine community, the offspring of early Christianity implanted in these remote districts. The earlier edicts of the dukes of Savoy speak of the "men of the valleys" and their "ancient faith," which "it had been found impossible to eradicate from thence, and which the dukes had been constrained to tolerate." An edict of 1584 speaks of privileges granted by former dukes, and cites edicts of 1448 and 1452. In the 'Theatrum Statuum R. C. Sabaudiæ Ducis,' published in 1682, it is stated that treaties four hundred years old secured personal and religious freedom to the Vaudois.

It is an historical fact that, some time in the 14th century, a colony of emigrants from North Italy, professing the tenets of the Vaudois, settled in Calabria, where they cleared the ground of whole districts, and became thriving tenants of the great landlords. They built the towns of La Guardia (which is still called Guardia Lombarda), San Sisto, La Rocco, and others, not far from Cosenza, where they lived in peace and unnoticed for about three centuries. But after the spreading of the Reformation in the 16th century they began to correspond with Geneva and other places, and invited some Protestant divines to come among them. This excited the attention of the local authorities; and the Duke of Alcalá, viceroy of Naples, sent commissioners and monks with troops to convert or destroy them. They resisted, and were destroyed with circumstances of great barbarity, in 1561. (Botta, 'Storia d'Italia,' book x.)

At one time the valleys of the Vaudois were subject to the marquises of Saluzzo; and the Vaudois have repeatedly asserted, without being contradicted, that "their ancestors professed their ancient faith long before the dynasty of Savoy was established in Piedmont." Their religious community extended then over many other valleys on both sides of the Alps; to the southward beyond the Po over part of the marquisate of Saluzzo, westwards in the valley of the Durance as far as Embrun and Briançon, and northwards to the banks of the Dora. The valleys of Queiras and Frassinière in France, and that of Pragelà in the province of Susa, at the foot of Mount Genèvre, professed their communion till within comparatively recent times. In the two former valleys there are still scattered evangelical congregations, in the villages of Dormilleuse, Frassinière, and Violin.

Concerning the persecutions which the Vaudois have sustained, and which fill up a large portion of their history, we must not trust implicitly either to Leger and the other Vaudois writers, who were themselves actors or sufferers in these occurrences, nor to the accounts of their persecutors. We prefer following a modern historian, Botta, a Piedmontese and a Roman Catholic, but a temperate, discriminating writer, far removed from those scenes of strife, and from the passions which excited them or were the consequence of them. The earlier persecutions of the Vaudois were the work of the inquisitors sent by Rome. Pope John XXII. issued a bull against them in 1332. Walter Lollard, who was burnt at Cologne in 1350, was a Vaudois clergyman. About the year 1400 a persecution is recorded against the inhabitants of Pragelà and the valley of Perosa, in which many perished. In 1487 Innocent VIII. issued a bull to Alberto de Capitaneis, papal nuncio and commissioner for the dominions of the Duke of Savoy on both sides of the mountains, enjoining "him to extirpate the pernicious sect of malignant men called the 'poor people of Lyon,' or the Waldenses, who have long endeavoured in Piedmont and other neighbouring parts to ensnare the sheep belonging unto God, under a feigned pretence of holiness," &c., and if expedient "to preach the crusade against them." But it was not until the following century that a general proscription took place. When Luther, Zwingli, and Calvin began preaching their reformed doctrines, the Valdenses acknowledged them to be similar to their own. Francis I. of France, who was also possessed of Piedmont, persecuted all heretics indiscriminately, whether of the new Reformed faith, or of the old Waldensis or Vaudois communion, and determined on extirpating them. The massacres of Dauphiné and Provence, especially at Merindol and Cabriere, are recorded in history. He at the same time wrote to the parliament of Turin, enjoining it to enforce religious conformity within its jurisdiction. The Vaudois of Piedmont then drew up a list of their articles of faith and laid it before King Francis, begging to be allowed to retain their ancient form of worship; to which Francis replied, that as he was putting to death the heretics in France, he could not tolerate them on the other side of the Alps. The parliament of Turin commanded the Vaudois to drive away their barbes, or pastors, and to receive Roman Catholic priests, who would be sent to instruct them. The Vaudois refused, and persecution followed. Several Vaudois who refused to renounce their faith were burned alive. (Botta, b. iv.: A.D. 1541-4.) Still their communion was not extirpated; and years after, Piedmont having been restored to the house of Savoy, Duke Emmanuel Philibert, after being repeatedly urged by the inquisitor Giacomello, sent by Pope Paul IV., ordered, in 1560, the Vaudois to attend the Roman Catholic service, and forbade them the exercise of their own form of worship under penalty of 100 golden "scudi" for the first transgression, and of the perpetual galleys in case of relapse. The Vaudois wrote an humble supplication with an apology for their faith to the duke, who, being little conversant with theological controversy, proposed a conference between the Vaudois and Roman Catholic divines. But Pope Paul IV. disapproved of this; and at last, being importuned by the inquisitor and the nuncio, and the court of Spain, the duke resorted to arms to enforce obedience. He sent into the valleys 7000 men under the Count of La Trinità, to whom the French king joined two regiments on the side of France. The French court at that time was persecuting the Huguenots, who were numerous in Dauphiné, and who were disposed to make common cause with the Vaudois. The Vaudois defended themselves bravely, and in one instance defeated the ducal troops at Pra di Torre. Many atrocities were committed in this desultory warfare, and women and children were not spared. Some of the prisoners were burnt alive at Carignano, Susa, and Piñerola. At last Duke Emmanuel Philibert, disgusted with this war, into which he had been pressed against his wish, and urged by the intercession of his wife, Margaret of France, who pitied the Vaudois, granted them, in June, 1561, peace and an amnesty, with the exercise of their religion, within certain stated limits, in the valleys of Lucerna and San Martino, on condition that the Roman Catholic service should also be performed simultaneously, in churches appropriated to the purpose in the various villages. This edict was signed by Philip of Savoy, lord of Racconigi on one part, and by two of the principal pastors of the Vaudois on the other. The court of Rome and the monks in Piedmont declaimed loudly against these concessions of Duke Emmanuel Philibert, and almost called him a heretic. (Botta, b. x.)

In 1601 and 1602 Charles Emmanuel I. confirmed to the Vaudois their religious immunities, but the Inquisition was molesting them at the same time, and even imprisoned some individuals, and when remonstrances were made to the ducal ministers, they replied, "These matters do not concern his highness." (Botta, b. xv.) The duke however issued two rescripts, dated 1603 and 1620, guaranteeing to the Vaudois the exercise of their religion within the limits prescribed in the three valleys of Lucerna, Perosa, and S. Martino. The Vaudois had asked the same favour for their co-religionists in the Marquisate of Saluzzo, but this was refused. Charles I. of England sent twice an embassy to the duke to intercede for the Vaudois, in 1627 and 1629. (Appendix to Gilly's 'First Excursion to the Mountains of Piedmont in 1823.')

Victor Amadeus I., who succeeded Charles Emmanuel, published an edict enjoining the non-conformists of the Marquisate of Saluzzo, who were chiefly in the communes of Pæsana, Praviglielmo, Bioleto, Bretonni, and Croesso, to embrace the Roman Catholic religion, under penalty of death and confiscation of property; and this edict was so strictly enforced, that not one non-conformist remained in those parts. But at the same time the duke issued an edict to protect the Vaudois of the valleys of Piñerola, who have always been held distinct from the others, and to check the prevailing practice among the Roman Catholic priests and laity of kidnapping the children of the Vaudois in order to bring them up in the Roman faith. (Botta, b. xxi.) After the death of Victor Amadeus, and during the civil war which raged in Piedmont, the Vaudois remained faithful to their lawful duke, and opposed by arms the factious marquises of Lucerna and Angrogna, who sided with Prince Thomas and the other pretenders to the Regency, and they were accordingly confirmed in their privileges by the Duchess Regent, and by the young Duke Charles Emmanuel II. But the same Charles Emmanuel afterwards directed a most fierce persecution against the Vaudois. Botta attributes the origin of this fresh storm to the turbulent disposition of Jean Leger, a pastor of some name among the Valdenses, who had more zeal than prudence. In March, 1653, the inhabitants of Villaro, in the valley of Lucerna, rose in a tumult, and drove away the Capuchins from their convent, to which they set fire. The ducal troops repaired to the spot, and, after some bloodshed, peace was re-established. But this affair led to further investigations, when the ducal government found out that the Vaudois had transgressed against their engagements by purchasing property and establishing schools and places of worship beyond the limits fixed by former edicts. In January, 1655, the duke caused his auditor Andrea Gastaldo to proceed to Lucerna, when he issued a manifesto ordering all Vaudois families to evacuate within three days the communes of Lucerna, San Giovanni, La Torre, Bibbiana, Fenile, Campiglione, Bricherasco, and San Secondo in the lower part of the valley of the Pelice, and retire to the higher part of the valley, to the communes of Villaro, Bobbio, Rorà, Angrogna, and Boneti. Within twenty days they were either to sell their property situated in the former districts or to embrace the Roman Catholic faith. The Vaudois resisted this command, and the duke sent the marquis of Pianezza with a body of regulars and some militia in the following April. The Vaudois deserted their villages, carrying their provisions to the mountains. The marquis followed them there, but he could not subdue them; and his soldiers, finding nothing to eat, withdrew. The Vaudois then issuing from their recesses, under two determined leaders, Jayer and Janavel, fell upon several Roman Catholic villages, and plundered and burnt them. They then entered La Torre, but being surprised by Pianezza, they fought desperately and most of them fell, but not without killing numbers of the ducal troops. In this warfare cruelties were committed by both parties, but the Vaudois, being the losing party, were, with their families, the greatest sufferers. Many atrocities were committed against the women and children by the Piedmontese soldiers, but still more by the mercenary French and Irish soldiers in the service of the duke, which horrors Jean Leger, who was an actor in the struggle, has detailed at length, and, Botta thinks, has exaggerated in his 'Narrative.' But there is a document in the University Library at Cambridge which tells strongly against the marquis of Pianezza himself. It is a declaration by Captain Du Petit Bourg, who was serving in a French corps under Pianezza, protesting against the cruelties which he saw committed, and for which he retired and quitted his corps. He says that the marquis ordered to give no quarter, saying that his highness was determined to have none of their religion in his dominions. This protest, a copy of which is given by Gilly in his first work, is dated Piñerola, 25th November, 1655, and is attested by other officers. It appears, however, that Pianezza ordered the women and children to be spared, and he rescued many from the hands of the brutal soldiers, and distributed them in the neighbouring districts of Piedmont. A number of Vaudois took refuge across the mountains in the French valley of Queiras, and returned after the fury of the massacre had abated. Others perished in the snow, and others lurked for a time in the recesses of the mountains, under their chief Janavel, who carried on a partisan warfare until he was killed some years after.

The news of the massacre of the Vaudois spread far and wide throughout Europe. The Protestant cantons of Switzerland, the Protector Cromwell, and the States of Holland, sent envoys to the duke of Savoy, to remonstrate in favour of the Vaudois. Cromwell sent Sir Samuel Morland, who collected numerous documents, and published them in his 'History of the Evangelical Churches,' fol., 1658. Cromwell's Latin letters to the duke and other princes on the subject were written by Milton, who in one of his sonnets has feelingly lamented the cruelties committed against the Vaudois. Subscriptions were made in England and other countries for the survivors. At last, at Cromwell's request, Louis XIV. offered his mediation, which the duke accepted, and a convention was concluded in August of the same year, 1656, at Piñerola, which then belonged to France, by which a general amnesty was granted, and the Vaudois were allowed to remain on the left bank of the Pelice within certain fixed boundaries, and to have the exercise of their religion, but at the same time it was agreed that the Roman Catholic worship should be performed in the same villages, and Catholic missionaries be sent to preach there, but no Vaudois should be constrained to become a Roman Catholic, and no girl under ten, and no boy under twelve years of age, should be taken from their parents. This convention was signed by Jean Leger and other Vaudois pastors. But after some years new complaints and disputes broke out, which Count Bagnolo, the governor of the province, wanted to settle in an arbitrary manner. Fresh resistance and a new persecution took place in 1663 and 1664, followed by a new edict of the duke, by which the Vaudois were forbidden to perform their worship in the village of S. Giovanni. Jean Leger emigrated, and visited various countries, urging the claims of the Vaudois and collecting subscriptions for them. He was at last appointed minister of the Walloon Church at Leyden, where he died. (Botta, b. xxv.)

Victor Amadeus II. succeeded Charles Emmanuel, and took the reins of goverment at the end of 1684, being then eighteen years of age. Piedmont was then the humble ally of the imperious Louis XIV., who about this time resolved to abolish Protestantism in France by the revocation of the Edit de Nantes, and he ordered Victor Amadeus to do the same with regard to the Vaudois. After some demur the duke was induced to submit, and in January, 1686, he issued an edict ordering the Vaudois either to abjure their tenets within fifteen days, or leave their country. Driven to despair, the Vaudois determined to resist. They were attacked on one side by the ducal troops, and on the other by those of Louis XIV., commanded by Catinat. After a gallant struggle the Vaudois were overpowered, and the survivors were obliged to submit unconditionally. Their whole property was confiscated, and given to Roman Catholic colonists, the old inhabitants with their families taking their departure for Switzerland. Those who had been taken prisoners were distributed in various prisons, in which a number of them died. At the expiration of three years, a band of 800 of these emigrants, under the command of one of their pastors, Henry Arnaud, undertook one of the most daring and romantic expeditions ever attempted by men. [ARNAUD, HENRI, in BIOG. DIV.]

This was the last persecution against the Vaudois; who however remained subject to various disabilities and exposed to several vexations, which are detailed by Gilly in his first excursion, p. 116; and in the second, p. 546, and fol.

In the wars of the French revolution the Vaudois remained loyal to their sovereign, and bravely defended for years the mountain-passes through which the French threatened to invade the valley of the Po, which ultimately they reached, but not on this side. In June, 1794, King Victor Amadeus III. published an ordinance, in which, after acknowledging the constant and distinguished proofs of their attachment and fidelity, he promised to redress several grievances, among others, that of taking away of children of the Vaudois, with the view of obliging them to embrace the Roman Catholic religion. He forbade the practice, and ordered those who had been so taken away to be restored. "Those who at the prescribed age, girls at ten and boys at twelve, voluntarily enter the hospital of Piñerola, must be under the direction of ecclesiastical judges; but no difficulty will be made in permitting the parents to see their children under proper precautions."

When Bonaparte annexed Piedmont to France, he placed the Vaudois on a footing of equality with their Roman Catholic countrymen, and assigned funds for the support of their clergy. At the restoration in 1814 the Vaudois were again placed under their former disabilities, and those who had purchased land beyond the limits of their valleys were obliged to sell it to Roman Catholics. King Charles Felix, who succeeded to the throne in 1821, showed some more indulgence towards the Vaudois. Under the present king of Italy, Victor Emmanuel, they have been admitted to an equality of rights with their fellow subjects.

VAULT, VAULTING. The continuation of an arched covering over a considerable surface is commonly spoken of in the Arts under the name of *vaulting;* and occasionally the word *vault* is applied to the actual assemblage of the voussoirs of an arch, in contradistinction to the haunches, spandrils, or other supplementary parts. Both of these significations may be retained without inconvenience, because they express conditions it may often be necessary to refer to in practice, and for which it is desirable to possess names.

There is little to be added to what has been already said under ARCH and BRIDGE, with respect to the mechanical principles of vaulting, excepting that in the case of intersecting arches it may be desirable occasionally to form the lines of intersection by arched ribs, springing from the respective abutments, but even in this case the resolution of the thrust must ultimately be the same, in principle, as in any ordinary arch. It is customary in practical works on architecture and engineering, to class the various descriptions of vaults as follows:—1, Waggon-headed and semicircular vaults; 2, Domical vaults; 3, Pointed arched vaults; 4, Groined arches, which in their turn may be made to pass through numberless modifications, according to the positions assigned to the various ribs, pillars, or points of support. It is in the latter form of vaulting that the fan tracery so much admired in Gothic architecture occurs; and the skill with which the mediæval architects concentrated the strength of the vaulting in the ribs, whilst they reduced the thickness of the spandril filling, enabled them to secure effects of the most elaborate and pictorial character. In the simple square groin the ribs near the wall, and those at the intersection of the arches, perform the office of supporting the vaulting; in the more ornate fan tracery, other ribs are introduced, so as to form, on plan, a star of four points, or the primitive arches may rise to different heights, either ultimately meeting by intersection, or truncated in the middle of the space. Polygonal spaces were covered in the mediæval period either by means of a series of fan-shaped ribs, starting from arches applied against the external wall, and from a central column, as in the cases of many of our chapter-houses, or by groined arches spanning the whole space between the walls; or by pendentive roofs, when the internal dimensions are not very great. Excellent examples of the first of these systems of vaulting over polygonal buildings are to be found at Winchester, Salisbury, Wells, Lincoln, &c.; of the second, at Durham, York, &c.; and of the third at Caudebec. In many of Sir C. Wren's churches, the system of groined vaulting has been applied with as much boldness and artistic success as in the buildings of the mediæval architects; but the compulsory use of the semicircular arch in the Italian architecture, rendered the intersections of the side vaults with the principal ones less susceptible of ornamental decoration than is the case with the diagonal ribs of the preceding style. The vaulting of St. Paul's, and of St. Peter's at Rome, may be referred to as illustrations of the most effective specimens of this mode of construction as applied to modern cathedrals. It must not be forgotten, however, that the ancient Romans had proved themselves to be perfectly able to overcome all the practical difficulties of vaulting; and the ruins of the palaces of Nero and of Diocletian, the reservoirs of Possilippo and of Constantinople, and the great church of Sta. Sophia may be cited as illustrations of the various solutions they had discovered of the problem of vaulting large areas.

It may be advisable to call attention to the mode of vaulting adopted in some parts of the London Docks, in which the space covered is vaulted by means of groined arches of brickwork, of elliptical form, springing from granite pillars. In cases where the vaults are intended to store combustible goods of great value, there are such manifest advantages in the use of the granite pillars, instead of cast-iron ones, that, writing under the impressions produced by the fearful misfortune of June 22nd, 1861, the author may be pardoned for dwelling on this detail of fire-proof construction.

VAVASSOR, VALVASSOR, a term applied in the ancient records of England, Scotland, France, Lombardy, and Aragon, to persons holding fiefs not immediately under the king or other persons possessing jura regalia (as the duke of Normandy, the earl of Chester, or the bishop of Durham), but under some intermediate lord. It appears also, that to constitute a vavassory, it was necessary that the party should have subordinate freeholders, as vassals holding of his vavassory. (Wilkins, 'Leges Angl.', 247; Bracton, 5 b, 6, 93 b; Ducange.) In England vavassories were generally held by knights' service; but in Normandy, besides the franches vavassories or vavassories nobles, there were socage vavassories held by the rent of a rose, a spur, or a glove, and also *vavassories vilaines.* The possessors of these inferior vavassories were sometimes called "valvassins."

Vavassors are twice mentioned in Domesday, pp. 53 and 1469; and in the laws of William the Conqueror, the relief due from a vavassor to his liege lord is described. (Kelham, 40.) A charter of Henry I. directs that pleas of the division of land between the vavassors of two different lords be determined in the county court. In the great Roll of the Pipe of 31 Henry I., mention is made of the vavassors belonging to the barony of the archbishop of York. In the laws of Henry II. the jurisdiction of vavassors is specified. Madox ('Baronia Anglicana,' note, p. 135), sets out a writ in which that prince requires the residence or constant attendance of all barons and vavassors, who owe service of castle-guard at Rockingham castle. Francis de Bohun, in the time of Richard I., was seised of two honours, one that of Bohun in Normandy, which he held of the king, as duke *per baroniam,* the other in England, consisting of the manor of Fordes, &c., in Sussex, which he held *in vavasseriâ.* ('Abbrev. Plac., in Domo Cap. Westm.' 88.) In the next reign Alice Briewiere claimed Plimtree in Devon, and Depeworth in Somerset and Dorset, assigned to her by her late husband Roger de Pole, on the day he set out for Jerusalem, for the full third part of three vavassories, namely, for the vavassories of the earl of Salisbury, the earl of Vernon, and of the vavassory of Earl William de Bohun ('Ib.', 61 b). In the close rolls of 4 H. III. is a writ to the sheriff of Wiltshire, directing him to give seisin to W. Mandevill, R. Maudut, W. Comyn, and W. de Fontibus of three vavassories of the fee of the Earl of Clare, belonging to the barony of Funtell (Fonthill), which barony Andrew Giffard had, with the assent of King John, resigned to those persons as the right heirs (presumptive) of the barony, reserving the vavassories, which vavassories would appear to have been seized into the king's lands upon the death of Giffard under the advice of the crown lawyers, the council of the minor king being afterwards of opinion that such seizure ought not to have been made. Here, vavassories held of the honour of Clare appear to have become in some way annexed to a barony held of the crown. In the record and process of the renunciation of Richard II., that prince absolves all dukes, marquesses, earls, barons, knights, vassals, and *vavassors*, and other his liege-men, from their oaths of fidelity (3 Rot. Parl., 416); and about the same period Chaucer, after describing his Franklin, says,

"Was no where swiche a worthy *vavasour*."

From this time we lose sight of the English vavassor. Numerous subseigniories however still exist, the owners of which, though not so designated, are in truth vavassors. From the inalienable quality of the Duchy of Cornwall, many manors in Devonshire and Cornwall are held, though the name is no longer continued, as vavassories of the duchy; of which there are many in the former county, holden of the duchy honour of Bradninch.

The breaking up of the old feudal baronies, and the frequent forfeitures incurred by those who held immediately of the crown, brought the great and many of the lesser vavassors into the position of immediate tenants to the crown. But as the extinction of vavassories was gradual, no new class of crown tenants arose, as was the case in Germany where the disappearance of the dukedoms of Suabia and Franconia (caused by the extinction of the House of Hohenstauffen in the person of Conradin, beheaded upon the failure of his attempt to recover the kingdom of Naples from Charles of Anjou), gave rise to a new order in the state, namely, the *immediate* chivalry (noblesse immédiate) of the empire, the reichsritterschaft, a body *mediatised* by the Congress of Vienna.

When James I., imitating the practice of France, introduced hereditary titles without peerages, a proposal for giving to the new order the designation of vavassors was rejected, and the novel but more appropriate title of BARONET was adopted.

(Terrien, *Cout. de Normandie*; *Testa de Nevill*, 166 a; Selden's *Titles of Honour*, 513, 520; Cragii, *Jus. Feud.*, 100, 141; Manning's *Serviens ad Legem*, 185, 291 a.)

VEADAR. The name of this month is literally "and Adar," meaning "another Adar." It occurs only in intercalary years, immediately after Adar. [ADAR.] This month has twenty-nine days, and the feast of Purim and fast of Esther, usually observed in the month Adar, are transferred to Veadar in the years where this month is inserted. The last time of this insertion was in 1859, when Veadar began on the 7th of March and ended on the 4th of April. The next will be in 1862, when it will extend from the 3rd to the 31st of March.

VEDA. This word (from the Sanskrit radical *vid*, 'to know'—kindred with the Latin *vid-*, Greek ἰδ-, Gothic *vait*) literally means 'knowing,' or 'knowledge;' but is emphatically used as the name of those ancient Sanskrit works which constitute the basis of Brahmanic belief, and are held by the Hindus to have been revealed to them by their deities. These works were originally three, namely, the *R'igveda*, the *Yajurveda*, and the *Sámaveda*. At a more recent period a fourth Veda was added to them, but it never obtained that degree of sanctity which was allowed to its predecessors; it is not mentioned, for instance, in the ninth verse of the Purusha-súkta of the R'igveda, which speaks of the R'ig-, Sáma-, and Yajur-veda; nor in the Chhândogya-Upanishad; nor even in the law book of Manu; for though the latter refers on several occasions to the three Vedas, it speaks only once (xi. 33) of "the revelations of the Atharvângirasas," by this expression alluding to, but not naming by name, the Atharvaveda; and even the writers on the Mimânsâ, a doctrine that has for its object to clear up doubtful passages and to reconcile discrepancies of vaidik texts, are merely concerned in those of the three former Vedas, not in those of the Atharvaveda.

Each of these four Vedas consists of two distinct parts: a *Sanhitâ* or collection of *Mantras*, and a portion called *Brâhman'a*.

Mantra (from *man*, 'to think,' literally 'that by which thinking is effected) means a hymn or prayer. According to the definition given by Mâdhava-Sâyan'a, the celebrated commentator of the Vedas,—in his work on the Mîmânsâ, the Jaiminîya-nyâya-mâlâ-vistara, and in his introductions to the *R'igveda* and Aitareya-brâhman'a,—a *Mantra* is sometimes addressed to the divinity with a verb in the first person; sometimes it ends with the verb 'thou art,' or with the word 'thee;' now it mentions the performance of ritual acts, then it contains praises, invocations, injunctions, reflections, complaints, puts questions or returns answers, &c. (Colebrooke, 'Misc. Ess.' i. p. 308; Müller, 'Ancient Sanskrit Literature,' p. 343; Goldstücker, 'Introduction to the Mánava Kalpa Sûtra, or Pân'ini,' p. 69.) The author of a *Mantra*, as we should say—or as the Hindu authorities state, the saint "by whom it was first spoken," the "seer" or "rememberer" of its text—in short the personage to whom the *Mantra* is supposed to have been revealed, is called its *R'ishi*. The deity to whom "the *R'ishi* seeking for the accomplishment of his objects, addresses his praise," is its *Devatâ* (Yâska's 'Nirukta,' vii. 1). But since there are *Mantras* which contain neither petition nor adoration, the subject of such *Mantras* is considered as the deity that is spoken of; for example, the praise of generosity is the *Devatâ* of many entire hymns addressed to princes from whom gifts were received by the authors. (Colebr., 'Misc. Ess.' i. p. 22.)

A *Brâhman'a* (neuter,—not to be confounded with the masculine word, or the name of the sacerdotal caste),—from *brahman*, prayer, is twofold; according to Mâdhava, it contains "either commandments or explanations;" in other words, it gives directions for the performance of sacrificial acts, and explains the origin and object of the rite, by giving citations of hymns, illustrations and legendary narratives, also by speculations of a mystical and philosophical kind. The *Brâhman'a* portion of the Vedas is therefore the foundation of the Vaidik ritual, which became fully developed and systematised in the ritual works called the *Kalpa-Sûtras*; and it is also the source whence sprang those mystical and theosophical writings, the *A'ran'yakas* and *Upanishads*, which at a later period expanded into the orthodox *Vedânta* philosophy, and which are frequently referred to even by the other philosophical schools, though their orthodoxy is extremely doubtful and widely different from that of the Vedânta doctrine.

That there was originally but one text of each of the four Vedas is plausible enough. Tradition records that the son of Parâs'ara R'ishi, Kr'ishn'a Dwaipâyana, surnamed Vyâsa, "having compiled and arranged the scriptures, theogonies and mythological poems, taught the several Vedas to as many disciples, namely, the R'igveda to Paila, the Yajurveda to Vais'ampâyana, the Sâmaveda to Jaimini, and the Atharvaveda to Sumantu." (Colebr., 'Misc. Ess.' i. p. 14.; Wilson, R'igveda, I. p. xx.) But inasmuch as these saints taught the lessons they had learned to their pupils, who in their turn communicated their knowledge to their disciples, and so forth, it is obvious that great variations must have crept into the text; and we know as a fact, that gradually many schools or *Charan'as* arose, each giving preference to its own readings, and, as particularly in the case of the Yajurveda, to its own arrangement and distribution of the sacred text. Hence it came to pass, that each of these Vedas branched off into various *S'âkhâs* (branches), or as we might say, into various editions, which though in the main concurring in their contents, nevertheless contained verbal differences enough to account for the divisions of their respective schools. A work which treats of these schools, the *Charan'avyûha*, enumerates several of them by name, and states that five, sixty-eight, a thousand, and nine were the respective numbers of the Charan'as of the *R'ig-*, *Yajur-*, *Sâma-*, and *Atharva-veda*. Very few only of these editions have come down to us, and the loss of the greatest part of them is the more to be deplored, as they would probably have enabled us to account for some (and important) differences in the verses common to some or all of these Vedas, and perhaps also for superstitions of later times, which are said to be founded on, but are not countenanced by, the text, as we possess it now, of the R'igveda-Sanhitâ.

If in order to gain an insight into the peculiar character of each of these Vedas, we consult the view entertained of it by the native writings, little aid will be afforded us by the mythological narrative of the S'atapatha-brâhman'a (xi. 5, 8, 1), and Manu's 'Law Book,' (i. 23), which tell us, in the same words, that (Brahmâ), "for the due performance of the sacrifice, drew out the threefold eternal Veda, the R'igveda from fire, the Yajurveda from air, and the Sâmaveda from the sun;" nor will our knowledge be more advanced by a passage from the Bhâgavata (iii. 12-37) and the Vishnu-Purân'a, which inform us (i. cap. 5) that "Brahmâ created the R'igveda .... from his eastern mouth, the Yajurveda .... from his southern, the Sâmaveda .... from his western, and the Atharvaveda .... from his northern mouth." But of greater importance is evidently a statement of the Kaushîtaki-brâhman'a which, while omitting to mention the Atharvaveda, calls the Yajur- and Sâma-veda "the attendants of the R'igveda" (Müller, 'Anc. Sansk. Lit.', p. 457). The real bearing of the latter words, however, becomes clear from what Sâyan'a says in his introduction to the R'igveda. After having inferred from the ninth verse of the Purusha-sûkta, mentioned before (comp. Muir's 'Original Sanskrit Texts,' i. p. 6), the precedence in rank of the R'igveda before the other Vedas, he continues: "the Taittirîyas, or followers of the Black Yajurveda, record that whatever sacrificial act is performed by means of the Sâma- and Yajur-veda is (comparatively) slender, whatever is done by means of the R'igveda is strong;" and ... "among the hymns found in the Yajurveda there are many R'igveda hymns, which are to be employed by the Adhwaryu priest; all the hymns of the Sâmaveda come from the R'igveda, and even those who make use of the Atharvaveda read in their own Sanhitâ to a considerable extent, the very hymns of the R'igveda" (Sáyan'a, in Müller's ed. of the 'R'igveda,' i. p. 2). It results from this statement, not only that the R'igveda was held to be prior in rank to the other Vedas, but that it was considered to be older than they, and that the hymns of the Sâmaveda were entirely, and those of the two other Vedas to a considerable degree, extracted from the R'igveda-Sanhitâ. And this information of the celebrated commentator is fully borne out by a comparison of the hymns of the four Vedas. For, though Professor Benfey has shown, in his edition of the Sâmaveda (p. xix), that seventy-one verses of the latter are not met with in the present text of the R'igveda, and that many readings of this Veda differ from those of the Sâmaveda, it does not follow "that the recension of the R'igveda-Sanhitâ took place at a later period than that of the Sâmaveda," nor "that the R'igveda verses occurring in the Sâmaveda are older than those of the present R'igveda text" (Professor Weber, in his 'Akademische Vorlesungen,' p. 9. 62); but, as Professor Müller justly observes ('Anc. Sansk. Lit.' p. 475), that this difference "may possibly be accounted for by the fact, that we do not possess all the S'âkhâs of the R'igveda."

The true nature, however, of this relation between the R'igveda and the other Vedas, appears from the purposes which they were made to serve, purposes, which, according to the concurrent statement of all native authors, are of a ritual or sacrificial character.

A vaidik sacrifice is a piece of machinery of a very complicated kind, A knowledge of it is imparted by a class of writings, the Kalpa works, which will be treated of hereafter. Good care was taken by their authors, or the authorities whence their contents are derived, that no man who intended to perform a regular sacrifice (a *yajamâna*), could satisfy his religious want—which was always connected with some worldly desire, such as the birth of a son, increase of cattle, attainment of military renown, conquest, and the like—without the assistance of one or more priests, who as a matter of course always belonged to the Brâhman'a caste. There were sacrifices which lasted one day, others which went on from two to eleven days, others which took up as many as a hundred days. Accordingly, to perform some sacrifices one *R'itwij*, or priest, sufficed; or, to complete others, four, five, or six priests were necessary; their fullest complement, however, is the number of sixteen, for a seventeenth R'itwij—the *Sadasya*, or superintendent—is not admitted by all authorities; and the assistants of the priests—the slayer, the butcher, the ladle-holder, the choristers, &c.—are not counted amongst the R'itwijs or real priests.

This full contingent of priests is enumerated by Âs'walâyana (S'rauta Sûtra, iv. 1) in the following way. First comes the *Hotr'i*, who has under him three men (*purusha*), the Maitrâvarun'a, Achchhâvâka, and Grâvastut; secondly, the *Adhwaryu*, with the Pratiprasthât'ri, Neshtr'i, and Unnetr'i; thirdly, the *Brahman*, with the Brâhman'âchchhansin, Âgnîdhra (or, Agnîdh), and Potr'i; lastly, the *Udgât'ri*, with the Prastotr'i, Pratihart'ri, and Subrahman'ya (comp. Müller, 'Anc. Sansk. Lit.,' pp. 468, 469, where, by a mistake, some of the *purushas* of the *Brahman* and the *Udgâtri* have changed their places). The same class arrangement, though sometimes in a different order, occurs likewise in other authorities (for example, Kâtyâyana S'r. S. vii., 1, 6; Mâdhava Jaiminîyanyây, iii. 7, 17; see also the note to p. 209, in Wilson's second volume of his translation of the R'igveda).

Now, of these R'itwijs, the Kalpa works enjoin that the Adhwaryu has to perform his duties with the Yajurveda, the Udgât'ri with the Sâmaveda, the Hotr'i with the R'igveda, and that the Brahman "has to set right any deficiency that may have occurred in the religious acts of the three former priests; he must, therefore, be acquainted with all the three Vedas—the Rig-, Yajur-, and Sâma-veda" ('Mâdhava Jaiminîyanyây,' iii. 7, 17; vi. 3, 14; Müller, 'Anc. Sansk. Lit.,' p. 469, ff.) It may be added, moreover, that the Adhwaryu had to mutter, inaudibly, the verses of the Yajurveda, that the Udgât'ri had to chant those of the Sâmaveda—probably in the same manner as the Pentateuch is intoned up to this day by the officiating Jews in their synagogues—and that the Hotr'i had to recite in a loud voice the verses of the R'igveda.

It follows, therefore, that each of these Vedas had its distinct ceremonial; but that no ceremonial was assigned to, and that no distinct priest or class of priests had to use, the hymns of the Atharvaveda. "The Atharvaveda," says Madhusûdana, "is not used for the sacrifice; it only teaches how to appease, to bless, to curse, &c." "Its songs," as Professor Müller observes ('Anc. Sansk. Lit.' p. 447), "formed, probably, an additional part of the sacrifice from a very early time. They were chiefly intended to counteract the influence of any untoward event that might happen during the sacrifice. They also contained imprecations and blessings, and various formulas, such as popular superstition would be sure to sanction at all times and in all countries." And the same scholar infers that it was probably part of the office of the Brahman priest, also, to know and to apply these songs, whenever their effect was supposed to be required for remedying any mistake committed by the other three classes of priests. At all events, it is certain that the Atharvaveda is not comprised among the sacrificial Vedas, and that its later date may be safely concluded from its not being mentioned in those works which regulate the ancient rites, even if such posteriority were not recognisable from the language of those of its hymns which do not occur in the other Vedas.

By comparing, however, the contents of the three sacrificial Vedas with the ritual precepts of the Kalpa works, we may ascertain another important fact. All the verses of the Yajurveda and all the verses of the Sâmaveda are used in one sacrificial act or another. Such, however, is not the case with the verses of the R'igveda. Many of the latter, indeed, are likewise indispensable for sacrificial purposes, as we are taught by the ritual books connected with this Veda; yet a good number remain, which stand quite aloof from any ceremony. This class bears purely a poetical or mystical character; and it may be fairly inferred that even the strong tendency of later ages to impress an entirely sacrificial stamp on each of these Vedas, broke down before the natural and poetical power that had evidently called forth these songs, as it could not incorporate them amongst the liturgic hymns. We may quote, for instance, a hymn from the tenth Mandala of the R'igveda (from Colebrooke's 'Misc. Ess.,' i. p. 33), as an illustration of those which belong to the mystical poetry of this Veda. It runs thus "Then there was no entity nor nonentity; no world, nor sky, nor aught above it; nothing anywhere in the happiness of any one, involving or involved; nor water deep and dangerous. Death was not; nor then was immortality; nor distinction of day or night. But THAT breathed without afflation, single with (*Swadhâ*) her who is within him. Other than him, nothing existed (which) since (has been). Darkness there was; (for) this universe was enveloped with darkness, and was undistinguishable (like fluids mixed in) waters; but that mass, which was covered by the husk, was (at length) produced by the power of contemplation. First, desire was formed in his mind, and that became the original productive seed; which the wise, recognising it by the intellect in their hearts, distinguish, in non-entity, as the bond of entity. Did the luminous ray of these (creative acts) expand in the middle? or above? or below? That productive seed at once became providence (or sentient souls) and matter (or the elements): she, who is sustained within himself, was inferior; and he, who heeds, was superior. Who knows exactly, and who shall in this world declare, whence and why this creation took place? The gods are subsequent to the production of this world; then who can know whence it proceeded? or whence this varied world arose? or whether it uphold itself or not? He who in the highest heaven is the ruler of this universe, does indeed know; but not another can possess this knowledge."

An instance of another kind of R'igveda hymns, which cannot have served any sacrificial purpose, is given by Professor Müller in his excellent work on 'Ancient Sanskrit Literature' (p. 495). It bears a satirical character, inasmuch as it ridicules the elaborate ceremonial of the Brahmans, and is rendered by him thus: "After lying prostrate for a year, like Brahmans performing a vow, the frogs have emitted their voice, roused by the showers of heaven. When the heavenly waters fell upon them, as upon a dry fish lying in a pond, the music of the frogs comes together like the lowing of cows with their calves. When at the approach of the rainy season, the rain has wetted them as they were longing and thirsting, one goes to the other while he talks, like a son to his father, saying, 'akkhala!' (βρεκεκεξ κοάξκοάξ). One of them embraces the other, when they revel in the shower of water; and the brown frog jumping after he has been ducked, joins his speech with the green one. As one of them repeats the speech of the other, like a pupil and his teacher, every limb of them is, as it were, in growth, when they converse eloquently on the surface of the water. One of them is Cow-noise, the other Goat-noise; one is Brown, the other Green; they are different though they bear the same name, and modulate their voices in many ways as they speak. Like Brahmans at the Soma sacrifice of Atirâtra, sitting round a full pond, and talking, you, O frogs, celebrate this day of the year when the rainy season begins. These Brahmans with their Soma have had their say, performing the annual rite. These Adhwaryus, sweating whilst they carry the hot pots, pop out like hermits. They have always observed the order of the gods as they are to be worshipped in the twelvemonth; these men do not neglect their season; the frogs who had been like hot pots themselves, are now released when the rainy season of the year sets in. Cow-noise gave, Goat-noise gave, the Brown gave, and the Green gave us treasures. The frogs, who give us hundreds of cows, lengthen our life in the rich autumn." In another hymn of the last Mandala a gambler laments over his evil passion, which beguiles him into sin. All these and similar hymns are evidently of quite a different character than those which praise the power of the elementary gods, and could find their place in sacrificial acts.

But there is further evidence to show that the collection of the R'igveda cannot have borne originally a ritual stamp. When songs are intended only for liturgic purposes, they are sure to be arranged in conformity with the ritual acts to which they apply; when, on the contrary, they flow from the poetical or pious longings of the soul, they may, in the course of time, be used at, and adapted for, religious rites, but they will never submit to that systematic arrangement which is inseparable from the class of liturgic songs. Now, such a systematic arrangement characterises the collection of the Yajurveda and Sâmaveda hymns; it is foreign to the R'igveda-Sanhitâ.

With the exception of the last book, which is of a mystical nature, all the other books of the whole Yajurveda contain verses which are classified according to the special sacrifices at the performing of which they were muttered. The Sanhitâ of the Sâmaveda consists of verses which had to be intoned especially at the moon-plant sacrifice. The arrangement of the R'igveda hymns, however, is quite of a different kind. It resisted the order of a finished ceremonial. The R'igveda hymns are not distributed with reference to sacrificial acts; they are partly arranged according to the divinities to whom they are addressed, and partly according to their authors, the R'ishis, who made them known. They must therefore have preceded the completion of that ceremonial, which is the indispensable condition of the Sâmaveda- and Yajurveda-Sanhitâs.

Having established the general character of the four Vedas, we shall now give a brief outline of their special features and of the principal works which owe them their origin.

The Rig-, or the first and principal, Veda, we possess only in the recension of the S'âkhala school. Its Sanhitâ, or collection of hymns, is arranged on two methods. The one has merely regard to the material bulk; the other seems to be based on the authorship of the Mantras. Both, however, run parallel with one another, without differing in the order of the hymns which constitute the Sanhitâ. According to the first method, the Sanhitâ is divided into eight *Asht'akas* or eighths, each of which is again subdivided into *Adhyâyas* or lectures, an Adhyâya consisting of a number of *Vargas* or sections, and a Varga of a number of *R'ich* or verses, usually five. According to the second method, the Sanhitâ is divided into ten *Man'd'alas* or circles, subdivided into eighty-five Annvâkas or lessons, which consist of one thousand and seventeen (or, with eleven additional hymns, of one thousand and twenty-eight) *Sûktas* or hymns, these again containing ten thousand five hundred and eighty and a half *R'ich* or verses. The first eight of these Man'd'alas begin with hymns addressed to *Agni*, which are followed by hymns addressed to *Indra*. After the latter come generally hymns addressed to the *Vis'we Devás*, or the gods collectively, and then those which are devoted to other divinities. The ninth Man'd'ala is entirely addressed to the Soma-plant, and is especially connected, therefore, with the Sâmaveda-Sanhitâ; while the tenth Man'd'ala has chiefly served for the collection of the Atharvaveda hymns. Again, as regards their author, the second Man'd'ala contains hymns which are attributed to the R'ishi Gr'itsamada; the third is said to belong to Vis'wâmitra, the fourth to Vâmadeva, the fifth to the Atris, the sixth to Bharadwâja, the seventh to Vasisht'ha, the eighth to Kanwa, the ninth to Angiras. The first and the tenth Man'd'ala are ascribed to the authorship of various R'ishis.

"The worship which the Sûktas describe comprehends offering prayer and praise: the former are chiefly oblations and libations,—clarified butter poured on fire; and the expressed and fermented juice of the Soma-plant, presented in ladles to the deities invoked,—in what manner does not exactly appear, although it seems to have been sprinkled, sometimes on the fire, sometimes on the ground, or, rather, on the *Kus'a*, or sacred grass, strewed on the floor, and in all cases the residue was drunk by the assistants. The ceremony takes place in the dwelling of the worshipper, in a chamber appropriated to the purpose, and probably to the maintenance of a perpetual fire, although the frequent allusions to the occasional kindling of the sacred flame are rather at variance with this practice. There is no mention of any temple, nor any reference to a public place of worship, and it is clear that the worship was entirely domestic. . . . . . . That animal victims were offered on particular occasions may be inferred from brief and obscure allusions in the hymns of the first book; and it is inferrible from some passages that human sacrifices were not unknown, although infrequent and sometimes typical: but those are the exceptions, and the habitual offerings may be regarded as consisting of clarified butter and the juice of the Soma-plant.

"The *Sûkta* almost invariably combines the attributes of prayer and praise: the power, the vastness, the generosity, the goodness, and even the personal beauty of the deity addressed are described in highly laudatory strains, and his past bounties or exploits rehearsed and glorified; in requital of which commendations, and of the libations or oblations which he is solicited to accept, and in approval of the rite in his honour, at which his presence is invoked, he is implored to bestow blessings on the person who has instituted the ceremony, and sometimes, but not so commonly, also on the author or reciter of the prayer. The blessings prayed for are, for the most part, of a temporal and personal description,—wealth, food, life, posterity, cattle, cows, and horses; protection against enemies, victory over them, and sometimes their destruction, particularly when they are represented as inimical to the celebration of religious rites, or, in other words, people not professing the same religious faith. There are a few indications of a hope of immortality and of future happiness, but they are neither frequent nor, in general, distinctly announced, although the immortality of the gods is recognised, and the possibility of its attainment by human beings exemplified in the case of the demigods termed R'ibhus, elevated for their piety to the rank of divinities. Protection against evil spirits (*Râkshasas*) is also requested, and in one or two passages *Yama* and his office, as ruler of the dead, are obscurely alluded to. There is little demand for moral benefactions, although in some few instances hatred of untruth and abhorrence of sin are expressed; a hope is uttered that the latter may be repented of or expiated; and the gods are in one hymn solicited to extricate the worshippers from sin of every kind. The main object of the prayers, however, are benefits of a more worldly and physical character: the tone in which these are requested indicates a quiet confidence in their being granted, as a return for the benefits which the gods are supposed to derive from the offerings made to them, in gratifying their bodily wants, and from the praises which impart to them enhanced energy and augmented power: there is nothing, however, which denotes any particular potency in the prayer or hymn, so as to compel the gods to comply with the desires of the worshipper; nothing of that enforced necessity which makes so conspicuous and characteristic a figure in the Hindu mythology of a later date, by which the performance of austerities for a continued period constrains the gods to grant the desired boon, although fraught with peril and even destruction to themselves." (Wilson, 'R'igveda,' vol. i. p. xxiii, ff.)

If we ask what divinities were worshipped by the authors of the R'igveda hymns, an answer is given by Yâska, the oldest Vaidik exegote of those whose writings are preserved, in the following manner:—"The Vaidik exegote says that there are *three* Devatâs, viz., Agni, who resides on earth; Vâyu, or Indra, who resides in the intermediate region (between heaven and earth); and Sûrya, who resides in heaven. Because each of these Devatâs has a variety of attributes, there are indeed many names of them" (vii. 5); and "of the Devatâ there is but one soul; but the Devatâ having a variety of attributes, it is praised in many ways: other gods are merely portions of the one soul" (vii. 4). The Anukraman'î, or explanatory index to this Veda, says, in a similar manner, "The deities are only three, whose places are the earth, the intermediate region, and heaven: (namely) fire, air, and the sun. They are pronounced to be (the deities of the mysterious names severally); and (Prajâpati) the lord of creation is (the deity) of them collectively. The syllable *Om* intends every deity; it belongs to (Paramesht'h'i) him who dwells in the supreme abode; it appertains to (Brahman) the vast one; to (Deva) God; to (Adhyâtman) the superintending soul. Other deities belonging to those several regions are portions of the three gods; for they are variously named and described, on account of their various operations: but (in fact) there is only one deity, the *Great Soul* (Mahânâtmâ). He is called the Sun; for he is the soul of all beings: (and) that is declared by the sage: 'the sun is the soul of (jagat) what moves and of (tasthivat) that which is fixed.' Other deities are portions of him." (Colebrooke, 'Misc. Ess.,' i. p. 27.)

If we took this account for a correct representation of the Vaidik creed we could not but draw the inference that it was based on the belief in one god, or, at least, one principle of creation, and that the many gods met with in the Vaidik hymns are merely poetical allegories of the One Great Soul. We have quoted indeed, before, a mystical hymn of the R'igveda, which would seem to countenance this view. But an unbiassed examination of the R'igveda poetry must lead to the conclusion that religion did not take this course in India; that we must distinguish between one or more hymns, evidently the product of a later and philosophical age, and the bulk of that collection which contains nothing but the adoration of the elementary powers in their various manifestations and degrees. Nor can we give an unqualified assent to the threefold classification of the Vaidik divinities, as given by Yâska, and repeated by the Anukraman'î; for neither is Agni's abode restricted to earth, nor could Indra be identified or placed on the same level with Vâyu, nor would it be correct to assign to Sûrya such a place in the Vaidik pantheon as would equalise his rank with that of Agni or Indra. The real position and quality of the *principal* Vaidik divinities of the R'igveda is, in short, this:—The chief deities are *Agni* and *Indra*, the two gods, as we have noticed before, to whom the first series of hymns is addressed in eight out of the ten Man'd'alas of the Sanhitâ. *Agni* (from *aj*, "to move," Latin, *igni-*) is the God of Fire, under a threefold aspect of this element: as it exists on earth, in its daily use and in its sacrificial capacity, as well as the heat of digestion and the principle of animal and vegetable life; secondly, as the fire of lightning; and thirdly, as the fire of the sun. Agni is praised therefore as the originator of the sacrifice, and as the mediator between gods and men: he conveys offerings to the former, and brings the gods to the worshipper. During the night he protects mortals from the demons who haunt the altars and are hostile to religious rites. On the other hand, as the fire of lightning, Agni is the "son, or the grandson, of the waters;" and as the fire of the sun he grants wealth, food, health, and life, destroys and revives all things. Not many subordinate divinities are mentioned in his train; sometimes the *Maruts*, or Winds, are, but they are more frequently the attendants of Indra; and the *Âpris*, female divinities, which also include insensible objects, such as the doors of the sacrificial hall. The proper offering to Agni is *ghee* (ghrita), or clarified butter.

Indra (a word of doubtful etymology, probably from an obsolete radical *id* or *ind*, "to see" or "to know") is the powerful god of the firmament. He bestows blessings and riches when propitiated by the juice of the Soma-plant, which is his appropriate offering. He has elevated the sun and fixed the constellations in the sky; but above all he is the conqueror of *Vr'itra* ("the enveloper"), the demon who hides the sun, and of the clouds which threaten to withhold their waters from the earth; he pierces them with his thunderbolt and the waters are let down. He is also represented as discovering, and rescuing with his thunderbolt, the cows which had been stolen and were hidden in the hollows of the mountains by a demon named Pan'i or Vala. It is possible that these cows, as Professor Whitney believes ('Journal Amer. Or. Soc.' iii. p. 320), are meant for an allegory of the reservoirs of water which are freed by Indra, like the waters in the myth of Vr'itra; but it is possible also that this legend is merely a poetical record of an occurrence of pastoral life, such as we frequently meet with in the R'igveda poetry. A subordinate class of gods who are naturally associated with Indra, are the *Maruts*, or Winds; they assist Indra in his battles with Vr'itra and the production of rain. "They ride on spotted stags, wear shining armour, and carry spears in their hands; no one knows whither they come nor whither they go, their voice is heard aloud as they come rushing on; the earth trembles and the mountains shake before them. They are called the sons of *Rudra*, who is conceived of as peculiar god of the tempest." (Ib. p. 315.) Besides them a god of wind, *Vâyu*, is named: "he drives a thousand steeds; his breath chases away the demons; he comes in the earliest morning, as the first breath of air that stirs itself at day break, to drink the Soma, and the Auroras weave for him shining garments." This god is sometimes identified with Indra; but there are verses in which both, Indra and Vâyu, are invoked conjointly to share in the sacrifice.

Amongst the gods assigned by Yâska to the sphere of heaven, we have to notice in the first rank the *Adityas*, or the sons of the *Aditi*. The latter word means "indestructibility," and the Adityas are described as "elevated above all imperfection; they do not sleep or wink; their character is all truth; they hate and punish guilt; to preserve mortals from sin is their highest office." One of these Adityas, is *Sûrya*, the sun, who is described as driving a chariot drawn by seven golden steeds, and is also personified as the ornamented bird of heaven.

But he does not occupy that prominent rank among Vaidik gods which we might expect, and which seems to be allowed to him by Yâska. It must be observed, too, that some other words which mean "sun" in classical Sanskrit, especially *Savitr'i*, *Pûshan*, and *Aryaman* are likewise Âdityas in Vaidik mythology; and that *Vishn'u* also is an Âditya when he is identified with the sun in its three stages of rise, culmination, and setting ('R'igveda,' i. 22,17). Of other Âdityas moreover we point out *Varun'a* (from *vr'i* "to surround,"—Greek, Οὐρανὸ). He is the "all-embracing heaven, the orderer and ruler of the universe; he established the eternal laws which govern the movements of the world, and which neither immortal nor mortal may break; he regulated the seasons; appointed sun, moon, stars, and their courses; gave to each creature that which is peculiarly characteristic .... From his station in heaven Varun'a sees and hears everything, nothing can remain hidden from him." He is said to be the divinity presiding over the night, to support the light on high, and to make wide the path of the sun: he grants wealth, averts evil, and protects cattle. He is frequently invoked, together with *Mitra*, another Âditya, who is the divinity presiding over the day, and a dispenser of water. (Wilson, 'R'igveda,' i. p. xxxiv.)

The adoration of the sun is naturally connected with that of *Ushas*, "dawn," or rather of *Ushasas*, "many dawns." "She is addressed as a virgin in glittering robes, who chases away the darkness, ... who prepares a path for the sun, is the signal of the sacrifice, rouses all beings from slumber, gives sight to the darkened, power of motion to the prostrate and helpless." (Whitney, 'Journal Amer. Or. Soc.,' iii. p. 322.)

The last divinities which deserve our special attention are the two *As'wins*. They are the sons of the sea, and are represented as ever young and handsome, travelling in a golden, three-wheeled, triangular chariot, drawn by an ass or two horses, and the precursors of the dawn. They are called *Dasras*, "destroyers of fever or of diseases," for they are the physicians of the gods, and *Nâsatyas*, "never untrue." Many legends are connected with their career: they brought back to a father his lost child, they restored the blind to sight; they relieved one man of his old body by giving him a new one instead; they supplied another with a metal leg to replace the one he had lost in battle; they assisted seafarers in their perils, and so on. They are probably the two luminous points which precede the dawn; some compare them with the Dioscuri of the Greek.

The constellations are never named as objects of worship, and although the moon appears to be occasionally intended under the name *Soma*, particularly when spoken of as scattering darkness, yet the name and the adoration are in a much less equivocal manner applied to the Soma-plant. (Wilson, 'R'igveda,' i. p. xxvi.)

The great gulf which lies between this elementary worship of the R'igveda and the later mythology need not be pointed out; but it will not be without interest to observe that we already meet in its poetry with some of those names which assume so different a character in the epic poems and the Puran'as. Thus Rudra, the father of the Winds, becomes in the later mythology another name for S'iva, who is unknown to the Vaidik hymns. Their Vishn'u, a name of the Sun, and one of the Âdityas, is the second person of the later Hindu triad; and his epithet Trivikrama, or "he who takes three steps," which means, as we have seen, the sun in its three stages, gives rise to the myth of the fourth Avatâra of Vishn'u, when, as a dwarf, he strides over the three worlds—earth, intermediate space, and heaven—and compels Bali, who threatened the sovereignty of Indra, to seek refuge in Tartarus.

From the nature of this worship, and from the desire for food, cattle, and the like, so frequently expressed in the hymns, it has sometimes been inferred that the condition of life as depicted in these hymns was that of a nomadic and pastoral people. There can be nothing more erroneous, if we look upon the actual collection of the hymns as a whole; as we did—and in the present state of Sanskrit philology are compelled to do—when drawing the previous sketch of the ancient Hindu belief. This collection, on the contrary, gives abundant proof that the Hindus of the R'igveda were settled in villages and towns, that they were a manufacturing people; for weaving, the melting of metallic substances, the fabrication of golden and iron mails, of ornaments, and the like, are not unfrequently alluded to. It is remarkable also that they were a seafaring and a mercantile people. Even a naval expedition against a foreign island is mentioned in a hymn (i. 116, 3). Tugra, a friend of the As'wins, we are told, "sent (his son) Bhujyu to sea, as a dying man parts with his riches; but you (As'wins) brought him back in vessels of your own, floating over the ocean, and keeping out the waters. Three nights and three days, Nâsatyar, have you conveyed Bhujyu in three rapid revolving cars, having a hundred wheels, and drawn by six horses, along the watery bed of the ocean to the shore of the sea. This exploit you achieved, As'wins, in the ocean, where there is nothing to give support, nothing to rest upon, nothing to cling to, that you brought Bhujyu, sailing in a hundred-oared ship, to his father's house." We find them in possession of musical instruments, practising medicine, computing the division of time to a minute extent; and there is sufficient evidence in the hymns to show that they had not merely laws of buying and selling, but even such complicated laws of inheritance as we meet with in the most advanced period of Hindu life. According to the latter, for instance, a son is the heir of the paternal property, to the exclusion of a daughter, as she transfers her property, by way of dower, to another family. But in default of a direct male heir, the son of a daughter may perform the funeral rites, or, what is equivalent, inherit the paternal property, provided that the daughter be *appointed* for such a purpose when given in marriage. (See Colebrooke's 'Digest,' 3. 161, and various authorities quoted in Goldstücker's 'Sanskrit Dictionary,' s.v. 'Aputrikâ.') The same law is laid down in the following verses of Rigv. iii. 31. 1. 2. (Wilson's translation):—"The sonless father regulating (the contract) refers to his grandson (the son) of his daughter, and relying on the efficiency of the rite, honours his (son-in-law) with valuable gifts; the father, trusting to the impregnation of the daughter, supports himself with a tranquil mind. (A son) born of the body, does not transfer (paternal) wealth to a sister; he has made (her) the receptacle of the embryo of the husband; if the parents procreate children (of either sex), one is the performer of holy acts, the other is to be enriched (with gifts)."

That so advanced a state of social life could not remain without its evils and vices is obvious; we find hymns which describe gambling, which speak of robbers and thieves, of secret births, of youths associating with courtesans.

This sketch of the religious and social condition of ancient India rests, as mentioned, on the supposition of the R'igveda-Sanhitâ having always been that which it is now—in fact, on the native theory of the eternity of the Veda. In the beginning we quoted some passages from the 'Purân'as' which show that these late productions of Hindu religion look upon all the Vedas as created by Brahmâ; but we also pointed out that the poets of the hymns are held even by the oldest authorities to be inspired seers, who received them from the deities. Mr. Muir, in one of the most interesting and elaborate works of Sanskrit philology, the 'Original Sanskrit Texts,' has given other and very copious proof that the doctrine of the eternity of the Veda pervaded the poetry and the philosophical reasoning of ancient and mediæval India; and we must content ourselves with referring for further detail to the third volume of this excellent record of the 'Original Texts.' It may suffice therefore to add that even the differences which exist between the various editions of the sacred texts were explained away by an ingenious theory. It says that "the Vaidik texts got lost in the several Pralayas, or destructions of the worlds; and since each Manwantara had its own revelation, which differed only in the expression, not in the sense of the Vaidik texts, the various versions represent these successive revelations, which were remembered through their excessive accomplishments by the R'ishis." ('Orig. Sansk. Texts,' iii. p. 231, 232.) In short, though according to this theory, a succession of revelations is admitted by the Hindu divines, they are conceived of as a reproduction of the first revelation, which comprised the whole bulk of the sacred text.

The utter improbability of an original contemporaneousness of all the hymns of the R'igveda is such that a theory founded on it would scarcely require a remark for the non-Brahmanic student of Hindu antiquity. In reading these hymns, such a student would not fail to perceive that some describe the most primitive features, and others—as we have shown—the most complicated mechanism of social life; that in some the first bud of religious life is perceptible, while others contain "the full-grown fruit of long experience in thought, or mark the end, not the beginning, of a phase of religious development.' In other words, he would perceive the gradual and historical growth of that oldest document of the Brahmanic creed, the R'igveda-Sanhitâ. But even the Brahmanic student could not remain indifferent to the fact, that the hymns themselves destroy this theory of the eternity of the Veda, built up, as it was, in a priestly and systematising age. There are passages, for instance, in which the R'ishis themselves describe themselves as composers or "fabricators" or "generators," not as "seers" of the hymns. "This hymn," we read in one, "has been *made* to the divine race by the sages." "Thus, O Indra," says another, "have the Gotamas *made* for thee pure hymns;" or, "desiring wealth, men have *fashioned* (lit. fabricated) for thee this hymn, as a skilful workman (fabricates) a car;" or, "thus have the Gr'itsamadas, desiring succour, *fashioned* (lit. fabricated) for thee a hymn, as men make roads;" or, "the sages *generated* a pure hymn and a prayer to Indra;" "Wise Agni Bâtavedas, I *generate* a hymn for thee, who receivest it with favour;" and so on in numerous other instances. (Muir, 'Orig. Sansk. Texts,' iii. pp. 128-140.)

In other hymns, says Mr. Muir (Ib. p. 117), "the .... passages from the R'igveda either expressly distinguish between contemporary R'ishis and those of a more ancient date, or, at any rate, make reference to the one or the other class. This recognition of a succession of R'ishis constitutes one of the *historical* elements in the Veda." If this succession were simply one of the poets, it might seem, from a Brahmanic point of view, to be not incompatible with the theory mentioned before; but it appears in conjunction with the narration of events, and thus excludes the possibility of their original coævity. "Those gods," we read, for instance, "who formerly grew through reverence, were altogether blameless. They caused the dawn to rise, and the sun to shine for Vâyu and the afflicted Manu;" or, "listen to S'yâvâswa pouring forth libations, in the same way as thou didst listen to Atri when he celebrated sacred rites." (Comp. Muir, 'Orig. Sansk. Texts,' iii. pp. 116-128.)

Whichever view, therefore, one takes, it is clear that there are periods in the arrangement of those thousand and twenty-eight hymns which form the present R'igveda-Sanhitâ, and that the growth of the religious and social life of ancient India cannot be fully understood until we have a knowledge of the relative age at least of these hymns, since their real date may perhaps for ever remain as much beyond the control of philological research as it has remained hitherto. In some cases the description of events or the allusion to institutions of a domestic or public kind, in others the character of the religious notions expressed and the detail of the rites explained, may lead to a surmise as to the chronological relation of certain hymns; but since the soundness of a criterion of this kind will more or less depend on personal feelings or views, a safer footing is obtained in those hymns where the R'ishi himself refers to a predecessor who is the poet of another hymn, or to events anterior to him, met with however in other portions of R'igveda poetry. For there it is possible at once to establish a relative order in time between such hymns. But as instances of this description are rare, the real burden of proof will probably always rest with the linguistic facts that may be gathered from the various hymns. They are the stubborn monuments which raise their heads above the confusion created by the systematising arrangement of later times. As yet, however, Sanskrit philology has done little or nothing to enable us to see clearly in the mist of the gradual development of the Vaidik age. It is struggling even at present to save the very meaning of the Vaidik words, as handed down to us by native scholarship, and the grammatical explanation of the Vaidik commentaries, from a conceit which strives to substitute its own fanciful notions for the traditional lore—the only real means we possess for understanding these ancient texts.

If now we turn to the Sanhitâs of the next two Vedas, our attention will be particularly engaged by the purpose for which they were collected, or, as observed before, for which they were either entirely, or for the most part, extracted from the R'igveda-Sanhitâ. This purpose, we stated, was a liturgic one. The verses of the Sâmaveda were intoned at those sacrificial acts which were performed with the juice of the Soma-plant. A short account of the manner in which the libations of this juice were prepared and offered to the gods is given in the introduction of Stevenson's translation of the Sâmaveda. "The first thing to be done is to collect the Soma, or moon-plant, and the aran'i-wood for kindling the sacred fire; and this must be done in a moonlight night, and from the table-land on the top of a mountain. The moon-plants must be plucked up from the roots, not cut down; and after being stripped of their leaves, the bare stems are to be laid on a cart drawn by two rams or he-goats, and by them to be brought to the house of the Yajamâna, the institutor of the sacrifice, for whose especial benefit, and at whose expense, all the ceremonies are performed. The stems of the plants are now deposited in the hall of oblation .... bruised by the Brahmans with stones, and then put between two planks of wood, that they may be thoroughly squeezed and the juice expressed. The stalks, with their expressed juice, are then placed over a strainer made of goats' hair, sprinkled with water, and squeezed by the fingers of the officiating Brahmans, one or two of which must be adorned with flat gold-rings. The juice, mixed with water, now makes its way through the strainer and drops into the Dron'a Kalasa, the receiving vessel placed below, and situated at that part of the Yajnavedi (or sacrificial ground), called the Yoni, or womb .... The juice, already diluted with water, is in the Dron'a Kalasa further mixed with barley, clarified butter, and the flour of a grain called by the Marathas *wari*, the Sanskrit names of which are *nivâra* and *tr'in'adhânya*. It is now allowed to ferment till a spirit is formed, after which it is drawn off for oblations to the gods in a scoop called *sruch*, and in the ladle called *chamasa*, for consumption by the officiating Brahmans. The vessel, scoop, and ladle, are all made of the wood of the catechu-tree (*Mimosa catechu*). Nine days are mentioned in the Bhâshya as required for the purificatory rites .... There are three oblations offered daily; one early in the morning, one at noon, and one at night."

The sacrifices at which such oblations were offered are very numerous. The principal one seems to have been the *Jyotisht'oma*, a great sacrifice, which, if complete, consisted of seven *sansthâs* or stages, each occupying the space of several days. The Mîmânsists, however, probably yielding to the necessity of circumstances, consider the *Agnisht'oma* only, the first stage of the Jyotisht'oma, as obligatory for the performance of this rite; while they look upon the six others—the Atyagnisht'oma, Ukthya, Shod'as'in, Atirâtra, Aptoryâma, and Vâjapeya—as voluntary and supererogatory. "The Soma offering," says Dr. Windischmann, in his 'Dissertation on the Soma worship of the Arians,' "was unquestionably the greatest and the holiest offering of the ancient Indian worship. The sound of the trickling juice is regarded as a sacred hymn. The gods drink the offered beverage; they long for it (as it does for them); they are nourished by it, and thrown into a joyous intoxication: this is the case with Indra (who performs his great deeds under its influence), with the As'wins, the Maruts, and Agni. The beverage is divine, it purifies, it inspires greater joy than alcohol, it intoxicates S'ukra, it is a water of life, protects and nourishes, gives health and immortality, prepares the way to heaven, destroys enemies, &c. The Sâmaveda distinguishes two kinds of Soma, the green and the yellow; but it is the golden colour which is for the most part celebrated." (Muir, 'Orig. Sansk. Texts,' iii. p. 471.)

And these exhilarating and inebriating properties of the plant, divested from their poetical association with the gods, sufficiently explain the religious awe in which they were held by a people which learnt to experience their influence, and ascribed them to some mysterious cause.

Having explained before that the Sâmaveda verses are entirely taken from the R'igveda-Sanhitâ, we may now show the artificial manner in which these extracts were brought together for the purpose described, and how little value they possess as a poetical anthology. The Sanhitâ of the Sâmaveda consists of two separate portions. The first, called *Ârchika*, or *Chhandograntha*, is composed of five hundred and eighty-five verses; the second, called *Staubhika*, or *Uttarâgrantha*, contains twelve hundred and twenty-five verses. The verses of the first are arranged into fifty-nine *Das'ati*, or decades, subdivided again into *Prapât'hakas*, or chapters, with another subdivision into *Ardhaprapât'hakas*, or half-chapters. The second portion is also divided into *Prapât'hakas* with *Ardhaprapât'hakas*; these however are for the most part arranged according to triplets of verses, the first of which is already contained in the Ârchika portion, and thus appears twice in the Sâmaveda-Sanhitâ. This first verse is called the *Yoni-verse*, or the womb-verse, that in which the two others—the *Uttarâs*—are generated, because all the modifications which take place during the intonation of the former—the modulations, disruptions of letters, stoppages, &c.—must be likewise observed at the chanting of the latter. These modifications are taught in the Gânas, or song-books, the *Veyagâna* and *Aran'yagâna*, which contain the composition of the Ârchika, and the *Ûhagâna* and *Ûhyagâna*, which comprise that of the Staubhika. In the Ârchika portion, the verses of the R'igveda are nearly always disjoined from the connection in which they originally stood, while a somewhat greater continuity of extracts is observed in the Staubhika. In a very valuable synopsis given by Professor Whitney (in the second volume of Professor Weber's 'Indische Studien'), it is shown in what proportion these extracts were made from the R'igveda; it enables the student moreover, by comparing both collections, to ascertain that the compilers of the Sâmaveda completely lost sight of the original nature of the R'igveda hymns, and of their poetical worth; that no respect was paid to the integrity of the poets' thoughts, or to the motives which called forth their lays. Still, however inferior the collection of the Sâmaveda is to that of the R'igveda, so powerful is the poetical greatness of the principal Veda, that it could not be entirely destroyed, even in the garbled assemblage of its verses in the Sâmaveda.

But even this mite of æsthetical praise can scarcely be bestowed on the *Yajurveda-Sanhitâ*. Like the Sâmaveda, it also is a liturgic book: it also has largely drawn on the R'igveda hymns. But the first difference we observe is that its contents are not entirely taken from the principal Veda, and the second is marked by the circumstance that it often combines with verses passages in prose, which are called *yajus* (lit. "that by which the sacrifice is effected"), and have given to the Yajurveda its name. Besides, the ceremonial for which this Veda was made up is much more diversified and elaborate than that of the Sâmaveda, and the mystical and philosophical allusions which now and then appear in the R'igveda, probably in its latest portions, assume a more prominent place in the Yajurveda. In one word, it is *the* sacrificial Veda, as its name indicates. Hence we understand why it was looked upon in that period of Hindu civilisation which was engrossed by superstitions and rites, as the principal Veda, superior in fact to the R'igveda, where there is no system of rites. To Sâyan'a, for instance, the great commentator of the Vedas, who lived only four centuries ago, the poetry of the R'igveda, and even the collection of the Sâmaveda, are of far less importance than the Yajurveda. "The R'igveda and Sâmaveda," he says, in his introduction to the Taittirîya-Sanhitâ, "are like fresco-paintings, whereas the Yajurveda is the wall on which they stand" (Müller, 'Anc. Sansk. Lit.' p. 175); and it is on the ritual works connected with the oldest recension of this Veda that the speculations of the Mîmânsists, who refer their doctrine to the Sûtras of Jaimini, are based. (Goldstücker, 'Pân'ini,' p. 9.)

There is one remarkable fact to be noticed in the history of this Veda, which has no parallel in that of the other Vedas, a schism to which its collection gave rise, and which ended in the putting forth of two Yajurveda texts, the one assuming the name of the Black, the other that of the White Yajurveda. The Vishn'u-Purân'a, iii. 5. 2 (and nearly in the same manner the Vâyu-Purân'a), contain the following legend concerning the origin of this schism: "Yâjnavalkya, son of Brahmarâti, was Vais'ampâyana's disciple, eminently versed in duty and obedient to his teacher. An agreement had formerly been made by the Munis, that any one of their number who should fail to attend at an assembly on Mount Meru on a certain day should incur the guilt of Brahmanicide within a period of seven nights. Vais'ampâyana was the only person who infringed this agreement, and he in consequence occasioned the death of his sister's child, by touching it with his foot. He then desired all his disciples to perform in his behalf an expiation which should take away his guilt, and forbade any hesitation. Yâjnavatkya then said to him, "Reverend sir, what is the necessity for these faint and feeble Brahmans? *I* will perform the expiation." The wise teacher, incensed, replied to Yâjnavalkya, "Contemner of Brahmans, give up all that thou hast learnt from me; I have no need of a disobedient disciple, who, like thee, stigmatises these eminent Brahmans as feeble." Yâjnavalkya rejoined, "It was from devotion (to thee) that I said what I did; but I, too, have done with thee; here is all that I have learnt from thee." Having spoken, he vomited forth the identical Yajus texts tainted with blood, and giving them to his master, he departed at his will. The other pupils having then become transformed into partridges (*tittiri*) picked up the Yajus texts, and were thence called Taittirîyas. And those who had by their teacher's command performed the expiation, were from this performance (*charan'a*) called Charakâdhwaryus. Yâjnavalkya then, who was habituated to the exercise of suppressing his breath, devoutly hymned the sun, desiring to obtain Yajus texts. [The hymn follows.]

Thus celebrated with these and other praises, the sun assumed the form of a horse, and said, "Ask whatever boon thou desirest." Yâjnavalkya then, prostrating himself before the lord of the day, replied, "Give me such Yajus texts as my teacher does not possess." Thus supplicated, the sun gave him the Yajus texts called *Ayâtayâma*, which were not known to his master. Those by whom these texts were studied were called Vâjins, because the sun (when he gave them) assumed the shape of a horse (vâjin)." (Muir, 'Orig. Sansk. Texts,' iii. pp. 32, 33.)

However absurd this legend may be conceived to be, the two recensions of the Yajurveda which are preserved, plainly bear out the fact, that the "White" Yajurveda is more recent than the "Black," and that the former is evidently intended as an improvement of the latter —whence it is but reasonable to infer that such an infringement on an existing text cannot have taken place without some, and probably a great, conflict between the followers of the one and the originators of the other. To understand, however, the nature of this improvement, we must advert to the character of the older text.

It has been stated before, that each Veda consists of a collection of hymns—the Sanhitâ portion—and of a Brâhman'a portion, which is especially intended for the explanation of the rites at the performance of which the hymns were employed. This division is maintained in its purity so far as the R'ig- and Sâma-veda are concerned. It is greatly obscured, however, in the Taittirîya-Sanhitâ, or that of the "Black" Yajur-veda. There, verses and description of ritual occur promiscuously; it is in reality a text-book for the guidance of the Adhwaryu priest, while the Hotr'i and Udgâtri had to study their special ritual books, in order to know when any particular verse of their Sanhitâs ought to come in at a certain rite. This motley character of the Taittirîya-Sanhitâ is probably indicated by the epithet "Black," or "Dark," which is given to the oldest recension of the Yajurveda; and though the Tittiris may be a real proper name, the meaning of this word being "partridge," it is not impossible that this coincidence suggested the etymological legend mentioned above. Now, the impurity of this text, as intimated by the legend, its "darkness," as it were, is removed in the "White" Yajurveda, which is ascribed to the R'ishi Yâjnavalkya; for in the latter we possess a "clear" Sanhitâ and a "clear" Brâhman'a.

The topics treated of in both redactions are on the whole the same, but they are differently placed, and vary sometimes in detail. The *As'wamedha* or horse sacrifice, which is merely alluded to in a few hymns of the R'igveda-Sanhitâ, is dwelt upon in the Yajurveda with considerable detail. The fact of six hundred and nine animals of various descriptions, domestic and wild, including birds and reptiles, being tied to twenty-one posts, and the intervals between them, at the performance of this sacrifice, may convey an idea of the complicated ritual which existed at the time when this Veda was composed. Of ceremonies, unknown to the other Vedas, we may mention also, the *Purusha-medha* or man-sacrifice—an emblematic ceremony, in which a hundred and eighty-five men of various specified tribes, characters, and professions, are bound to eleven posts, and consecrated to various deities—the *Sarva-medha* or all-sacrifice, and the *Pitri-medha* or sacrifice to the manes. It is worthy of notice, too, not only that all the four castes, the institution of which cannot with certainty be traced to the period of the R'igveda-Sanhitâ, make their distinct appearance in the Yajurveda, but also that it contains many words which in the mythology of the epic poems and the Purân'as are names of S'iva, the third god of the later Hindu triad.

The Taittirîya-Sanhitâ of the Black Yajurveda is arranged in seven *Kân'd'a* or books, with forty-four *Prapât'haka* or chapters, containing altogether six hundred and fifty-one *Anuvâka* or sections, divided into two thousand one hundred and ninety-eight *Kan'd'ikâ* or portions. The *Vâjasaneyi-Sanhitâ* of the White Yajurveda, in the Mâdhyandina recension, is divided into forty *Adhyâya* or lectures, with three hundred and three *Anuvâka* or sections, comprising one thousand nine hundred and seventy-five *Kan'd'ikâ* or portions. Other schools connected with either form of this Veda adopted other divisions, which, however, need not be adverted to here.

That the *Sanhitâ* of the *Atharvaveda* is not a sacrificial collection in the sense of that of the Samâ- and Yajur-veda we have explained already. It is divided into twenty *Kân'd'a* or books, the first eighteen of which contain thirty-four *Prapât'haka* or chapters, which comprise ninety-four *Anuvâka* or sections: the seventeenth Kân'd'a consisting of one Prapât'haka only, which has no further subdivision; the nineteenth Kân'd'a is not divided into Prapât hakas, but simply into seven Anuvâkas; and the twentieth contains nine Anuvâkas, the third of which has three *Paryâyas*. The Anuvâkas in their turn consist of about six thousand verses. "Its first eighteen books," of which alone it was originally composed, Professor Whitney, the learned editor of the 'Atharvasanhitâ,' observes ('Journal of the American Oriental Society,' vol. iv. p. 254), "are arranged upon a like system throughout: the length of the hymns, and not either their subject or their alleged authorship, being the guiding principle; those of about the same number of verses are combined together into books, and the books made up of the shorter hymns stand first in order. A sixth of the mass, however, is not metrical, but consists of longer or shorter prose pieces, nearly akin in point of language and style to passages of the Brâhman'as. Of the remainder, or metrical portion, about one-sixth is also found amongst the hymns of the R'ik, and mostly in the tenth book of the latter; the rest is peculiar to the Atharva. Respecting their authorship the tradition has no information of value to give; they are with few exceptions attributed to mythical personages.

"As to the internal character of the Atharva hymns, it may be said of them, as of the tenth book of the R'ik, that they are the productions of another and a later period, and the expressions of a different spirit, from that of the earlier hymns in the other Veda. In the latter, the gods are approached with reverential awe, indeed, but with love and confidence also; a worship is paid them that exalts the offerer of it; the demons, embraced under the general name *Rakshas*, are objects of horror, whom the gods ward off and destroy; the divinities of the Atharva are regarded rather with a kind of cringing fear, as powers whose wrath is to be deprecated and whose favour curried for; it knows a whole host of imps and hobgoblins, in ranks and classes, and addresses itself to them directly, offering them homage to induce them to abstain from doing harm. The *mantra*, prayer, which in the older Veda is the instrument of devotion, is here rather the tool of superstition; it wrings from the unwilling hands of the gods the favours which of old their good-will to men induced them to grant, or by simple magical power obtains the fulfilment of the utterer's wishes. The most prominent characteristic feature of the Atharva is the multitude of incantations which it contains; these are pronounced either by the person who is himself to be benefited, or, more often, by the sorcerer for him, and are directed to the procuring of the greatest variety of desirable ends; most frequently, perhaps, long life, or recovery from grievous sickness, is the object sought; then a talisman, such as a necklace, is sometimes given, or in very numerous cases some plant endowed with marvellous virtues is to be the immediate external means of the cure; farther, the attainment of wealth or power is aimed at, the downfall of enemies, success in love or in play, the removal of petty pests, and so on, even down to the growth of hair on a bald pate. There are hymns, too, in which a single rite or ceremony is taken up and exalted, somewhat in the same strain as the Soma in the Pâvamânya hymns of the R'ik. Others of a speculative mystical character are not wanting; yet their number is not so great as might naturally be expected, considering the development which the Hindu religion received in the periods following after that of the primitive Veda. It seems in the main that the Atharva is of popular rather than of priestly origin; that in making the transition from the Vedic to modern times, it forms an intermediate step, rather to the gross idolatries and superstitions of the ignorant mass, than to the sublimated pantheism of the Brahmans." (Ib. vol. iii. p. 307.)

The general character of the *Brâhman'a*, or dogmatic, portion of the Vedas having been explained before, a short notice of the principal works of that class, and a few extracts from them, will illustrate the position they hold between the collection of hymns and the remainder of the Vaidik literature.

The Brâhman'a of the Bahvr'ichas, or the priests of the R'igveda, is still preserved in two editions. The former—the *Aitareya-Brâhman'a*—consists of eight *Panchikâ* or pentades of *Adhyâyas*, thus comprising forty Adhyâyas or lectures, which again are subdivided into two hundred and eighty-five *Khan'd'a* or portions. The latter, the *S'ânkhâyana-Brâhman'a*, which bears also the name of the *Kaushîtaki-Brâhman'a*, consists of thirty Adhyâyas, likewise subdivided into a number of Khan'd'as. Both Brâhman'as contain on the whole the same matter; but the difference of the manner in which their subjects are arranged and treated leads to the supposition that the first thirty lectures of the Aitareya-Brâhman'a are older than those of the S'ânkhâyana, whereas the last ten lectures of the former contain rites not explained in the latter, and are probably therefore more recent than the S'ânkhâyana. These Brâhman'as do not follow the order of the hymns of the R'igveda-Sanhitâ, but quote them as they would be required by the Hotr'i priest for the performance of the rites described. In order to give an idea of the elaborate ceremonial which called these Brâhman'a into life, and of the mysticism which connects them with a subsequent class of works, we will first give an abstract of an important ceremony, treated of with great detail in the last books of the Aitareya-Brâhman'a, and several times alluded to in the epic poetry of the Mahâbhârata and Râmâyan'a,—the *Abhisheka* or inauguration of a king.

This ceremony is either part of a Râjasûya, and performed by a king at the end of this sacrifice, or it is not part of a sacrifice, and then occurs at a king's accession to the throne. For celebrating the former ceremony there must have been prepared a throne-seat of the wood of the *udumbara* (*Ficus glomerata*), resting on four legs a span high, with boards placed on them, and side-boards of the dimensions of a cubit or two spans; the whole well fastened together with a texture made of cords of *munja* grass (*Saccharum Munja*); a tiger skin, which is placed on the seat with the hair upward and the neck to the east, a large four-cornered ladle of *udumbara* wood, and a branch of the same. In the ladle have been put eight things: curd, honey, clarified butter, water proceeding from rain during sunshine, before it has fallen down, blades of *S'yâma* grass, sprouts, spirituous liquor, and *Du'b* grass (*Panicum dactylon*). To prepare a site for the throne three lines have been drawn on a place of sacrifice .... one southwards, another westwards, and a third northwards; the one to the south is that on which the throne is to be placed, with its front towards the east, so that the two feet to the north come to stand within the *Vedi* or sacrificial ground, and the two to the south without; this latter spot occupied by the throne seat, is called *S'rî* (comm., as a type of happiness or prosperity). The place within the *Vedi* being small, but that without being illimited, this portion of the throne indicates that the sacrificer may obtain definite and indefinite wishes within and without the *Vedi*. The tiger skin is the type of increase of military power, for the tiger is the hero of the wild beasts; the udumbara wood of the throne, ladle and branch, is the type of nourishing juice and of food (which the sacrificer is supposed to acquire by this symbol); curd, honey, and clarified butter typify the essence of water and plants (curd and butter, as the commentator observes, because they originate in grass and water, which are the food of cattle; honey, because it originates in the juice of plants collected by bees); water proceeding from rain during sunshine, before it has fallen down, typifies lustre (or energy); and rain (being the consequence of oblations to the gods) holiness; grass and sprouts typify food, hence prosperity and progeny; spirituous liquor is the type of a Kshatriya's power (comm., on account of its fierceness or hotness); Du'b grass (being the Kshatriya of the plants, and firmly established in the soil with its many roots) is the type of military power and of a firmly established rule. The principal features of the ceremony itself are the following. The king, who performs the sacrifice, kneels down at the back part of the throne-seat with his face to the east, and his right knee touching the ground. He then touches with his hands the throne-seat, and invites the gods to ascend it together with various metres—*Agni* with the metre Gâyatrî, *Savitr'i* with the Ushnih, *Soma* with the Anusht'ubh, *Br'ihaspati* with the Br'ihatî, *Mitra* and *Varun'a* with the Pankti, *Indra* with the Trisht'ubh, the *Vis'we Devâs* with the Jagatî—for the purpose of obtaining "kingly power, righteous government, increase of enjoyment, independent rule, attainment of more distinguished qualities than those possessed by other kings, coming (after death) into the world of Brahman, and obtaining there dominion, a mighty rule, mastership, independence, and a long residence there." The gods have arrived, and the king now ascends himself the throne-seat, first with his right and then with his left knee. The next ceremony is the propitiation of the liquid in the ladle, which is performed by the priest, who will pour it over the king by reciting these verses (from the Atharvaveda): "Waters, behold me with a favourable eye; with a favourable body touch my skin; all fires, for they reside in water, I invoke on your account; do you produce in me beauty, bodily strength, and energy;" and by the king repeating these words after him. If this propitiation did not take place, the liquid would destroy the vigour of the king. After this, the priest covers the head of the king with the udumbara branch, and pours the liquid over him while reciting the following three R'igveda verses: "These waters are most propitious; they have healing power to free from all disease; they are the augmenters of kingly power and its supporters; they are immortal." "With which Prajâpati (the lord of creatures) sprinkled Indra, the king Soma and Manu, with these I sprinkle thee, that thou becomest king of kings in this world." "The queen, thy mother, bore thee to be great amongst the great, and a righteous ruler over men; an auspicious mother bore thee." And this Yajurveda verse: "The divine Savitr'i has given his consent, therefore, I pour (this liquid) over thee with the arms of the As'wins (comm., not with my own), with the hands of Pûshan, with the beauty of Agni, with the radiance of Sûrya, and with the senses of Indra, for the sake of strength, prosperity, glory, and increase of food." After the recital of other verses, by which spirituous liquor and Soma are intended to become identified, the king drinks the liquor, and presents the rest to a friend. He then places the udumbara branch on the ground, and prepares himself for descending from the throne-seat; but while he is still seated, and puts his feet on the ground, he says: "I firmly stand on heaven and earth, I firmly stand on exhaled and inhaled air, I firmly stand on day and night, I firmly stand on food and drink; on what is Brâhman'a, on what is Kshatriya—on these three worlds stand I firmly!" He then descends, sits down on the ground with his face towards the east, utters thrice the words, "adoration to what is Brâhman'a!" and offers a gift (comm., a cow) to a Brâhman'a. The object of this gift is the attainment of victory in every quarter, and over every description of enemies; and his threefold expression of adoration to what is a Brâhman'a, implies that a kingdom prospers and has valiant men when it is under the control of the Brâhman'as, and that a valiant son will be born to him. Then the king rises, puts fuel into the sacrificial fire, and takes three steps to the east, north, and to the north-east, while reciting several verses specified. Upon this he sits down by the domestic fire, and the Adhwaryu priest makes for him, out of a goblet, four times three oblations, with clarified butter, to Indra, while reciting other R'igveda verses. "A king for whom these libations are made to Indra in the indicated manner, becomes free from disease, cannot be injured by enemies, is exempt from poverty, everywhere protected against danger, and thus becomes victorious in all the quarters, and, after death, established in Indra's heaven."

The rites of the Abhisheka ceremony, which are performed at a king's accession to the throne, are founded on the proceedings which are described as having taken place when Indra was consecrated by the gods as their supreme ruler. The latter are, as a matter of course, of an entirely mystical kind. Thus, the eight parts of his throne-seat are said to have consisted of Sâmaveda verses; of the threads of the texture which was to hold this structure together, those that went lengthwise were made of R'igveda-, and those that went crossways of Sâmaveda-, the intervals being Yajurveda-verses; the covering of the throne was the goddess of Glory, the pillow the goddess of Happiness; Savitr'i and Br'ihaspati supported the fore-legs, Vâyu and Pûshan the hind-legs, Mitra and Varun'a the two top-boards, and the two As'wins the two side-boards, of the throne-seat, &c. The inauguration of the mortal king begins with the priest calling upon him to take the following oath:—"If I (the king) do ever harm to thee, thou (the priest) mayst deprive me of all pious acts which I have done from the time of my birth up to that of my death, of heaven, and whatever else good has been accomplished by me, of long life and offspring." He then orders his attendants to bring four kinds of fruits: the fruit of the *Nyagrodha* (*Ficus Indica*), of the *Udumbara* (*Ficus glomerata*), of the *As'wattha* (*Ficus religiosa*), and of the *Plaksha* (*Ficus infectoria*); besides, four kinds of grain: rice with small grain, rice with large grain, *Priyangu*, and barley. Next they bring at his command a throne-seat of udumbara-wood (made in the manner as described before), a ladle of udumbara (or, instead of the latter, a vessel of udumbara), and an udumbara branch. Then they put the various kinds of fruit and grain in the ladle or vessel, and pour over them curds, honey, clarified butter, and water proceeding from rain during sunshine, before it has fallen down; afterwards, having placed the ladle or vessel on the ground, they address the throne-seat with a Mantra, which recalls the component parts of Indra's throne, and thus tends to identify both. Then the priest asks the king to ascend the throne-seat, inviting the Vasus, Rudras, Âdityas, and the other divinities which were invited by Indra at his inauguration to ascend his throne, with the same metres and songs, and for the same purposes. Upon this the relatives of the king proclaim his high qualities in the same words as the gods proclaimed the greatness of Indra; the priest recites a certain R'igveda verse, and, placing himself before the throne with his face towards the west, covers the head of the king with the udumbara branch, the leaves of which have been wetted, and with a gold Pavitra, and sprinkles him with the liquid (in the ladle or vessel) while reciting the three R'igveda verses, and the Yajurveda verse quoted above, and uttering the three sacred words *Bhûr*, *Bhuvar*, *Swar*. Lastly, he addresses the king with the prayer that the Vasus, the Rudras, and the other divinities who performed this ceremony for Indra in the east, south, &c., may severally do the same for him in thirty-one successive days, and to the same effect as they did it for him. Of the ingredients of the sacred liquid, the Nyagrodha, being, on account of its wide spread, the king of the trees, and rice with small grains, being among plants principally productive of strength, the fruit of the former and the grain of the latter are the type of the qualities of a Kshatra; the fruit of the udumbara and the grains of the Priyangu are the type of increase of enjoyment; the fruit of the As'wattha and rice with large grains, the type of righteous government; the fruit of the Plaksha, the type of independent rule and attainment of more distinguished qualities than those possessed by other kings; barley is the type of military commandership; curds, that of sharpness of the senses; honey, that of the essence of plants and trees; and water is the type of freedom from death, or that of long life (because it nourishes). The ceremony having been completed, the king has to make a present to the inaugurating priest, namely, a thousand nishkas of gold, a field, and cattle; but this amount seems merely to constitute a minimum acknowledgement of the exertions of the priest, for the text of the Aitareya-Brâhman'a adds that "they say, a king should give innumerable, illimited presents, since a king is illimited (in wealth), and thus will obtain illimited benefit to himself;" and it adds, too, several instances in which kings bestowed unbounded wealth on the officiating priests. After the priest has received the gift, he hands to the king a goblet of spirituous liquor in reciting an appropriate R'igveda hymn, which has the power of transforming the qualities of the liquor drunk by the king into those of the juice of the Soma-plant. Lastly, the king recites some other verses specified. (For a fuller account of this ceremony, compare Goldstücker's 'Sanskrit Dictionary,' s.v. 'Abhisheka.')

As an illustration of those passages of the Aitareya-Brâhman'a, which partake more of an incantatory nature, we may quote the description of a rite which occurs in its last chapter, and relates to rites to be performed, under the direction of a proper Purohita or chaplain, for the destruction of the king's enemies. "Foes, enemies, and rivals," we read there, "perish around him who is conversant with these rites. That which (moves) in the atmosphere is air (Brahman), around which perish five deities—lightning, rain, the moon, the sun, and fire. Lightning having flashed, disappears behind rain: it vanishes, and none knows (whither it is gone). When a man dies, he vanishes; and none knows (whither his soul is gone). Therefore, whenever lightning flashes, pronounce this prayer: 'May my enemy perish: may he disappear, and none know (where he is).' Soon, indeed, none will know (whither he is gone). Rain having fallen (evaporates and), disappears within the moon, &c. When rain ceases, pronounce this (prayer), &c. The moon at the conjunction, disappears within the sun, &c. When the moon is dark, pronounce, &c. The sun when setting, disappears in fire, &c. When the sun sets, pronounce, &c. Fire, ascending, disappears in air, &c. When fire is extinguished, pronounce, &c. These same deities are again produced from this very origin. Fire is born of air; for, urged with force by the breath, it increases. Viewing it, pronounce (this prayer), 'May fire be revived: but not my foe be reproduced; may he depart averted.' Therefore, does the enemy go far away. The sun is born of fire. Viewing it, say, 'May the sun rise, but not my foe be reproduced,' &c. . . . . . The observance (enjoined) to him (who undertakes these rites, is as follows): let him not sit down earlier than the foe; but stand while he thinks him standing. Let him not lie down earlier than the foe; but sit while he thinks him sitting. Let him not sleep earlier than the foe, but wake while he thinks him waking. Though his enemy had a head of stone, soon does he slay him: he does slay him." (Colebrooke, 'Misc. Ess.,' i. p. 45.)

The legends narrated in this, as well as in other Brâhman'as, intend always, as indicated before, to explain the origin of a rite, or to illustrate its efficacy. Among those met with in the Aitareya-Brâhman'a, we may point particularly to one, as it is remarkable in several respects. It had to be recited by the Hotr'i, sitting on a gold-embroidered carpet, to a king whose inauguration had been completed; and another priest, sitting on a similar carpet, had to repeat the words of the Hotr'i. But a victorious king is likewise recommended to have this legend recited to him, though he may not have performed the sacrifice; and a man desirous of progeny is promised the birth of a son if it is properly read to him. We mean the legend of *S'unah's'epa*. Its substance is as follows:—

Once upon a time there lived Haris'chandra, a son of Vedhas, and a descendant of Ikshwâku. Though he had a hundred wives, he did not obtain a son from them. His desire, however, of having one became still stronger than it was, when Parvata and Nârada visited him, and when Nârada explained to him the boons a man derives from being blessed with the birth of a son. Following the advice of Nârada, Haris'chandra addressed himself, therefore, to Varun'a, and promised the god to sacrifice him his son, if he granted him one. Varun'a assented to the offer. Now a son, who received the name of Rohita, being born to Haris'chandra, Varun'a presented himself, and claimed the fulfilment of the compact. But Haris'chandra said: "Cattle is fit for a sacrifice when it is ten days old; let him then become ten days old and I shall sacrifice him to thee." Varun'a assented; but the ten days having passed away, Haris'chandra again said: "Cattle is fit for a sacrifice when it has got teeth; let him then get teeth, and I shall sacrifice him to thee." Once more Varun'a assented; but when Rohita had got his teeth, his father said to Varun'a: "Cattle is fit for a sacrifice when it loses again his teeth; let him then lose his teeth, and I shall sacrifice him to thee." Again Varun'a assented; but Rohita having lost his teeth, his father said to Varun'a: "Cattle is fit for a sacrifice when it recovers its teeth; let him then recover his teeth, and I shall sacrifice him to thee." Varun'a assented; but Rohita having recovered his teeth, his father said to Varun'a: "A warrior is fit for a sacrifice when he is able to use his weapon; let him then learn to use his weapon, and I shall sacrifice him to thee." Again Varun'a assented; and when Rohita knew how to use his weapon, his father said to him: "Varun'a, my son, has given thee to me, and I shall sacrifice thee to him." But Rohita refused, took his bow and went to the forest, where he wandered about during a whole year. Varun'a, however, now seized Haris'chandra, and made him swell. On hearing this, Rohita went about and met Indra, who encouraged him to wander first for another, then a third, a fourth, a fifth, and a sixth year.

At the end of this period he saw in the forest a R'ishi of the name of Ajîgarta, the son of Suyavasa, who lived there in great poverty with his three sons, *S'unaspuchchha*, *S'unah's'epa*, and *S'unolângula*. Rohita offered him a hundred cows if he gave up one of his sons to be sacrificed instead of him to Varun'a. Ajîgarta accepted the offer, but retained his oldest son; and his wife claiming the youngest, both agreed to give up S'unah's'epa. Rohita then took him to his father, Haris'chandra, and Varun'a also having confirmed the barter, since, he thought, a Brâhman'a is of greater value than a Kshatriya, Haris'chandra in celebrating the rite of the Râjasûya substituted S'unah's'epa for the victim to be immolated at this sacrifice. The Hotr'i priest who officiated at it was Vis'wâmitra, Jamadagni fulfilled the functions of the Adhwaryu, Vasisht'ha those of the Brahman, and Ayâsya those of the Udgatr'i. Yet the preliminary rites having being fulfilled, no one could be found who would tie S'unah's'epa to the sacrificial post. Upon which Ajîgarta offered to do this if they gave him another hundred of cows. They did so; but though S'unah's'epa now was tied to the post, no one would immolate him. Again Ajîgarta came forward and promised to immolate his son if they would give him a third hundred of cows. They did so, and Ajîgarta sharpened his knife and approached his son. Now S'unah's'epa resolved to implore the gods to release him. He addressed himself first to Prajâpati with an appropriate R'igveda hymn, but the god told him to pray to Agni. Agni, invoked with another hymn, told him to pray to Savitr'i; and Savitr'i told him to address Varun'a; but Varun'a sent him once more to Agni, who now recommended him to praise all the gods with an appropriate hymn. S'unah's'epa obeyed; his ties were released, and Haris'chandra was restored to health. S'unah's'epa, on his part, now instituted a new sacrifice. But when he placed himself at the side of Vis'wâmitra, and Ajîgarta claimed him back, Vis'wâmitra replied: "No, the gods (*devâs*) have given him (*arâsata*) to me;" and from that time (he was no longer S'unah's'epa, that is, Dogstail), but Devarâta (Θεόδοτος), the son of Vis'wâmitra. (For a literal and excellent translation of this legend by Professor Roth, see Weber's 'Indische Studien,' i. p. 458, ff.; and for some additional remarks, *ibid.*, ii. p. 112, ff.)

After these instances, which will convey an idea of the contents of the Brâhman'a in general, we must content ourselves with giving the names of the other *principal* works of this category. For, the difference which exists between them, however great, would be intelligible only if we could enter into the detail of the Vaidik rites, and into the growth of the legendary life which pervades this portion of the ancient literature of India.

Suffice it therefore to state that the Brâhman'a literature has found its greatest development in the train of that Veda which, as we might expect, would require more than any other Veda an explanation of the purposes for which it was formed—the Yajurveda. On the other hand, since the Sanhitâ of the Black Yajurveda is already a combination, as we have seen, of hymns and Brâhman'a, it is intelligible that we find in connection with the White Yajurveda that Brâhman'a which, though probably the most recent, still is the most systematic and the most complete of all the Brâhman'a. It is called the *S'atapatha-Brâhman'a*, and is ascribed, like the Sanhitâ of the White Yajurveda, to Yâjnavalkya. It is, like the Sanhitâ, preserved in the edition of the *Mâdhyandina* and in that of the *Kânwa* school. The former is divided into fourteen *Kân'd'a* or books, which contain one hundred *Adhyâya* or lectures; or into sixty-eight *Prapât'hakâ* (sections) with four hundred and thirty-eight *Brâhman'a*, and seven thousand six hundred and twenty-four *Kan'd'ikâ* (portions). In the *Kânwa* edition it comprises seventeen *Kân'd'a*, with a hundred and four *Adhyâya*, four hundred and forty-six *Brâhman'a*, and five thousand eight hundred and sixty-six *Kan'd'ikâ*. The first nine Kân'd'a of this Brâhman'a follow the first eighteen books of the Sanhitâ almost step for step, in quoting their verses and explaining their application at the sacrifices. The last five Kân'd'as, however, refer only partially—some even not at all—to the contents of the Sanhitâ, and may therefore be a later increase of this extensive Brâhman'a, which is extremely rich in antiquarian and mythological contents; but, on account of its purely ritual character, cannot be understood without the complete and excellent commentary of Sâyan'a.

The Brâhman'a of the Black Yajurveda is preserved in the school of the Taittirîyas, and bears the name of the Taittirîya-Brâhman'a, differing but little in character from its Sanhitâ.

As regards the Sâmaveda, Sâyan'a enumerates eight Brâhman'as connected with it, namely, the *Praud'ha* (also called *Tân'd'ya-* or *Pancha-vins'a*), the *Shad'vins'a*, the *Sâmavidhi*, *Ârsheya-Brâhman'a*, the *Devatâdhyâya-Brâhman'a*, and the *Upanishad*, which, according to Professor Müller ('Anc. Sansk. Lit.' p. 349) is probably the *Chhândogya-Upanishad*. The first two are the most important of these works, the Panchavins'a treating of the sacrifices which are performed with the juice of the Soma-plant, in rites which last from one to one hundred days. The *Sha'dvins'a* is remarkable on account of the incantatory ceremonies it describes; it ends with a chapter on omens and the rites to be performed on unlucky occasions, such as diseases, or at portentous occurrences, such as earthquakes, unusual phenomena, and the like.

The Brâhman'a of the Atharvaveda is the *Gopatha-Brâhman'a*. "That it was composed after the schism of the Charakas and Vâjasaneyins (the followers of the Black and White Yajurveda), and after the completion of the Vâjasaneyi-Sanhitâ, may be gathered from the fact that where the first lines of the other Vedas are quoted in the Gopatha, the first line of the Yajurveda is taken from the Vâjasaneyins, and not from the Taittirîyas. It is more explicit on the chapter of accidents than the Brâhman'as of the other Vedas . . . . The ceremonial in general is discussed in it in the same manner as in the other Brâhman'as." (Müller, 'Anc. Sansk. Lit.,' pp. 451, 452.)

The Sanhitâ or collection of Mantra, and the Brâhman'a, constitute that which is properly called the sacred literature of the Hindus, *the Veda;* they are also comprised under the name of *S'ruti* or revelation. But in speaking of the Veda we should not feel justified in leaving unnoticed that class of works, one portion of which is so intimately connected with it that it was held by later generations in the same awe as the Veda, whereas another portion has become so essential an appendage to it, that it was justly called Vedânga or "limb of the Veda."

The former category comprises the theological or theosophical writings, which have sprung from the Brâhman'a, and are perhaps more popular among European students than any other portion of the Vaidik literature—the *Upanishads*. The word *Upanishad* is rendered by the native dictionaries "mystery." *S'ankara*, the great Vedânta philosopher and glossator of the Upanishads, assumes that the word being derived from the radical *sad*,—with the prefixes *upa* and *ni*,—which amongst others has also the sense of "destroying," literally means the science which distroys erroneous ideas or ignorance. European scholars, on the contrary, have expressed the belief that it "means originally the art of sitting down near a teacher, of submissively listening to him" (from *upa* "below," *ni* "down," and *sad* "to sit" (for instance, Müller, 'Anc. Sansk. Lit.,' p. 319). But there is a strong probability that the word has been already used by a Hindu grammarian, who preceded the existence of the Upanishad works, in the sense of "secret" (Goldstücker, 'Pân'ini,' p. 141, note 164); and since this meaning is not incompatible with the etymology of the word—which may signify "entering into that which is hidden"—it seems certain that at no period the Upanishads were looked upon as mere lessons imparted to their pupils by old divines, but as the mysterious science which, through bestowing real knowledge on the human mind, leads to the attainment of eternal bliss.

For such is the object of all the Upanishads; and the knowledge they intend to convey is chiefly that of the production and nature of the world, of the properties of a Supreme Divinity, and of those of the human soul, which they conceive to be part of it. The same object is pursued, and the same views of the nature of the divine and the human soul as in the Upanishads are entertained by the Vedânta philosophy. We perceive therefore at once the close connection which exists between the Upanishads and this orthodox system of Hindu philosophy. Their difference, indeed, is merely that which separates the beginning from the end of a certain kind of philosophical reasoning. In the Vedânta the Hindu mind possesses a system which endeavours to deduct and to connect its ideas on the creation of the world, on the identity of the absolute and individual soul. Its method would not stand the test of *our* philosophical reasoning; but its explanations evidently aim at scientific precision and shortness of expression; and they are generally free from mythological mysticism. In the Upanishads, on the contrary, there is merely the material for a system of philosophy. The subject treated of by them is frequently dealt with in a desultory manner; it is intercepted by legends and allegories; it is adapted to the form of dialogues; it abounds in repetitions and verbose phraseology. But all these negative features of the Upanishads must be viewed in the mirror of the Hindu mind; and then we easily comprehend that, accessible to the popular understanding of the educated, they became the basis of that more enlightened belief which at all periods of Indian history has struggled against the idolatry and the gross practices produced by a misconception of the sacred texts, and doubtless also by the interested motives of a degenerated class of priests.

Within the circle of the Upanishad literature several periods are clearly distinguishable, though Sanskrit philology possesses no means of rendering them into intelligible dates. The first is that of the *Âran'yaka*. As the name indicates, and as it is explained by *Kâtyâyana* in one of his criticisms on the great grammarian *Pân'ini*, this class of Upanishads was studied in the solitude of the forests, apparently because it was thought necessary that the mind should divest itself from all contact with the world when meditating on the mysteries of life. These *Âran'yaka* are more immediately connected with the Brâhman'a than the Upanishads properly so called. The Br'ihad-Âran'yaka, for instance, is a part itself of the S'athapatha-Brâhman'a of the White Yajurveda; the Aitareya-Âran'yaka is added to the Aitareya-Brâhman'a, and the Chhândogya-Upanishad, as we have seen, though not bearing the name of an Âranyaka, is counted amongst the Brâhman'a of the Sâmaveda. These works combine their speculations with a considerable amount of legendary detail, in the same way as the Brâhman'a themselves; and they are held in especial respect on account of the obscure allusions in which they abound. A second class is much less burdened with mythological and allegorical detail; it is brief, and addresses itself more to the philosophical mind; it comprises the greater mass of the Upanishad literature, and is apparently more recent than the Âran'yaka. A third and last category is marked by the tendency it has to reconcile the doctrines of later sects with Vaidik theology; Upanishads belonging to it identify the universal Spirit with one or the other form of the gods of the Trimûrti, as it appears in sectarian belief. This latter description of Upanishads is chiefly connected with the Atharvaveda. We choose as an instance of the Âran'yaka class the following passages from the Aitareya-Âranya:—"This (world) verily was before (the creation of the world) soul alone, and nothing else whatsoever active (or non-active). He reflected: 'Let me create the worlds.' He created these worlds, namely, the sphere of water, the sphere of the sun-beams, the sphere of death, and the sphere of the waters. The sphere of water lies above the heavens, the heavens are its resting place; the sphere of the sunbeams is the atmosphere; the earth the world of death; the worlds which are beneath it, are the sphere of the waters. He reflected: These worlds indeed are created. Let me create the protectors of the world. Taking out from the waters a being of human shape, he formed him. He heated him (by the heat of his meditation). When he was thus heated, the mouth burst out as the egg (of a bird),—from the mouth speech,—from speech fire. The nostrils burst out,—from the nostrils breath,—from breath the wind. The eyes burst out,—from the eyes sight,—from the sight the sun. The ears burst out,—from the ears hearing,—from hearing the regions of space, &c. . . . . . He reflected: Those worlds and protectors of the worlds (have been created). Let me now create food for them. He heated the waters (with the heat of his reflection). From them when heated, a being of organised form sprung forth; the form which sprung forth is verily food. When created it cried (by fear), and tried to flee. He (the first-born male) desired to seize it by speech. Had he seized it by speech (all) would be satisfied by pronouncing food. He desired to seize it by breath; he could not seize it by breathing. Had he taken it by breathing (all) would be satisfied by smelling food, &c. . . . . Of what nature is the *soul* which we worship by the words 'this soul,' and which of the two (the universal and individual) is the soul? (Are the instruments by which objects are perceived the soul, or the perceiver? No, not the instruments). Is it that by which the soul sees form, by which it hears sound, by which it apprehends smells, by which it expresses speech, by which it distinguishes what is of good, and what is not of good taste? The heart and the mind, knowledge about one's self, knowledge about one's power, the knowledge of the sixty-four sciences, the knowledge of what is practicable at this or another time, understanding of instruction, perception, endurance of pain, thinking, independence of mind, sensibility, recollection, determination, perseverance, desire, submission—all these are names of knowledge (as an attribute of the soul in its modification as life, of the inferior Brahman, not attributes of the supreme Brahman, which is of no form whatsoever). This soul is Brahman (the inferior Brahman), this Indra, this Prajâpati, this all gods and the five great elements and the light . . . . All this is brought to existence by knowledge, is founded on knowledge; the world is brought into existence by knowledge; knowledge itself is the foundation; Brahman is knowledge." (Rover's 'Translation of the Upan. Bibl. Ind.,' vol. xv. p. 28, ff.)

In the Br'ihad-Âran'yaka it is told that Janaka, the king of the Videhas, performed a sacrifice at which many Brahmans were assembled. The king having a great desire to know who among those Brahmans knew best the Vedas, tied a thousand cows in a stable, and covered the horns of each of them with ten pâda of gold. He then said to the pious men: "O venerable Brahmans, whoever amongst you is the best knower of Brahman shall drive home these cows." The Brahmans, however, did not venture to come forward. Then said Yâjnavalkya to his student: "Drive home those cows." But the Brahmans became angry, and began to examine the sage as to his knowledge of the Veda. "Then asked him Uddâlaka, the son of Arun'a," the legend continues, —"'Yâjnavalkya,' said he, 'in the country of the Madras we abode in the house of Pantchala, of the family of Kapi, for the sake of studying the science of offering. His wife was possessed by a Gandharva. We asked him (the Gandharva), 'Who art thou?' He said, 'Kabandha, the son of Atharvan'a.' He said to Patanchala, of the family of Kapi, and to (us) priests, 'O Kâpya, knowest thou that Thread by which this world, and the other world, and all beings are bound together?' Patanchala, of the family of Kapi, said, 'I do not know it, O Venerable.' He said to Pantanchala, and to (us) priests,—'Knowest thou, O Kâpya, that Inner Ruler who within rules this world, and the other world, and all beings?' Patanchala said,—'I do not know this, O Venerable.' He said to Patanchala, and to (us) priests,—'O Kâpya, whoever knows the Thread and the Inner Ruler, knows Brahman, knows the worlds, knows the gods, knows the Vedas, knows the elements, knows the soul,—knows all.' Then (the Gandharva) said (all about the Thread and the Inner Ruler) to them. 'Therefore do I know this. If thou, O Yâjnavalkya, ignorant of the Thread and the Inner Ruler, hast taken away the cows (destined for the best knower of Brahman), thy head will certainly drop down.' 'I know verily, Gautama, the Thread and the Inner Ruler.' 'Any one may say this, I know, I know, but tell the manner in which thou knowest.' He said,— 'The wind, O Gautama, is the Thread; by the wind, as by a thread, are this world, the other world, all beings bound together, O Gautama. Therefore, O Gautama, it is said of a dead man, that his members are relaxed; for by the wind, O Gautama, as by a thread, they are bound together.' 'This is so, O Yâjnavalkya; now explain the Inner Ruler.' 'He who dwelling in the earth is within the earth, whom the earth does not know, whose body is the earth, who within rules the earth, is thy soul,—the Inner Ruler—immortal. He who dwelling in the waters is within the waters, whom the waters do not know, whose body are the waters, who within rules the waters, is thy soul,—the Inner Ruler—immortal. He who dwelling in the fire is within the fire, &c. . . . . he who dwelling in the atmosphere, &c. . . . . he who dwelling in the wind, &c. . . . . in the heavens, &c. . . . . in the sun, &c. . . . . in the regions of space, &c. . . . . in the moon and stars, &c. . . . . in the ether, &c. . . . . in the darkness, &c. . . . . in the light, &c. . . . . in all elements, &c. . . . . in the vital air, &c. . . . . in speech, &c. . . . . in the eye, &c. . . . . in the ear, &c. . . . . in the mind, &c. . . . . in the skin, &c. . . . . in knowledge, &c. . . . .; he who dwelling in the seed is within the seed, whom the seed does not know, whose body is the seed, who from within rules the seed, is thy soul—the Inner Ruler—immortal. Unseen, he sees; unheard, he hears; unminded, he minds; unknown, he knows. There is none that sees, but he; there is none that hears, but he; there is none that minds, but he; there is none that knows, but he. He is thy soul— the Inner Ruler—immortal. Whatever is different from him is perishable.'" (Ib., vol. ii. part iii., p. 199, ff.)

An Upanishad of the second class is, for instance, the I's'a-Upanishad, which derives an additional interest from the circumstance that it is the only Upanishad which forms part of a Sanhitâ itself, namely, of that of the White Yajurveda, and thus strengthens the proofs which may be alleged for the later recension of this Veda. It runs as follows: "Whatever exists in this world is to be enveloped by (the thought of) God (the Ruler). By renouncing the world, thou shalt save (thy soul). Do not covet the riches of any one. Performing sacred works, let a man desire to live a hundred years. If thou thus (desirest), O man, there is no other manner in which thou art not tainted by work. To the godless worlds, covered with gloomy darkness, go all the people, when departing (from this world), who are slayers of their souls. He (the soul) does not move, is swifter than the mind, not the gods (the senses) did obtain him, he was gone before. Standing, he outstrips all the other (gods, senses), how fast they run. Within him the ruler of the atmosphere upholds the vital actions. He moves, he does not move; he is far and also near; he is within this all, he is out of this all. Whoever beholds all beings in the soul alone, and the soul in all beings, does hence not look down (on any creature). When a man knows that all beings are even the soul, when he beholds the unity (of the soul), then there is no delusion, no grief. He is all-pervading, brilliant, without body, invulnerable, without muscles, pure, untainted by sin, he is allwise, the Ruler of the mind, above all beings, and self-existent. He distributed according to their nature the things for everlasting years. Those who worship ignorance, enter into gloomy darkness, into still greater darkness those who are devoted to knowledge. They say, different is the effect of knowledge, different the effect of ignorance; thus we heard from the sages who explained (both) to us. Whoever knows both, knowledge and ignorance together, overcomes death by ignorance, and enjoys immortality by knowledge. Those who worship uncreated nature, enter into gloomy darkness, into still greater darkness those who are devoted to created nature. They say, different is the effect from (worshipping) uncreated nature, different from (worshipping) created nature. This we heard from the sages who explained (both) to us. Whoever knows both, created nature and destruction together, overcomes death by destruction, and enjoys immortality by created nature. To me whose duty is truth, open, O Pûshan, the entrance to the truth concealed by the brilliant disk, in order to behold (thee). O Pûshan, R'ishi thou alone, O dispenser of justice (Yama), O Sun, offspring of Prajâpati, disperse thy rays (and) collect thy light; let me see thy most auspicious form; for the same soul which is in thee, am I. Let my vital spark obtain the immortal air; then let this body be consumed to ashes. *Om.* O my mind, remember, remember (thy) acts, O mind, remember, remember thy acts. Guide us, O Agni, by the road of bliss to enjoyment; (guide us), O God, who knowest all acts. Destroy our crooked sin, that we offer thee our best salutation." (Ib., vol. xv. p. 71.)

The principal Âran'yaka and Upanishads connected with each of the four Vedas are the following: to the R'igveda belong, the Aitareya-Âran'yaka and the Kaushîtaka-Âranyaka, the third book of which is the Kaushîtaky-Upanishad. The Upanishads of the Sâmaveda are the Chhândogya- and the Kena-Upanishad. To the Black Yajurveda belongs the Taittirîya-Âran'yaka, the four last books of which contain two Upanishads, namely, the Taittirîya- and the Nârâyan'îya-Upanishad; besides the Swetâs'watara-, Maitrâyan'a-, and Kât'haka-Upanishad. That the Br'ihad-Âran'yaka is attached to the Brâhman'a of the White Yajurveda, has been stated already.

The largest number of Upanishads, however, has grown up in connection with the Atharvaveda, which seems to have favoured more than the sacrificial Vedas the tendency for mystical reasoning. Among them we name especially the Mun'd'aka-, Pras'na-, Brâhma-, and Mân'd'ûkya-Upanishad, as treating of the nature of the divine and human soul. The Jâbalâ-, Sannyâsa-, As'rama-, and Hansa-Upanishad are some of those which describe the means by which deep meditation or the abstract union with the Supreme Soul can be obtained. A third class, as mentioned above, has a sectarian character, by identifying the Supreme Soul with Vishn'u or S'iva in their various forms; among those referring to Vishn'u we notice the Nârâyan'a-, and the Nr'isinha-tapanîya-Upanishad; among those connected with the worship of S'iva we find the S'atarudriya-, Kaivalya-, Skanda-Upanishad, and one called Atharvas'iras. (For a fuller account of this class of works, see Professor Weber's 'Akademische Vorlesungen über Indische Literaturgeschichte,' and his 'Indische Studien.')

While the Upanishads are the intermediate link between the Vedas and the later systems of Hindu philosophy, the *Vedângas* show us how scientific research grew up in India from the soil of the sacred texts. If we consider the bulk of literature which is comprised by the Sanhitâs and Brâhman'as, and the anxious desire which every Brahmanic believer must have felt to preserve it in its integrity, it is easily understood that in the course of time various means were devised for securing the correctness of the sacred texts, for guarding their sense against erroneous interpretations, and for maintaining in its purity a proper practice of the rites which were taught in the Brâhman'a. This is the object of the Vedânga works. The Brâhman'a of the Sâmaveda speak of six Vedânga or "limbs of the Veda," in other words, of six works or classes of works which were instrumental in maintaining the integrity of the Veda. But it is not certain whether this Brâhman'a means the same six Vedângas which have come down to us; Yâska, again, alludes to Vedângas, but does not state that they were six. We must distinguish therefore between categories of works which were called Vedângas, and between certain works which are the surviving representatives of these categories, but need not have been the first Vedânga works.

The doctrines comprised under this name are the following:—*S'ikshâ*, *Chhandas*, *Vyâkaran'a*, *Nirukta*, *Jyotisha*, and *Kalpa*.

S'ikshâ is the science of a proper pronunciation. One little treatise only is considered as representing this Vedânga,—the S'ikshâ ascribed to the authorship of the great grammarian Pân'ini. It consists in one recension of thirty-five, in another of fifty-nine verses, and treats of the nature of the letters, of the accents, and the proper mode of sounding them. A chapter of the Taittirîya-Âran'yaka treats likewise of S'ikshâ; but though it is possible that Pân'ini's S'ikshâ may not be the original Vedânga of this class, it is more than doubtful that this chapter of the Âran'yaka was ever considered as such.

Chhandas means "metre;" and the Vedânga which is quoted by this name is referred to the authorship of Pingalanâga. But as the work of the latter treats of Prakrit as well as of Sanskrit metres, it becomes doubtful again whether we possess in it an original Vedânga work.

Vyâkaran'a signifies "grammar," but literally means "undoing," that is, analysis; for to the Hindu scholar grammar is linguistic analysis; his grammar *un-does* words and *un-does* sentences; it examines the component parts of a word, and therefore teaches the properties of a base and affix, and all the linguistic phenomena connected with both; it examines the relation, in sentences, of one word to another, and likewise unfolds all the linguistic phenomena which are inseparable from the meeting of words. The most renowned representative of this science is *Pân'ini*, who wrote a work in eight chapters, comprising thirty-two sections and three thousand nine hundred and ninety-six rules, three or four of which, however, probably did not belong to him. And so great was the renown of this wonderful labour, which may be placed at the side of the best grammatical works of any nation and any age, that Pân'ini was looked upon as a R'ishi who had received it, by inspiration, from the god S'iva himself. Pân'ini, it is true, quotes in his work various grammarians who preceded him, but Vyâkaran'a is typified by the grammar of Pân'ini, which has remained, up to this day, the standard for Sanskrit speech. We may add, that his work was criticised and amplified by Kâtyâyana, who in his turn was criticised by Patanjali, a grammarian who lived in the middle of the second century before Christ; and that these three grammarians are considered to be the greatest authorities in the science they taught. But Pân'ini only can be held to be the representative of the Vedânga we are speaking of. Nor should the Vyâkaran'a be confounded with a class of works which apparently stands in a closer relation than itself to the Veda-Sanhitâs—with the Prâtis'âkhya works; for though the latter are concerned in Vaidik language alone, whereas Pân'ini's work is even more engaged in teaching the classical than the Vaidik dialect, their aim and their contents materially differ from those of the Vyâkaran'a. Their object is merely the ready-made word, or base, in the condition in which it is fit to enter into a sentence or into composition with another base. They are nowise concerned in analysing or explaining the nature of a word or base; they take them such as they are, and teach the changes which they undergo when they become part of a spoken hymn. Whether there existed at one period other Prâtis'âkhyas than those which have survived, it is not easy to say in the present condition of Sanskrit philology; but it has been proved that the present Prâtis'âkhyas are even more recent than Pân'ini's work. (Goldstücker, 'Pân'ini,' p. 183, ff.)

Nirukta, or "explanation," is represented by the *Nirukta* of *Yâska*, which is the oldest attempt, known to us, of an explanation of obscure passages of the Vaidik Sanhitâs. "It is important, however," says Professor Müller ('Anc. Sansk. Lit.,' p. 154), "not to confound Yâska's Nirukta with Yâska's Commentary on the Nirukta, although it has become usual, after the fashion of modern manuscripts, to call that commentary Nirukta, and to distinguish the text of the Nirukta by the name of Nighan't'u. The original Niruktas that formed an integral part of the Vedânga literature, known to Yâska himself, can have consisted only of lists of words arranged according to their meaning, like that upon which Yâska's Commentary is based. . . . . Sâyana gives the following account of this matter:—'Nirukta is a work where a number of words is given, without any intention to connect them in a sentence. . . . . The first part (of the Nirukta) is the *Naighant'uka*, the second the *Naigama*, and the third the *Daivata*. . . . . The word *Nighantu* applies to works where, for the most part, synonymous words are taught. Therefore, the first part of this work also has been called Naighant'uka, because synonymous words are taught there. In this part there are three lectures: in the first, we have words connected with things of time and space in this and the other worlds; in the second, we have words connected with men and human affairs; and in the third, words expressing qualities of the preceding objects, such as thinness, multitude, shortness, &c. *Nigama* means Veda. As Yâska has quoted many passages from the Veda, which he usually introduces by the words, "For this there is also a Nigama;" and as in the second part, consisting of the fourth Adhyâya, words are taught which usually occur in the Veda only, this part is called Naigama. Why the third part, consisting of the fifth Adhyâya, is called *Daivata*, is clear. The whole work, consisting of five Adhyâyas and three parts, is called

Nirukta, because the meaning of words is given there irrespective of anything else. A commentary on this has been composed by Yâska, in twenty Adhyâyas. This also is called Nirukta, because the real meaning conveyed by each word is fully given therein.' "

The fifth Vedânga is called *Jyotisha*, or "astronomy." Its object was to teach how to fix the proper time for the performance of sacrificial acts. It is a Vaidik calendar. There is but one manuscript work, in the library of the India Office, which would seem to belong to this category, but it is difficult to say whether it may aspire to the proud name of a Vedânga work.

The sixth Vedânga, on the contrary, the *Kalpa*, is represented by a great number of works, several of which are preserved in manuscripts in our libraries. *Kalpa* means "ceremonial," and the works of this class are the code of the Brahmanic rites. It was stated before that the Brâhman'a portion of the Veda contains explanations of the purposes for which the verses of the Sanhitâs were used, in consequence that it conveys a knowledge of the Vaidik rites. This knowledge, however, which apparently sufficed for the period at which these works were composed, must have been deemed insufficient at later ages, which required a more copious detail for a proper performance of the rites. Moreover, the Brâhman'a, as a first attempt, are wanting in proper arrangement of the matter they contain, and abound in legendary narratives, which interrupt their comment on the sacrificial acts. The Kalpa-Sûtras remedy this practical defect; they contain a complete system of the Vaidik rites according to the Veda to which they belong. Of such Kalpa-Sûtras, those connected with the ceremonial of the R'igveda are, the Sûtras of S'ânkhâyana, Âs'walâyana, and S'aunaka. Kalpa-Sûtras explaining the rites of the Sâmaveda are those of Mas'aka, Lât'yâyana, Gobhila, Drâhyâyan'a, and a Sûtra called Anupadasûtra, which explains the ceremonial taught in the Panchavins'a-Brâhman'a. Kalpa-Sûtras of the Black Yajurveda are the Âpastamba, Baudhâyana, Satyâshâdha-Hiranyakes'in, Mânava, Bhâradwâja, &c.; of the White Yajurveda, that of Kâtyâyana; of the Atharvaveda, that of Kus'ika.

Two other classes of Sûtras gradually completed the code of these Kalpa works, which, in being founded on S'ruti or the Veda, bear also the name of *S'rauta-Sûtra*, namely, the *Gr'ihya-* and the *Sâmayâchârika-Sûtras*. The Gr'ihya-Sûtra describe the domestic ceremonies, as distinct from the great sacrificial acts enjoined by the S'rauta or Kalpa works: "First, the marriage ceremonies; then the ceremonies which are performed at the conception of a child, at various periods before his birth, at the time of his birth, the ceremony of naming the child, of carrying him out to see the sun, of feeding him, of cutting his hair, and, lastly, of investing him as a student and sending him to a Guru, under whose care he is to study the sacred writings. . . . . It is only after he has served his apprenticeship and grown up to manhood that he is allowed to marry, to light the sacrificial fire for himself, to choose his priests, and to perform year after year the solemn sacrifices prescribed by Smr'iti and S'ruti. The latter are described in the later books of the Gr'ihya-Sûtras; and the last book contains a full account of the funeral ceremonies and of the sacrifices offered to the spirits of the departed." (Müller, 'Anc. Sansk. Lit.,' p. 204.)

The Sâmayâchârika-Sûtras regulate the relations of every-day life. "It is chiefly in them that we have to look to the originals of the metrical law-books, such as Manu, Yâjnavalkya, and the rest." (Ibid., p. 200.) Both these Sûtras are comprised under the name of *Smârta-Sûtra* (from *Smr'iti*, "tradition"), as they are based on it. Of the Gr'ihya-Sûtras of the R'igveda, we possess those of S'ânkhâyana and Âs'walâyana; a Gr'ihya-Sûtra of the Sâmaveda is that of Gobhila; the Yajurveda in both its recensions seems to have had many Sûtras of this kind. Of the Black Yajurveda, we name especially the Baudhâyana; and of the White Yajurveda, the Pâraskara Gr'ihya-Sûtra.

We conclude these outlines of the principal works of the Vaidik literature with mentioning another class of compositions which arose from the desire of securing the integrity of the Vaidik texts, as well as the traditional and exegetic material connected with them,—the *Anukraman'î*, or Indices to various portions of this literature. The completest of this kind is that by Kâtyâyana, to the R'igveda-Sanhitâ. It gives the first words of each hymn, the number of verses, the name and family of the poets, the names of the deities, and the metres of every verse. Its name is *Sarvânukraman'î*,—that is, "the index of all things;" and it seems to have improved on four similar writings which preceded it and are ascribed to S'aunaka. For the Yajurveda there are mentioned three Anukraman'î, for the Samâveda two, and there is one for the Atharvaveda. (Müller, 'Anc. Sansk. Lit.,' p. 215, ff.)

It would be but natural to ask, what date could be assigned to all or any of the various works which have been named in the course of this brief sketch of Vaidik literature; but Sanskrit philology is as yet not able to answer this question satisfactorily. It may offer conjectural dates according to the impressions of the individual mind, but it is bound to avow that past research has not provided it with facts which would impart to its chronological surmises any degree of plausibility.

VEDANTA. [Sanskrit Language and Literature, col. 269.]

VEDUR. [Veadar.]

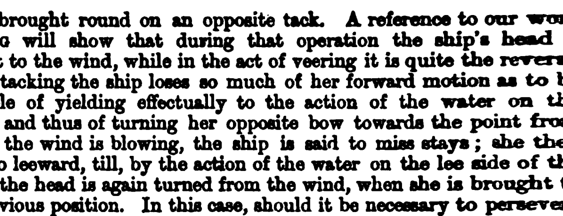
VEERING, or WEARING (from the French, *virer*), is that movement of a ship in which, supposing her to have been previously sailing with the wind on either bow, she is brought, by her head being turned to leeward, into such position that the wind is on the *other* bow, and she is brought round on an opposite tack. A reference to our word Tacking will show that during that operation the ship's head is brought to the wind, while in the act of veering it is quite the reverse.

If in tacking the ship loses so much of her forward motion as to be incapable of yielding effectually to the action of the water on the rudder, and thus of turning her opposite bow towards the point from whence the wind is blowing, the ship is said to miss stays; she then drifts to leeward, till, by the action of the water on the lee side of the rudder the head is again turned from the wind, when she is brought to her previous position. In this case, should it be necessary to persevere in endeavouring to change the course, and should the ship be not too near a point of danger, the proposed end may be gained by veering, and the evolution is thus effected:—When, in drifting to leeward, the ship begins to fall off, or to turn her head from the wind, the helm is placed hard a-weather, and the after-sails are hauled up so that the wind may act upon the head-sails only, and that the ship may be brought before the wind; when, the velocity of rotation continuing, the ship's head begins to turn towards the wind, which will then be on the opposite bow. The helm being now turned to leeward, and the after-sails set, the ship comes rapidly into the required position.

This evolution is frequently the only one which can be performed in stormy weather when little sail can be carried, and also when sailing with a light breeze; since, in either of these cases, the ship may not have sufficient velocity to allow of being put about by tacking: the disadvantage of veering is that, during the evolution, the ship is sometimes carried far to leeward, and the loss of space can only be diminished by executing the movement with as much rapidity as possible.

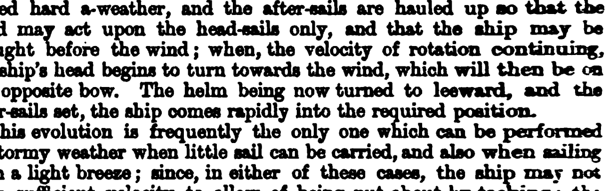
When a heavy sea is running, veering is a perilous operation, as may be inferred from the following diagrams. During a hard gale good experience in seamanship is required in order to prevent the decks being swept by the waves. There are two periods, while a ship is veering, at which the danger is most threatening: namely, soon after a ship's head has payed broad off when she is liable to be caught in the trough of the sea, as in *fig.* 1; and, next, when she has come with

Fig 1.



head right off the wind, and is scudding, as in *fig.* 2. In either case the breaking of the sea upon deck might destroy everything thereon, if

Fig. 2.



it did not lead to the foundering of the vessel. The latter case is that of a ship receiving a sea over the stern, when she is said to have been "pooped." In small fore and aft vessels, and especially in open boats, veering is attended with some risk even in moderate weather, and should be always done with caution; the sudden "swag" of the mainsail and boom from one side to the other as the wind catches the vessel upon the other quarter, may snap the boom with the suddenness of the jerk, or capsize the vessel altogether. To obviate this it is proper to round in the main sheet as it comes aft, and then check and ease it.

Box-hauling is an evolution similar to that of veering, and is put in practice when a rock or some other danger is suddenly seen a-head. If it be supposed that the ship is already close hauled, the after-sails are to be taken up, the helm turned a-lee, and the head-sails laid back; by these means the ship's head begins to turn from the wind, and her forward motion is arrested. As the ship's head continues to turn, the wind begins to act on the after-surfaces of the head-sails, giving a small motion forward; and then the helm is shifted so as to co-operate with the wind in causing the ship's head to fall farther off. The rest of the evolution is similar to that which is performed in the act of veering.

VEINS, DISEASES OF. The physiology of the veins may be found in the article CIRCULATION, in NAT. HIST. DIV.: in the present article their principal diseases will be described. Of these the most frequent is that in which they become what is called *Varicose*, that is, dilated, and unnaturally tortuous, a disease which occurs especially in the subcutaneous veins of the lower extremity. It is the result of the coats of the veins losing their elasticity, and thereby their power of resisting the pressure of the column of blood above them. The loss of elasticity is commonly due to disease of their coats, and is frequently accompanied by an increase of their thickness, and by destruction or impairment of their valves. The dilated veins appear like large tortuous blue canals beneath the skin, or in extreme cases, where many are coiled together, they form projecting tumours. They produce inconvenience, both by the pain which results from their distension, and occasionally by the skin over them ulcerating, and allowing them to burst and bleed profusely; but their more common effect is, that in parts of the skin below them, either spontaneously or after slight injuries, ulcers form, which, in consequence of the circulation being impeded through the dilated veins, are very tedious in healing.

For this varicose state of the large veins numerous remedies have been proposed; but the best are only palliative. A temporary remedy is afforded by the recumbent posture, in which the walls of the veins are relieved from the weight of the column of blood: constant advantage is afforded by the wearing of a well-applied bandage, or of an elastic stocking, by which a sufficient pressure is applied to prevent the further distension of the veins. The obliteration of the venous trunks may be effected by cutting or tying them in various ways, or by applying some caustic, so as to make the tissues over them slough; but these proceedings are not without danger, and at present it is very doubtful whether they are often productive of permanent advantage. Patients had better, in general, be content with the palliative remedy of the bandage or elastic stocking.

A form of varicose disease of the veins, which often accompanies that of the venous trunks, but sometimes exists alone, and with which ulcers of peculiar obstinacy occur, affects the small vessels about the ankle and lower part of the leg. The skin in this disease is almost uniformly red, through the number of small veins that are distended; the neighbourhood of the ulcer, when one exists, is livid, tense, and shining; and the ulcer itself is indolent, and very painful, and discharges a thin sanies. This state can be treated only by the same remedies as the preceding: but, though commonly overlooked, it is by far the more mischievous disease of the two.

Varicose affection of the veins of the spermatic cord constitutes the disease named *Varicocele;* and that of the veins of the rectum, or skin around it, forms hemorrhoids, or piles. In these, and in all the other cases, the blood is apt to stagnate in the dilated veins, and to coagulate within them. The clots thus formed may assume a definite form, becoming elliptical, or more often elliptical with pointed extremities, and the fibrine in them arranges itself in concentric layers: after this they harden, and one of their extremities becoming connected with the walls of the vessel, small blood-vessels may form in them, and communicate with those of the surrounding parts. Lastly, the colouring-matter of the blood is removed, and earthy-matter is deposited in the clots, arranged in concentric layers, and giving them considerable hardness: thus *phlebo-lithes*, or vein-stones are formed. They are usually spherical, measuring from one to four lines in diameter, lying loose within the veins, and producing no apparent inconvenience, except by obstructing the passage of blood. They are especially common in the dilated veins in the pelvis of old persons, and in the veins of legs which have been long varicose: they neither need nor admit of surgical treatment.

That which is particularly termed a *Varix* is either a mass of dilated and tortuous veins, or a single saccular and circumscribed dilatation of a vein, analogous to the circumscribed aneurism of an artery. This circumscribed dilatation is a very rare disease, but in its consequences does not differ from ordinary dilatation. An aneurismal varix is produced when, a communication being made, either by a wound or by ulceration, between an artery and a vein, the latter is dilated by the force of the arterial blood into a circumscribed sac. [ANEURISM.]

The most serious disease to which the veins are subject is acute inflammation, or *phlebitis*. It sometimes occurs after the slight wound made in ordinary bleeding; it is more common after operations upon varicose veins; and yet more frequently occurs after amputations of the limbs. Slight cases of phlebitis not unfrequently come on, as if spontaneously, or after exposure to cold, in varicose veins. The dilated veins become hard, like knotted cords beneath the skin, and very painful; the skin around them inflames, and the parts below become œdematous; and sometimes a slight erysipelas spreads over the limb. Such affections are usually of little moment; leeches, rest, and external cold are sufficient to subdue the inflammation, and it often has the favourable result of obliterating the veins, and thus curing the disease by which they were previously affected.

The more severe phlebitis is a most dangerous disease. Lymph is effused into the cavity of the vein, and into the tissue of its walls, rendering them thick and hard; the vein and the tissues immediately around it become exquisitely tender, and the parts whose blood should be returned through the diseased vein are usually œdematous. In a further stage pus is effused into the cavity of the vein, and, mixing with the blood, it may pass into the general current of the circulation, though more commonly the vein is obliterated above the chiefly inflamed part by lymph deposited on its walls, and thus the passage of pus into the circulation is prevented. With the local inflammation of phlebitis a state of low typhoid fever, with muttering delirium and great exhaustion, is usually combined; and under these the patient dies.

In connection with suppurative phlebitis a condition often occurs to which the name of *purulent diathesis* has been given. Its chief characteristic is, that collections of matter form coincidently in many different parts of the body, most frequently in the joints, lungs, and liver, accompanied by a kind of fever similar to that which attends phlebitis. It has been thought that this state depends on pus formed in an inflamed vein being carried into the circulation, and deposited again in some remote part; or that there is a kind of metastasis of suppuration from the vein to the parts secondarily affected. But cases occasionally happen in which all the signs of the purulent diathesis are well marked, although no vein is diseased; so that there is no necessary connection between the disease and phlebitis, although in the tendency to suppuration the veins generally take a prominent place. The most probable explanation of the disease is, that some morbid matter, such as is formed in the decomposition of the discharge from sores or wounds, is introduced into the blood, whose chemical composition it impairs, engendering a state in which pus is apt to be formed, and in which, as in typhoid fever, every function is seriously disordered.

The treatment of these cases of acute phlebitis and purulent diathesis cannot be laid down in general terms. Very commonly the former requires the coincident employment of large local bleedings, and of medicines and regimen calculated to maintain the patient's strength. The due observance of the indications for one or both of these proceedings affords the only prospect of success; but most frequently the best directed means are ineffectual.

One of the most fatal forms of phlebitis is that which affects the veins of the uterus and the neighbouring parts after labour, and which chiefly constitutes one of the diseases included under the name of puerperal fever. *Phlegmasia dolens*, or *phlegmasia alba*, is due to phlebitis of a less severe kind affecting the iliac or femoral vein, or both, and many others adjacent to them. By obliterating the venous trunks, and preventing the circulation through them, the disease gives rise to the firm œdema, accompanied by the tightness and glossy paleness of the skin of the leg and thigh, which peculiarly indicate it. It occurs sometimes, but rarely, after exposure to cold: its usual origin is in a comparatively slight inflammation of the veins of the pelvis of women during pregnancy, or after delivery, which extends from them to the veins of the lower extremity. It is attended by the same tenderness and hardness of the diseased veins as exist in other cases of phlebitis; and in its treatment, as in theirs, the general state of the patient's health, and the degree and extent of the local affection, considered together, must determine the measures to be adopted.

VELLUM. [PARCHMENT.]

VELOCITIES, VIRTUAL. [VIRTUAL VELOCITIES.]

VELOCITY. This word, rendered into English, is simply swiftness or quickness, and would be soon disposed of, if it were not that various circumstances connected with its measure and calculation render its consideration one of the most useful exercises which the student can have, not only in mechanics, but also in pure mathematics. And since the views which must be developed in treating properly of this word are almost identical with those which arise in explaining the meanings of other words nearly as important, we have made references from all quarters to this article, which, though they will increase its length, will upon the whole save room.

The difficulty in the way of a beginner, which he meets with in acquiring a clear notion of the measure of velocity, is the tendency to confound the velocity and its measure; a tendency which is increased by any elementary work which hastens too rapidly to the mathematical treatment of the word. The consequence of this confusion is (since the measure of velocity must be a length described, or rather a length capable of being described) a want of power to distinguish between the space which a body *does* describe in a given time, and that which, judging from its velocity, it seems to be going to describe at the beginning of that time. Hence arise many notions mathematically false: these might perhaps be prevented by attributing volition to the moving particle, and distinguishing between its apparent intention at the beginning of the given time and that which it actually accomplishes in the given time. Such an illustration would probably receive no approbation; but the errors to which it would lead would not be of the least consequence in mathematics.

A point is in motion, and during a certain second it moves over ten feet: if the same thing should happen in preceding and succeeding seconds, there is a presumption that the body is moving uniformly at the rate of ten feet a second; that is to say, there is a presumption that, in any portion of time whatsoever, during its motion, there is a length described which bears to ten feet the same proportion as that portion of time bears to one second. But this is a presumption only. It does not follow, because ten feet are described in one second, that five feet are described in each half of a second, and one foot in each tenth of a second. If the second could be divided into a million of parts, and it could be shown that the millionth part of ten feet is described in each and all of these parts, it would be no doubt a very strong presumption that the motion is really uniform, but still not amounting to certainty; for it is possible that in each of those parts of time there may be a variation of speed: for instance, the moving point may do all its work in the first half of the small interval, and rest during the remainder. Something of this kind takes place in the motion of the minute-hand of a clock, which is propelled once in each second during a portion of the second, and rests during the remainder. But so rapidly do the small propulsions follow one another, and so small are their individual effects, that, even when the hand has been watched until its motion is certain, there is no irregularity discoverable by ordinary eyes. And, speaking with reference to common purposes, there is no occasion to deny uniformity of motion so long as the lengths described in those times which are convenient to be mentioned are equal or nearly equal. It would be useless, in speaking of the pace with which a man walks four miles an hour, to remind the hearer that no person walks uniformly, and that in every step the centre of gravity of the body moves up and down, advancing most rapidly when it is at the highest, and most slowly when it is lowest. But for mathematical purposes a correct measure of speed must be obtained, and the preceding account would at first seem to lead to the inference that it is impossible to have such a measure. Nor indeed has velocity yet received its definition in this article, at least not its measure: we have spoken of velocity and of its changing, but without alluding to any mode of estimating the quantity of change. But there is that about the word which needs no definition: when we say that the railroad carriage moves "faster" than the old stage-coach, or that two bodies which set out together and keep together are always moving "at the same rate," there is no need of explanation of the words which are in marks of quotation. And we must now refer to the considerations in UNIFORM, as a constituent part of this article, showing that we may have a perfect idea, both of velocity that it is a magnitude, and that there is such a thing as uniform velocity, previous to any definite ideas of the most proper mode of measuring even that uniform velocity, to go no farther.

If a body move uniformly, it is customary at once to lay down as the measure of the velocity the space described in a given time, usually the unit of time, a second, a minute, an hour, as the case may be. So far as the great object of calculation is concerned, this definition is perfect: by instituting measures of velocity, we can but want to answer one or other of these questions: Where will the moving point be at the end of a given time? or, In what time will the moving point pass over a given length? The body moves at the rate of v feet per second, it moves over vt feet in t seconds, and moves over the length s feet in $s \div v$ seconds. Let us now take a point moving with a variable motion, that is, not describing equal lengths in equal times, say a particle descending by its own weight in a vacuum. In the first second it falls 16 feet; but in the first half of this second it falls only 4 feet, and the remaining 12 feet in the second half-second. The space described in one second is therefore no measure of the rate of motion during that second, and it is now to be asked, What is the way of obtaining a measure of the speed after any interval has elapsed? What is velocity itself, when it cannot for want of uniformity be ascertained by the space described in any given time? If the action of gravity were removed at the end of that time, so that the point would go on uniformly with its last acquired velocity, how much would it then describe in one second? All these questions are the same, and the answer cannot be given without the introduction of the notion of a limit, whether with or without the forms of the differential calculus. At the end of the time t seconds, let the moving point be at A, distant by s feet from the fixed point O. During

the ensuing fraction h of a second, let it describe the further space AB $(=k)$. The length k is then moved over in the time h, and, if the velocity were uniform, that velocity would be $k \div h$ feet in one second; for as h is to 1 (second), so (on the supposition of uniform velocity) is k to the space which would be described in one second. If AB were very small, we might reason (with tolerable exactness) as follows: In a very small time the change of speed will be slight, and the motion of the point nearly uniform, though not absolutely so; whence we may say, without material error, that AB is described as with a uniform velocity at the rate of $k \div h$ feet per second. The process which the mathematician adds is the following:—The error of the preceding process, small when h is small, becomes smaller when h is still smaller, and may be diminished to any extent: that is, little as may be the departure from uniform motion in moving through a small length, it is less in moving through a smaller. If, then, instead of making h simply small, and then finding $k \div h$, we diminish h without limit, and find the limit towards which $k \div h$ approaches, we find that uniform velocity which may be said to represent the speed of the point in passing through A, so far as any uniform velocity can be said to do so. Using such language as supposes the point to have volition, we have, in the limit of $k \div h$, the length per second with which the point shows an intention of proceeding at the instant when it passes through A, though it does not preserve that intention wholly unaltered for any portion of time, however small.

Suppose for example that the point moves in such a way as to describe $t+t^2$ feet in t seconds, for all values of t, whole or fractional. We have then $s=t+t^2$, $s+k=(t+h)+(t+h)^2$, whence we obtain

$$k=h+2th+h^2 \qquad \frac{k}{h}=1+2t+h.$$

At the end of three seconds, what is the velocity? Judging from the length described during the succeeding fraction h (and making $t=3$), we should say that, $k \div h$ being $7+h$, the limit of this, or 7, obtained by diminishing h without limit, is the velocity required; that is, the point is then moving 7 feet per second. If we suppose 7 feet per second, the length described in the fraction h of a second is the fraction $7h$ of a foot; take any other uniform velocity p feet per second, and ph is the length described in the same time. Now what is really described is $7h+h^2$; so that the errors are h^2 and $(7-p)h+h^2$, which are in the ratio of h to $7-p+h$. Now if p differ (as we have supposed) from 7, the first error diminishes without limit as compared with the second, when h diminishes without limit: so that, *of all uniform velocities*, 7 feet per second is the one which best represents the motion of the point in any small time following the end of the third second; and the better the smaller the time.

It appears then that we do not, properly speaking, undertake to say at what rate the point is moving at the end of three seconds, but what fictitious *uniform* rate best represents, at the instant, the *variable* rate at which it is moving. This will, for a moment, seem rather unsatisfactory to the student who imagines that he has got an absolute idea of velocity, and here he should compare his notion on this subject with that of the direction of a point moving in a curve. [DIRECTION; TANGENT.] What do we mean by saying that a point which moves in a curve has, at every instant, the direction of motion which is represented by the tangent of that curve? Answer, in nearly the same words as before, We do not, properly speaking, undertake to say in what direction the point is moving at any period of its motion, but what fictitious *line of uniform direction* (straight line) best represents, at that instant, the *line of variable direction* (curve) on which it is moving. The study of these two things together, velocity and direction, is useful, as each throws illustration upon the difficulties of the other. In both cases the laws of matter agree in preferring that which is indicated as most simple by the laws of mind; for if a point moving along a curve be suddenly relieved of the forces which keep it in a perpetual change of speed and direction, it will proceed with that very velocity which we have said it shows its intention to proceed with, uniformly; and will quit the curve for that straight line which we might equally well have said it showed a disposition to prefer to any other while moving on the curve, namely, the tangent of the curve.

If it should be said that we are reduced, in treating of variable velocities, to a necessity which does not occur in describing those which are uniform, namely, the use of limits, we altogether deny the fact; that is, we say that we are as much compelled to the use of limits in defining a uniform velocity as a variable one. For what does uniform velocity mean? A point has uniform velocity when equal spaces, any equal spaces whatsoever, are described in equal times; or when, k being described in the time h, $k \div h$ is always the same. That is, $k \div h$ must retain its value, however small h may be; or the limit of $k \div h$ must also have that value. And we have seen that it would be impossible to declare, experimentally, the existence of uniform velocity, even if our senses had no imperfections, upon the experience of comparisons of any finite equal spaces, however small; nothing but assurance of *the limit of* $k \div h$ being the same thing wherever the point A might be placed, would give mathematical evidence of the velocity being uniform.

In all cases, then, by the velocity of a point in motion, at any particular period of its motion, is to be understood the limit of the ratio which the increment of the length described bears to the increment of the time expended in the description of that increment of length. That is, if the length be measured in feet, and the time in seconds, and if k be the fraction of a foot described in the fraction of a second h, the limit towards which the fraction k divided by the fraction h continually tends while h is diminished without limit, is the number of feet per second which, we may say, expresses the rate of motion at the period in question. The student of the differential calculus will now have no difficulty in altering the preceding into the following form: if the length s be described in the time t, the velocity (v) at the end of the time t is thus expressed:

$$v=\frac{ds}{dt}.$$

If y be any function of x, and if x represent the number of units of length described by a moving point in the time t, and y the same for another moving point, and if $y=\phi x$, we have by the rules of the differential calculus:

$$\frac{dy}{dt}=\frac{dy}{dx}\frac{dx}{dt}.$$

Here $dy:dt$ and $dx:dt$, represent $\dot{y}$ and $\dot{x}$, Newton's FLUXIONS of y and x; and $dy:dx$ is obviously the same thing as $\dot{y}:\dot{x}$. The term fluxion merely means velocity, and, after all, there can be formed no clearer notion of a differential coefficient than one which is formed from a consideration closely resembling the fluxional one. If y be a function of x, $dy:dx$ is the rate at which y is increasing, as compared with that at which x increases. Thus if $y=x^4$, $dy:dx=4x^3$, which when $x=10$ is 4000. What does this mean? We say that nothing can answer more clearly than the following: If a number be imagined to be gradually increased [VARIABLE], by the time it becomes 10 its fourth power will be, at that instant, increasing 4000 times as fast as itself.

ACCELERATION is the increase of velocity; and in the article cited uniform acceleration has been considered, and its laws deduced, if not with the forms, yet on the principles, of the differential calculus. Precisely the same difficulties come before us in the development of the measure of acceleration as in that of velocity, and they are to be met in the same manner. In fact, by the acceleration is meant the rate of increase of the velocity, the velocity of the velocity. Suppose the velocity, first, to increase uniformly: that is to say, let b feet be added to it in every second, and in that proportion for all times elapsed; if then a be the initial velocity, that at the end of the time t is $a+bt$, and we have

$$\frac{ds}{dt}=a+bt \qquad s=at+\tfrac{1}{2}bt^2$$

if s be measured from the point of starting. Here at is the length due to the initial velocity a, and $\frac{1}{2}bt^2$ the effect of the continual acceleration. Now suppose, returning to the diagram, that the velocity at B is greater by l than that at A, and the fraction h of a second having elapsed between the two positions: that is, suppose that at A the point begins to move as if it meant (continuing our illustration) to describe v feet in the next second; but that by the time of coming to B it begins (from B), as if it would describe $v+l$ feet in the next second. If this increase of velocity were uniformly given, that is, if in the time $\frac{1}{2}h$ its velocity had become $v+\frac{1}{2}l$, in $\frac{1}{3}h$, $v+\frac{1}{3}l$, and so on for every fraction of h, we might then infer that the acceleration at A, that is, the rate at which velocity is then increasing, measured by the quantity which would be gained in a second at the same rate, is $l\div h$: for as h is to one second, so is l gained in the time h to what would be gained in a second at that rate. But if this supposition be not true, that is, if the speed receive *unequal* additions in equal times, we must then begin to reason as before, and to find what (pursuing the same illustration) we may call the intention of the velocity. If l be added to the velocity in the small time h, it will be added nearly uniformly; if h be still smaller, still more nearly, and so on: in such manner that while, practically speaking, $l\div h$ is a sufficiently good representative of the current rate of acceleration, when h is small, the (uniform) rate of acceleration which best represents the state of things at A is the limit which is deduced by making h diminish without limit. And here again, copying our own preceding words, we do not undertake to say at what rate the velocity is increasing when the moving point is at A, but what fictitious *uniform* rate of increase best represents, at the instant, the *variable* rate of increase which would be detected if the changes of velocity between A and B could be noted. And hence, if w be called the acceleration, the student of the differential calculus will easily deduce,

$$w=\frac{dv}{dt}=\frac{d^2s}{dt^2}\text{ since }v=\frac{ds}{dt}$$

and also $vdv=wds$.

Thus if the motion of the point be such that in t seconds there are described t^3+t^4 feet, we have as follows:—

$$s=t^3+t^4,\ v=3t^2+4t^3,\ w=6t+12t^2$$

At the end of two seconds, then, the state of things is this:—the point has advanced 8 + 16 or 24 feet, and if allowed to move on without further change of velocity, would describe 12 + 32 or 44 feet in the next second, and has the velocity 44 (feet) in one second; while at the same time there is an acceleration taking place which would, if allowed to remain uniform for one second, add 12 + 48 or 60 to the velocity, making it 44 + 60 or 104 at the end of the third second. But this rate of acceleration is itself increasing, since at the end of the third second the velocity is 27 + 324 or 351.

So far the subject, and all notions connected with it, fall within the province of pure mathematics: if there were no such thing as either matter or force, but only motion and a mind to conceive it, all that has been said might be intelligible. It is very much to be regretted that the connection between the mathematical doctrine of motion and the laws of matter is unduly made, and at too early a stage, by the application of the term *accelerating force*, instead of simple *acceleration*, to the result $dv:dt$. Acceleration would be what we have described it to be, if matter were not inert, if it moved by its own volition, or on any supposition whatever, provided only that it moved. Why then should a theory be made to supply the name of a result antecedent to that theory, and which would be perfectly true even if that theory were false? The consequence of this is, that when the laws of matter come to be applied to the mathematical expressions of motion, things are taken for granted which ought to be learnt.

The connection between these two subjects is made in the manner described in the article FORCE, according to which it appears that if the weight of a particle be W, and if (this weight being taken away, as by laying the particle on a table without friction) a pressure be constantly exerted upon it such as would be produced by a weight P, in any direction in which it can move freely, the amount added to the velocity will be uniform, at the rate of 32·19 P ÷ W feet in every second. Hence the following equation:—

$$\frac{32\cdot19\,P}{W}=\frac{dv}{dt},\text{ or }P=\frac{W}{32\cdot19}\frac{dv}{dt}.$$

For example, what pressure must act uniformly for one second on a particle of 7 ounces weight, to add 13 feet per second to its velocity, or that the rate of motion at the end of that second may be 13 feet per second greater than at the commencement? Here $dv:dt=13$, W = 7, and the answer is

$$P=\frac{7\times13}{32\cdot19}=2\cdot83\text{ ounces.}$$

The numerical divisor 32·19, the uniform acceleration of bodies falling free in vacuo at the earth's surface, is usually denoted by g, and the factor W ÷ g usually stands for the MASS of the body, or the measure of its quantity of matter. Hence the following equation:—

$$P=M\frac{dv}{dt};$$

and this remains true, whatever unit of mass be employed, provided only that the pressure which is called unity shall be that which, exerted for one second upon the unit of mass, shall add a unit to the velocity. [VARIATION.] And now comes another consequence of the application of the term force to the simple consequence of force, acceleration. The word is wanted again to signify this pressure which produces acceleration, and for distinction the pressure is called *moving force*. [MOMENTUM; MOVING FORCE.] So, then, the name of the pressure which acts and produces continual accessions to the speed is moving force, while the name of the rate of acceleration is accelerating force. To mend this confused use of terms, some writers endeavour to create a notion of moving force independent of the pressure; but as they always end in saying that the moving force varies as the pressure and never tell us more of its definition than that it is the product of the mass and acceleration, they might save themselves trouble, and their readers also, if they would simply establish the above equation, where P means the pressure which produces acceleration, and that pressure is the unit of its kind when it is of that magnitude which creates in the unit of mass a unit of velocity per second.

As we are now differing from men of deservedly good authority, both at home and abroad, and intending to make our assertion in a more positive manner than is usual with us, we may be excused for dwelling a little more upon the subject. If we consider the natural meaning of moving force and accelerating force, it is obviously as follows:—Moving force is force which makes motion; accelerating force is force which makes acceleration, or increased motion. Were the distinction ever so necessary, these words would be very bad ones, and would always obstruct the learner. Nor does this origin of the word moving force—namely, that which produces MOMENTUM—give any help; for the synonyme for momentum—namely, *quantity of* motion, meaning really quantity of matter moved multiplied by the velocity—is a perversion of words of the same kind. To *momentum* we have no objection; it is a Latin word to which an English ear may easily be familiarised in any sense. If geometers had chosen to call an equilateral triangle a *momentum*, the etymological student might have been startled, but the shock would soon have been got over; but if they had called the same figure a *quantity of motion*, every beginner would have been puzzled, and the impression would have been lasting. But returning to the two species of forces, so called, we find a double inconsistency: the idea of motion is introduced into the word which only means pressure (for *moving force* is but pressure), while the idea of pressure is introduced into a word which has only reference to motion (for *accelerating force* is but acceleration). There are two distinct and leading ideas in mechanics, pressure and motion: on keeping them perfectly distinct till the time comes for joining them experimentally it must depend whether a student sees mechanics to be a science or not. If any one should say that pressure producing motion ought to be distinguished from pressure which is in a state of equilibrium with other pressures, we could not of course raise any objection: let, then, *moving force* and *resting force* be used in these two senses, with a clearly expressed distinction. Here force would be synonymous with PRESSURE, in the derived or secondary sense of the article cited. But let acceleration be then acceleration, not accelerating *force*.

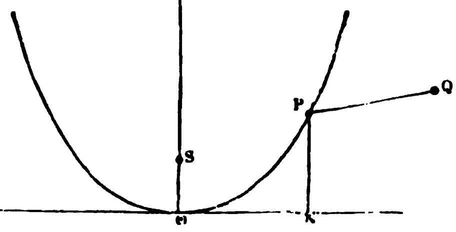
The COMPOSITION of velocities and accelerations is so easily proved that we do not think it necessary to lengthen this article by dwelling upon it. Two of a sort, whether velocities or accelerations, acting upon one particle, at any one instant, are equivalent to a third represented in magnitude and direction by the diagonal of a parallelogram, the two sides of which represent in magnitude and direction the two components. And by the law of motion which is commonly called the second [MOTION, LAWS OF], the several accelerations which act on any particle *in any given directions* may have their effects computed separately without any error being introduced. If, then, supposing a particle to move in a plane, the pressures P and Q be applied to it in the directions of the rectangular co-ordinates x and y, the mass of the particle being M, we have

$$M\frac{d^2x}{dt^2} = P, \quad M\frac{d^2y}{dt^2} = Q$$

equations which are only true on the supposition that there is this connection between the unit of mass and that of pressure, namely, that the latter acting on the former during one unit of time shall add to the line which represents its velocity one unit of length. These equations are enough to determine the equation of the curve in which the particle must move, P and Q being given functions of both x and y; and the time of motion through any arc of the curve s is then found from the following equation:—

$$\left(\frac{ds}{dt}\right)^2 = 2\int(Pdx + Qdy) \text{ or } dt = \frac{ds}{\sqrt{\int(2Pdx + 2Qdy)}}.$$

It is not here our business to proceed further with the consequences of the definitions of velocity and acceleration; but we must explain a point which will arise in our subsequent article on VIRTUAL VELOCITIES. When we have the means of actually ascertaining the motion of a particle of given mass,—that is to say, of finding at every instant its actual place, its velocities in the directions of its co-ordinates, and its accelerations in those directions,—we are prepared to assign the pressures which must act upon it in those directions, at the instant we are speaking of, either in mathematical units of pressure, as before described, or, if the reader please, in pounds or ounces averdupois. To show this, let us propose an instance, as follows:—A particle whose



weight (if weight were allowed to act) is 10 ounces, moves uniformly along the arc of a parabola O P (whose focus is S, O S being half a foot) at the rate of 2 feet per second: What pressures in the directions of O N and N P (or of x and y) are necessary to keep up the motion; and in particular what are the pressures and the velocities at the point P at which N P = 3 feet? The equation of the curve is $2y = x^2$, whence we get

$$\frac{dy}{dt} = x\frac{dx}{dt}.$$

Or the velocity in the direction of y is to that in the direction of x always as x to 1.

But, s being the arc O P, we have

$$\frac{ds}{dt} = 2, \quad \frac{ds^2}{dt^2} = \frac{dx^2}{dt^2} + \frac{dy^2}{dt^2} = 4$$

$$\text{whence } \frac{dx^2}{dt^2} = \frac{4}{1+x^2} \quad \frac{dy^2}{dt^2} = \frac{4x^2}{1+x^2}.$$

At the point in question $y = 3$, $x^2 = 6$, from which the velocities in the directions of x and y are found to be $\pm\sqrt{(\frac{4}{7})}$ and $\pm\sqrt{\frac{24}{7}}$, or ·756 and 1·852. We take the positive signs, since both motions obviously tend to increase* their co-ordinates. Differentiate the last equations again, and we have,—

$$2\frac{dx}{dt}\frac{d^2x}{dt^2} = -\frac{8x}{(1+x^2)^2}\frac{dx}{dt}, \quad 2\frac{dy}{dt}\frac{d^2y}{dt^2} = \frac{8x}{(1+x^2)^2}\frac{dx}{dt}$$

$$\frac{d^2x}{dt^2} = -\frac{4x}{(1+x^2)^2} \qquad \frac{d^2y}{dt^2} = \frac{4}{(1+x^2)^2},$$

or the velocity in the direction of x is always retarded, while that in the direction of y is always accelerated. And at the point in question we have $-4\sqrt{6} \div 49$ and $4 \div 49$ for the accelerations, say −·200 and ·082; by which we mean that if the pressures then acting in the directions of x and y were allowed to continue uniform for one second, they would alter the velocities in the direction of x and y from ·756 and 1·852 to ·756−·200 and 1·852 + ·082. The weight of the particle, if weight* were allowed to act, being 10 ounces, the pressures which would produce the preceding accelerations are, in ounces—

$$-\frac{10}{32\cdot19}\frac{4x}{(1+x^2)^2} \text{ and } \frac{10}{32\cdot19}\frac{4}{(1+x^2)^2},$$

the pressures in the direction of x being in the direction from N towards O. At the point in question these pressures are −·062 and ·0255 ounces.

The pressures thus derived from the motion which actually takes place, by means of the accelerations $d^2x : dt^2$ and $d^2y : dt^2$, are usually called the *effective* forces; and the name is very appropriate, because it is true that these must be the forces which do really act. Different pressures produce different accelerations upon the same mass; or to one acceleration there is but one producing pressure, the mass being given. But it may happen that the forces actually *impressed*, or the pressures actually employed, at the point P, may be very different from those which just produce the motion that is produced. Suppose for example that the mass P were attached to the mass Q by the rigid rod P Q without weight; and suppose such forces to be applied at P and Q as, whatever may become of Q, cause P to move uniformly along the parabola in the manner above described. We may assign an infinite number of different motions to Q, and for each motion of Q we may assign an infinite number of pressures which, being applied to P and Q, will give the two their supposed motions. But in no one of these cases can the total amounts of pressure really applied to P, in the directions of x and y, be any other than those which are calculated above: whatever may be the pressures actually applied at P, the thrust or pull, as the case may be, of the rod P Q, will supply what is necessary to make all the forces that act on P (those directly applied and that arising from the said thrust or pull) together equivalent to the pressures above calculated. This is the foundation of *D'Alembert's principle*. [FORCES, IMPRESSED AND EFFECTIVE; VIRTUAL VELOCITIES.]

The connection between velocity and pressure is not only obscured by phrases as cloudy as "moving force," but also by the use of the unit of mass instead of the unit of weight. This measurement by masses instead of weights is so convenient and so desirable on rational grounds, that it cannot ultimately be dispensed with; but at the first outset the student should be taught to reduce the new mode of proceeding into terms of that with which he is then better acquainted. A beginner in the theory of gravitation is not allowed to have the least idea of the amount of the attractions of the several bodies upon each other in pounds or tons, or any other unit which he can at once understand. And we should not be surprised if many who can easily compare the sun's attraction upon the earth with the earth's attraction upon the moon, so as to find either of them when the other is given, would be awkward at, if not actually puzzled by, the question of comparing either of them with the weights in a grocer's shop. Undoubtedly there would not be much of astronomical utility in the question; but for clear conception of the meaning and mode of derivation of mechanical results, nothing can be of more importance than the actual comparison of all results with those which are best known, because actually felt and perceived.

VELVET, a variety of manufactured silk, remarkable for the softness of its surface. Velvet was unknown at least several centuries after the introduction of plain woven silks; and it is not mentioned in any documents earlier than the 13th century. For a long time the manufacture was confined to Italy, where, particularly in Genoa, Florence, Milan, Lucca, and Venice, it was carried on to a great extent. It was subsequently introduced into France, and brought to great perfection. On the revocation of the Edict of Nantes, in 1685, this branch of weaving was begun in England by the refugees.

The peculiar softness of velvet is owing to a loose *pile* or surface of threads, occasioned by the insertion of short pieces of silk thread doubled under the shoot, weft, or cross threads. These stand upright so thickly as entirely to conceal the interlacing of the warp and shoot. The richness of the velvet depends upon the closeness of the pile-threads. The insertion of these short threads is effected in the following manner:—Instead of having only one row of warp-threads, which will be crossed alternately over and under by the shoot, there are *two* sets, one of which is to form the regular warp, while the other is to constitute the pile; and these two sets are so arranged in the loom as to be kept separate. The quantity of the pile-thread necessary is very much more than that of the warp-thread; and, therefore, must be supplied to the loom by a different agency. If the pile-threads were worked in among the shoot in the same way as the warp-threads, the fabric would be simply a kind of double silk, but without any pile. The pile-threads are, therefore, formed into a series of loops, standing up from the surface of the silk, and by subsequently cutting these loops with a sharp instrument, the pile is produced. The loops are formed in a very singular way. After the weaver has thrown the shuttle three times across, making the shoot interlace three times

* We have not entered into the distinction of meaning between positive and negative velocities and accelerations, since the question is a purely algebraical one, unnecessary to be treated here if the student really understand algebra, and impossible to be explained within our limits to one who does not.

* The weight has been throughout supposed to be neutralised, as it would be if the parabola were in the plane of a table, on which the particle is laid.

among the threads of the warp, he inserts a thin straight brass wire at right angles to the length of the piece, or parallel with the shoot. The wire is so placed as to occupy a position through the whole breadth of the fabric, above the warp-threads and below the pile-threads. The treadle is then put to work, the alternate threads of the warp raised, and the shuttle again thrown; by which a shoot-thread is thrown *over* the pile-threads, and also over one-half of the warp-threads; the wire becomes thus, as it were, woven into the substance of the fabric. Two more traverses of the shoot are then made, passing alternately under and over the warp threads in the usual way, but not interfering with the pile-threads. Another wire is then laid in, below all the pile-threads and above all the warp-threads, and this is secured by subsequent shoot-threads, as in the first case. By a delicate and difficult process, these wires are removed by the same operation which produces the raised pile. Each wire is nearly a semicylinder in form, and has along its upper surface a carefully constructed groove; along this groove the weaver passes the sharp edge of a cutting instrument called a *trevat*, severing the pile-threads in his progress. It necessarily follows from this operation that two ends of each thread are thus loosened; and these ends, being afterwards brushed up and dressed, constitute a portion of the pile, sufficiently long to hide completely the woven fabric beneath. Two wires are employed, because if one only were used, the pile-threads would become disarranged when it was removed. When the liberated wire has been again inserted, and three shoots thrown to secure it, the second line of loops is cut and the second wire removed; and so on during the weaving of the whole length.

Striped velvets are produced by some of the pile-threads being uncut. The slowness and delicacy of this branch of manufacture may be judged from the fact that forty or fifty insertions of the grooved wire are made in the space of one inch, the loops of the pile being cut an equal number of times. In addition to the other complications, the weaver has to use two shoot-threads, and consequently two shuttles; for the shoot thrown immediately after the insertion of the wire is stouter than the two following. It is considered to amount to a good day's work when one yard of plain velvet has been woven. Cotton is now employed, as well as silk, in the manufacture of velvet. The different varieties of fustian are a kind of cotton-velvet.

Among recent inventions in the velvet manufacture, one, by Mr. Gratrix, is applicable to velvets in which the pile is produced by the weft, and the cut made in the direction of the warp. The pile-threads are woven on a series of fine longitudinal knives with elongated points. The knives are stationary, and have their cutting ends attached to a bedding-frame. Simultaneously with the weaving, the portions of weft intended to form the pile slide consecutively upon the points of the knives as the cloth is woven; and the weft, when it arrives at the cutting portions of the knives, is severed. Another arrangement, by the same inventor, is for severing the pile without cutting at all. Wires are woven in with the threads, so as to leave the pile above them; they pass between two peculiarly-formed rollers, which press open the fibres over each wire, and thus liberate all the wires. Some of the processes recently introduced enable the weaver to cut and emboss the velvet at the same time.

VENA CONTRACTA. [HYDRODYNAMICS.]

VENDOR AND PURCHASER. The law of vendors and purchasers of real estate in England is a subject of great extent, which may be said to comprise nearly the whole practical application of the law of real property.

Contracts for the sale and purchase of land or other real estate may be entered into either privately between the parties, or upon a sale by auction. At common law, agreements for the purchase of real estates might be made by parol, but by the Statute of Frauds (29 Car. II. c. 3, ss. 1, 2, 3, and 4), "All leases, estates, interests of freeholds, or terms of years, or any uncertain interest of, in, or out of any messuages, manors, lands, tenements, or hereditaments, made and created by livery and seisin only, or by parol only, and not put in writing by the parties so making or creating the same, or their agents thereunto lawfully authorised by writing, shall have the effect of leases or estates at will, any consideration for making any such parol leases or estates notwithstanding." But leases not exceeding three years, whereupon the rent reserved should amount to two-thirds of the full improved value, are excepted. The act requires the assignment, grant, and surrender of existing interests to be in writing, and enacts that "no action shall be brought whereby to charge any person upon any agreement made upon any contract or sale of lands, tenements, or hereditaments, or any interest in or concerning them, unless the agreement upon which such action shall be brought, or some memorandum or note thereof shall be in writing, and signed by the party to be charged therewith, or some other person thereunto by him lawfully authorised." The note or memorandum of agreement required by the statute need not be a formal document, and any writing, such as a letter, or receipt for purchase-money, may constitute an agreement within the statute, provided it contain the terms of the agreement within itself, or by reference to another writing; and if the document be written by the party, the occurrence of his name anywhere in the document is a sufficient signing.

Upon sales of estates by public auction, the highest bidder, upon being declared the purchaser, is considered to have entered into a contract for purchase according to the particulars and subject to the conditions of sale; and the auctioneer, who is for this purpose considered as the agent of both vendor and purchaser, is thereupon authorised to sign an agreement of purchase. The writing down the purchaser's name upon any memorandum of sale at the time of the bidding is a sufficient signing. Sales by auction of lands are within the above-mentioned enactments of the Statute of Frauds; but sales before a master under a decree of a court of equity will be carried into execution although the purchaser did not subscribe any agreement, for the judgment of the court in confirming the purchase takes it out of the statute. The subject of the sale and purchase of estates is discussed at length in Sugden's (now Lord St. Leonards) and Dart's 'Treatises on the Law of Vendors and Purchasers of Estates.'

VENEERING, in cabinet-work, is the art of laying thin leaves, called *veneers*, of a valuable kind of wood upon a ground or foundation of inferior material, so as to produce articles of elegant appearance at smaller cost than if they were made solid, or composed entirely of the ornamental wood which appears on the surface. Small veneers are cut by hand with a thin saw, the block being held firmly in a vice; but large ones are usually cut by machinery, for a notice of which see SAW-MILL. They are carefully brought to the right thickness by fine planes; cut precisely to the required shape; and then glued down to the ground, which should be of dry wood, with strong glue. If the form of the article will permit, it is then put in a press until the glue is dry; but if not, the newly-laid veneers are covered with a board, which is pressed down either by weights or by poles abutting against the beams in the roof of the workshop. In veneering on curved surfaces a somewhat different course is pursued, but with the same object, that of keeping the veneer in its place until the glue is sufficiently set to hold it securely. The work is afterwards finished with very fine planes and scrapers, and polished with fish-skin, wax, and a brush or polisher of shavegrass.

It may here be mentioned, that before the saw-mills were rendered applicable, the elder Brunel devised a mode of cutting timber into veneers by a kind of knife. This knife was formed of several pieces of steel, exactly in a line on their lower surface. The block of wood was carried sideways beneath the knife by a screw slide, worked by a handle, and the knife cut it by a short reciprocating or sawing action. The block was raised, after each cutting, to a height equal to the thickness of the required veneer. The method answered well for straight-grained and pliant wood, such as Honduras mahogany, but not for other kinds.

Ivory veneers, or rather thin sheets for miniatures and for memorandum books, are sometimes not more than one-sixtieth of an inch in thickness, requiring much nicety in their manipulation. [IVORY.] *Vulcanite*, or vulcanised india-rubber, is now used as a veneer. It is rolled into thin sheets, which may be either plain or embossed, and it receives a polish by the rolling. In applying this substance as a veneer, the sheets are dipped for a few minutes in boiling water, till they become as tractable as moist paper; and the workmen can then veneer with them round and over the sharpest curves and angles. Ordinary wood veneers cannot well be bent round corners; a patent to effect this has been taken out by Mr. Meadows; but in general it is not attempted.

The Americans have recently introduced, under the name of *pressed work*, veneering of a remarkable kind. Instead of a thin veneer being placed upon a thicker substratum, the whole substance consists of veneer. It comprises four, six, eight, or any other number of layers. Some strong plain wood, such as black-walnut, is selected for the interior layers, and rosewood or other fancy wood for the exterior. The veneers, which are of the usual thickness, are well saturated with glue, and placed one upon another, with the grain of each layer at right angles to that of the next. The mass, while hot, is placed in moulds, named *cowls*, and pressed forcibly for twenty-four hours. When taken out, the wood is found to be firm, elastic, and strong, and to conform to any curvature which the mould may have given to it. On account of the crossing of the fibres, the wood can scarcely split, except by a force that would rend it to pieces. The pores have become so filled with glue, as to add in a remarkable way to the strength of the substance. Mr. Belter introduced this art; and at the present day, pressed-work is very much used in the United States for the better kinds of furniture. Chairs of this make are in demand, for their great strength and remarkable lightness; it is the *back* of the chair, generally elegantly curved, that consists of pressed work. There are usually seven layers for the back of a chair, making a substance surprisingly thin in relation to its strength. An odd number of veneers is usually selected, in order that the grain may extend in the same direction on both surfaces. The frame-work for bedsteads is formed in a similar way; and so are the bodies of such musical instruments as the violin and violoncello. M. Bogaud, another inventor, has succeeded in producing *dished* or *spheroidal* pressed work: that is, articles in wood presenting much deeper curves than those just described. To effect this, the veneers are cut by machines into stripe, each of which varies in width according to the part of the mould into which it is to be pressed; the cutting must be very accurate to effect this, and can only be done by apparatus mathematically adjusted. A curve of double curvature may be produced by this method. Hitherto, this dished pressed work has necessarily been very expensive.

We must notice also M. Amies' method of veneering in relief. Two moulds, an upper and an under, as in cameo and intaglio, are gently heated, and a sheet of veneer is placed between them. One side of the veneer takes the device in relief; the other side, hollow, is then filled up with mastic or any plastic substance. The veneer is in the first instance smoothed or polished on the surface which is to be in relief. Paper is pasted on the back; and it is while the wood is yet damp with the paste that it is pressed between the dies; the paste assists the veneer to conform to the dies, and to retain the device when cold. The veneer is not removed from the mould till quite dry. Medallions are produced in this way, remarkable for the sharpness and perfection of the device.

VENETIAN SCHOOL OF PAINTING. [PAINTING.]

VENIRE FACIAS, or *Venire*, the name of a writ addressed to the sheriff or other returning officer, commanding him "to cause to come" (*venire facias*) the parties set forth at the place named in the writ. The purpose to which the writ was formerly applied, and in reference to which it is generally known, is in summoning juries to serve for the ordinary trial of civil causes. It has long ceased to be acted upon, the court assuming that the jurors had been summoned upon it and had failed to appear at Westminster, where anciently the trial itself took place, another writ thereupon issuing to bring them to the assizes. Now, however, the sheriff is simply commanded to summon the jurors to appear before the judges of Assize or Nisi Prius. (*Common Law Procedure Act*, 1852.) [JURY; VENUE.]

VENTILATION. [WARMING AND VENTILATION.]

VENTRE INSPICIENDO, WRIT DE. "When a widow is suspected to feign herself with child in order to produce a suppositious heir to the estate, the heir presumptive may have a writ *de ventre inspiciendo*, to examine whether she be with child or not; and, if she be, to keep her under proper restraint till delivered; which is entirely conformable to the practice of the civil law: but if the widow be, upon due examination, found not to be pregnant, the presumptive heir shall be admitted to the inheritance, though he hath to lose it again, on the birth of a child within forty weeks from the death of a husband." (Blackstone, 'Comm.' i. 456) The Roman practice is explained in the title of the 'Digest' (25 tit. 4): "*De inspiciendo ventre custodiendoque partu.*" The practice originated in the joint reigns of Aurelius and Verus, in a case in which a wife denied her pregnancy and the husband maintained it. The wife had separated from the husband, and probably wished to keep the child that might be born, though by law it would belong to the husband. If a woman alleged that she was left pregnant by her deceased husband, it was her duty to announce the fact to those whom it concerned, and to inform them that they might, if they pleased, send women to inspect her (*quæ ventrem inspiciant*). All the proceedings of inspection and of watching the woman, if she should be reported to be with child, are minutely prescribed in the Prætor's Edict. The penalty in case of the woman not complying with the edict was, that the prætor would refuse to the child the *bonorum possessio*.

The form of the English writ *de ventre inspiciendo* is given Co. Litt. 8 b. It is directed to the sheriff, and commands him to empanel a jury of twelve women to search whether she be enceinte. If they find that she is with child, another writ issues which commands that she shall be safely kept and duly inspected by the women, who must be present at the delivery.

The use of this writ is an instance in which what is called a proceeding at common law is taken from the Roman system. (Co. Litt. 8 b., and N. 44 in Butler's edition; Comyns, 'Digest,' Bastard, C.)

VENTRILOQUISM (literally "belly-speaking:" from *venter*, the belly; and *loquor*, I speak) is a vocal mimicry of sounds, by which an illusion is produced on the hearer that the sound comes, not from the mimic, but from some other appropriate source. The various phenomena of vocal mimicry may be conveniently considered under two general heads, namely: 1st, The simple imitation of the voices of persons, of animals, of musical instruments, and other sounds and noises of every description, in which no illusion is intended, but, on the contrary, the imitation avowedly and perceptibly comes from the mimic; and 2nd, The imitation of those voices, sounds, and noises, not as originating in the mimic, but in some other, an appropriate source at a given or varying distance, in any or even in several directions successively. And when these imitations are made without moving the mouth, features, or body, the illusive effect of the mimicry is enhanced. The terms mimicry, or imitation, are commonly adopted to designate efforts under the former general head where no illusion is intended, while the term ventriloquism distinguishes those under the latter where an illusion is produced.

The various kinds of divination amongst the nations of antiquity which were stated by the priesthood to be by a spirit, a familiar spirit, or a spirit of divination, are now supposed to have been effected by means of ventriloquism. Divination by a familiar spirit can be tracked through a long period of time. By reference to Leviticus, xx. 6, 27, it will be seen that the Mosaic law forbade the Hebrews to consult those having familiar spirits, and to put to death the possessor. The Mosaic law was given about fifteen hundred years before Christ. Divining by a familiar spirit was however so familiar to the Jews, that the prophet Isaiah draws a powerful illustration from the kind of voice heard in such divination, see Isaiah, xxix. 4. In the Acts of the Apostles, xvi. 16, mention is made of a young woman with a familiar spirit meeting the Apostles in the city of Philippi in Macedonia. And St. Chrysostom and other early fathers of the Christian Church mention divination by a familiar spirit as practised in their day. The practice of similar divination is still common in the East, and is even practised amongst the Esquimaux. This divination by a familiar spirit has been practised upwards of three thousand years.

The witch of Endor divined by a familiar spirit; 1 Sam. xxviii. 7, in Hebrew אוֹב—(Ob.) The word is also adopted in the Hebrew Bible to designate those persons, whether male or female, in whom there is a familiar spirit. The plural of אוֹב is אוֹבוֹת—Oboth, which in the Septuagint version of the Scriptures is mostly rendered by the Greek Ἐγγαστριμύθους, which is compounded of ἐν, in, γαστήρ, the belly, and μῦθος, speech, and corresponds with the word ventriloquism. The rendering of the Hebrew in the Septuagint, Professor Lee accounts for by the muttering of those having a familiar spirit—the אוֹבוֹת: see his Hebrew Lexicon, or 'Thes. Heb.' Gesenii, *sub voce*.

The Greeks practised a mode of divination termed gastromancy, from γαστήρ, the belly, and μάντις, a prophet; where the diviner replied without moving his lips, so that the consulter believed he heard the actual voice of a spirit speaking from its residence within the priest's belly. St. Chrysostom adopts the same Greek word as the translators of the Septuagint version to designate the diviners by familiar spirits, namely, Ἐγγαστριμύθους.

The earliest description of a ventriloquial illusion in modern days is that performed by Louis Brabant, valet-de-chambre of Francis I. By the aid of ventriloquism he extorted from the mother of a young woman her consent to their marriage which she had previously opposed, and from a rich old man a large sum of money. The work of M. l'Abbé de la Chapelle, published 1772, descriptive of the feats of Baron Mengen at Vienna, and of M. St. Gille near Paris, claims attention. Baron Mengen made a doll with moveable lips, which he could control by his hand under its dress. With this doll he held witty and satirical dialogue. Baron Mengen said he owed his art to a passion for counterfeiting the cries of animals and the voices of persons, that the passion manifested itself in early life; and that he had the power of imitating sounds so accurately as to make them appear to come from other places than his own mouth.

M. St. Gille, in 1771, made an experiment to test his ventriloquial talent before MM. Leroy and Fouchy, commissioners of the Royal Academy of Sciences, and many other persons of the highest rank. The object of the experiment was to show that M. St. Gille's mimicry of sounds was so perfect as to produce illusion. For this purpose it was reported that a spirit's voice was at times heard in the environs of St. Germain, and that the commission was appointed to verify the fact and to discover the cause. All the company were in the secret except one lady, who, without suspecting it, was to be the subject of the illusion. They all dined in the country in the open air, and while they were at table a voice, as of a spirit suspended in the air, addressed the lady: now it seemed at the top of the trees; then descending, it approached her—then receding, it plunged into the ground, whence it ceased not to make itself heard. The conversation was sustained upwards of two hours with such adroitness that the lady was fully convinced she had talked with a sylph; and when the illusion was explained to her, she doubted if it were an illusion.

M. St. Gille, like Baron Mengen, made no secret of his art, but referred it all to mimicry, for which he had a strong propensity. The French Academy adopted the views contained in the statements of these two ventriloquists, namely, that the art consists in an accurate imitation of any given sound as it reaches the ear.

Adopting these views, physiologists have offered a variety of possible actions of the vocal organs to explain its production; and some have even supposed a peculiarity of structure of the vocal organs as necessary, but have wisely omitted to specify what. Many physiologists think that ventriloquism is vocally produced by speaking during inspiration of the breath. It is possible to speak during inspiration, and it may be occasionally adopted; but close observation on many public ventriloquists, and private friends who can ventriloquise, convinces the author of this article that the general current of utterance is, as in ordinary speech, on an expiration of the breath.

Adopting the views of the French Academy, some have thought that the vocal means of effecting the required imitation consist in a skilful management of the echoes of sound. Unfortunately, however, for this theory, an echo merely repeats what is already produced; and several ventriloquists, including the late Mr. Mathews, have produced the vocal illusion while walking in the streets.

Baron Mengen thus describes his mode of speaking when the voice was to seem to come from his doll:—"I press my tongue against the teeth, and thus circumscribe a cavity between my left cheek and teeth, in which the voice is produced by the air held in reserve in the pharynx (*gosier*). The sounds thus receive a hollow and muffled tone, which causes them to appear to come from a distance." The Baron says it is necessary to well manage the breath, and to respire as seldom as possible.

It was observed that M. St. Gille appeared fatigued after long exertion, when the vocal illusion became less perfect. Those ventriloquists with whom the author of this article has conferred have acknowledged fatigue in the chest, which they have attributed to the extremely slow expiration of the breath. M. St. Gille, like most professional ventriloquists, was observed to cough very frequently.

Now, in order to arrive at exact and positive knowledge of the modifications of voice termed ventriloquism, it is necessary to be familiar with the distinctions of vocal sound; and to know how the organs act in producing those vocal modifications, it is necessary to know how the breath is vocalised in all its distinctions of pitch, loudness, and quality, by the ordinary actions of the vocal organs.

In ordinary language we speak of noise, of sound, and of musical sound; and Dr. Thomas Young adopts those terms in illustrating the mechanical causes of sounds:—"A quill striking against a piece of wood causes a noise; but striking successively against the teeth of a wheel, or of a comb, a continued sound; and if the teeth of the wheel are at equal distances, and the velocity of the rotation is constant, a musical sound." ('Lect. Nat. Phil.')

The general terms pitch, loudness, quality, and duration embrace all the distinctions which the musician discovers in musical sounds, and which he employs in his art. The distinguishing feature of musical sound is its uniform pitch throughout its duration. And, acoustically musical sound is composed of an equal number of impulses or noises produced in equal times. [ACOUSTICS; VOICE.]

The general terms pitch, loudness, quality, and duration also embrace all the distinctions heard in ordinary sounds. These sounds differ from the musical in the pitch constantly varying throughout their duration, as the human voice in speaking, and the voices of quadrupeds. Acoustically, such sounds are composed of an unequal number of impulses or noises produced in equal times. And from this circumstance pitch, in the strictly musical sense, is not a property of ordinary sound.

The general terms loudness and quality embrace all the distinctions heard in a noise, as in the collision of two inelastic sticks. The momentary collision of the clapper against a bell is a noise, but this mere noise is immediately followed by the ringing sound of the bell, which is a musical sound. Pitch and duration can scarcely be considered as belonging to common noise. Thus we have:—

I. Noise, whose audible distinctions are comprehended under the general terms loudness and quality.

II. Common sound, whose audible distinctions are comprehended under the general terms loudness, quality, duration, and ever-varying pitch.

III. Musical sound, whose audible distinctions are comprehended under the general terms loudness, quality, duration, and an uniform pitch.

Phonation, or the production of voice, is a result of actions taking place under two distinct classes of laws, namely: 1. The ordinary mechanical laws of acoustics; and 2. The physiological laws of muscular movement. The adjustment of the vocal mechanism to be acted on by the current of air is made by actions under the latter laws; and phonation is the result of the re-action of the mechanism on the current of air, by mechanical movements under the former laws. [LARYNX, in NAT. HIST. DIV.] The pitch of the voice essentially depends on the tension of the vocal ligaments; the loudness on the extent of excursion of the vocal ligaments in their vibration; the duration on the continuance of the vocalising causes; and the quality on the organisation of the larynx, and also on the form and size of the vocal tube. Now the form and size of this tube can be altered in various ways, as by dilating or contracting the pharynx [PHARYNX, in NAT. HIST. DIV.]; by dilating or contracting the mouth; by contracting the communication between the pharynx and mouth so as to make them distinct chambers, or by dilating the opening so as to throw them into one, which is chiefly effected by movements of the soft palate; by altering the form of the mouth's cavity, which is produced by varying the position of the tongue. It will be found that each of these modifications of the vocal tube confers a peculiarity of quality to the voice. All these, however, are vocal or laryngeal sounds.

Sounds can be produced in the vocal tube apart from the larynx. These are not vocal sounds. Some of them, however, may be of a definite and uniform pitch, while others are mere noises, as rustling, whispering, gurgling, whistling, snoring, and many others.

Now, as every audibility comes under the classes of noise, sound, or musical sound, and as each variety under these classes is producible by the vocal apparatus of man, it is an obvious conclusion that an ordinary vocal apparatus is all that is required to vocalise the mimetic conceptions of the ventriloquist. A larynx capable of producing a larger compass of voice than another has a greater range of pitch within its power of imitation.

A person having an ear acutely perceptive to the nice distinctions of sounds may, by a little practice, imitate many sounds with accuracy. Those persons, however, who are highly endowed with the mental requisites, which consist of an intense desire to mimic, coupled with the ability to originate mimetic ideas, are able to imitate sounds at first hearing, and without previous practice. Passing from the imitation of sounds, as that of knife-grinding, sawing and planing wood, the voices of animals and men, we proceed to treat of those illusions where the voice so perfectly counterfeits the reality intended, that it appears not to issue from the mimic, but from an appropriate source, in whatever direction and at whatever distance that source may be. The essence of ventriloquy consists in creating illusions as to the distance and direction whence a sound has travelled; which are thus explained:—

I. *Distance.* We do not hear the distance which a sound has travelled from its source, but we judge the distance from our former experience, by comparing the loudness which we hear with the known distance and known loudness of similar sounds heard on former occasions. Common experience will confirm, that we oftener err in estimating the distance of uncommon than of familiar sounds. In apology for such an error the ordinary language is, "It seemed too loud to come so far," or "It seemed too near to be so faint a sound," as the case may be. Both of which are apologies for an erroneous judgment, and not for hearing.

Near sounds are louder than distant ones. Now, by preserving the same pitch, quality, and duration, but with an accurately graduated reduction of loudness, a series forming a perspective (if the term be allowable) of sounds may be created, which, falling in succession on the ear, will suggest to the mind a constantly increasing distance of the sound's source.

Loudness is a property of sound which has not had justice done to its importance in the schools of music and elocution. Its nomenclature is vague and meagre, and it can scarcely be said to have a notation. The author of this article has observed that one of the high excellences which singers of genius have snatched beyond the rules of art has been a skilful management of the degrees of vocal loudness, and a nice adaptation of them to aid the melody in expressing the intended feeling. The varieties of loudness remain still unmeasured, and the abrupt transitions in loudness made by musical performers suggest that these distinctions are ill perceived.

The estimate, then, which is formed of the distance which a sound has travelled before reaching the ear is a judgment of the mind formed by comparing a present perception (by hearing) with the remembrance of a former loudness in connection with its known distance.

II. *Direction.*—The direction whence a sound comes seems to be judged of by the right or left ear receiving the stronger impression, which however can only take place when the sound's source is in a plane, or nearly so, with a line passing through both ears. It is familiarly known that a person in a house cannot by the noise of an approaching carriage judge with certainty whether it is coming from the right or left. He accurately judges it to be approaching, passing, or receding, as the case may be, by the gradations of loudness, but is unable to decide with certainty whether its approach or recession is from up or down the street. Common experience shows the judgment to be more fallible concerning the direction than the distance of sounds. Professor Müller of Berlin states, in his 'Physiology,' that Venturini's experiments, detailed in Voigt's 'Mag.,' bd. ii., demonstrate the impossibility under certain circumstances of estimating whence a sound comes to the ear. Now, without entering upon the merits of those valuable experiments, enough has been above stated to show that we do not hear, but that we judge, the direction a sound has travelled from its source on reaching the ear.

It has been remarked, and the writer of this article confirms its truth from observations made both in public and in private ventriloquy, that the ventriloquist indicates either directly or indirectly the direction which he wishes his audience to believe the sound is coming. Thus they directly indicate it by words, such as—"Are you up there?" "He is up the chimney," "He is in the cellar," "Are you down there?" &c. And they indirectly indicate it by some suggestive circumstance, as an action or gesture which is so skilfully unobtrusive and natural as to effect its object without being discovered. Thus, when the ventriloquist looks or listens in any direction, or even simply turns towards any point, as if he expected sound to come thence, the attention of an audience is by that means instantly directed also to the same place. Thus, before a sound is produced, the audience expect it to come in the suggested direction. And the ventriloquist has merely, by his adjustment of vocal loudness, to indicate the necessary distance, when a misjudgment of the audience will complete the illusion which he has begun.

The effect which is produced on sound by its travelling from a distance is observed to be—

1. That its loudness is reduced in proportion to the distance.
2. That its pitch remains unaltered.
3. That its quality or tone is somewhat softened.
4. That its duration remains unaltered.
5. That human speech is somewhat obscured, chiefly in the consonant sounds.

Now, the ventriloquist imitates the sound, not as it is heard at its source, but as it is heard after travelling from a distance. A skilful ventriloquist can effect his imitations without much movement of his lips and features. Now, it has been observed that ventriloquists, during their efforts, turn the front face away from the audience and scarcely even show the profile. The author of this article confirms this observation, as far as regards moderate-sized rooms, but he has seen the front face in a theatre.

It is quite easy to speak without moving the jaw, and it is the jaw's movements which disturb the features in utterance. Now the labial sounds, such as B, P, M, when the jaw is thus fixed, can be made with a slight movement of the lips. The lips and jaws being always somewhat open during ventriloquy, a slight labial movement remains unnoticed, unless special attention be directed to it; and all the modifications of voice can be produced without at all distorting the features or moving the lips.

The preceding outline of the philosophy of ventriloquism is sufficient to exhibit the nature of the art. To enter upon the consideration of all the vocal means adopted to accomplish the various imitations would fill a volume. The mode of counterfeiting variations in loudness by changes of pitch, and also by changes from the natural to the falsetto register of voice, are amongst the wonders of vocal science, and are capable of extensive application by the scientific ventriloquist.

VENUE (*vicinetum*, *visne*, "neighbourhood"). The county in which the trial of a particular cause takes place is said to be the venue of that cause. The old practice in this matter is connected with the original functions of the jury, as persons who were acquainted with the facts in issue. [JURY.] In order, then, that a proper *venire* might issue to the sheriff, the place in which the action was brought was stated in the margin of the declaration, and on the statement throughout the pleadings of any issuable fact a statement was also made of the place at which such fact was alleged to have occurred. As to all such facts upon which issue was taken, a *venire* was sued out applying to each different place. The sheriff returned jurors from that place, and by those jurors the facts were decided, so that several distinct *venires* and trials might be necessary to dispose of the issues in one action.

When juries ceased to act on their own knowledge, and began to determine on the evidence of witnesses, the necessity ceased for summoning them from the particular part of the country, and the practice gradually declined, till at last, the *venire* itself gave way to a precept commanding the attendance of the jurors at the assizes. (*Common Law Procedure Act*, 1852.)

A distinction was long since established between local actions (that is, actions relating to real estate) and transitory (that is, actions of debt, contract, for personal injuries, &c.). In regard to the former, it was held that the actual place in which the subject-matter was situated must be laid as the venue in the action, and that rule still prevails. The reason is said to proceed from the circumstance that, unless the action were brought in the actual county, the sheriff of the county would be unable to give effect to the judgment in the action. In transitory actions, on the contrary, the subject-matter of them being held not to have any fixed place, the plaintiff is at liberty to bring his action in any county in which he please. As a consequence of which it follows, that though the cause of action has occurred even out of the kingdom, it is still open to the plaintiff to bring his action in the courts of this country. The plaintiff has still this liberty in a transitory action; but the courts assert an authority upon application made to them of changing the venue. This is done upon its being made to appear that great inconvenience would arise from trying in the original county, because the body of the evidence lies in another, or because from local prejudices a fair trial cannot be had, &c. And the same authority may be exercised even in local actions, in spite of the technical difficulty which has been before referred to.

In criminal trials the venue is usually the county in which the offence charged was actually committed. The courts however have the same discretion as to the power of changing the venue as in civil cases; and as to criminal trials, many exceptions have been introduced by various statutes.

VENUS DE MEDICI. [APHRODITE.]

VENUS, the name of the planet which is nearest to the earth, and, except Mercury, nearest to the sun. The principal point of its physical description is the distinctness with which its phases are seen through a telescope, in which it exhibits all the changes of appearance which are, to the naked eye, characteristic of nothing but the moon. With regard to these phases, there is a remarkable historical error which we cannot trace higher than Dr. Smith's 'Optics,' but which has been copied by Hutton and others. It is said, "When Copernicus revived the ancient Pythagoric system, asserting that the earth and planets moved round the sun at the centre of their orbits, the Ptolemaics objected, if this were true, that the phases of Venus should resemble those of the moon. Copernicus replied, *that some time or other that resemblance would be found out.*" (Smith's 'Optics,' p. 415.) Now, first, Copernicus never answered an objection to his system in the manner implied in the story; for he literally only lived to lay his hand upon a copy of his own work, and never opened it. [COPERNICUS, in BIOG. DIV.] Secondly, Gassendi, his biographer, in stating the verification of his system (as he calls it), derived from these phases, never alludes to any such prophecy; nor does Galileo, in announcing the telescopic discovery of the phases of Venus (A.D. 1611), and in giving praise to Copernicus and Kepler for not having abandoned the motion of the earth on account of the difficulty arising out of the apparent want of them, ever suppose that Copernicus, or any of his followers, had the slightest idea of that apparent want arising from imperfection of vision. Thirdly, Copernicus himself, in mentioning the difficulty, expressly meets it by the supposition that Mercury and Venus, the "stellæ" alluded to in the coming quotation, either shine by their own light, or are completely saturated with the solar rays: "Non ergo fatemur in stellis opacitatem esse aliquam, lunari similem, sed vel proprio lumine, vel solari totis imbutas corporibus fulgere, et idcirco solem non impedire" (lib. i. cap. 10). And the objection itself has nothing to do with the difference between the system of Copernicus and that of Ptolemy, for it had long before been raised against the latter: all, in fact, who maintained that the orbit of Venus comes between the earth and sun having to meet it in one way or another, whether they made the earth or the sun the centre of their system.

In the theory of the motion of Venus, the most remarkable circumstance is the *long inequality* discovered some years ago by Mr. Airy, depending upon the earth. [GRAVITATION.] A satellite was at one time suspected to belong to this planet, but no such thing has ever been detected. It may be remarked that the satellite of an inferior planet might not be easy to find, if it were very small; for when the planet is nearest the earth, and circumstances are most favourable for its discovery in other respects, the dark side would be turned towards the earth. Though in the earlier period of telescopic observations, spots of various sorts were detected on the disc of Venus, yet the general description of its appearance in our day, as given by Sir J. Herschel, is as follows:—"Although it occasionally attains the diameter of 61″, which is larger than that of any other planet, it is yet the most difficult of them all to define with telescopes. The intense lustre of its illuminated part dazzles the sight, and exaggerates every imperfection of the telescope; yet we see clearly that its surface is not mottled over with permanent spots like the moon; we perceive in it neither mountains nor shadows, but a uniform brightness, in which sometimes we may indeed fancy obscurer portions, but can seldom or never rest fully satisfied of the fact. The most natural conclusion, from the very rare appearance and want of permanence of the spots, is, that we do not see, as in the moon, the real surface of this planet, but only its atmosphere, much loaded with clouds, and which may serve to mitigate the otherwise intense glare of its sunshine."

Venus, like Mercury, from the orbit being entirely within that of the earth, is never at more than a certain angular distance from the sun; her greatest angular distance, or elongation, being from 45° to 47° 12′. Her mean apparent diameter is 16″·9, but varies from 9″·6 to 61″·2. The real diameter is ·975 of that of the earth, or about 7700 miles, and the volume is ·927 of that of the earth. The density is very nearly that of the earth; but this element, as also the mass, is rather uncertain. The mass of this planet is stated by Laplace at $\frac{1}{356632}$th of that of the sun, but later writers give $\frac{1}{405871}$th as more probable. Mr. Rothman ('Mem. Astron. Soc.,' vol. xii. pp. 409-415) has shown strong reasons for supposing that the mass given by Laplace has been too much diminished by his successors, and that the second fraction above named should be increased by about its tenth part at least, and probably by more. The most uncertain of all the results of the theory of gravitation is the mass of a planet which has no satellite.

This planet revolves on its axis in about $23^h\ 21^m\ 7^s$; though this, owing to the absence of definite spots on its disc, can hardly be considered as very accurate. Its light and heat are to that of the earth as 1911 to 1000.

The elements of the orbit of Venus, which are usually taken from Lindenau's Tables (1810), have lately undergone a searching examination by comparison with seven years' observations made at Greenwich. Messrs. Main and Glaisher, who made this examination, have given their own resulting elements, compared with those deduced for their own epoch, from the above-mentioned tables. In the following list we have adopted the new elements, placing the old ones after them in parentheses; but taking the secular variations entirely from those given as the result of the investigation just quoted ('Mem. Astron. Soc.,' vol. xii.). The semiaxis major alone remains untouched; for though the examiners found reason to suspect that it was somewhat in error, they did not feel able to decide with certainty as to the amount of the alteration.

Elements of the Orbit of Venus.

Epoch 1836, January 1, 0^h mean astronomical time at Seeberg ($42^m\ 56^s$ east of Greenwich).

Semiaxis major ·7233316, that of the Earth being assumed as the unit.

Eccentricity ·00684568 (·00682265); its secular diminution (or diminution in 100 years), ·00008200.

Inclination of the orbit to the ecliptic, 3° 23′ 34″·34 (3° 23′ 31″·11); its secular increase, 10″·035.

Longitudes from the mean equinox of the epoch (1) of the ascending node, 75° 12′ 3″·60 (75° 12′ 25″); its secular increase (combined with the precession), 3095″·23: (2) of the perihelion, 129° 15′ 3″ (129° 11′ 18″); its secular increase (combined with the precession), 49″·62; of the planet (mean), 332° 1′ 35″·23 (332° 1′ 33″·1).

Mean sidereal motion in 365¼ days, 2106641″·49; sidereal revolution, 224·7007869 mean solar days.

When Venus is to the west of the sun she rises and sets before him, and was then called Phosphorus and Lucifer by the ancients; but when she is to the east of the sun she rises and sets after him, and was then called Hesperus. The old terms of our almanacs, "Morning-star" and "Evening-star," have reference to these positions.

VENUS, TRANSIT OF. [TRANSITS OF MERCURY AND VENUS.]

VERANTIN. [MADDER, COLOURING MATTERS OF.]

VERATRIC ACID ($C_{18}H_{10}O_8$). The acid with which veratrine exists combined in Cevadilla. It crystallises in short prisms, which are transparent and colourless, and slightly sour to the taste. It is slightly soluble in cold water, but more soluble in hot, and readily dissolved by alcohol, but not at all by ether.

Neither concentrated nitric nor sulphuric acid decomposes veratric acid, but a mixture of them renders it yellow. When heated to 212° the crystals lose water, and then become of a dull white colour; at a high temperature they melt into a colourless liquid, and sublime without leaving any residue.

The crystals contain one equivalent of water. Veratric acid forms crystallisable salts with the alkalies, which are very soluble in water and alcohol. Their solutions precipitate the salts of lead and silver, and the veratrate of the latter is white, and slightly soluble in alcohol.

VERATRINE ($C_{64}H_{52}N_2O_{16}$), a vegetable alkali prepared from Cevadilla, the seed of the *Veratrum sabadilla*. It was discovered by Meissner in 1818, and obtained by Pelletier and Couerbe in 1819.

Veratrine is a white or greenish-white powder, which has a silky and crystalline appearance under the microscope; it is inodorous, very acrid and poisonous. It is insoluble in water and alkaline solutions; very soluble in alcohol and sparingly so in ether; the solution when evaporated deposits transparent laminæ. The solutions have the alkaline property of restoring the blue colour of reddened litmus.

The salts of veratrine are neutral, and have a slight styptic taste; the hydrochlorate crystallises in short needle-form crystals, which are very soluble in water and alcohol; the sulphate crystallises in quadrilateral prisms; concentrated nitric acid renders veratrine first scarlet and then yellow; concentrated sulphuric acid gives it at first a yellow colour, afterwards a blood-red, and eventually violet.

VERATRUM ALBUM (White Hellebore)—*Medical Properties of.* Of this, two varieties, or distinct species, are officinal: one termed *V. album;* the other *V. album β*, or *Lobelianum.* This last prefers a chalky soil; the plants occur in the meadows of the Swiss Alps, the Pyrenees, the mountains of Austria, and in Siberia. The rhizomas of both kinds are collected indiscriminately. This part occurs single, double, or many-headed, in cylinders, or pyramidal pieces, from two to four inches long, and from three-quarters to two inches thick, rough, wrinkled, of a grayish-black colour externally, but of a yellowish-white within. Some root-fibres, intermingled with slender flexible radicles, adhere to it; and on the upper part are found the scales, or withered remains of former leaves, which from their tunicated appearance have led some writers to describe it as a bulb. This, though incorrect, is useful to remember, as a good discriminative mark between it and other plants confounded with it, which, being *roots* and not *rhizomata*, are devoid of this character. A transverse section presents a large central portion, sometimes termed the medulla; and, according to the age of the specimen, one, two, or more external circles, bounded by the dark-brown epidermis. The rhizoma is nearly devoid of odour, but has an acrid, bitter, burning taste. It is easily powdered, but the person engaged in powdering it should wear a mask, as it excites a heat and eruption of the skin, and any drawn up the nostrils causes violent sneezing and inflammation of the Schneiderian membrane: hence its German name of *nieswurzel.* By time the acridity and activity are diminished, so that old specimens become not only mouldy, but of inferior strength, and should be rejected.

Veratria, called also Sabadillin, is procured from the seeds of *Asagræa officinalis* (Lindley, *Helonias officinalis*, Don) and the *Veratrum Sabadilla*, Retz, as well as probably other seeds of *Melanthaceæ.*

Veratrum viride is used in America as a substitute for *V. album* and also for colchicum. White hellebore is an agent of great and dangerous power. According to the experiments and inquiries of Schabel ('Dissertatio de eff. Veratri albi et Hellebori nigri,' Tübingen, 1817), it is poisonous to all classes of animals, and acts fatally, if in sufficient quantity, by whatever way it is introduced into the system. It appears to have a specific effect on the intestinal canal and nervous system, its effects on these parts being uniform, whether applied directly to them or to remote parts, provided absorption take place. The action is that of a narcotico-acrid poison; but its narcotic effect is less, while its acrimony is greater, than that of black hellebore. It is doubtful whether the plant now spoken of is the *white hellebore* of the ancients. In doses short of any dangerous or violent effect, white hellebore exercises a peculiar action on the secreting organs, the stomach and intestines, and the nervous system. Almost all mucous surfaces, and the glands connected with them, as well as the kidneys, are excited to increased secretion. But when the quantity is more considerable, heat of the mouth, tongue, and throat, with spasmodic constriction of the pharynx, thirst, pains in the stomach and intestines, alternate heats and chills of the whole body, perspirations, anxiety, pain of the head, giddiness, depression of spirits, gloomy expression, and even spasms of the countenance, are experienced: if vomiting fortunately occur early, these symptoms are alleviated. Schabel says that no substance so certainly acts as an emetic; but while tartar emetic or ipecacuanah, or sulphate of zinc, can be had, it ought never to be employed. If the substance be introduced into the rectum, the symptoms are the same, except that the heat of the mouth and pain of the stomach are less. In decidedly poisonous doses its action is that of a violent narcotico-acrid, causing severe vomiting and purging, often bloody stools, tenesmus, burning feeling from the mouth to the rectum, constriction amounting to a sense of strangulation in the throat, with small pulse, faintings, cold sweats, giddiness, blindness, dilated pupils, loss of voice, convulsions, and insensibility, generally terminating in death. The tincture and the alcoholic extract act more powerfully than the watery infusion or extract. A cutaneous eruption sometimes follows the use of white hellebore. Where death does not ensue, palpitation with intermitting pulse, along with dyspeptic and nervous symptoms, remain for some time. The application of white hellebore to wounds or any broken surface, either to destroy vermin or to cure the itch, may produce the above effects; and this result occurs whether it is used in powder, as a wash, or ointment. The popular use of these is therefore to be discouraged. White hellebore is occasionally mistaken for Galanga root, and the seeds for those of cumin: intentional poisoning with it is rare; but from the use of it among soldiers, who have recourse to it from its property of producing palpitation of the heart, and thus simulating disease of that organ, in hopes of obtaining their discharge, violent and indeed fatal effects ensue. It is the active ingredient in some quack medicines for gout or rheumatism, often producing dangerous consequences. It is also the efficient agent in many insect-destroying powders. An efficient antidote is scarcely to be found. Samuel Hahnemann, overrating the antagonising power of coffee, recommends that article; but at best it can only combat the narcotic symptoms, which are not the most formidable. Astringent drinks have also been proposed, but they are not to be relied on. Acid drinks seem more serviceable: hence tamarinds, or cream of tartar may be given, followed by demulcent or oily fluids. Vomiting should be encouraged.

The medicinal employment of white hellebore is not very great in the present day; but when administered with due caution it is of great service in gouty and dyspeptic disorders, where there is torpor of the liver, sluggish bowels, and defective secretion from the kidneys. From its influence on these organs it often proves useful in chronic cutaneous diseases, in which the digestion is always impaired. It is likewise used as a sternutatory, largely diluted with some starchy powder. Externally, veratria is employed to relieve nervous pains; but its use requires the greatest caution.

VERB. [LANGUAGE.]

VERDERER. [FOREST LAWS; WOODS AND FORESTS.]

VERDIC ACID, an acid discovered by Runge, and so named from its property of becoming green by exposure to the air. It is obtained from several of the *Umbelliferæ*, *Plantagineæ*, &c., but chiefly from the root of the *Scabiosa succisa.* When combined with excess of base, it becomes green in the air, owing to the absorption of oxygen; Berzelius, therefore, proposes to call the colourless the *verdous*, and the coloured the *verdic* acid. The former is obtained by digesting the dried and powdered root of the scabiosa in alcohol, from which on the addition of ether white flakes are thrown down; to these, dissolved in water, acetate of lead is added, and the precipitate thrown down is decomposed by hydrosulphuric acid. By evaporating the filtered liquor the acid is obtained in the state of a brittle yellow mass, which reddens litmus and does not alter in the air. When it is saturated with an alkali, ammonia for example, and exposed to the air, it absorbs oxygen and becomes gradually green. The acids then precipitate it in the form of a reddish-brown powder, which is verdic acid: this redissolves and becomes green with the alkalies. The earthy or metallic *verdites* are yellow, while the *verdates* of the same bases are green. Runge states that he found by analysis that verdic acid contains one equivalent of oxygen more than the verdous acid.

VERDICT. [JURY.]

VERDIGRIS. [ACETATE; *Diacetate of Copper.*]

VERDITER. [COPPER; *Acetate of Copper.*]

VERDOUS ACID. [VERDIC ACID.]

VERMICELLI, a dried paste, manufactured chiefly in Italy in the form of smooth round strings. The name has been given to it on account of its worm-like appearance, *vermicelli* in Italian signifying little worms. *Maccaroni*, which the Italians spell *maccheroni* or *maccherone* (a word of doubtful etymology), is manufactured of the same kind of paste as vermicelli, and in a similar manner; but it is rather larger in diameter, and is hollow like the tube of a tobacco-pipe. *Fedelini* is a kind still smaller than vermicelli.

The paste is made of wheat stripped of the husk, and ground roughly into a sort of grit. The kind of wheat preferred by the Italians is a small hard-grained species which they now cultivate on purpose, but which they formerly imported from the coasts of the Black Sea—*grano di Mar Nero.* The ground wheat is mixed with clear soft water, and made into a paste by kneading it on a large block with a wooden lever ten or twelve feet long. The short end of the lever is made sufficiently heavy to lift the long end, on which one or two men or boys get astride, and alternately sitting down and springing up, work the paste for a long time. The toughness and elasticity of the paste result from this long and powerful process of kneading. The paste is next forced by strong pressure through round holes in the bottom of a cylinder; but, to form maccaroni, a wire extends from a bridge in the upper part of the cylinder through the centre of each of the largest holes, and the paste, being forced through each hole around the wire, is consequently hollow. The strings, several feet in length, whether of maccaroni, vermicelli, or fedelini, having been thoroughly dried, are ready for use.

The Italians manufacture the paste into many other forms; into thin flat strips like ribbons, into thin sheets like paper, into round balls, and into beans and peas. The Neapolitans, who use great quantities of maccaroni as their favourite food, use nothing but the pure paste of wheat and water, but the Genoese mix saffron with it, which gives it a yellow tinge. The French, who also manufacture a good deal of it, frequently season the paste with various condiments.

VERMILION. [COLOURING MATTERS; MERCURY.]

VERNAL, VERNAL EQUINOX. The word vernal is the adjective derived from *ver*, the spring; and the vernal equinox is that point of the equator which the sun crosses when it passes into the hemisphere of the observer, and when his days begin to be longer than the nights. Consequently that point of the ecliptic which is called the first point of Aries is the vernal equinox to those in the northern hemisphere, while the first point of Libra is the same to those in the southern. If there were any decidedly astronomical nations south of the equator, some confusion might perhaps have arisen; but as all the science will be carried from the north, it is probable that the terms and modes of measurement peculiar to the north will be universally retained.

VERNIER. We shall give under this head a short account of the different methods employed to measure the parts of the divisions of astronomical and geodesical instruments. This and the article GRADUATION may be considered as a sort of introduction as well as supplement to the description of each particular instrument. It is necessarily both meagre and imperfect, but the references will point out the principal authorities to be consulted. We shall conclude with a brief account of the vernier in its simplest form.

We are not aware that the Greeks or their successors the Arabs had any contrivance for subdivision. They seem to have simply divided their circles as accurately as possible, and into small convenient portions. Ptolemy's catalogue does not profess to distinguish less quantities than 10′; or rather, the parts of degrees are marked fractionally with no larger denominator than 6. Ulug Beigh used instruments of greater dimensions, and seems from his catalogue to have noted minutes. At the revival of astronomy in Europe the instruments were very rude, and the simple division, aided by estimation, was probably considered sufficiently accurate without any artificial contrivance.

Peter Nonius, in the third proposition of his treatise 'De Crepusculis Olyssipone,' 1542, proposed the following graduation for astronomical instruments:—Forty-five concentric circles are to be inscribed on the limb, and separated into quadrants by diameters intersecting at right angles. The quadrants are then to be sub-divided as follows:—the outermost into 90 equal parts, each of which consequently equals 1°; the next into 89, that following into 88, and so on to the innermost, which is to be divided into 46 equal parts. Each circumference is marked at a convenient place with the number of its subdivisions. The fiducial edge of the bar carrying the sights passes, when produced, through the centre, and the author assumes that whatever be the direction of the line of sight, the fiducial edge will cut some one of these circles at a division without sensible error. The corresponding angle in degrees, minutes, seconds, &c., is readily computed from the number of parts intercepted and the order of the circle. Thus if the exact coincidence takes place at division 29 of that quadrantal arc which is divided into 77 parts, the corresponding arc in degrees is $\frac{29}{77}$ of 90°, which is, when reduced to its ordinary denomination, 33° 53′ 46″ very nearly.

Tycho applied the graduation of Nonius, or a modification of it, to some of his earier instruments, but "quia hæc subtilitas, cum ad praxim deventum est, plus habeat laboris quam fructus, neque id in recessu præstet, quod primâ fronte pollicetur," he abandoned it, and adopted the method of *transversals*, which is well known to most of our readers as the diagonal scale in the case of drawing-instruments. This Hooke says ('Animadversions,' &c.) "was first made use of in England by the most skilful mathematician Richard Cantzler." Tycho describes this mode of subdivision in the supplement to his 'Mechanica,' Norimbergæ, 1602. Two concentric circles are drawn upon the limb at about $\frac{1}{10}$ of the radius from each other, and divided into equal parts of 10′. The space from the zero of the inner circle to the 10′ division of the outer circle is divided into 10 equal parts by 9 fine dots; and in like manner the space between the 10′ of the outer circle and the 20′ of the inner, and so on. These rows of points form a sharp zigzag with the angles in the two circles. The index, which may be either a fiducial edge or a fine hair, will pass over or near one of these dots in every position, and the angle to be read off is the number of degrees and tens of minutes which is taken from the circles, inner or outer, + the number of minutes and parts of a minute (the latter by estimation) reckoned by counting the points from the preceding angle. Tycho became acquainted with this division by diagonals as applied to straight lines when a student at Leipzig, and in the place above referred to he proves that this subdivision, though not theoretically exact when applied to curved lines, was yet sufficiently true for his purpose. Instead of dots, other astronomers struck nine concentric circles at equal distances, and then drew straight lines where Tycho placed his dots.

In the year 1631 Pierre Vernier, Capitaine et Chastellain pour sa Majesté au Chasteau Dornans, &c., published at Bruxelles 'La Construction, l'Usage, et les Proprietez du Quadrant nouveau de Mathematique,' which he dedicated to the Princess Isabella. He supposes a quadrant divided into half-degrees on the limb, the surface of which rises above the plane of the instrument (this he calls the base), and a moveable plate of the form and figure of a sector (and so named by him), which is concentric with and exactly fitted within the limb, the surfaces of the two forming one plane. An arc of 15° 30′ is then set off on the sector, which is subdivided into thirty equal parts. He directs two lines of sight to be fixed on the extreme radii of the sector, which therefore include an angle of 15° 30′, and orders the division to degrees and half-degrees to be numbered one way on the limb from left to right, and the divisions of the sector to be numbered up to 30′ from right to left. Suppose the line of sight towards the zero end of the quadrant to be directed to any object:—If the division 30′ on the sector (we will now call this the *vernier*) which answers to the line of sight, seems to be a continuation of a division of the quadrant, the angle read off will be that degree or half-degree of the quadrant, and the 0′ of the vernier will exactly correspond to another division of the quadrant. No other division of the vernier will so correspond if the division be exact. Now it will easily be seen that as the arc of 15° 30′ is divided on the vernier into 30 equal parts, each part is equal to 31′; and therefore that when 0′ is placed opposite a division of the quadrant, the division 1′ of the vernier overshoots the next division of the quadrant 1′ in the direction of the vernier, and contrary to the numbering of the limb. If the line of sight were pushed forward 1′, the vernier division of 1′ would therefore agree with a division in the quadrant, and so on; so that in fact, whatever be the position of the line of sight, the true angle is to be read off, first as to degrees and half-degrees from the quadrant, and then for the minutes from the vernier.*

In 1643 Benedictus Hedræus published at Leyden his 'Nova et Accurata Astrolabii Geometrici, nec non Quadrantis Astronomici Structura,' dedicated to his sovereign, Queen Christina of Sweden. In his preface he objects to the inaccuracy of Tycho's method of transversals, and gives himself a correct construction, namely, by describing a circular arc through 10′ of the outer division, 0′ of the inner division and the centre of the quadrant, and dividing that portion which is included between the inner and outer circles into ten parts, when the subdivision will be true. Hedræus has adopted the vernier, but without naming the inventor: his astrolabe and quadrant are well contrived.

Hevelius applied to his instruments the transversal division of Tycho as well as the vernier. He seems to claim the invention of the tangent-screw for giving a slow motion to his line of sight, and dwells at great length on the subdivision of the larger divisions by the revolution and parts of the tangent-screw. ('Machina Cœlestis,' Pars Prior, cap. xv. Gedani, 1673.) So far as we can judge from his assertions and description, he arrived at great excellence in this part of mechanical construction, which however his unaccountable rejection of telescopic sights rendered of little value.

The next year after the appearance of Hevelius's book, Hooke published at London his 'Animadversions on the first part of the Machina Cœlestis of the honourable, learned, and deservedly famous astronomer Johannes Hevelius,' a tract distinguished by its acuteness and originality. It is remarkable that he did not see the merit of Vernier's invention,† nor, as it would seem, of Hevelius's application of the revolutions of the tangent-screw to measuring very minute quantities. He suggests a very elegant application of the diagonal scale, with rules for its accurate division when applied to circular arcs, but recommends racking the outer edge of the quadrant and measuring the angle by the revolutions and parts of the screw which carries the telescope by working in the racked limb.

Hooke's unlucky idea was carried into execution in Flamsteed's sextant, and turned out so ill that the diagonal division was applied as an after-thought. See his prolegomena ('Historia Cœlestis,' vol. iii. p. 106, and Baily's Flamsteed.) Hooke's advice was afterwards followed in making a quadrant for the Greenwich Observatory, which was also found to be useless. In the mural arc which Flamsteed erected at his own expense and under his own direction, he drew diagonals after having divided the inner and outer arcs to 5′. The subdivision was performed by dividing the fiducial edge of the index, not into five equal parts but into such parts as would give the minutes exactly, and each of these was divided into six equal parts; so that the instrument

* Vernier's tract is very scarce, and the injustice of those writers who persisted in giving the name of Nonius to his invention has induced us to enter into a more particular exposition of both principles. The second line of sight is merely to enable the observer to extend the angle to 90° without carrying the sector beyond the quadrant. He gives a very prolix account of the graduation proper for quadrants and astrolabes of different sizes, and how angles exceeding 90° are to be measured, but of this no further notice is required here.

† Hooke conjectures that Tycho had invented Vernier's contrivance and rejected it, but without any probability. Tycho's words and figure refer clearly to some change of Nonius's divisors.

read off to 10″, and by estimation to 5″. The outer edge was also racked after Hooke's method, but rather, we think, as a check against erroneous reading, than as a means for exact measurement.

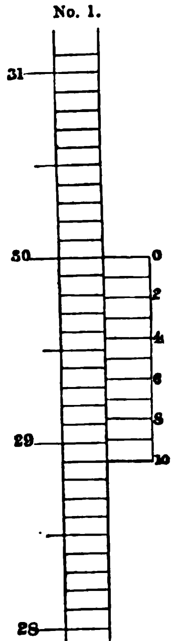
Römer proceeded in a totally different manner. The limb of the circle was divided to 10′, and a magnified image of each division was formed in the focus of a microscope, so as exactly to fill the space between eleven threads at equal intervals. Thus the arc was read off to minutes by the threads and the seconds estimated, which they easily might be to 5″, according to Horrebow.

The vernier appears to have come into general use after Flamsteed's time, and in the larger quadrants there were usually two sets of divisions, one into 90° and the other into 96 parts, each with their peculiar vernier: the approximate divisions were brought into exact coincidence and the quantity measured by the revolutions and parts of the tangent-screw, after Hevelius's method. Such were the mural quadrants at Greenwich and elsewhere, erected by Bird, Ramsden, &c., in the last century; and the portable astronomical quadrant had the same or similar contrivances for subdivision. In the sector employed in the French survey, and described in 'La Méridienne de Paris verifiée,' Paris, 1744, the arc was divided by fine points to every 10′. In making the observation the plumb line was first brought directly over one of these dots, and the star afterwards bisected by a micrometer-screw carrying a wire in the focus of the telescope. The degrees and tens of minutes being read off on the limb, the revolutions and parts of the screw furnished the remaining minutes and seconds. This method of subdivision was applied by La Caille to the sextant with which he observed at the Cape of Good Hope and at Paris. The invention is due to the Chevalier de Louville, whose memoir is to be found in the 'Mémoires de l'Académie' for 1714.

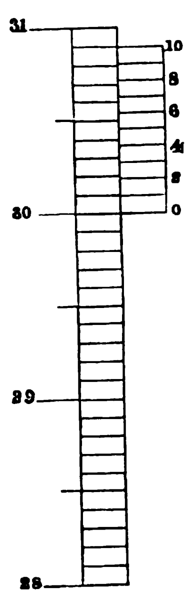
We have already mentioned Römer's optical method of subdivision. The invention of the micrometer-microscope, in which the divisions are first magnified and the intervals measured by the revolutions and parts of a screw carrying a wire or cross-wires in the focus of the object-glass of the microscope, is due to the Duc de Chaulnes, whose account was published in 1768: 'Description d'un Microscope et de differents Micromêtres,' &c. The reader will find some account of the construction and verification of the micrometer-microscope in the article CIRCLE.

We will now briefly explain the principle of the vernier in its simplest form. If that be well understood, the reader will have little difficulty in making out the value of the divisions in any instrument to which the vernier is applied, though he may require considerable practice before he is able to read off well and quickly.

No. 1.



No. 2.



Number 1 is the figure of a vernier for measuring hundredths of an inch, such as is usually applied to common barometers. The scale is on the left hand, on which the inches and tenths are marked. The portion on the right hand, which can be slipped up or down, remaining always in contact with the scale, is the vernier. It is merely a length of 11 parts of the principal scale divided into 10 equal parts. Each of these parts, therefore, equals $\frac{11}{100}$ of an inch, or ·11 and the difference between a part of the scale and a part of the vernier is ·01 inch. In the figure the zero of the vernier is made to coincide, that is, to form one continued line with the division 30 on the scale, and consequently 10 on the vernier also coincides with 28·9 on the scale. Division 1 on the vernier is, from what we have said, ·11 inch below the zero of vernier, while the next lower division on the scale is only ·10 below it: hence the vernier division 1 is ·01 inch below the division 29·9 on the scale. For the same reason division 2 on the scale is twice as much, or ·02 below 29·8 on the scale, and so on, the divisions on the vernier overlapping those on the scale until 10 on the vernier stretches over to exact coincidence with 28·9 on the scale. Now suppose the vernier to be raised ·01 inch, it is evident that division 1 of vernier will coincide with 29·9 on the scale. If the vernier were raised ·02 inch, the vernier division 2 would coincide with 29·8 on scale; and so on; so that in order to read off the hundredths of an inch which the vernier zero advances beyond any tenth in the scale, we have merely to see what vernier division comes nearest to a division of the scale, and set that down for the hundredth required.

This is the form which was given to the vernier by its inventor, in which the parts of the vernier are larger than those of the scale, and in which the numbering of the parts of the vernier runs contrary to the numbering of the scale. But if, as in No. 2, the vernier has the length of nine divisions of the scale, and this is divided into ten equal parts, each part will be equal to ·09 inch, while the divisions of the scale are equal to ·1 inch. The vernier in this form is to be numbered *forwards*, as well as the scale. It is clear that raising the vernier ·01 will bring the division 1 of the vernier into coincidence; and so on, exactly as before; and, therefore that the inches and tenths being read from the scale, the hundredths are to be taken from the vernier. The reading both scales forward is some advantage in favour of the latter mode, while the size of the vernier divisions is larger, and consequently clearer, in the first. There might perhaps be some advantage in particular cases in uniting both verniers, as the reading would be made on two divisions and by two sets of independent subdivisions, but we do not remember to have seen this in actual use.

In modern astronomical and geodesical instruments the vernier usually reads forward. Sometimes, for greater compactness, the zero is placed in the middle of the vernier, and the graduation, after running on to the end of the vernier, is continued from the other end of the scale to the middle, and reads both backwards and forwards. There is a great liability to confusion in these verniers, which can only be avoided, at first, by guessing the value of the subdivision before reading the vernier. We prefer simple verniers, reading always forward with the zero at one end.

The ordinary subdivision in English instruments is to minutes, half-minutes, twenty seconds, and ten seconds. Thus if the circle be divided to 30′, and the vernier taken equal to 29 half-degrees, and then divided into 30, each part of the vernier will equal $\frac{29}{30}$ of 30′ or 29′, and the difference between a part of the circle and a part of the vernier be 1′. If the circle be divided to every 10′, and the vernier taken equal to 59 of these parts (=9° 50′), and divided to 60, each part of the vernier will be $\frac{59}{60}$ of 10′, that is, will be equal to 590″ or 9′ 50″, and the difference between a part of the circle and a part of the vernier be 10″. This division is legible in circles of 8 inches diameter. In circles of 18 inches diameter we should still adopt the same division, as it is easy to estimate the difference, and less fatiguing to read an open division than a crowded one.

The continental artists generally make one circle turn closely, but freely, within another, and nearly in the same plane, as we have seen was directed by Vernier. The reading is much more pleasant and exact in this way. Troughton objected to it, that if a particle of dust should get between the circles it would necessarily grind and tear the edges of the circles, leaving a muddy and ragged ditch between them. We do not know whether this objection is confirmed by experience. The English artists generally place their verniers on thin plates which move upon the divided circles. There is some chance of rubbing, and a certainty of wearing, if the verniers press on the circle; and if they stand off from it they are awkward to read, with a chance of considerable error from parallax. The subdivision by the vernier seems to be preferred by the German artists in general to that by micrometer microscopes, which are in England universally applied to large meridian circles, and indeed to all considerable instruments where the fixing of the microscopes is not subjected to a varying effect of gravity. On the side of the verniers may be pleaded cheapness, and freedom from changes, such as those which the scale of a microscope suffers when the distance between the limb and the object-glass of the microscope, or the body of the microscope itself, from expansion or other cause, is altered. On the other hand, the micrometer microscope certainly admits greater magnifying power, keeps the observer away from the instrument, can be fixed with greater firmness, and remains more steady. It is not easy to fix a vernier firmly without running the risk of affecting the motion of the circle. On the whole we prefer the micrometer microscope, although it must be admitted that the perfection which the continental artists give to the centering of their circles and verniers may well cause a difference of opinion. For small instruments, and those which, like the declination circle of an equatorial, are placed under different strains in different positions, the vernier is indispensable.

There is difficulty very often in getting the proper light on the divisions. It is desirable that those of the vernier as well as those of the limb should appear sharp and black, and the divisions before and after that which is nearest to coincidence should be scrutinised in order to estimate the decimal or fraction which is wanted for perfect coincidence. A more perfect setting will generally be obtained by making the divisions before and after the coincident division equally discordant, than by attempting to get a perfect coincidence. The observer should be careful to view the divisions directly, and in the centre of the magnifier, or he will have an error arising from parallax which may be considerable.

The truth of a vernier in one respect, that of its embracing a proper portion of the limb, may be tried in different parts of the limb. If the circle be very excentric this may give a little trouble at first, and be confounded with bad division. In ordinary cases, however, if there are opposite verniers, and their extreme divisions sometimes overlap and sometimes fall short of the corresponding portion of the limb, the mean will be true although the excentricity is sensible. The number of verniers may be either two, three, or four, at equal distances. Two are absolutely necessary to get rid of excentricity, and three or four will also nullify any error, original or superinduced, which gives the circle an elliptic form. But it is not easy in all cases to apply these readings conveniently, and the fatigue of many readings is scarcely recompensed by a little superior accuracy, at least in well-made and well-divided instruments which are carefully handled.

VERSED SINE. [TRIGONOMETRY.]

VERSION. The word version, or translation, is used to express the transferring of some written composition from one language into another. Like many other terms, translation cannot be briefly defined: the notion of translation must be attained by a consideration of all the conditions of translation; and the right understanding of its nature involves a part of the general theory of language.

If two languages corresponded perfectly; if every term in the one language had its equivalent in the other; and if the forms of speech in the two languages were also perfect equivalents, the difficulty of translation would not be great. It would only be necessary to discover the equivalent terms and the equivalent forms of speech in the two languages, and translation would be effected by mere substitution. In this supposed case, as the terms and the forms of expression would be perfectly equivalent, a person who should read the translation would understand it exactly as a person would understand the original; for the supposition of the two languages being perfect equivalents involves the supposition of the objects of thought and the mode in which their relations to one another are viewed being the same for the people who use the two languages. Now no two languages have this perfect equivalence of terms and forms of speech, and therefore a perfect translation cannot be made.

The general distribution of words into notional and relational words is explained in the article NOTION. In no two languages are all the notional words perfectly equivalent. Such words as express many of the ordinary objects of sense, as sun, moon, man, woman, are perfect equivalents; but all the words which express objects of sense in one language have not their equivalents in another. Various nations have various articles of dress, various utensils, implements, and ornaments which are peculiar to them, and consequently have not their equivalents in another language. If such terms are rendered by some other term in the language into which the translation is made, the translation will not convey the exact notion of the original, though it may come near enough for many purposes. In some cases the difference is immaterial, as may be shown by instances; in others the difference is material. The Latin words "domus" and "navis" may be respectively rendered by the English "house" and "ship," though Roman houses and ships differ considerably from English houses and ships. But if the word "domus" is merely used to signify the general notion of a dwelling for man, as for example, when one wishes to say that a "man was killed in a house and not in the street," the precise difference between Roman houses and English is immaterial, for house in such case is used in its most general sense. But if in the original Latin passage anything turned on the difference between "domus" and "villa" as opposed to one another, then, unless the English language possessed two words which should stand in the same opposition to one another as "domus" and "villa," a translation could not be made simply by equivalent terms: it must be effected in some other way. Material objects then, for which there may be equivalents in two languages when the object is used in its most general sense, may not have equivalents in the two languages when used in this special sense. Thus the Latin words "patera," "urna," "lanx," are words which express the general notion of a thing that is used to contain other things; but as they are also used to indicate a particular kind of containing vessel, there can be no translation of such terms unless we have both the things and the name for them. It appears then that, even in the case of such ordinary things as domestic utensils, a translator will often be at a loss to find a word equivalent to the original word; and he must either find a word which comes the nearest to it, or he must adopt the original word. In the one case he will not convey an exact notion to the reader, and he may convey a very erroneous notion; in the other he will convey none at all, unless the reader happens to know the thing intended by the term in the original language. The context may often help to the right understanding of a term, but that is not the matter at present under consideration.

The terms which denote the political and religious institutions or usages of a country often present still greater difficulty. The Roman terms "Ædilis," "Consul," "Comitia," "Tribus," "Judex," "Pontifex," "Augur," cannot be rendered into our language by any equivalent terms. In these and many similar instances it has become usual to adopt the original term, with the termination sometimes slightly altered, and the reader of such translations is supposed either to know what these terms mean, or to have books which will explain them. This is in fact the only practicable mode of translating such terms, and such translation is not liable to more objection than a book in one's own language which contains numerous technical terms, the explanation of which is not given in the book, and cannot be got from the context, but must be sought for in a dictionary or work of reference.

If the original language has been more cultivated than the language into which the translation is made, the translator will find that he is ill provided with terms equivalent to those of the original. Foreign works on jurisprudence or philosophy, when translated into English, present this difficulty, which can only be overcome by adopting the technical terms of the original language. If the translator were to attempt to make names which should correspond to the original terms, he would not be so likely to succeed in getting them adopted as by transferring the original terms into his translation.

That part of translation then which consists simply in finding equivalent notional terms is limited. It depends on the character of the two languages, the original and that of the translation, how far equivalent terms can be found. In all matters which characterise the usages of a people, it is impossible to find equivalents in two languages, for by the term character is here meant something which each has and the other has not. As to all terms which are the expression of universal notions, such as are in a great degree independent of the character of a people, those languages which have been cultivated to an equal degree do possess terms which are sufficiently equivalent. But even here there is often a very great difficulty in ascertaining the equivalent terms, as any one may satisfy himself by attempting to translate into English such a work as Cicero's treatise on the Orator, or some parts of Tacitus.

Perhaps it is often easier to translate from one language into another when the two languages have no historical connection, than when they are related as original and derived languages, or as languages which have interchanged terms, or where the exchange has been all on one side; for it often happens that words which are transferred from one language into another retain nearly the original form, and yet have either been adopted in a different sense from the original sense, or have in course of time acquired such different meaning. It would be easy to find numerous examples of such change of meaning in words that have been introduced into the English either directly from the Latin or through the medium of other languages.

The union of notional words into connected speech or language is effected by the words of relation, which are either appendages added to words, or separate small words, or both; and it is also effected by the order of the words. Now the words of relation and the order of words differ considerably in most languages, and hence arises a great difficulty in translation; for language consists not of single words, no more than a ship consists of trees: in the case of language and a ship, words and timber are materials, but materials without form have no significance. Yet in everything the nature of the material is an element in the capacity for receiving form; and in language the possession or absence of case-endings, and of suffixes which show the modifications of words, called mode and tense, materially influences the capacity of the language for expressing a given idea with perspicuity, brevity, and force: it also materially affects the possible order of the words. Those languages which possess case-endings and verbal terminations in abundance can vary the order of the words in a great number of ways, so as to place particular words in those positions where they shall be most effective. A language like the English, which, in its present form, has few suffixes, is much more limited in this power than the German, the Greek, and the Latin. Languages also differ greatly in the number of small words (relational words) which are adapted to express the relation of notional terms to one another. Some of the more delicate colours which are thus expressed in one language are absolutely incapable of being expressed in another by any corresponding relational words, and sometimes they cannot be expressed by any combination of words.

It will now not be difficult to ascertain in a general way what can be effected in a translation, and what ought to be attempted. Some people have had a notion that a translation should be literal, or near to the original, by which it is meant that every word of the original should have its equivalent in the translation, or nearly so. There is no objection to this, so far as it can be done consistently with the proper idioms of the translator's language; yet such a translation is not commendable because it is literal, but because it is true. The idiom of the translation must not be corrupted by an imitation of the idiom of the original. If what is called a literal version is a sufficient version of the meaning, and if it is also expressed in a true idiom, the translation is good; but its literal character is a mere accident. It will depend both on the character of the two languages and on the character of the original work how far the version shall in its form correspond to the original. Simple narrative is generally easily rendered from one language into another without varying much from the form of the original. Works which have more of an artistic character present greater difficulties, whether they are historical, critical, or poetical. Poetry presents the greatest difficulties, because, in addition to the general difficulty of transferring the meaning of one language into another, there is the difficulty of reproducing the rhythmical form of the original, and this is sometimes impossible. Horace succeeded in introducing the Greek lyric metres into the Latin language in his translations or imitations; but Horace was a master of his art, and he had a language which was sufficiently near to his original. The translations of Voss from the Greek and Latin poets have the advantage of being in a language which, from its copiousness, its grammatical forms, and its capacity of combining words, renders such an undertaking practicable in skilful hands. The English language has copiousness and energy, but less flexibility than the German, and the imitation of the rhythmical forms of other languages is sometimes impossible in an English version; and without this imitation the translation of poetry is incomplete, for the metrical form is a part of poetry. It is indeed often as easy to express in a prose translation the ideas of poetry as those of prose composition, for the essential qualities of poetry are not destroyed by reducing it from its metrical into a prosaic form. In this form it may still fill the mind with the images of the original, but it will not equally affect the passions; for the passions are most vehemently moved by direct sensuous impressions, and the sensuous character of poetry is its metrical form. All attempts therefore at poetical translation from one language into another can only be partially successful unless the character of the two languages admits of a perfect metrical imitation in the translation.

A translator should show his judgment by the choice of his subject as well as by his manner of handling it. He will not choose what is incapable of being rendered adequately. He will not attempt to fashion his form of expression to that of the original by doing violence to his own idiom. He will neither servilely follow the division of sentences nor the forms of expression. He will labour to penetrate through the author's language to his meaning, and he will then strive to express that meaning in his own language. He must rigidly scrutinise the result of his labour, to see if it conveys the same meaning as the original, and neither more nor less. When this is accomplished, his translation will be sufficient, though it may not be perfect. It will be all that a translation often can be—a sufficient copy of the original.

But there may be something wanting. Every writer has peculiarities which constitute his style. One writer is sententious, compressed, and energetic, but perhaps obscure; another is diffuse, flowing, and redundant, but fills the ear more than the mind; a third may be perspicuous and simple, but withal feeble. Now a translator who should so far mistake his original as to give a diffuse version of a sententious writer, or to express any original in a form which should be altogether unlike it, would show that he had ill appreciated the writer's character, and this would not be the only blunder that we might expect from him. A version of a prose writer which should possess a general character altogether unlike the original, would as little merit the name of a translation as a dull prosy version of the 'Iliad' would deserve the name. To fix a true medium between a close imitation of the style of the original and a wide departure from it, belongs to that department of the business of translation in which taste is concerned. It is something wherein precise rules can never be laid down, and yet the best critics will not disagree in their judgment. It is a gross error which we see in some attempts to translate Tacitus, to reproduce the original with all its obscurity and brevity: it is a grosser blunder to weaken his sententious energy by a profusion of words, many of which, being impertinent and idle, only form a stronger contrast with those of the original, which have been selected and arranged with studious care.

Like portrait-painting, translation has only one rule, and that not a rule which shows us how to act, but only prescribes a certain end. Make your copy like the original: let no man mistake it. Many copies may be made, and all may be pronounced to be likenesses. Compare the likenesses with one another, and you will find one which shall be more like than the rest. Ask the master how he made it: he will say that he copied the original; but how he did it you cannot understand, nor can he say.

VERTEX, a name given to any remarkable or principal point, particularly when that point is considered as the top or summit of a figure. Thus we have the three vertices of a triangle, the vertex of a cone or pyramid, &c.

VERTICAL. The zenith being considered as a vertex, which in fact it is, when the word vertex means summit, a vertical plane is one which passes through the line drawn from the spectator to his zenith; a vertical plane therefore merely means one which is perpendicular to the horizon, and a vertical line has the same meaning.

VERTICAL, ANGLE OF THE. A name given to the angle made by the diameter through any point of the earth, supposed a spheroid, with the direction of gravity at that point, or the perpendicular to the tangent plane.

VERTIDINE. A base, not yet analysed, contained in shale tar.

VERTIGO, or giddiness, is a peculiar sensation depending probably on some disturbance of the circulation in the brain. It need not be described, for whoever has not felt it may do so at once by turning round a few times rapidly. The nature of the change produced in the brain by the numerous causes of giddiness is altogether unknown; probably the sensation may be the result of several different conditions, for it ensues alike when the pressure of the blood upon the brain is diminished by bleeding, and when it is increased in plethora, or what is called determination of blood to the head: it is a sign too as well of deficiency of food as of repletion; and of the various continued movements by which the steady flow of blood through the brain may be disturbed, though the rotatory motion is the most general cause of giddiness, yet the movement of the head backwards and forwards or from side to side will produce it as effectually, and the vertical movement, such as is endured in the pitching of a ship, more certainly still. At present therefore it must be concluded that whatever disturbs the movement or the pressure of the blood within the brain may produce giddiness; and that in some cases it occurs without any cause of this kind, as a sympathetic or purely subjective sensation, dependant on the state of the substance of the brain itself.

As a sign of disease vertigo by itself indicates very little. No judgment can be formed from it except by taking it in connection with the other characters of the affection of which it is a part, and these will generally be sufficiently indicative. Its most common cause is some disturbance of the digestive organs, and it may be safely treated in that view, except in those who are prone to apoplexy or other cerebral disease, in whom it must be always regarded with fear.

VESICANTS. [BLISTERS.]

VESTA. [ASTEROIDS.]

VESTA (Ἑστία or Ἱστίη, Hestia, or Histiē), one of the great divinities of the ancients, and common both in name and mode of worship to the Greeks and Romans. According to Hesiod, she was the first-born daughter of Kronos and Rhea, and sister of Zeus, and the Romans therefore made her the daughter of Saturn and Ops. She was a maiden divinity, and was said to have vowed eternal virginity by the head of Zeus.

Vesta was the goddess of the hearth; and as the hearth was with the ancients the centre of the family, where the members met, conversed, and took their meals, Vesta was regarded as the goddess of domestic union and happiness. Strangers and friends were hospitably received at the hearth; suppliants sought safety and protection there; and there the members of a family swore fidelity to one another. The fire burning on the domestic hearth, the symbol of domestic union, was also regarded as the symbol of Vesta herself. As according to the notions of the ancients the state was formed on the model of a single family, each political community, city, or state had its public hearth or altar of Vesta, on which a perpetual fire was kept burning. At Athens the public hearth of Vesta was in the Prytaneum, and here the guests of the state and foreign ambassadors were received and hospitably treated. The public hearth was to the members of a civil community what the domestic hearth was to the members of a family; and when a state sent out colonists, they took from the public hearth of the metropolis the fire which was henceforth to blaze on the public hearth of the colony. Larger communities than a mere town or city had likewise their public hearth and centre of union. Thus the common hearth of the Greeks was at Delphi, and that of the Latins at Lanuvium, the metropolis of the Latins. Later speculators and mystics extended this idea even farther, and spoke of a central fire or a common hearth of the earth and the universe. Vesta, as the protectress of the family, is intimately connected with the Penates, and she herself is sometimes called a Penas or Dea Penetralis. Her connection with the house led some ancients even to ascribe to her the art of building houses.

In Greece, Vesta had very few temples, because every house and every prytaneum was regarded as her sanctuary, and because she had her share in all the sacrifices which were offered to other gods; and at all sacrificial feasts the first and last libations were offered to Vesta. But at Hermione in Argolis she had a special temple, though, like her temple at Rome, it contained no image of the goddess. The sacrifices offered on her altar consisted of seeds, fruit, libations of water, oil, or wine, and of young cows.

Æneas was believed to have brought the sacred fire of Vesta together with the Penates and the Palladium from Troy to Italy; and at Rome the worship of Vesta was said to have been introduced by Romulus or Numa. Her worship at Rome was of much greater importance than in Greece. Her temple, which was of a round form, stood in the forum near that of the Penates; it was open during the day and closed by night. According to Ovid's description, its walls consisted in the earliest times of wicker-work, and the roof of reeds. The temple contained the altar of the goddess with her sacred fire, the extinction of which was regarded as an omen of the greatest calamity to the republic, and priestesses (at Athens and at Delphi widows, and at Rome virgins) were appointed to keep the fire alive. With the exception of the Pontifex Maximus, no male being was allowed to enter the temple of Vesta; and hence we never hear of the senate meeting in it as in other temples. The Roman prætors, consuls, and dictators, on entering upon their offices, had to offer sacrifices to the Penates and to Vesta at Lanuvium. Representations of Vesta in works of art were not frequent in antiquity, as she was worshipped in the form of the sacred fire burning on the hearth. But some are mentioned by Pausanias and Pliny, and she was represented in the grave and dignified attitude and expression of a majestic and pure maiden, with the attire and veil of a matron, and holding in her hand a sceptre or a lamp.

(Hartung, *Die Religion der Römer*, ii., p. 111, &c.; R. H. Klausen, *Æneas und die Penaten*, ii., p. 624, &c.; Müller, *Arch. der Kunst*, § 362; Hirt, *Mytholog. Bilderbuch*, i., p. 70.)

VESTAL (" Virgo vestalis," ἑστιάς), a priestess of the Roman deity Vesta. The number of these priestesses, according to the regulations of King Numa, was four, two for each of the ancient tribes. Servius Tullius, or, according to others, Tarquinius Priscus, added two more, to represent the third tribe, or Luceres. In the earliest times they were chosen by the kings, but afterwards by the Pontifex Maximus, who had the especial superintendence of everything connected with the worship of Vesta. At first the selection seems to have been left to his discretion, but subsequently, whenever there was a vacancy in the sisterhood, he drew by lot one out of twenty select virgins in the assembly (in concione). It might happen that a parent offered his daughter, though this seems to have been the case very rarely. After the lot was drawn, the Pontifex took hold of the virgin, as if she were a prisoner, and having pronounced a certain solemn formula, he conducted her to the atrium of Vesta. Parents could only oppose their daughter being thus taken from them and devoted to the service of the goddess, in three cases: first, if one of her sisters was already a vestal; secondly, if the parents had no more than three children; and, thirdly, if the father held one of certain high priestly offices. In these cases parents were exempt from the obligation of allowing their daughter to become a priestess of Vesta. The conditions, on the other hand, on which alone a virgin could be made a vestal were—1, that her father was not carrying on a disreputable occupation; 2, that her parents were free and free-born, and settled in Italy; 3, that both her parents were alive; and, 4, that she was neither younger than six nor older than ten years. From the moment that a vestal virgin was chosen and taken to the atrium of Vesta, she was emancipated from her father's power; she required no patron in any court of justice, and had the right to dispose of her property by testament; and if she died without having made a will, her property fell to the republic. A vestal virgin, if once appointed, was obliged to serve the goddess for thirty years. The first ten years were a period of noviciate, during which they received instruction respecting the various duties that they had to perform. Then followed ten years during which they were allowed to perform all the functions of their office; and during the last ten years they instructed those who were going through their apprenticeship. After the expiration of the thirty years they might, if they liked, unconsecrate (exaugurare) themselves, and might marry. This, however, happened very seldom: it was considered unlucky for vestals to marry. The habits which they had acquired during their priesthood generally induced them to continue in the service of their goddess for life. These virgin priests enjoyed at Rome the highest distinctions. When they went out a lictor walked before them; prætors and consuls when they met them lowered the fasces, and any criminal whom their eye caught sight of was immediately set free. In the theatres honorary seats were set apart for them. Augustus however prohibited their being present at the athletic games. Nero, on the other hand, abolished this law, and permitted them to be present, on the ground that the priestesses of Ceres were allowed to be present at the Olympic games. They had an official residence on the Via Sacra, and salaries derived from estates of the goddess, which were increased from time to time. A vestal virgin was considered to be of the same rank as the Flamen Dialis, and in a court of justice she could not be compelled to confirm her evidence by an oath. Their prayers were believed to be of particular efficacy, and wills and important documents were often intrusted to their keeping. They had also the privilege of being buried within the pomœrium.

The duties of the vestals were to keep the fire on the altar in the temple of Vesta burning, to guard the sacred relics and symbols preserved in the temple, to sprinkle the temple of the goddess every morning with water from the Egerian well, and various other things connected with the worship of Vesta. Besides the functions directly connected with the worship of Vesta, they had to perform in the course of the year various others. Thus, for instance, they conducted the mysterious worship of the Bona Dea on the first of May, and had to prepare the sacrifice to be offered on certain occasions. If ever the sacred fire in the temple of Vesta became extinct by the carelessness of a priestess, the neglect was atoned for by sacrifices, and the guilty vestal was scourged by the Pontifex Maximus on her naked back. The fire was not rekindled from a common fire, but from one produced by the Pontifex by the friction of two pieces of wood, or from the rays of the sun by means of a burning-glass, and the vestal caught it in a brass sieve by means of tinder, and thus carried it into the temple. On entering on the priesthood every vestal had to make a solemn vow to keep her chastity pure, like the goddess whom she served, during the years of her priesthood. A breach of this vow was regarded as a terrible crime and as a fearful calamity to the whole state. When a vestal was found guilty by the college of pontiffs, she was condemned to death without having the right of appeal to the people. As nothing but death could atone for her crime, and as it was nevertheless not allowed for any mortal to lay hands on the priestess of Vesta, she was buried alive in a subterraneous vault in the Campus Sceleratus, near the Colline gate. The mournful solemnity on such occasions was this. The guilty vestal was laid on a bier, tied fast with leather thongs, and covered in such a manner that not even the sound of her voice could be heard. In this position she was carried, as it were, in a funeral procession, accompanied by her friends and relations, amidst the dead silence of all the people, to the place of execution near the Colline gate. On her arrival here she was relieved of her bands, the Pontifex Maximus with uplifted hands said a mysterious prayer, and then conducted the veiled vestal to the ladder which led into the tomb. The executioner took her down and drew up the ladder; and during this process the pontiff and the other priests turned away their faces. In her tomb the vestal found a couch, a lamp, and some bread, water, milk, and oil. The tomb was closed and covered over with earth to a level with the rest of the ground. The man who had seduced a vestal was scourged to death. Notwithstanding the severity of the punishment, Roman history has on record several instances in which the punishment was inflicted. During the time of the republic the violation of chastity on the part of a vestal was always visited by the punishment prescribed by law, unless the goddess herself interposed in some miraculous manner to show that her priestess had been unjustly charged with the crime. Several interesting instances of this kind are related by the Roman historians. During the early part of the empire the conduct of the vestals appears to have become rather loose, since Domitian found it necessary to make the law concerning it more strict.

(Lipsius, *De Vesta et Vestalibus Syntagma*; Hartung, *Die Religion der Römer*, ii., p. 115, &c.; Göttling, *Geschichte der Römischen Staatsverfassung*, p. 189, &c.)

VESTED REMAINDER. [REMAINDER.]

VESTRY is the name of that part of a parish church where the ecclesiastical vestments are kept; and inasmuch as meetings of parishioners have been usually held in this part of the church for parochial purposes, such meetings, duly convened, have acquired the name of vestries; so that even where a building remote from the church has been erected for parochial meetings, it is usually called the *vestry-room*. When the meeting is held in the church, or even in a building within the precincts of the churchyard, the ecclesiastical courts claim jurisdiction over the conduct of the parishioners.

By the common law all rated inhabitants of a parish have a right, either periodically or when specially convened, to meet in vestry for the affairs of the parish, and to vote the necessary pecuniary rates. But this common law right has been modified in many ways.

1. By custom, which has vested the government of some parishes in a select and usually a self-elected body of persons, probably the successors of individuals to whom the parishioners at some previous time delegated the management of their parish for a stated period, but who, by the indifference and neglect of their constituents, came to hold permanently the powers intrusted to them. The principal act for the regulation of these vestries is the 58 Geo. III., c. 69, but it does not extend to parishes within the city of London or borough of Southwark.

2. The act 10 Anne, c. 11 (for the purpose of erecting fifty new churches in London and its neighbourhood) appoints "a select vestry for each parish." The 59 Geo. III., c. 134, also permits the election of a select vestry out of the "substantial inhabitants of the district," parish, or chapelry; and several local acts have also created vestries.

3. The 59 Geo. III., c. 12 (Sturges Bourne's Act), enables general vestries to appoint special vestries for certain purposes; but they are little more than committees of the general vestries, to which they are responsible.

4. A fourth kind of vestry is created by 1 & 2 Wm. IV., c. 60 (Sir John Hobhouse's Act), but the adoption of this act is left to the discretion of each particular parish; rural parishes of less than 800 rated householders being excluded from its operation.

It is the duty of vestries to provide funds for the maintenance of the edifice of the church and the due administration of public worship; to elect churchwardens; to present for appointment fit persons as overseers of the poor; to administer such estates and other property as belong to the parish; and in some cases, under local acts, to superintend the paving and lighting of the parish, and to levy rates for those purposes.

The remedy for neglect of duty by a vestry is a *mandamus* from the Court of Queen's Bench, directed to the officer whose duty it would be to perform the particular act, or in some cases by an ordinary process against him, or by a process against the churchwardens out of the ecclesiastical courts.

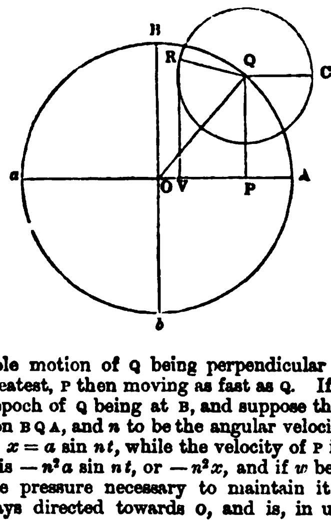
VIADUCT. A bridge erected over a valley, for the purpose of avoiding the necessity for carrying a roadway either by long inclines, by zigzags, or by precipitous descents, from a high level on one side of the hills bounding the valley, to a corresponding height on the other side. The conditions under which it is advisable to incur the expense of such a work, are principally when the annual cost of the traction upon the additional length of the inclined roads would exceed the interest upon the capital invested in the construction of the viaduct, added to the cost of its repairs; or when the rate of inclination of the roads is such as to render economical traction impossible. In roads designed to accommodate rapid traffic, for instance, inclines of 1 in 12 are inadmissible under any circumstances, and inclines of 1 in 30 are objectionable; but in either case the construction of a viaduct for the purpose of obviating the necessity for the incline must depend upon the number of the carriages likely to resort to it. In railway structures viaducts are more commonly employed than in common roads, on account of the greater influence of the inclinations of the roadway upon the traction; but even in them the use of viaducts can only be justified by considerations of economy.

In the article BRIDGES will be found a summary description of the dimensions of the most celebrated viaducts hitherto constructed. The principles upon which they are built have been discussed either in that article, or under ARCHES. It may suffice, therefore, here to add, that the skill of the engineer may be as usefully displayed in the execution of an embankment for the purposes of the roadway as in the construction of a monumental viaduct; and that the repairs of the former would be in all probability much less than those of the latter. The Highgate Archway, the North Bridge at Edinburgh, the Dee Viaduct near Chirk, the Crumlin Viaduct, the Aricia, Barentin, Chaumont, Dinting Vale, Elsterthal, Goeltzchthal, Malaunay, Ouse Valley, Portage, Tyne, viaducts, may be cited as the most remarkable works of this description.

VIBRATION. We have had in many articles to consider the effects of vibratory motions, but we have not yet given the explanation of the simple vibration, so as to enable a student with no very extensive knowledge of mathematics to form some conception of its character. The theory of the vibrations of the particles of an elastic fluid is the key to what is known of the phenomena of sound and light [ACOUSTICS; UNDULATORY THEORY]; and there is some reason to suspect, or at least those whose opinions are worthy of attention have suspected, that the causes of the sensible phenomena of heat, electricity, and magnetism will also be found in the vibrations of matter of some kind. All the particles of material bodies, even when solid, are probably in continual vibration; and it is certain that very slight disturbances will communicate sensible amounts of vibration to considerable distances, and this through all manner of different substances, from loose earth to compact stone, and through those in every kind of state, from the aëriform to the solid.

Little as may be known of most of the vibrations which are perpetually occurring, nothing is more certain, from the fundamental laws of mechanics, than that every such vibration in every individual particle is either made up of one or several motions of one particular kind, or of an exceedingly close approximation to such simple motion or combination of motions. It is not merely swinging backwards and forwards which constitutes a vibration; such a motion might certainly be so called, at the pleasure of any one, but another name must then be invented to designate that particular sort of vibration of which, and of no other, we have to speak in the first instance. The piston of a steam-engine, for example, when it is forced upwards with continually accelerated velocity until it strikes the top of the cylinder, and is then forced downwards in the same manner, does not show what is mathematically called a vibration; but take one of those more recent constructions, in which the steam is checked as soon as the piston has acquired momentum enough to carry it to the top of the cylinder, so that the force is nearly spent before it begins to return, and we have something to which the term vibration is much more nearly applicable.

The simple vibration, of which we have said all others may be compounded, is best imagined as follows:—Let a point Q revolve *uniformly* round a circle A Q a b, and from Q draw Q P perpendicular to A a. Then P moves over A a in the manner of a simple vibration; the whole vibration being from A to A again. At A and a the velocity of P is



extinct, the whole motion of Q being perpendicular to A a; but at O the velocity is greatest, P then moving as fast as Q. If we measure the time t from the epoch of Q being at B, and suppose the motion of Q to be in the direction B Q A, and n to be the angular velocity of Q, we have (O P $= x$, O A $= a$) $x = a \sin nt$, while the velocity of P is $na \cos nt$, the acceleration of P is $-n^2 a \sin nt$, or $-n^2 x$, and if w be the weight of a particle at P, the pressure necessary to maintain it in this state of vibration is always directed towards O, and is, in units of the same kind as w,

$$\frac{n^2 x}{32 \cdot 1908} \times w,$$

if x and a be measured in feet, n in theoretical angular units [ANGLE], and t in seconds [VELOCITY]. If T be the number of seconds in the whole vibration from A to A again, we have $n = 2 \times 3 \cdot 14159 \div$ T, and the pressure is $1 \cdot 2264\, xw \div$ T^2. The pressure, it appears, requisite to maintain a simple vibration must be always in a given proportion to the distance of P from O, and always directed towards O; and the relation between the pressure at a given value of x and the time of vibration is wholly independent of a, the *excursion* of the particle. For the mechanical reason of this property, see ISOCHRONISM. To form a more convenient expression, let N be the number of vibrations in a second, and let x be measured in hundredths of inches instead of in feet; then T $= 1 \div$ N, and for x we must write $x \div 1200$, which gives for the pressure $\cdot 001022$ N$^2 xw$. For example, if a particle vibrate only 100 times in a second, which is not much [ACOUSTICS], and have an excursion of one five-hundredth of an inch (N $= 100$, $x = \cdot 2$), the force of restitution at the extremity of the excursion is more than twice the weight of the particle. By this formula it is easy to get a just idea of the greatness of the molecular forces required to produce those vibrations which are constantly excited in sonorous and other bodies.

If we suppose a second vibration to be communicated to P, in the same line, *and of the same duration*, but whether of the same extent or not does not matter, the compound vibration is only equivalent to another simple vibration. Let a circle move with Q, and in that circle let a point (R) revolve uniformly, and let R V be perpendicular to O A. Then, while P vibrates about O, V performs a vibration in the same time relatively to P; or a spectator who does not see the motion of P, will see no motion in V except a vibration about P. Now it is easily shown that R not only describes a circle about Q, but also actually describes either a circle in space, about the centre O, or an ellipse, in the manner presently explained. And V, vibrating about P, which itself vibrates about O, does, if these vibrations be of the same duration, nothing but vibrate about O. Mathematically, this is easily obtained as follows:—Let the angles A O Q and C Q R (Q C being parallel to O A) be at some one moment a and β, and let O Q $= a$, Q R $= b$, and let the time be measured from the instant at which the angles are a and β. Then we have

$$x = a \cos (nt + a) + b \cos (nt \pm \beta),$$

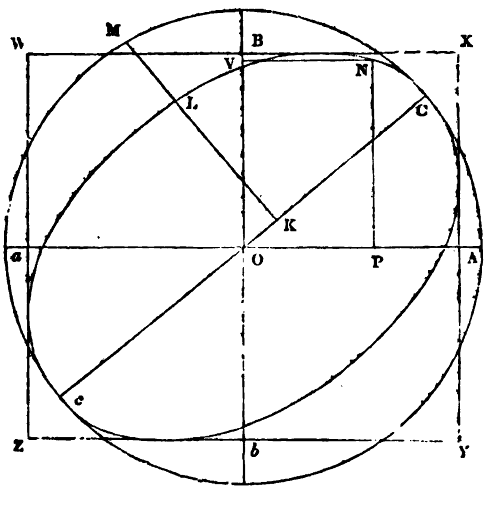
the sign + being used when the circular vibrations are in the same; − when they are in opposite directions. This is equivalent to $x = l \cos (nt + \lambda)$, provided l and λ be found from

$$l \cos \lambda = a \cos a + b \cos \beta \text{ , } l \sin \lambda = a \sin a \pm b \sin \beta;$$

and the joint vibration is one of the excursion l, and such that the angle is λ when the angles of the component vibrations are a and β. It is easy to show in like manner that any number of vibrations whatsoever, made in the same times and in the same lines, are not distinguishable from one single vibration, of the same duration and in the same line.

Again, it is easily shown that a vibration which is represented in direction and excursion by the diagonal of a parallelogram is the compound effect of two vibrations of the same duration, represented in direction and excursion by the two sides of the parallelogram, if the particles of the component vibrations begin to describe the sides at the same instant as the particle of the resultant vibration begins to describe the diagonal; and the same thing may be shown of the diagonal of a parallelopiped and its three sides. Hence any number of vibrations of equal times about any lines drawn through one point may each be decomposed into three in the direction of three given axes passing through that point, and those in the several axes may be compounded together into one. The student who appreciates the similarity of the laws by which velocities, pressures, and rotations are compounded and decomposed, will see that to the list must be added vibrations. But the only vibrations which bear the application of these rules are those of equal duration.

Let us now suppose that any number of vibrations of equal times, and about the same point, are reduced to three, in the directions of three axes of x, y, and z. When $a \cos \xi$ represents the distance of a vibrating particle from its centre of vibration, let the angle ξ be called the *phase* of the vibration. If the three vibrations be always in the same phase, the diagonal of the parallelopiped described on the three excursions represents the direction and excursion of the resulting vibration, which is simple and rectilinear. But if the simultaneous phases be not the same, so that $x = a \cos (nt + a)$, $y = b \cos (nt + \beta)$, $z = c \cos (nt + \gamma)$, represent the simultaneous distances in the three vibrations, and also the co-ordinates of a point which is affected by them all, the particle, thus triply vibrating, does not move in a straight line, but in an ellipse. Let us consider two vibrations in a plane, and let A a and B b be their double excursions about the common centre O. The axes in the figure are drawn at right angles, but any angle will do equally well. Draw the parallelogram W X Y Z, which always contains the particle, and suppose that P and V are contemporaneous positions in the two vibrations, whence N is one of the positions of the particle. Through N can be drawn two ellipses, having the centre O, and touching all the four sides of the parallelogram W X Y Z. The particle must describe one or other of these ellipses: one when P and V are both leaving the centre or both returning to it; the other when one is leaving the centre and one returning to it. In the figure, and supposing C N c to be the direction of motion, V is leaving, and P returning to, the centre. And if C M c be the circle described about



this ellipse, and K L M be always perpendicular to C c, the law of the motion of the particle L is that M moves uniformly round the circle, or K moves through a simple vibration. This is exactly the law of motion shown by Newton to obtain when the particle L is attracted towards O by a force which varies as its distance from O; and mechanical considerations might easily be used to establish the whole theorem. If the vibrations be thus compounded for each pair of axes, three ellipses are obtained on the three co-ordinate planes, which are the projections of the ellipse which the particle describes in space.

We may attempt to compound two different vibrations on the same line, that is, two vibrations of different durations. If in the first figure we suppose the angular velocity of R round Q to be different from that of Q round O, we see that R describes a trochoidal curve, and supposing such a curve to be described by uniform circular motions, the motion of the projection of R upon the line of vibration will show the effect of the two vibrations. Some simple instances may be readily obtained from the diagrams in the article cited; but an attempt at a description of the multifarious effects of even two vibrations would baffle all human power of classification.

We now proceed to some account of the principal mechanical considerations connected with vibrations. If any system whatsoever be slightly disturbed from a position of stable equilibrium, every particle makes an effort to return to that position; and it can be shown that the force of restitution varies as the distance from the position of equilibrium, so that all the particles perform either simple vibrations, or motions compounded of simple vibrations. Not that it is accurately and geometrically true that the force of restitution always varies as the distance from the position of equilibrium, but only exceedingly near to it. The consequence of the restitutive force is, that the system, in returning to its position of equilibrium, acquires velocity, and the several particles pass through or near to their positions of equilibrium with their several velocities, until the force of restitution, which begins to act in a contrary direction the moment the position of equilibrium is passed, destroys the acquired velocity, and causes the particles to return. The same vibration is then repeated, or rather would be repeated if there were no retarding forces: as it is, the resistance of the air, &c., continually diminish the extent of the vibrations, until at last they become insensible. But it can be satisfactorily shown that these resistances have no sensible tendency to alter the times of the vibrations; and few persons are aware how much of their comfort depends upon this circumstance. Whenever a sound is produced, a musical note generally accompanies it; the sound is the consequence of the vibrations excited in the disturbed system, and the permanency of its musical pitch is the consequence of these vibrations being all made in the same time, or very nearly so. The air does not retain the vibrations communicated to it, but passes them on, so to speak; and it is therefore an agent which communicates the successive vibrations of a disturbed body just as they are communicated to it. If the vibrations gradually slackened in their *times*, as they do in their excursions from the effect of the resistances, the consequence would be that there would be no sustained notes, but every sound would be a sliding chromatic descent, like the cry of some animals, which are therefore considered very annoying neighbours; and most musical instruments would be rendered unusable.

There is a principle in mechanics which is called that of the *coexistence of vibrations*, and sometimes the *superposition of vibrations*, which seems to be only a particular case of what might be called the coexistence or superposition of small changes of any kind. If a set of small vibrations be given to any system, solid or fluid, the disturbance of any particle at any one instant, arising from the united effect of the vibrations, will be the sum or difference of the disturbances arising from the several different vibrations, according as they are in the same or opposite directions. This is not strictly true in any case, but it is very nearly true when the vibrations are small, and the more nearly so the smaller the vibrations are. For instance, two stones are dropped into water at two different places, and at a certain time, on a certain part of the surface, the resulting waves cross one another. If there be a particle which is at the same time raised on both waves, a tenth of an inch say, from one only, and three-tenths of an inch from the other, that particle will altogether be raised four-tenths of an inch, or insensibly near to it. Thus the effects of the two waves travel without any apparent interference with each other, and the eye can easily follow any one wave, even though a dozen disturbances should have been excited at the same time. A handful of small pebbles thrown into smooth water will show the coexistence of the resulting waves very satisfactorily; and it is curious to observe how readily the non-interference of the several disturbances is seen when looked for, so readily, that it never is looked for unless the attention be specially directed to it.

VIBRATIONS OF HEAT. [HEAT.]

VICAR (from the Latin *vicarius*, "one who discharges the functions of another"). The origin, constitution, and functions of this class of ecclesiastical persons have been already fully treated of. [BENEFICE.] One part of the subject is alone omitted in that article, namely, the dissolution of vicarages. Of this it suffices to say that since the 13th Elizabeth, c. 10, the property neither of a vicarage nor of any other ecclesiastical office can be alienated, and that although a vicarage may be dissolved, as already described, by the vicar acquiring all the rights of the parson, yet the appropriator, whether lay or ecclesiastical, cannot dissolve the vicarage by alienating its property or by neglecting to present. A vicarage may be dissolved if the parson or appropriator presents the clerk to the benefice, whether by design or by accident: it may also be dissolved and become a parsonage, or, to speak technically, disappropriate, by the dissolution of the corporation to which the benefice is annexed. Thus if a college which is the appropriator of a certain benefice is dissolved, the vicar becomes entitled to the great tithes, and his vicarage is thenceforward converted into a rectory. [BENEFICE; TITHES.]

VICAR APOSTOLIC. [CATHOLIC CHURCH (Roman).]

VICARAGE. [VICAR.]

VIENNA LAKE. [COLOURING MATTERS.]

VIENNA, TREATY OF. [TREATIES, CHRONOLOGICAL TABLE OF.]

VILL. [TOWN.]

VILLEIN, or VILLAIN, denotes a species of bondman subject to his feudal superior. The word is from the low Latin form *Villanus*, which is from the Latin word *Villa*. In England, during the Anglo-Saxon period, a large part of the people appear to have been in a servile condition, either as domestic slaves or cultivators of the land. The power of the master among the Anglo-Saxons, though very extensive, had some limits. If a master beat out the eye or the tooth of his slave, the slave was entitled to his freedom; if he killed him, he paid a fine to the king, unless the slave lived a day after the wound was inflicted, in which case the offence was unpunished. The Norman Conquest did not materially alter the state of slavery in England. The lands were transferred to Norman masters, and the slaves passed as part of the property. After the Conquest there were four classes of slaves: 1, Villeins in gross, who were the personal property of their lords, and performed the lowest household duties. They were very numerous, and were frequently sold and even exported to foreign countries. (Walsingham, 'Hist. Ang.,' p. 258.) 2, Villeins regardant, or prædial slaves, who were attached to the soil, and specially engaged in agriculture. These were in a better condition than villeins in gross, were allowed many indulgences, and even, in some cases, a limited kind of property; yet the law held that the person and property of the villein belonged entirely to his lord, the rule being the same as that in the Roman law, that whatever was acquired through the slave was acquired by the lord. 3, A class called *Cottarii* is mentioned in Domesday Book; and 4, in the same book a class called *Bordarii*. But the first two classes in fact comprised all the villeins.

The legal condition of villeins in the reign of Edward IV., when Littleton wrote his Book of Tenures, appears from that work, Sections 172–208.

In England a few instances of prædial servitude existed so late as the reign of Elizabeth, and perhaps at a still later period. (Barrington, 'On the Statutes,' 274; Hallam's 'Middle Ages,' vol. i.) In some parts of France it existed down to the time of the Revolution. [SLAVERY.]

(Bracton; Littleton; Coke's *First Inst.*; Reeves, *Hist. of English Law*; Blackstone's *Commentaries*.)

VILLEINAGE was a base tenure of land. This tenure was founded on the servile state of the occupiers of the soil [VILLEIN], who were allowed to hold portions of land at the will of their lord, on condition of performing base and menial services. Where the service was base in its nature, and uncertain as to time and quantity, the tenure was called pure villeinage; but where the service, though base, was certain and defined, it was termed privileged villeinage, and sometimes villein-socage.

Villeinage is generally supposed to be the origin of copyhold tenure. [COPYHOLD; ENFRANCHISEMENT.]

VINCULUM, a name given in algebra to the line, brackets, parentheses, or other symbol, by which various terms are compounded into one, or supposed to be so compounded, in order that the result may be further operated on. As in—

$$\overline{a+b+c}\,x\ ,\ (a+b+c)\,x\ ,\ \{a+b+c\}\,x\ ,\ \&c.,$$

which are, by the vinculum, prevented from being confounded with $a+b+cx$.

VINE. [VINEYARD.]

VINEGAR, MEDICAL USE OF. [ACETIC ACID.]

VINEGAR-MAKING. Vinegar is a dilute acetic acid obtained by the vinous fermentation. [FERMENTATION.] In countries which produce wine, vinegar, as its name imports, is obtained from the acetous fermentation of wine; but in this country it is usually procured from malt, and the process employed resembles the first stage of the brewer's operations. [BREWING.] The malt is ground and mashed with hot water. The wort, after being cooled, is transferred to the fermenting tun, where, by the addition of yeast, it undergoes the acetous fermentation; and when this is over, the liquor is transferred to small vessels, which are kept warm by means of a stove: in this it remains for a shorter or longer period, according to the temperature of the stove and the strength of the liquor. The process of acetification is assisted by introducing into the casks with the wort what is called *rape*, the residuary fruit which has served for making domestic wines, or has been preserved by the vinegar-maker from one process to another in his own factory. The use of the rape is to act as an acetous ferment, and thus induce sourness in the wash, it being well impregnated with vinegar and continually kept sour. Acetification is sometimes carried on by transferring the wort, after it has undergone the vinous fermentation, into casks, the bungholes of which are left open and loosely covered with tiles; the casks are then exposed for a long time to the air. But the use of stoves has greatly superseded this mode, and has abridged the time of the operation and rendered it less liable to failure. The vinegar, after it has reached its greatest degree of sourness, is rendered clear and fit for use either by subsidence or the employment of isinglass. The manufacturer is allowed by act of parliament to mix $\frac{1}{1000}$ of its weight of sulphuric acid with vinegar; and what is termed by the Excise *proof vinegar* contains 5 per cent. of real acetic acid.

Vinegar may be prepared in small quantities from the fermentation of a solution of sugar mixed with yeast; or it may be obtained by the fermentation of various fruits: thus, the juice of good apples contains a sufficiency of sugar to afford tolerably good vinegar without any addition.

In France, vinegar is made from poor wine, and there are two kinds: the white, prepared from white wine; and the red, by the acetification of the red wine. These are finer flavoured and somewhat stronger than the malt-vinegar of this country.

Vinegar-works in this country are but few in number; they require a large amount of space and the investment of much capital. There are about half-a-dozen of them in the metropolis. At most of those in this country, as has been said, malt is the kind of grain employed; but the vinegar-maker holds himself free to the use of unmalted grain, if price and other circumstances should render it desirable, or saccharine substances instead of grain. From whatever substances the *gyle* is produced, the conversion of it into vinegar is managed nearly in the same way. Where the *rape* is not to be procured easily, the vinegar-maker uses wood-shavings, straw, or even tanners' spent bark; but the rape is so far preferable, that a large expenditure is sometimes incurred to obtain a sufficient quantity: hence the advantage of carrying on the "British wine" manufacture and the vinegar manufacture in the same establishment (which is sometimes done); refuse raisin-stalks and skins result from the making of raisin-wine. Vinegar is known by certain numbers, such as Nos. 18, 20, 22, and 24; these originally represented, it is supposed, the number of pence per gallon at which the vinegar was sold; and although the price no longer agrees with the numbers, they have been retained as designations for different kinds or strengths of vinegar. The quantity made in the United Kingdom is not now known; some years ago it was about 3,000,000 gallons annually.

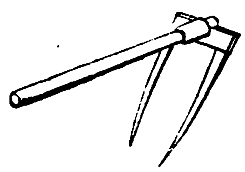
It may be well to remark that, in country districts, much vinegar, but of inferior quality and insipid flavour, is made by the aid of the singular substance known as the *vinegar-plant*. This substance is rather a scum than a plant. In Staffordshire, a vinegar-plant is thus produced:—About a quarter of a pound of sugar and half a pound of treacle are put into three quarts of water; the solution is simmered, poured into a jar, covered up, and kept in a warm corner for six weeks: an inferior kind of vinegar is formed, and on the top of it is a scum, with very much the appearance of tripe, constituting the so-called vinegar-plant. Vinegar can thus be made from a sweet liquor alone; but when a vinegar-plant is once produced, it greatly quickens the process of vinegar-making, without materially altering the proportions of the other ingredients. A gallon of vinegar is thus made at a cost of about sixpence. During the process the vinegar-plant thickens, by the formation of a new layer on the under surface; the two layers may easily be separated, and each will be available for a further process of vinegar-making, and this three or four times over. The substance is a kind of fungus, whitish in colour, semi-transparent, jelly-like, and sometimes an inch in thickness. In some country places strong pickling-vinegar is made by cottagers, by mixing cowslip flowers and stalks with sugar and water, adding a little yeast, closing it up, and allowing it to remain in a warm place for several weeks.

VINEYARD. The vine only thrives in particular climates, where the autumns are not excessively hot, nor the springs subject to late frosts. It has been observed in France, that the line which marks the northern boundary of the vineyards is not parallel to any circle of latitude; but that it lies obliquely, advancing more to the north on the eastern boundary of the country than on the western. It seems to depend more on the nature of the climate in spring and autumn, than in summer and winter. A hard frost at the time the sap is quiescent has no bad effect on the vine, but rather the contrary; while a late frost in spring disappoints all the hopes of the vine-grower. There was a time when the vine was cultivated in England for the purpose of making wine; but whether the climate is altered, or the foreign wines have superseded the sour home-made wines, no one now attempts to cultivate the vine except for the purpose of obtaining grapes for the table, and the mode of cultivation is a branch of horticulture.

It may however be interesting to know how the vine is cultivated in the countries which produce good wine; of which France is one of the principal and nearest in climate to England. The vine grows best in a soil where few other shrubs or plants would thrive, and it seems a wise distribution of Providence, that where there is the best soil for wine, there it is the worst for wheat, and *vice versâ*. The vine delights in a deep loose rocky soil, where its roots can penetrate deep into fissures, so as to insure a supply of moisture when the surface is scorched by the sun's rays. On the steep slopes of hills towards the south and sheltered from the north-east, the grapes attain the greatest maturity, and the vintage is most certain. So great an influence has a favourable exposure, that in the same vineyard the greatest difference exists between the wine made from one part and that made from another, merely because there is a turn round the hill, and the aspect varies a very few degrees. A change of soil produces a similar effect. The famous Rhine wine called Johannisberg, when made from the grapes which grow near the castle, is worth twice as much as that made a few hundred yards farther off. Here both soil and aspect change. The *Clos de Vougeau*, which produces the finest Burgundy, is confined to a few acres; beyond a certain wall the wine is a common Burgundy, good, but without extraordinary merit.

The best vineyards in Europe formerly belonged to monasteries, and the quality was then thought of more importance than the quantity: of late the demands of commerce have made the quantity the principal object; and to this the quality is frequently sacrificed.

When a vine is first established on any spot where none grew before, the first thing is to prepare the ground for planting. In steep places, where the soil might be carried away by rains in winter or spring, terraces are formed by building massive stone walls along the slope, and levelling the soil behind them. The walls serve to reflect the heat, and form a shelter to the vine below. Thus a whole hill is sometimes covered with terraces from top to bottom, and there the wine is generally good, if the exposure be favourable. Limestone, gravel, or coarse sand, with a small mixture of clay, forms a good soil for a vine; vegetable substances alone should be used to enrich it, such as the leaves and tendrils of the vine, the residue of the grape when pressed, and, failing these, the leaves of trees collected when green, and formed into a compost with earth. The ground should be well trenched, if it will admit of it, or loosened with the mattock and pickaxe. The different parts of the soil should be intimately mixed, keeping some fine earth or soil at top to set the plants in. When the ground is prepared, holes are dug in rows four or five feet wide, at the same distance from each other, so as to alternate; some of the finest of the soil is put into each hole, and the vine-plants, which have been rooted in a nursery, or else simple cuttings, are carefully inserted, pressing the mould round the roots and levelling the earth round them. Rooted plants will bear the second or third year, but cuttings take a much longer time. The season for planting is during the winter, when the weather is open. If cuttings are used, they are taken off the vine on which they grew at the usual time of pruning after the vintage; a piece of the preceding year's wood is left on the cutting, and when it is planted, the end where the old wood is left is bent or twisted to facilitate its striking: three or four eyes are buried, so that the end is a foot at least under ground. If the plant is already rooted, care is taken not to wound or bend the roots, but to spread them out and cover them with mould. During all the time that the vine is growing, the ground must be regularly cultivated and kept perfectly clear of all weeds. The usual instrument of tillage in stony and rocky soils is a two-pronged fork fixed in a short handle, at an angle less than a right angle with the prongs, which are a foot long, and very strong, like a double pickaxe (see figure, col. 631). This is struck into the ground and then drawn towards the workman, while the handle is lifted, which acts as a lever in raising the soil. The roots are by this means enabled to spread through the soil in search of moisture and food. The next year it is usual to prune the young vine down to one or at most two eyes or buds; but some experienced vine-dressers recommend deferring this operation to the second year, by which although the vine will not be so forward in



fruiting, it will be much strengthened, and fully repay the apparent loss of time in the end.

In the third year the vine is trained, that is, the shoots are tied to upright stakes planted at each root, or they are laid in an arch and tied from one root to another along the ground. In southern climates trees are planted at a certain distance from each other, and the vine, planted at their foot, is allowed to run up their branches, from which it is led in festoons from tree to tree, while the head and branches of the tree are cut off to prevent too much shade. This is by far the most elegant mode of training the vine; but in France the stakes and the low training are the only methods suitable to the climate. The pruning is generally done in the beginning of winter.

When vineyards are established in the plains, where sometimes, as those of Medoc, they produce very good wine, the intervals between the plants can be stirred by the plough, although forking and digging by hand is more common; hoeing is as necessary in a vineyard to destroy weeds as it is in a field of turnips or any other crop sown in rows. Wherever a vineyard is overrun with weeds, you may be sure that there is no good wine, and much poverty in the proprietor. The pruning of a vine in bearing, the object of which is to produce much fruit without weakening the plant, can only be learnt by experience and practice; much of the success of a vineyard depends on this operation. In the best vineyards no manure is used, except that which we mentioned before, of leaves and tendrils; but some soils require to be recruited, and without manure would produce little or no wine. In this case there is no alternative, and composts must be formed, as is done in common cultivation, with animal and vegetable substances mixed and decomposed. Manure from the cow-house should be mixed with virgin earth from pastures and meadows, and laid in small heaps in the intervals between the rows. It may be left a little while, if it have any rank smell, and then forked in round the roots; the more it is decomposed the better. Many a vineyard has lost its reputation after having been abundantly manured. The Johannisberg was much reduced in value, after having been dunged, while in the possession of General Kellerman.

After a certain time, which differs in different situations, the vine becomes less productive from the exhaustion of the soil, as is the case when the same crops are repeatedly sown in the same ground: this depends on the depth of the soils. All perennial plants shoot out their roots farther and farther every year in search of fresh earth, and it is by this means that trees flourish for a long time on the same spot; but if the roots are prevented from spreading, or, the plants being too crowded, their roots interfere, a diminution of vigour is the consequence. So it is with the vine. In some situations, where the roots strike in crevices of rocks in which rich earth has accumulated, the vines will continue in vigour for many years; but where their progress is arrested by a solid rock or substratum, they will in time show signs of exhaustion. In this case the remedy is the same as for land bearing corn. A fallow, or rest, as it is usually called, is necessary, together with the addition of such manures as shall restore the lost fertility. For this purpose a portion of the oldest roots are dug up every year, and the ground trenched or loosened two feet deep or more with the mattock, to expose it to the influence of the atmosphere. A compost is prepared with sods taken from pastures, or any virgin earth which can be procured; this is mixed with some lime and turned over several times, to rot all the roots and grass which may be in it, and to make it a uniform and rich mould. Holes are now made, exactly as when a new vine is planted, and in each of them a basket or barrowful of earth is thrown; in this the new plants or cuttings are planted to produce new vines in due time: thus the vineyard is gradually renovated. The proportion thus fallowed every year depends on the natural duration of the vine in that particular situation. In inferior soils one-seventh is thus renewed every year, in some a twentieth part is sufficient, and there are vineyards which have never been renewed in the memory of the present generation, but these are few in proportion to the rest.

Vineyards for several years past, and in almost every country, have been subject to attacks of the *Oidium Tuckeri*, a destructive fungus that has in many cases entirely ruined the vineyards. No perfect remedy has been yet found for the attacks of this fungus, but the most successful hitherto has been the sprinkling of the plants with powdered sulphur. [VITIS, in NAT. HIST. DIV.]

VINIC ALCOHOL. [ALCOHOL.]

VINOUS FERMENTATION. The process by which sugar, in the presence of yeast, is transformed into alcohol and carbonic acid. [FERMENT.]

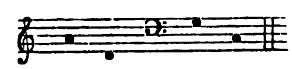
VIOL, an ancient musical instrument, which is traced back as far as the 8th century, and may be considered as the parent of all modern instruments of the violin family.

The Viol was a fretted instrument, of three sorts—treble, tenor, and base, each furnished with six strings, and played on by a bow. The Treble Viol was rather larger than our violin, and the music for it was written in the treble clef. The Tenor Viol was in length and breadth about the size of the modern viola, but thicker in the body, and its notation was in the soprana or C clef. The Base Viol scarcely differed in dimensions from our violoncello: the music for it was written in the base clef.

"Concerts of viols," says Sir J. Hawkins (iv. 339), "were the usual entertainments after the practice of singing madrigals grew into disuse; and these latter (that is, viols) were so totally excluded by the introduction of the violin, that at the beginning of the 18th century Dr Tudway was but just able to give, in a letter to his son, a description of a Chest of Viols. He tells us that it 'was a large hutch with several apartments and partitions in it, each lined with green baize. Every instrument was sized in bigness according to the part played upon it; the least size played the treble part,' &c. The humorous Thomas Mace, of Cambridge, in his 'Music's Monument' (p. 245), says, 'Your best provision (and most complete) will be a good chest of viols, six in number, namely, two bases, two tenors, and two trebles, all truly and proportionably suited. Of these the highest in esteem are by Bolles and Ross (one bass of Bolles' I have known valued at 100*l*). These were old; but we have now very excellent workmen, who (no doubt) can work as well.'"

VIOL DA GAMBA (or properly, *Viola di Gamma*), that is, the *leg-viol*, so called from being held between the legs, was the last survivor of the family of viols, and did not entirely fall into disuse till the latter part of the 18th century. In form and dimensions it resembled the modern violoncello, but had six strings. The tone was nasal and disagreeable, and the instrument is so thoroughly supplanted by the violoncello, that in all likelihood its restoration will never be attempted.

VIOLA, or TENOR-VIOLIN, a larger kind of violin, to which the part between the second violin and base is assigned. It has four gut strings, the two lowest covered with silver wire, which are tuned A, D, G, and C, an octave above the violoncello; or



VIOLA ODORATA, *Medical Properties of.* Though every part of the sweet-scented violet possesses some property which renders it useful, it is chiefly the qualities of the flower which entitle it to notice here. The petals possess a colour and an odour which render them useful. The former serves as a chemical test, the latter recommends the preparations to the sense of smell by its pleasantness. It is not always innocuous, as very sensitive persons have sunk under its influence. Violets should not be kept during the night in sleeping-rooms.

The petals may either be employed fresh to form a syrup, or preserved dry, and used when required. The drying must be carefully performed, to preserve the colour, and afterwards kept in the dark, either in bags of thick brown paper, or bottles lined with paper. The syrup is used more as a chemical test, to show by the action on its colour the presence or absence of acids or alkalies, than as a medicine. It ought, for either purpose, to be perfectly pure; but few things are more sophisticated. Its medical properties are slight, if any. It is reputed to be a mild, safe laxative, mixed with almond-oil, for even the youngest children.

The seeds are demulcent, and they, as well as the leaves, are emollient, from the mucilage they contain. They are both used for fomentations and cataplasms. The root is emetic and purgative. It contains an alkaloid termed *Violina*. This resembles Emetina, and can be used like it.

Viola tricolor, or Pansy, is recommended in the skin disease of children called *Crustalactea*, or *Porrigo larvalis*. It communicates, as does a Spanish sweetmeat or preserve, a peculiar odour to the secretion from the kidneys. The occurrence of this odour is therefore no criterion of a beneficial action over the disease. *Viola primulæfolia*, Linn., *V. ovata*, Rafinisque, is reputed good against the bite of the rattlesnake.

Ionidium Ipecacuanha is the emetic of Brazil, while *Ionidium microphyllum*, of Quito, is most useful in *Elephantiasis*.

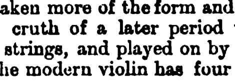
VIOLET. The botanical characters are given in the NAT. HIST. DIV., under VIOLA; but there are many varieties. There are hardly any species of violet that do not deserve cultivation on account of their beauty; but the varieties of *odorata*, the sweet-scented species, and *tricolor* [PANSY], are the chief favourites. They are all readily raised by seeds, or by parting the roots. The annuals may be sown on the open border or on rockwork; the perennials, on a mixture of loam, peat, and plenty of sand. The shrubby kinds are best propagated by cuttings, and the herbaceous by dividing the roots. The Neapolitan violet, which is white, is somewhat more difficult to raise in this country. The best way is, in May, after they have done flowering, to sift some light soil over the plants to the depth of a couple of inches, in order to promote the production of runners, but leaving as much of the foliage as possible exposed to the air. In about six weeks the runners have formed roots. Then take up the old plants and select the best runners. These are to be planted in a bed formed of two parts of turfy loam and one part of leaf mould, placed so as to be shaded by trees, but well exposed to the air. A trench is to be made by removing the soil to a depth of about four inches, which is to be filled up to a level with leaf mould, over which the removed soil is to be placed. Upon this the runners are to be planted, at distances of about four inches, the rows being at least seven inches apart. They are then to be well watered, and the watering repeated frequently during the summer months. In September they will have become strong enough to be removed, with good bulbs at their roots, and may be transplanted to frames under glass, well watered and shaded from the sun, for about a week, when they will have rooted well again, and may be freely exposed to the air. By October they will be in bloom, and will continue flowering till May.

VIOLET SAUNDERS. [Colouring Matters.]

VIOLIN. The colouring matter of violets. Its composition is unknown. This name has also recently been applied to one of the numerous and beautiful colouring matters derived from aniline. Dr. David Price prepares this colour by heating an aqueous liquid containing two equivalents of sulphuric acid and one equivalent of aniline to the boiling point, and then adding one equivalent of binoxide of lead, boiling the mixture for some time and then filtering it whilst hot. The filtrate is of a dark purple hue, is boiled with potash both to separate the excess of aniline and also to precipitate the colouring matter. When all the free aniline is volatilised the residue is thrown on a filter and slightly washed with water, and then dissolved in a dilute solution of tartaric acid. This solution after filtration is evaporated to a small bulk, re-filtered, and then precipitated by means of an alkali. Thus obtained violin presents itself as a blackish purple powder, which, when dissolved in alcohol and evaporated to dryness, appears as a brittle, bronze-coloured substance, similar to aniline purple, but possessing a more coppery reflection. It is nearly insoluble in water, very soluble in alcohol, and insoluble in ether and hydrocarbons. These solutions possess a colour somewhat similar to that of the field violet. Concentrated sulphuric acid dissolves it, forming a green solution, but excess of water restores it to its original colour. Reducing agents deprive it of its colour, which is, however, restored by the action of the atmosphere. Tannin produces an insoluble compound with it.

VIOLIN (*Violino*, It., *a small viol*), a musical instrument known, in some shape, as used with a bow, in nearly all parts of the world, is by many antiquaries believed to have existed in very remote times. Be that as it may, the Abbé le Beuf has produced a strong proof that the violin—or perhaps rebec [Rebec]—acted on by a bow, was known in France during the 8th century, and thus has left little if any doubt of the use of the instrument from that period, however uncertain we may be as to its previous existence. The Welsh cruth, or crwth, or crowd, which pretends to great antiquity, seems originally to have partaken more of the form and character of the harp than of the violin. The cruth of a later period was, however, certainly a violin, with gut strings, and played on by a bow. (See 'Hudibras,' I. ii. 105.)

The modern violin has four gut strings, the last, or lowest, covered with silver-wire. These are tuned in 5ths, E, A, D, G; or,



M. Baillot, one of the finest modern performers, in his 'Méthode' for the violin, adopted by the Conservatoire de Musique, says that the compass of the violin exceeds three octaves. Supposing this to signify three octaves and a half, the legitimate extent of the instrument will be from G, the fourth space in the base, to the octave above the second added line in the treble. But we cannot refrain from expressing our wish that violinists would confine themselves within a more limited compass. The highest sounds of the instrument are disagreeable to most ears; are often harsh, and almost always squeaking; and though they display a kind of mechanical skill in the performer, they, in most instances, betray his vanity and want of true taste.

When complete, says M. Otto (instrument-maker to the court of Weimar), in his 'Treatise on the Construction, &c. of the Violin,' this instrument consists of fifty-eight different parts, or pieces: but such small divisions are not indispensably necessary, for in many instruments of a cheap description the parts are not so minutely divided. "The wood is generally of three sorts. The back, neck, sides, and circles are of sycamore: the belly, bass-bar, sound-post, and six blocks, of deal: the finger-board and tail-piece of ebony." The finest violins now in use were made by one family, living in Cremona. The oldest came from the hands of Hieronymus Amati, at the commencement of the 17th century. He was followed by Antonius Amati, about the middle of that century; and succeeded by Nicolas Amati, towards the end of the same. To these is to be added Antonius Straduarius, of Cremona also, who was contemporary with the two latter of the Amatis. And last, Joseph Guarnerius, at the beginning of the 18th entury. "All their instruments," M. Otto adds, "were constructed after the simplest rules of mathematics (?), and the six which came into my possession *unspoilt*, were made after the following proportions: —The belly was thickest where the bridge rests; then it diminished about a third at that part where the *f* holes are cut; and, where the belly rests on the sides, it was half as thick as in the middle. The same proportion is observed in the length. The thickness is equally maintained all along that part on which the bass bar is fixed: thence to the upper and under end blocks the thickness decreases to one-half, so that the cheeks are three-fourths the thickness of the breast, and the edges all round only one-half. These proportions are best adapted for imparting a full, powerful, and sonorous tone. The back is worked out much in the same proportion as the belly."

Steiner, of Apsam, is also celebrated for his violins. "They differ," M. Otto tells us, "from the Cremonese, both in shape and tone. They are higher modelled, and their proportions of strength are calculated quite differently. A Cremonese has a strong reedy tone, something like that of a clarionet, while a Steiner approaches that of a flute." The same author also gives the names of many German violin-makers; but as they are not generally known out of their own country, we cannot afford any space to them, but refer our readers to the translation of M. Otto's work, by Mr. Fardeley of Leeds.

Many years ago, M. Savart constructed a violin with straight sides, and differing in several other particulars from the ordinary instrument. It was tested by musicians, and reported on most favourably by M. Biot ('Annales de Chimie et de Physique,' tom. xii.). It would appear from this report, that a first-rate violin may be constructed for a few shillings, provided the parts be selected and put together on the acoustic principles therein described. We are unable to say what is the cause of failure, but it seems that out of Savart's own skilful hands the experiment has not succeeded.

VIOLIN STRINGS. [Catgut.]

VIOLONCELLO (a diminutive of *Violone*, Ital., a *contra-basso*, or double-base), a musical instrument of four gut strings, the two lowest covered with silver-wire, and tuned in 5ths, A, D, G, and C; or,

This fine rich instrument is an improvement of the *viol da gamba*, the latter having formed one of the family of viols. [Viol; Viol Da Gamba.] England may justly claim the merit of having given birth to the best performers on the violoncello that Europe has produced.

VIRGINAL, a musical instrument now entirely disused. It is described by Dr. Burney as "a keyed instrument of one string, jack, and quill to each note, like a spinet, but in shape resembling the present small piano-forte. It," he adds, "has been imagined to have been invented in England during the reign of Elizabeth, and to have been thus denominated in honour of that virgin princess; but a drawing and description of it appeared in Luscinius's 'Musurgia' before she was born." ('Hist. of Music,' iii. 5.) The compass of the virginal was from the second added line below the base to the second added line above the treble—or four octaves.

VIRGO (Constellation), the sixth constellation in the zodiac, surrounded by Libra, Bootes, Leo, and Corvus. It is best known by two remarkable stars: the first, Spica (α Virginis), a star of the first magnitude, is in the hand, which holds ears of corn, typical of the harvest, which approached in the time of the Greeks as the sun neared this star; the other, Prævindemiatrix, or Vindemiatrix (ε Virginis), took its name from the vintage. The star Spica forms a remarkable triangle with Arcturus and β Leonis (or Denebola); and of the bright stars in this triangle, Vindemiatrix is the one nearest to the line joining Arcturus and β Leonis.

The principal stars are as follows:—

Character. Not in Bayer. ( )	No. in Catalogue of Flamsteed.	No. in Catalogue of British Association.	Magnitude.
β	5	4002	3
η	15	4145	3
γ	29	4268	3
δ	43	4340	3
ε	47	4367	3
θ	51	4401	4
α	67	4480	1
ζ	79	4532	4
κ	98	4716	4
ι	99	4727	4
λ	100	4743	4
φ	105	4792	4
μ	107	4855	4
(z)	109	4878	4

Hesiod and Aratus unite in representing Virgo to be justice, who retired to heaven when the golden age came to an end: the former makes her the daughter of Jupiter and Themis; the latter, of Astræus and Aurora: others make her to be Fortune, others Ceres, &c.

VIRIDIC ACID. [Tannic Acid; *Viridic Acid.*]

VIRTUAL VELOCITIES. The name of the *principle of virtual velocities*, which is given to what is perhaps the most important generalisation in mechanics, is very ill-fitted to express the idea which is to be conveyed. It will take some space to prepare even the mathematical reader, unless he be already acquainted with the subject, for the reception of this principle as a real and physical consequence of the laws of matter. So long as it is only treated as a mathematical mode of expressing geometrical conditions, its import is hardly seen, and its value is lessened by a want of perfect conviction.

Our works on mechanics are now written in so very cold a style, and mathematical deduction has so completely taken the place of everything else, that little space is given even to interpretation of results, and none to illustration of first principles. The consequence is a strong leaning to purely mathematical definitions, which, though they place the student in the smallest possible time at the beginning of his career of deduction, nevertheless make it difficult for him ever to connect his first principles (first equations we ought rather to call them) with the actual properties of the matter around him, and with the phraseology which sight and touch make him feel to be justifiable. We do not like the system of mechanics in which velocity is only $ds : dt$, moving pressure but a name for $mdv : dt$, and the principle of virtual velocities nothing but a nickname for $\Sigma Pdp = 0$. For a proper description of real facts, we would rather that nature should *abhor* a vacuum, that fluid should *try* to find its level, that the centre of gravity should *endeavour* to descend as low as possible, and so on. Of such language the mathematician must allow the use, if the learner be to feel the truth of the results of mechanics: and in no case is such permission of more importance than in the illustration of the principle before us.

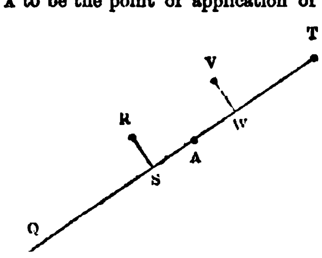
When we say that any system whatever is in equilibrium under the action of forces, it is obvious that the word equilibrium is only used for a state for rest, as opposed to one of motion; which last is possible to be imagined, and might actually take place, if it were not that the impressed forces mutually counteract each other's efforts. If a system could not move, if so many of its points were fixed that, consistently with those points remaining fixed, no geometrical possibility of motion was left, it would be useless to ask whether any given set of forces would keep that system in equilibrium or not. For the answer would be that the system must be in equilibrium, forces or no forces. But when it is left possible that a system may move, it then becomes a question whether a given set of forces will entirely prevent all motion, or will cause one of the possible motions to begin: and the alternative may be restricted by the use of as small a portion of time as we please. What will take place during the first millionth of a second after the forces are applied, rest or motion? And instead of the millionth of a second, any smaller fraction may be used; so that we may say the question of rest or motion, the settlement which of the two is to take place, may be considered as one which involves but an infinitely small portion of time. We shall throughout this article use the language of the infinitesimal calculus, leaving it to the reader to reduce it to the stricter form, if he think that there is such a thing.

Now all the different infinitely small motions of which it is possible that a system may take any one during the infinitely small time dt which elapses after forces are applied to it—are called *virtual* motions. This word is not used in the meaning which it commonly bears, as when we say that a man who does not prosecute a claim virtually (as good as) abandons it. When John Bernoulli used this adjective (and we can find none prior to him who did so) it was in a sense which it will not now bear: by a virtual velocity he meant any infinitely small velocity, or increase of velocity. But in modern times, virtual is used in the sense of potential, or possible: a virtual motion is one which a system might take, whether it take it or not: thus if forces keep a system at rest, it will not take any one whatsoever of the virtual (or possible) motions; but if they do not keep it at rest, it will, in the time dt which elapses after the forces are applied, take some one of the virtual motions, to the exclusion of the rest. Nevertheless, so long as it is geometrically possible that any one given motion might have taken place, we are at liberty to suppose that that motion has taken place (which is simply making an arbitrary displacement of the system), if by so doing, and noting the displacements which the different parts receive, we can draw any conclusions as to the conditions of equilibrium.

When we see a system in equilibrium, experience tells us that there are efforts at motion which are counteracted. Remove any one of the forces, or any part of one of them, and motion immediately begins. It is true that friction and other resistances prevent our having so good a perception of this truth as we otherwise might have; since, when equilibrating forces are removed in whole or in part, friction frequently supplies the place and maintains the equilibrium. A little reflection will however make it apparent that when a system is once in equilibrium, no addition nor subtraction of forces can be made without producing motion, unless the forces added or withdrawn be such as by themselves would maintain equilibrium.

A system, then, at rest, makes efforts to move, which efforts are counteracted; and the mathematical conditions of equilibrium, whatever they may be, must express that every force endeavours to produce motion; must contain, directly or indirectly, a measure of the energy of that force; and must show that a complete counteraction of all the efforts at motion takes place. But here arises a question, and one which is of the utmost importance in the comprehension of our principle. The number of virtual motions is usually infinite:—Does any given system of forces make an effort to produce every one of them, or some only? We know that, if the forces do not produce equilibrium, *one* of the virtual motions ensues in the first dt following the application of the forces, to the exclusion of all the rest; it ought not, therefore, to surprise the student if he were told that, for every given set of forces (a given system being always understood), some one motion prevented is every motion prevented. But in point of fact the direct contrary is true, in rigid systems at least: generally speaking, there is but one class of virtual motions which a given set of forces has not a tendency to produce, and any one of the rest may be produced. Our meaning will appear in the following explanation:—We have seen [ROTATION] that every infinitely small motion of a rigid system may be produced by a screwlike motion,* namely, rotation round an axis, accompanied by a slipping up or down that axis. Take any line for an axis, and suppose a screw, fitted to its receiving screw (the latter immoveably fixed in space), to be described with that axis: suppose also that the system to which the forces are applied is fixed to the screw. Here then is every virtual motion prevented, except one; so that if the system begin to move, it must take that one motion. Now apply the given set of forces, and resolve them all in directions parallel to the axis, and in planes perpendicular to it. There must be motion unless the former forces destroy each other, and the latter have a resultant or resultants passing through the axis. Consequently, with certain exceptions (which, though infinite in number, are few compared with the rest), a given set of forces, acting on a given system, will produce any virtual motion, if others be excluded: but when there are various virtual motions not excluded, the system, if the forces do not balance one another, will take one in preference to any of the rest. The preceding argument ought to be more developed, but we have not room for such an explanation as would be intelligible to every one: most of the difficulty indeed lies in the purely geometrical conception of motion, and is foreign to our article.

We are to expect, then, as the condition of equilibrium, a collection of conditions, an infinite number, implying that, of an infinite number of motions, possible *à priori*, the given system of forces makes each *and* every one impossible. To make it appear in what the condition may probably consist, look at the following cases:—If one point of the system be fixed, forces applied at that point are useless, for they *only* produce a pressure or strain on the fixed point, and neither promote nor retard any virtual motion. If one point be restrained to move upon a given surface or curve, forces applied at that point perpendicular to that surface or curve are useless, for a similar reason. Thus suppose one point must be retained on a given horizontal plane: any weight added to that point has no effect on the equilibrium; it *is* merely equivalent to so much weight† laid upon the plane. Generally, then, a force produces no effect in equilibrium unless the point to which it is applied can move *in the direction of that force*: thus weight produces no effect when applied to a point of which all the virtual motions are horizontal. But let the plane be ever so little inclined to the horizon, a point restricted to move upon it has somewhat of vertical motion: weight applied at that point will have some effect in equilibrium. It would be natural to conclude (and let it be remembered that in these *à priori* views we are only stating strong probabilities) that the more freely a point may move in the direction of the force which acts upon it, the greater the effect of that force in producing or disturbing equilibrium. Now since it is sufficiently evident that, *cæteris paribus*, a force has more or less effect in proportion to its magnitude, for instance, that, under given circumstances, two pounds of pressure produce twice the effect of one pound, it seems that for any given virtual motion, the effect of each force varies jointly as the magnitude of the force, and the length over which, in that virtual motion, the point of application moves in the direction of the force. That is, suppose A to be the point of application of the force, and AQ



to represent its direction and magnitude. In one virtual or possible motion of the system, let A be transferred to R, infinitely near to A. Draw RS perpendicular upon QA, then AS is the space moved over in the direction of the force; and if the force contain P units of pressure, P × AS is the product on the value of which the efficiency of the force seems to have some dependence. Here, however, the motion AS is in

* Simple translation is the extreme case in which the thread of the screw becomes parallel to the axis; and simple rotation the other extreme case in which the successive coils of the thread coincide.

† Here again the common ideas derived from friction must be abandoned; a weight attached to such a point might help, by the friction on the plane, to equilibrate the system.

the direction of the force, and the force helps to produce that motion; for it is obviously easier, *cæteris paribus*, that the point A should move in the direction A B, when the force acts in the direction A Q, than it would have been if the same force had acted in the opposite direction A T. But suppose that another virtual motion might bring A to V. Draw V W perpendicular to A T; then A W is the space moved over in the direction of the force, and P × A W is the product on which the efficiency of the force seems to depend. But here the motion A W is in the direction opposite to that of the force, and it is obviously less easy that the point A should move in the direction A V, when the force acts in the direction A Q, than it would have been if the force had acted in the opposite direction A T. Hence, to what has preceded, we may probably add that the efficiency of a force, in promoting or preventing one given kind of virtual motion, is to be considered as of one kind or another according, as, for that motion, the virtual motion of the point of application, estimated in the line of action of the force, is with the direction of the force, or opposite to it.

These conjectures, for they are nothing more, will show of the principle of virtual velocities, the moment it is announced, that it is a highly reasonable and probable principle. It may be announced as follows:—Let the forces which are applied to a system, at different points, be P, Q, R, &c., each in an assigned direction. Let one of the virtual (that is, possible) motions which the system may undergo in the infinitely small time dt succeeding the moment of application of the forces, be supposed to be given, upon trial. Decompose the several motions of the points of application of the forces each into two, one in the line of the applied force, the other perpendicular to that line: let dp, dq, dr, &c., be the resolved motions in the lines of the forces, and let those be reckoned positive which are in the directions of the forces, and negative which are in the contrary directions. Then $\mathrm{P}dp + \mathrm{Q}dq + \mathrm{R}dr$ + &c., is a quantity on which it depends whether the given virtual motion can actually take place or not. If $\mathrm{P}dp + \mathrm{Q}dq + \mathrm{R}dr$ + &c., $= 0$, that motion cannot be the result of the applied forces: but if $\mathrm{P}dp + \mathrm{Q}dq + \mathrm{R}dr$ + &c. be not $= 0$, that motion *may* take place. And there is equilibrium, that is, no one of the possible motions can actually take place when $\mathrm{P}dp + \mathrm{Q}dq + \mathrm{R}dr$ + &c. is always $= 0$, for every virtual motion; and there is not equilibrium when one or more virtual motions can be assigned, for which $\mathrm{P}dp + \mathrm{Q}dq + \mathrm{R}dr$ + &c. is not $= 0$. This is the principle of *virtual velocities*, as to which perhaps the first thing that will strike the reader is that the word velocity does not occur in the explanation of it. But if we suppose the virtual motion of the system to be actually performed in the time dt, then the velocities of the points of application, in the directions of the several forces, are $dp : dt$, $dq : dt$, $dr : dt$, &c., and the principle above stated may be affirmed of

$$\mathrm{P}\frac{dp}{dt} + \mathrm{Q}\frac{dq}{dt} + \mathrm{R}\frac{dr}{dt} + \&c.$$

instead of $\mathrm{P}dp + \mathrm{Q}dq + \mathrm{R}dr$ + &c. But the latter is the more convenient of the two. The product $\mathrm{P}dp$ is called the *moment* of the force P, which is not a well-chosen term, since "moment" is used in other senses. It would be much better (though we shall not here depart from established usage) that $\mathrm{P}dp$ should be called the measure of the equilibrating power of the force P, or, in one word, the *power** of the force P: with reference, of course, to the promotion or hindrance of those virtual motions only, in which dp is the part of the motion which is in the line of P's action. No perfectly general proof of this principle has been given; indeed to apply it demonstratively to the cases of fluid and gaseous systems would require a knowledge of the constituent parts of matter, and of their connection with each other, which we do not possess. But the cases in which it can be strictly shown are very extensive: all cases whatsoever in which the conditions of equilibrium can be established admit of the truth of this principle being shown *à posteriori*, with certain exceptions, the reasons of which will presently appear; and when it is assumed, it always leads to results which are consistent with the other known principles of mechanics. In the demonstration which we give, we shall confine ourselves to the case of forces which act upon points, which are either independent of each other, or some or all of which are connected by rigid rods without weight: and our limits require us to speak but briefly of all the steps which are purely mathematical. Ordinary works on mechanics give the simple illustrations which the beginner wants: and it is impossible to read anything like a general demonstration without being well acquainted with the infinitesimal calculus and with the principal formulæ of algebraic geometry of three dimensions.

First, let there be a single point A, the co-ordinates of which are x, y, and z. Let there act upon this point the forces P, in a direction which makes with the axes, angles α, β, γ; P′, the direction of which makes angles α', β', γ'; P″, the direction of which makes angles $\alpha'', \beta'', \gamma''$, &c. Let the point A move to B, the co-ordinates of which are $x + dx$, $y + dy$, $z + dz$, and let A B make the angles λ, μ, ν with the axes. Then,

$$\mathrm{AB} = \sqrt{(dx^2 + dy^2 + dz^2)},$$

* Either of the words activity, efficiency, energy, would do as well; anything but *moment*, which has other meanings.

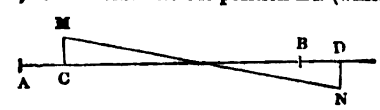
$$\cos\lambda = \frac{dx}{\mathrm{AB}},\ \cos\mu = \frac{dy}{\mathrm{AB}},\ \cos\nu = \frac{dz}{\mathrm{AB}}.$$

Now the line A B decomposed in the direction of P, gives A B × cos (angle made by P with A B) or

$$\mathrm{AB}\,(\cos\lambda\,.\,\cos\alpha + \cos\mu\,.\,\cos\beta + \cos\nu\,.\,\cos\gamma)$$
$$\text{or } \cos\alpha\,.\,dx + \cos\beta\,.\,dy + \cos\gamma\,.\,dz = dp.$$

Hence the moment of the force P is $\mathrm{P}\cos\alpha\,.\,dx + \mathrm{P}\cos\beta\,.\,dy + \mathrm{P}\cos\gamma\,.\,dz$, and the sum of the moments of all the forces is $dx\,\Sigma\,(\mathrm{P}\cos\alpha) + dy\,\Sigma\,(\mathrm{P}\cos\beta) + dz\,\Sigma\,(\mathrm{P}\cos\gamma)$, where $\Sigma\,(\mathrm{P}\cos\alpha)$ stands for $\mathrm{P}\cos\alpha + \mathrm{P}'\cos\alpha'$ + &c., and so on. But when there is equilibrium $\Sigma\,(\mathrm{P}\cos\alpha) = 0$, since $\mathrm{P}\cos\alpha$, $\mathrm{P}'\cos\alpha'$, &c., are the components of the several forces in the direction of x. For similar reasons $\Sigma\,(\mathrm{P}\cos\beta) = 0$, $\Sigma\,(\mathrm{P}\cos\gamma) = 0$, whence $\mathrm{P}dp + \mathrm{P}'dp'$ + &c., is $= 0$ for every motion of which the point is capable.

Let there be any number of points, and let each of them be acted upon by any number of forces: but as all the forces which act upon a given point may be reduced to one, let R_1 be the force which acts on the first, and $\alpha_1, \beta_1, \gamma_1$, be the angles it makes with the axes: let $\mathrm{R}_2, \alpha_2, \beta_2, \gamma_2$, stand in the same relations to the second point; and so on. Let x_1, y_1, z_1, be the co-ordinates of the first point, and so on. Let any of the points be connected by rigid bars without weight: and suppose A to be one of the points, and A B the bar connecting it with another point B. The point A, then, besides other forces, is acted on by a pressure called the tension of the bar, either in the direction A B or B A: while B, besides the other forces, is acted on by the same tension, but in a contrary direction. Supposing A B to receive one of its virtual motions, and to come into the position M N (which need not be



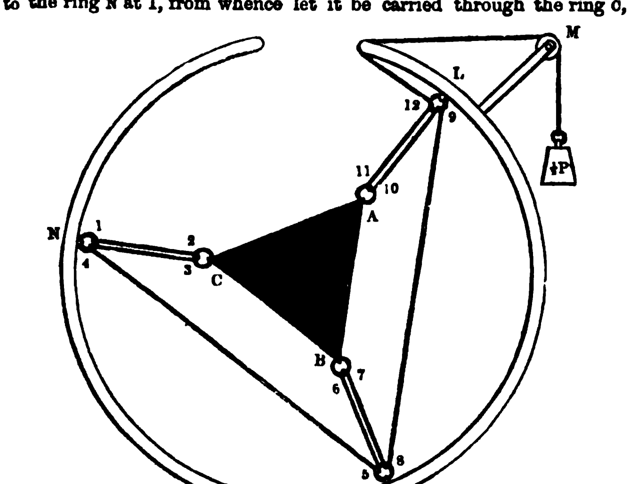
in the same plane with A B), then if M C and N D be drawn perpendicular to A B, and if the position M N be infinitely near to A B, so that M C and N D need not be distinguished (so far as small quantities of the first order are concerned) from arcs of circles with the centres B and A —it follows that A C may be considered as the diminution of the line if A only changed place, and came to M, while B D may be considered as the quantity by which it would be lengthened, if B only changed place, and came to N. Hence, since the bar remains of the same length, we have A C = B D, or at least the two only differ by an infinitely small part of either. But A C gives the virtual velocity of the tension at A, and B D that of the tension at B, and these lines being equal, and the tensions equal, their moments are equal; but these moments have different signs, one of the virtual velocities being in the direction of its force, and the other in the opposite direction. Hence the sum of these two moments is $= 0$; and the same follows for the two moments of any other of the tensions, exerted by any other of the connecting bars. Let T_1 be the sum of the moments of the tensions which act on the first point, T_2, T_3, &c., of those which act on the second, third, &c., points; then, taking the principle as established above, for each point separately, we have $\mathrm{R}_1\,dr_1 + \mathrm{T}_1 = 0$, $\mathrm{R}_2\,dr_2 + \mathrm{T}_2 = 0$, &c.; by summing which we have $\mathrm{R}_1\,dr_1 + \mathrm{R}_2\,dr_2$ + &c., $+ \mathrm{T}_1 + \mathrm{T}_2$ + &c. $= 0$. But $\mathrm{T}_1 + \mathrm{T}_2$ + &c. $= 0$; for, as shown, every term in each of T_1, T_2, &c., finds an equal and contrary term in one of the others. Hence $\mathrm{R}_1\,dr_1 + \mathrm{R}_2\,dr_2$ + &c. $= 0$, or the principle is established for any system consisting of forces applied to points connected by rigid bars, and this whether there be connections enough to ensure complete stability of form or not.

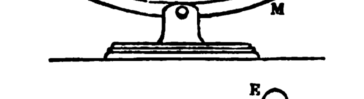
Various other cases may be examined in which the same conclusion as the last will be arrived at, namely, that the principle of virtual velocities is true of the external forces only, and that those which arise from the internal forces of the system may be neglected. If, for example, one of the points to which a force is applied slide upon a string, in the manner of a bead, the ends of the string being attached to other points of the system, the two tensions are the same on both sides of the bead, and any virtual motion of the bead alone shortens one part of the string as much as it lengthens the other. Those parts, by which one side is lengthened and the other shortened, are, when the motion is infinitely small, the spaces from which the virtual velocities of the tensions are obtained, and they are of contrary signs. The moments of the tensions are therefore equal and contrary; or the principle is true independently of those tensions. Again, suppose one of the points of the system is restrained to move upon a given surface or curve; being tied in such a manner as to slip freely upon the surface or curve, without being able to leave it. The force which retains the point thus attached is perpendicular to the surface or curve, but every virtual motion of that point is (when infinitely small) in the tangent plane of the surface or tangent of the curve: so that there is no component in the direction of the force, and the moment of the force vanishes.

When questions occur in which friction is an element, the principle of virtual velocities is not of very easy application. Even in the ordinary modes of solving such problems, the formulæ which must vanish when there is no friction, are not required to vanish, but must lie between certain positive and negative limits, depending on the friction. A similar change must be predicated of the sum of the moments of the impressed forces; but as even Lagrange does not appear to have thought the principle before us conveniently applicable to friction problems, we may well dispense with the consideration of them here. When elastic bodies are in question the principle can be applied, but only on condition that the elasticities of the several parts of the system are considered as external, not internal forces: an hypothesis rendered necessary by our ignorance of the molecular constitution which gives rise to elasticity. It may also be said that in its application to hydrostatics there are mathematical conventions (expressive, no doubt, of truths, but foreign to the mere enunciation of the principle) which represent our ignorance of the molecular constitution of a fluid. On this point we should recommend the student who has enough of mathematics to have recourse to the 'Mécanique Analytique' of Lagrange, the standard work on virtual velocities: the demonstrations, so called, given by all the elementary writers we know of (even Poisson, see his 'Mécanique,' vol. ii., p. 512, 2nd edition) are mere illustrations conducted upon the most limited suppositions. These are more than excusable, considered with reference to the supposed mathematical knowledge of the reader; but it is not right to make him believe that he is considering a subject generally, when nothing but a limited case is presented to him. The great fault of the mathematical writers of our day is the *want of avowal of incompleteness:* and any one who looks in Poisson's table of contents for 'Démonstration du Principe des Vitesses Virtuelles dans l'Equilibre d'un Liquide,' and compares it with the article indicated, will see a notable instance.

When we look at the preceding demonstration of the principle, we see that it depends upon knowledge of the mode of compounding and decomposing forces; but there is an *à priori* proof of a most singular character, as extensive as can be given by the mode already used. This proof was prefixed by Lagrange to the 'Mécanique Analytique,' and judging from the slight degree of notice which it has obtained from succeeding writers on mechanics, we should suppose that it was disputed or thought unsound. We have ourselves strong objections to the form given by Lagrange; but we believe that a sound and sufficient method of proof does exist in the principle which he has used; and this we shall endeavour to develope.

Suppose, first, that all the forces which are applied are equal to one another; the case of unequal forces will follow very readily. As an instance, suppose three equal forces applied at the points A, B, C, in the directions AL, BM, CN; ABC being a solid triangle without weight. At A, B, C, attach rings* to the triangular system, and at L, M, N, attach rings to a solid frame unconnected with the system, except by the flexible string now to be mentioned. Let this string be made fast to the ring N at 1, from whence let it be carried through the ring C,





and again through the ring N at 4, from whence it is passed through M at 5; being nowhere attached to the frame except at 1. Its course is then denoted by the numbers 1, 2, 3, 4, &c.; and, when it emerges at 14, let a weight be attached, equal to the half of the force which is required to act at each of the points A, B, C; this force being P, the weight is ½P. The tension of the string being everywhere the same, it is everywhere equal to ½P: and at the point A each of the parts of the string (10, 9), and (11, 12), applies a force equal to ½P, so that the force P is, from the two strings, applied at A. The same may be said of the points B and C. If then, at the outset, the system ABC were so placed that forces P, P, P, applied at the three points in the given directions would produce equilibrium, it follows that there will be no motion when the weight ½P is made to act on the string; for equilibrating forces will at that instant be applied to the system: and the weight ½P cannot move unless the triangle move.

Now it is obvious *à priori* that if any forces keep a system in equilibrium, forces exactly opposite to those forces will also keep it in equilibrium: if P, Q, R, keep a system in equilibrium: so will −P, −Q, and −R, forces equal and opposite to the first three. For it is obvious that all the six, P, −P, Q, −Q, R, −R, keep it in equilibrium, being three sets of equilibrating forces. Take away the set P, Q, R, which, by hypothesis, equilibrate the system, and the remaining set, −P, −Q, −R, will then equilibrate it. But here it must be noticed that when the inversion of directions is made, the inversion of the tensions must also be possible: a force which before the inversion pulls by a string, must, after the inversion, be supposed to push that string: that is to say, the string must have the property of a rigid bar as to pushing or pulling being indifferent. The reader of theoretical mechanics must accustom himself to the idea of a string which, though laterally flexible, can transmit a push or thrust in the direction of its length. Imagine the direction* of gravity to be changed in the machine, so that ½P acts upwards, the string being capable of transmitting the thrust through the whole of its length. Nothing is then changed except the directions of the forces acting at A, B, C, in such manner that, if the original position be one of equilibrium, the weight ½P cannot ascend, any more than it could descend in the first supposition.

When there is equilibrium, then, the weight ½P, whether it be supposed to pull downwards or thrust upwards, cannot either ascend or descend. But what is to hinder ½P from descending in the first case, or ascending in the second? The weight is only counterbalanced at 1, which is made fast to the ring at N, and if more string can be drawn out beyond (13) by the descent of ½P, or pushed in by its ascent, there is no mechanical reason why such drawing out or pushing in should not take place. The reason why the ascent or descent cannot take place must be of a geometrical character, and Lagrange reasons as follows:—It will be sufficient that any infinitely small displacement of the triangle ABC should produce no displacement of the weight; and this will also be necessary: for if any possible infinitely small displacement of the system could let out string and give motion to the weight, the tendency of the weight to descend would produce that small displacement. But (implies Lagrange) it is enough that any infinitely small displacement of the system should only produce a displacement of the weight which is of an inferior order: or it is enough that the second displacement should be an infinitely small part of the first. Here we cannot follow the reasoning: why should the weight not be capable of descending because the first infinitely small motion of ABC is attended by one of an inferior order in the weight ½P? We could name any number of cases in which continued motions begin in this manner. We can only understand Lagrange's argument to this extent: if there be a position of equilibrium at all, it must be that in which a given infinitely small displacement produces the smallest effect upon the weight; so that, if there be one position in which every displacement produces relatively an infinitely small displacement of the weight, that position, or none, must be the position of equilibrium. We shall, however, proceed with Lagrange's reasoning, and shall then endeavour to show that it may be saved from the preceding objection at least, if not rendered absolutely rigorous. Let S be the fixed ring to which D (moveable with the system) belongs; and let the latter, in a certain infinitely small displacement of the system, be removed to E. If SD be greater than SE, the string SD is shortened by the removal, and drawing the arc EK and the perpendicular E*k*, the virtual velocity of the force acting in the direction DS is *k*D (and is positive), while the quantity by which each string is shortened is KD; but if SE be longer than SD, the virtual velocity is negative, and the string is lengthened. Hence, if α, β, γ, be the virtual velocities of the forces in their own directions, the expression $2\alpha+2\beta+2\gamma$ is, if positive, the quantity of string let out by the displacement; if negative, the quantity taken in. Or rather we should say that $2\alpha+2\beta+2\gamma$ differs from the quantity let out or taken in by an infinitely small quantity of the second order; for *k*D and KD, even when E is infinitely near to D, are not equal, but differ by a small quantity of the second order. Lagrange, then, confounding an infinitely small quantity of the second order with absolute *nothing*, compared with one of the first order, takes $2\alpha+2\beta+2\gamma=0$, or, multiplying by ½P, $P\alpha+P\beta+P\gamma=0$, as the condition that an infinitely small displacement of the system will allow no displacement whatever of the weight; from which, by the aid of the mathematical consideration already alluded to, he completes what he gives as the proof that $P\alpha+P\beta+P\gamma=0$ is the condition of equilibrium: which is for this case the enunciation of the principle of virtual velocities.

* Pulleys, in Lagrange; but the wheel in the pulley is only a friction-wheel, and, as we are at liberty to dispense with friction in our thoughts, we may also deprive the pulley of its wheel.

* Lagrange avoids this second case by an appeal to mathematics, which not only destroys the elementary character of the proof, but is of a character incongruous with the other parts of it, and is moreover not always correct.

Before proceeding to give our view of the manner in which this proof may be amended, we shall point out how to proceed when the forces are not equal. In such case they are either commensurable or incommensurable: let them be commensurable, and let them be lP, mP, nP, where l, m, n, are integers. Instead of passing the string twice only through each ring, pass it $2n$ times through C and N, $2m$ times through B and M, $2l$ times through A and L. Then, the instant the weight $\frac{1}{2}$P is applied, there are $2l$ strings in the direction AL, each with the tension $\frac{1}{2}$P, or altogether there is the force lP, applied to A in the direction AL; and similarly of the rest. If, then, α, β, γ, be as before, we have $2l\alpha+2m\beta+2n\gamma$, differing only by an infinitely small quantity of the second order from the quantity of string let out or taken in by an infinitely small displacement of the system. The usual methods apply for the extension of this reasoning to the case in which the forces are incommensurable.

Let AL $= a$, BM $= b$, CN $= c$: then the whole length of the string as far as (13) is $2la + 2mb + 2nc$ + a constant made up of (4, 5), (8, 9), and (12, 13). Hence $2lda + 2mdb + 2ndc$ is the infinitely small quantity taken in or let out by an infinitely small displacement; taken in when positive, let out when negative; so that da, db, dc, answer to $-\alpha$, $-\beta$, $-\gamma$, in the preceding. Now

1. It is established that, equilibrium existing, equilibrium will remain when all the forces take opposite directions.

2. Neither a, b, c, nor their differential coefficients, can become infinite in any position of the system; so that the only way in which $2la + 2mb + 2nc$ can become a maximum or a minimum is by $2lda + 2mdb + 2ndc$ becoming, in the language of the differential calculus, *nothing*, that is, more strictly, an infinitely small quantity of the second order.

Now let the weight $\frac{1}{2}$P act *downwards*, and let it draw out all the string possible, and then rest. There must then be equilibrium, for every displacement makes the weight rise; and the weight has no tendency to take advantage, so to speak, of this power of rising. Consequently, there must be equilibrium when $2la + 2mb + 2nc$ is a minimum, the weight acting downwards; that is, when $2lda + 2mdb + 2ndc$ is always positive, and of the second order; or when $Pl.\alpha + Pm.\beta + Pn.\gamma$ is always negative, and of the second order. And this equilibrium is stable; for any displacement makes the weight rise, and its tendency is to descend, and restore the former state. Now reverse the direction of the weight, and let the string communicate thrust instead of pull, as before described. Then there is still equilibrium (which is demonstrable independently) because only the directions of the forces are changed; but since the forces change direction, the virtual velocities change sign, and $Pl.\alpha +$, &c., is always positive, and of the second order. Here, then, though the weight (we call $\frac{1}{2}$P *weight* always, whether it tend upwards or downwards) tends to rise, and (geometrically speaking) can rise, it does not rise: observe, also, that the rise would be an infinitely small quantity of the second order. The equilibrium in this case is unstable, for every displacement raises the weight, which does not tend to return. Now let the weight $\frac{1}{2}$P act *upwards*, and let it push in all the string possible, and then rest. There must then be equilibrium, for every displacement makes the weight fall, and the weight has no tendency to take advantage of this power of falling. Consequently, there must be equilibrium when $2la +$, &c. is a maximum, the weight acting upwards; that is, when $2lda +$, &c. is always negative, and of the second order; or when $Pl.\alpha +$, &c. is always negative,* and of the second order; and this equilibrium is stable, for any displacement makes the weight fall, and its tendency is to rise and restore the former state. Now reverse the direction of the weight, and let the string pull, instead of thrust. There is still equilibrium (because only the directions of the forces are changed): the virtual velocities change sign, and $Pl.\alpha +$, &c. is always positive, and of the second order; and in this last case, though the weight tends to fall, and (geometrically speaking) can fall, it does not fall. Observe, also, that the fall would be an infinitely small quantity of the second order; and the equilibrium in this case is unstable, for every displacement lowers the weight, which does not tend to return.

Collecting these cases, it appears then that whenever $Pl.\alpha +$, &c. is, for every infinitely small displacement, an infinitely small quantity of one given sign, there is equilibrium; stable when that sign is negative, unstable when it is positive. But supposing $Pl.\alpha +$, &c. to be of the second order, sometimes of one sign, and sometimes of the other, according to the displacement, the preceding reasoning does not apply. Nor do we see how it can be applied without the assumption that an equilibrium, which is produced, though all the displacements of the weight favour the motion which it tends to take, is *à fortiori* produced when some only do the same. Taking the case in which the weight acts downwards, we have seen that there is equilibrium when the descent of the weight is of the second order, and *always* downwards; the circumstance of the descent being of the second order, produces equilibrium, even though its direction is that which the weight can take. Still more must there be equilibrium when all the descents are of the second order at least, and some only downwards.

Hence, in every case, $Pl.\alpha +$, &c. $= 0$ (in the common language of the differential calculus) gives a position of equilibrium; and we have now to prove the converse, namely, that every position of equilibrium gives $Pl.\alpha +$, &c. $= 0$ (Lagrange proves this converse first). This converse can be proved, we submit, without taking it for granted, at once, with Lagrange, that if any motion of $\frac{1}{2}$P of the first order were possible, the weight would, by its tendency to descend, take that motion.*

Supposing the system to be at rest, and the weight to act downwards, it is obviously physically possible that a given finite velocity should be communicated to the weight. Suppose a blow to be given to the weight in a downward direction, such as would communicate a finite velocity; what would be the effect upon the system at the instant when the weight receives the blow downwards? An impulsive strain upon the string, which would only communicate forces proportional to those already existing,† and could not disturb the equilibrium. The system then cannot move, neither therefore can the weight move. Now as it is unquestionably physically possible that the weight may take a finite velocity, the impossibility of moving the system must be geometrical; or a velocity communicated to the system must, be it what it may at the first instant, communicate none to the weight; and the definition of velocity shows that this can only happen when, the displacements of the system in the time dt bearing a finite ratio to dt, that of the weight is infinitely small compared with dt; that is, when the displacement of the weight is infinitely small compared with those of the system. From this it follows that $2l\alpha +$, &c. is infinitely small as compared with α, &c.

We do not know how to make the preceding prove its converse, and we object to the mode pursued by Lagrange. Having proved that equilibrium gives $2l\alpha +$, &c., that is, having proved it on the distinct assumption that the weight cannot descend in the first instant through a quantity comparable to α, &c., he then proceeds as follows:—Reciprocally $2l\alpha +$, &c. $= 0$, gives a case of equilibrium; for "the weight remaining immoveable under all displacements, the powers which act upon the system remain in the same state, and there is no more reason why they should produce one of the two displacements than the other, of any two in which α, &c. have contrary signs. It is the case of the balance which remains in equilibrium, because there is no more reason why it should incline on one side than the other." Now, first, this reasoning might just as well be applied to prove equilibrium when $2l\alpha +$, &c. is *not* $= 0$; secondly, it is not the case of the balanced lever of Archimedes, for there is not that same symmetry, either geometrical or mechanical, which makes it impossible to admit either motion in preference to the other [STATICS; SUFFICIENT REASON]; thirdly, there is a mechanical reason why one of the motions should be taken rather than the other, namely, that one in which the displacement of the weight (even though supposed of the second order) is positive. This last will appear sufficiently in the sequel.

We shall now proceed to show that the moment the principle of virtual velocities is granted, a problem of statics becomes one of pure mathematics. This is all we can undertake to illustrate; and for this purpose any mathematical result may be taken for granted. First, let the force P be decomposed into three, X, Y, Z, in the direction of x, y, and z; and let the point of application move until the co-ordinates are $x+dx$, $y+dy$, $z+dz$. Then a force equal and opposite to P (of which the moment is $-Pdp$) balances X, Y, and Z; so that the principle gives $Xdx+Ydy+Zdz+(-Pdp)=0$, or $Pdp=Xdx+Ydy+Zdz$. Do the same with each of the forces, and we have $\Sigma(Pdp)=\Sigma(Xdx)+\Sigma(Ydy)+\Sigma(Zdz)$. If the system be rigid, every virtual motion may be decomposed into two: a motion of translation of any one given point, and a motion of rotation round an axis passing through that point. Let x_0, y_0, z_0, be the co-ordinates of any point which moves with the system, and let this point move so that its co-ordinates shall become x_0+dx_0, y_0+dy_0, z_0+dz_0, at the same time that the system revolves through an angle $d\phi$ about an axis passing through the point (x_0, y_0, z_0), and making angles λ, μ, ν with the three axes. If the consequence of this motion be that the point whose co-ordinates are x, y, z, moves so that its co-ordinates become $x+dx$, $y+dy$, $z+dz$, we have

$$dx = dx_0 + \{\cos\mu\,(z-z_0) - \cos\nu\,(y-y_0)\}\,d\phi$$
$$dy = dy_0 + \{\cos\nu\,(x-x_0) - \cos\lambda\,(z-z_0)\}\,d\phi$$
$$dz = dz_0 + \{\cos\lambda\,(y-y_0) - \cos\mu\,(x-x_0)\}\,d\phi$$

from which we find for

$$\Sigma(Pdp) \text{ or } \Sigma(Xdx) + \Sigma(Ydy) + \Sigma(Zdz),$$

the following expression:—

$$\Sigma X.dx_0 + (z_0\Sigma Y - y_0\Sigma Z)\cos\lambda\,d\phi + \Sigma(Zy - Yz).\cos\lambda\,d\phi$$
$$+\Sigma Y.dy_0 + (x_0\Sigma Z - z_0\Sigma X)\cos\mu\,d\phi + \Sigma(Xz - Zx).\cos\mu\,d\phi$$
$$+\Sigma Z.dz_0 + (y_0\Sigma X - x_0\Sigma Y)\cos\nu\,d\phi + \Sigma(Yx - Xy).\cos\nu\,d\phi$$

* When the action of the string is that of a thrust, it will be seen that da is $= \alpha$, &c., since the virtual velocities change sign.

* It seems to us just as sound to say that if there be any motion of the second order possible, the weight will take that motion, and in an infinitely small time acquire a velocity of the first order, which is exactly what takes place in a body falling freely from rest.

† It is here assumed that whatever forces keep a system at rest, impulses proportional to those forces, and applied in the same manner, will not disturb the equilibrium.

and in the case of equilibrium this is always = 0. Since dx_0, dy_0, dz_0, cos $\lambda d\phi$, cos $\mu d\phi$, cos $\nu d\phi$, can each receive any value we please independently of the rest, the preceding can only vanish when the six following conditions are fulfilled:—

$$\Sigma X = 0 \qquad \Sigma Y = 0 \qquad \Sigma Z = 0$$
$$\Sigma(Zy - Yz) = 0 \qquad \Sigma(Xz - Zx) = 0 \qquad \Sigma(Yx - Xy) = 0$$

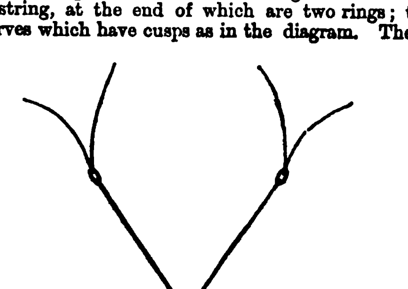
which are the six well-known equations of equilibrium of a rigid system.

We might give more examples, but our limits require us at once to enter upon a point which will require fuller explanation, because the student will not find it in any elementary work. "When $\Sigma(Pdp)$ is = 0 for every virtual motion, there must be equilibrium:" but the converse, namely, that "when there is equilibrium the equation $\Sigma(Pdp)$ = 0 must be true for every virtual motion," has not the same universality as the direct proposition. If we look carefully at the proof, we shall see that, taking any particular instance of virtual motion, the only reason why we want $\Sigma(Pdp)$ to be = 0 for that particular motion, is, that the forces may not be able to make the system set off with that motion: or that the incapability might exist even though that motion were the only one which the system could take. If then there be in the nature of the system itself any reason why a particular case of virtual motion should be unattainable by the action of those forces, we have no longer any reason to say that $\Sigma(Pdp)$ must be = 0 in that case.

As a general rule, if P, Q, R, &c. be the acting forces, and $Pdp + Qdq + Rdr +$ &c., the sum of their moments; and if in one virtual motion $dp = \alpha$, $dq = \beta$, $dr = \gamma$, &c., that one virtual motion has its opposite, in which $dp = -\alpha$, $dq = -\beta$, $dr = -\gamma$, &c. And we shall presently see that if that one motion and its opposite be by proper restrictions made the only ones which the system can take, the system will begin to take the first motion if $P\alpha + Q\beta + R\gamma +$ &c. be positive, and the opposite if $P(-\alpha) + Q(-\beta) + R(-\gamma) +$ &c. be positive. In fact, a system must set off from rest in such manner that the sum of the initial moments is positive: and it is clear enough that either $P\alpha +$ &c., or $P(-\alpha) +$ &c. must be positive unless both vanish. As a general rule then, $P\alpha +$ &c. must vanish; for if not, either the virtual motion first named, or its opposite, has a positive sum of moments, and can be, and (if no other motion can take place) will be, an initial motion of the system. But if ever it should happen that there are cases in which a virtual motion is possible, but its opposite motion is impossible, then all that is requisite is that for the possible one of the pair, ΣPdp should be 0 or negative, *not positive*. There is another exception of a remarkable character, for which it will be better to wait until we come to see the meaning of the sum of the moments in a dynamical point of view. Excluding this for the present, let a virtual motion which has its opposite be called a double motion, and one which has not its opposite, a single motion: then the true statement of the principle of virtual velocities is as follows:—

If ΣPdp be nothing for every double virtual motion, and nothing or negative for every single one, there is equilibrium: and if there be equilibrium, then $\Sigma(Pdp)$ is nothing for every double virtual motion, and nothing or negative for every single one.

We might easily have incorporated the consideration of these exceptional cases of single virtual motions in the general proof. We shall now give a simple instance. Let a weight be fastened to the middle of a string, at the end of which are two rings; these rings slide upon curves which have cusps as in the diagram. The weight is



in equilibrium, and the weight is the only external acting force: but its moment is not nothing (that is, is not of the second order with reference to the displacement of the rings), but is negative. The virtual motions of the rings are single, and can only be upwards. The reader who compares the preceding omission in the statement of the principle of virtual velocities with VARIATIONS, CALCULUS OF, will see a remarkable likeness between the cases: in fact, these errors and several others depend upon the same sort of omission, which may be stated as follows:—If there be a proposition (A) which is true on condition that the quantity B is never positive; and if, generally speaking, every negative value of B be accompanied by a corresponding positive one, then, generally speaking, (A) cannot be true if B be negative: that is, the truth of (A) requires B = 0. But if there be exceptional or singular cases in which negative values of B are *not* accompanied by corresponding positive ones, then B = 0 is no longer necessary; it is enough that B should be negative. Now the error which has run through the results of the differential calculus from book to book, from country to country, and from century to century, consists in taking the usual and general case for universal, and forgetting the exception.

The principle of virtual velocities is applied to dynamics by means of the celebrated principle which goes by the name of D'Alembert, propounded by him in his treatise on dynamics, published in 1743. We have touched upon this principle in FORCES, IMPRESSED AND EFFECTIVE, but we have referred the complete development of it to the present article.

It will do for our present purpose to suppose a system of points connected together, each point being considered as a certain mass of matter. Whatever may be the faults of the system of Cavalieri [CAVALIERI, in BIOG. DIV.] for geometrical deduction, it is sound enough mechanically considered: a point may not be taken to be one of the constituent parts of a length, but there is no difficulty in considering it as endowed with weight and impenetrability, or as rigidly connected with other points. If we imagine a mass of matter to be divided into an infinite number of infinitely small elements, each of which is an extended mass, though we may not, for geometrical purposes, suppose each of these elements to have its *bulk* collected in any one of its points, there is no difficulty in supposing its *mass* to be so collected. If then we begin with the consideration of a finite number of points, having various masses, we may, by increasing the number of our points and diminishing their masses, approach as near as we please to the case of a continuous geometrical solid, all the parts of which have weight, and of which the density varies according to any law. Again, when a system moves, and when the law of its motion is known, we can determine, at any one instant [VELOCITY], the velocity of any one point in any one direction, and the acceleration (or retardation, *negative* acceleration) at that one instant: that is to say, the rate per second at which the motion is receiving acceleration at the moment named. From this acceleration, as in the place last cited, we can determine the pressure which the mass of the point in question is actually experiencing at the moment; for on one mass there is but one pressure which can produce acceleration at one given rate. In this way then we can determine the pressures which the various points (or molecules*) of the system are undergoing; and this determination is made *in terms of the motion*, that is, in terms of the velocities and accelerations of the molecules, the pressures being derived from the accelerations by reference to the known masses of the molecules. The pressures so obtained are called *effective forces*, a sufficient and expressive name. But it by no means follows that the forces *applied* at the different molecules are those which are *effective* on those molecules. Two molecules are inseparably joined by a rigid bar without weight, and thrown into vacuous space. If these molecules were thrown separately, each would describe a parabola; but as the case stands, the centre of gravity of the molecules describes a parabola, and the bar revolves round its centre of gravity [TRANSLATION and ROTATION]: the effective forces are very different from the impressed forces. Now D'Alembert's principle is the expression of this simple law, that *force is never lost*† *nor gained*. If a force applied to any molecule of the system be not wholly effective on that molecule, the part which is not effective on the molecule of application is effective elsewhere; and if the motion gained by or rate of acceleration shown by any given molecule be greater than is due to the force impressed on that molecule, some other molecule of the system must have less than is due to its impressed force. Thus the motion of a system of connected molecules involves a collection of debtor and creditor accounts, the balances of which cannot show, when put together, the smallest amount of momentum in any direction, except what the system either had at the beginning or has received from the impressed forces during the motion. The consideration of the third law of motion [MOTION, LAWS OF,] would make such a result appear extremely probable, if not necessary; but a specific demonstration of the truth of the principle can be given.

Let the molecules have the masses m_1, m_2, &c., and let the impressed forces be such as, in their directions, would give the rates of acceleration P_1, P_2, &c., if these molecules were free and unconnected. Then [FORCE; MASS; VARIATION; VELOCITY] m_1P_1, m_2P_2, represent the pressures impressed, on the condition that the unit of pressure is that which produces a unit of acceleration in the unit of mass. Let the effective pressures, derived from the velocities in the directions of the co-ordinates of x, y, and z, and compounded into one force for each molecule, be such as would produce the rates of acceleration Q_1, Q_2, &c.; so that the effective pressures are m_1Q_1, m_2Q_2. &c. When two forces act on a point, either is equivalent to the other with a certain third force; let m_1P_1 be equivalent to m_1Q_1 and m_1R_1; let m_2P_2 be equivalent to m_2Q_2 and m_2R_2, and so on. Then the system (P) of impressed forces is equivalent to the system (Q) of

* A molecule, in geometrical mechanics, means a point, endowed with the properties of a mass of matter, finite or infinitely small, as the case may be.

† We here exclude friction and resistances, but only on account of our ignorance of the action of these forces. The forces lost (that is, lost with respect to the system) are here communicated to other substances, to the mass in contact or to the air.

effective forces, together with the system (R): for (P) substitute (Q) and (R), and the effect upon the system, in the infinitely small time following the moment of which we speak, is what it would have been if (P) had continued. But that effect is precisely what is produced by (Q); for (Q) was nothing but the pressures necessary to produce the actual effect of which we are speaking. Therefore (R) has no effect, and would of itself equilibrate the system: to suppose that (R) would not equilibrate, or would produce some motion, while (Q) is actually calculated to produce all that is to take place, is to suppose that the system will, in the infinitely small time next ensuing, have another motion besides that which (Q) would produce, which is absurd. Consequently (R) is a system of equilibrating forces, which is expressed by saying that the forces lost and gained balance one another: for if $m_1 P_1$, the force impressed on m_1, be equivalent to $m_1 Q_1$ and $m_1 R_1$, of which $m_1 Q_1$ is enough to produce what takes place, it is obvious that $m_1 R_1$, so far as the molecule m_1 is concerned, is lost. It would be better to say that $m_1 R_1$ is transferred, and that all the forces transferred balance one another. Again, since (R) is wholly without effect, it follows that (P) is equivalent to (Q); or, at every instant of the motion, the impressed forces are a set of equivalent statical powers with the effective forces: so that if either set were applied to the system at rest, and also the opposites of all the forces in the other set, there would be equilibrium. Or the impressed forces balance the effective forces with their signs changed. Now the effective forces on m_1, in the directions of x, y, and z, are $m_1 \frac{d^2x_1}{dt^2}$, $m \frac{d^2y_1}{dt^2}$, $m_1 \frac{d^2z_1}{dt^2}$, and similarly for the rest; while, if we decompose the rate of acceleration P_1, into X_1, Y_1, Z_1, in the directions of x, y, and z, the impressed pressures in these directions are $m_1 X_1$, $m_1 Y_1$, and $m_1 Z_1$. And [VARIATIONS, CALCULUS OF,] to distinguish the virtual motion which the problem of equilibrium requires, from the actually coming motion in terms of which the effective forces are expressed, we may use δx, instead of dx, in the former, and so on. Hence, changing the signs of the impressed forces and combining them, so changed, with the effective forces, we have, for the fundamental equation of every dynamical problem—

$$\Sigma\left(\frac{d^2x}{dt^2} - X\right) m\delta x + \Sigma\left(\frac{d^2y}{dt^2} - Y\right) m\delta y + \Sigma\left(\frac{d^2z}{dt^2} - Z\right) m\delta z = 0.$$

From which are obtained, as in a preceding process, the following six equations of motion, abbreviating $d^2x : dt^2$ into x'', and so on—

$$\Sigma(mx'') = \Sigma(mX) \qquad \Sigma\{m(z''y - y''z)\} = \Sigma\{m(Zy - Yz)\}$$
$$\Sigma(my'') = \Sigma(mY) \qquad \Sigma\{m(x''z - z''x)\} = \Sigma\{m(Xz - Zx)\}$$
$$\Sigma(mz'') = \Sigma(mZ) \qquad \Sigma\{m(y''x - x''y)\} = \Sigma\{m(Yx - Xy)\}$$

These equations express the property already mentioned [TRANSLATION], namely, that the centre of gravity moves as it would do if all the masses were collected there, and all the pressures applied there. We shall merely enumerate the steps of the proof of this proposition. The co-ordinates of the centre of gravity being x_0, y_0, z_0, we have $x_0 \Sigma m = \Sigma(mx)$, &c., whence $x_0''\Sigma m = \Sigma(mx'') = \Sigma(mX)$, &c., which are precisely the equations for the motion of a molecule of the mass Σm, and to which the force $\Sigma(mX)$ is applied. With regard to the initial velocity which ought to be given to the centre of gravity when the molecules are there collected, observe that $x_0' = \Sigma(mx') \div \Sigma m = \left\{A + \Sigma\left(\int mX dt\right)\right\} \div \Sigma m$, where A is the initial value of $\Sigma(mx')$. Consequently, at the commencement of the motion x_0' should have the same value as $\Sigma(mx') \div \Sigma m$), or we should have $x_0'\Sigma m = \Sigma(mx')$ at the outset; that is, the momentum of the collected mass, in the direction of x, should be the same as the sum of the momenta of the molecules in the system, and the same of the other co-ordinates. Again, let ξ, η, ζ, be the co-ordinates, referred to the centre of gravity, of the point whose original co-ordinates are x, y, z.

We have then $x = x_0 + \xi$, $y = y_0 + \eta$, $z = z_0 + \zeta$; also $\Sigma . m\xi = 0$, $\Sigma m\eta = 0$, $\Sigma m\zeta = 0$. Substitution gives

$$\Sigma\{m(z''y - y''z)\} = y_0\Sigma mZ - z_0\Sigma mY + \Sigma\{m(\zeta''\eta - \eta''\zeta)\}$$
$$= \Sigma\{mZ(y_0 + \eta) - mY(z_0 + \zeta)\}$$
$$\text{whence } \Sigma\{m(\zeta''\eta - \eta''\zeta)\} = \Sigma\{m(Z\eta - Y\zeta)\}$$

which, with the two other equations similarly deduced, are precisely those which would determine the motion if the centre of gravity were fixed and the forces then applied. We must refer to works on the subject for further development of these conditions, and shall proceed to cases more illustrative of the principle under consideration.

Among the virtual motions, one of course is the motion the system is actually about to take. In this case δx is dx, &c., and the fundamental equation becomes

$$\Sigma\{m(x''dx + y''dy + z''dz)\} = \Sigma\{m(Xdx + Ydy + Zdz)\}.$$

Now the first side of this equation is nothing but the differential with respect to the time of $\frac{1}{2}\Sigma\{m(x'^2 + y'^2 + z'^2)\}$, or $\frac{1}{2}\Sigma mv^2$, v_1, v_2, &c., being the actual velocities of the molecules at the end of the time t. Hence we have

$$\Sigma mv^2 = A + \Sigma\left\{m\int(Xdx + Ydy + Zdz)\right\}$$

where A is the value of Σmv^2 at the commencement of the motion, and the integral also begins at that commencement. Suppose the system to be at rest at the commencement of the motion, then $A = 0$, since each of the incipient velocities is nothing; consequently at the end of the first infinitely small element dt, Σmv^2 has changed from 0 to $m(Xdx + Ydy + Zdz)$. But this is precisely the sum of the moments of the impressed forces in the principle of virtual velocities; and Σmv^2 being $m_1 v_1^2 + m_2 v_2^2 +$ &c., must be a positive quantity. Hence the sum of the moments must be positive, for the virtual motion which the system actually tends to take: and this is the principle of which we have forestalled the use in completing the correct enunciation of the principle of virtual velocities. This might be suspected beforehand from the following consideration:—The forces which have positive moments are those which tend, so far as they go, to produce the virtual motion in question; and those which have negative motions to hinder it. Whatever motion the system takes, it must be one in which the forces tending to produce that motion predominate over those which tend to hinder it: or the forces with positive moments must have those moments together larger than the forces with negative moments.

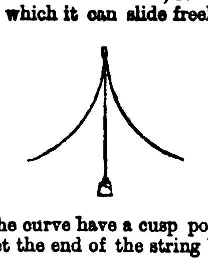
The choice which the system * makes among all the virtual motions, in which to begin its motion, is that in which the sum of all the moments of the forces is a maximum, in the sense which will presently be explained. Since every motion of a system can be reduced to a translation of the centre of gravity and rotation round an axis passing through that centre, let us reduce the virtual motion to terms of the motion of and round the centre of gravity. If ΣmX, &c., be P, Q, R, and if $\Sigma\{m(Zy - Yz)\}$ &c., be L, M, N, it follows from what has been shown respecting the motion of this centre that its first direction of translation (the system starting from rest) is such that dx_0, dy_0, dz_0 are in the proportion of P, Q, R, and that the axis round which the system begins to turn makes angles with the axes of x, y, and z, whose cosines are in the proportion of L, M, and N. Now suppose any motion of and round the centre of gravity, and returning to the expressions in which the sum of the moments is given in terms of those motions, observe that we must write mX for X, &c., because the pressures are now represented by mX, &c., which were then represented by X, &c. Moreover $z_0\Sigma mY - y_0\Sigma mZ$, and the other terms corresponding, all vanish, because $z_0 = \Sigma mZ \div \Sigma m$, &c. We have then for the sum of the moments,

$$P dx_0 + Q dy_0 + R dz + (L\cos\lambda + M\cos\mu + N\cos\nu)\, d\phi.$$

Let the displacement of the centre of gravity be du, we have then $du = \sqrt{(dx_0^2 + dy_0^2 + dz_0^2)}$. Now the theorem is, that for given values of du and $d\phi$, for a given amount of translation and rotation, the direction of translation and the position of the axis of rotation, in the virtual motion which the initial effect of the forces actually causes, are such as to make the preceding expression a maximum.

First, it must be shown by the common methods that for a constant value of $p^2 + q^2 + r^2$, the expression $Ap + Bq + Cr$, *if then positive*, is a maximum when p, q, r are in the proportion of A, B, C. Now in the actual motion of the system, $P dx_0 + Q dy_0 + R dz_0$, and $(L\cos\lambda + \&c.)\, d\phi$, *are positive quantities*; for the first is the initially obtained value of $\frac{1}{2}\Sigma mv^2$ when the system is all collected in the centre of gravity and all the forces are then applied: and the second is the same when the centre of gravity is fixed and the system begins to move about it. And since the variables of the first and second are entirely independent of each other, the sum of the two is a maximum when each separately is a maximum. In the first $dx_0^2 +$ &c., is a constant, being du^2, and therefore the first is a maximum when dx_0, dy_0, and dz_0 are in the proportion of P, Q, R. But in the second, $\cos^2\lambda + \cos^2\mu + \cos^2\nu = 1$, whence the second is a maximum when $\cos\lambda, \cos\mu, \cos\nu$ are in the proportion of L, M, N. But these two sets of conditions put together precisely represent the motion which at the outset the system does take from the impressed forces. Whence the theorem is true, as asserted.

We may now treat the exception of which we have spoken in a preceding part of this article. Suppose that the moments in all the directions in which the system can move are equal, or else that there is among them a set which are equal, and each of them greater than any of the rest. Which of all the virtual motions having these moments is the system to take? It cannot prefer either, and will remain in equilibrium. As an instance, let the end of a string be attached to a curve on which it can slide freely, while the string sup-



ports a weight. Let the curve have a cusp pointing upwards, with its tangent vertical, and let the end of the string be placed at the cusp, as

* We confine ourselves here to a rigid system, though the proposition is true universally. But the universal proof would be too long.

in the diagram. There will be equilibrium, but the principle of virtual velocities will not be true, even in the extended form which we have used. The moments belonging to the two possible motions are positive, but they are equal. On which side is the descent to take place?

The mathematician has a warning in such cases, which may be easily and briefly expressed. The expression ΣPdp, before it is used, requires that the quantities p_1, p_2, &c., should be reduced to the smallest number of independent variables. Let $q_1, q_2 \ldots$ be these variables, and let the sum of the moments, when reduced to terms of these variables, be $Q_1dq_1 +$ &c., or ΣQdq. The principle is then intelligible when, for all the virtual motions, dp_1, dq_1, &c., have finite ratios to one another. But if there be any position in which for a certain virtual motion one or more of the set dp_1, dp_2, &c., become infinite with respect to those of the set dq_1, dq_2, &c., the equation becomes incapable of being used. For if we take the actual virtual *velocities*, and attempt to reduce

$$\Sigma Q \frac{dq}{dt} \text{ to its equivalent } \Sigma P \frac{dp}{dt},$$

the first side, which may be made finite, is equated to an expression in which infinite terms occur, which is always a warning to expect the possibility of cases of exception. Circumstances of this sort have never received sufficient investigation, and in all probability there are numerous varieties of the cases of equilibrium which arise out of them, and which cannot be treated by the ordinary principle. So much we may certainly say, that if there be different virtual motions with the sums of the moments positive and maxima, either there must be equilibrium, or the test for determining which of the motions will ensue is wholly unknown.

On the history * of virtual velocities, there is not much to say. Guido Ubaldi saw it in some cases, Galileo in some others; Wallis adopted it as a principle, and after him John Bernoulli, who gave it in the most general form. Lagrange made it the foundation of his 'Mécanique Analytique,' and since his time it has formed part of every well-constituted treatise on mechanics. It was in the 'Mécanique Analytique' that the principle given by D'Alembert was first joined to that of virtual velocities in such a manner as to give the science of dynamics its present uniformity of system.

VIS INERTIÆ. [INERTIA.]

VIS VIVA, or *living force*, a name given in mechanics to the following index of the state of a system in motion:—the sum of all the masses, each multiplied by the square of its velocity. If the system be considered as composed of a finite number of molecules, the vis viva may be expressed by the symbol Σmv^2; but if it be a continuous mass, or a collection of continuous masses, by $\int v^2dm$, or $\Sigma \int v^2dm$. It is enough that the mass of every particle be found in the expression, multiplied by the square of its velocity.

In the article VIRTUAL VELOCITIES we see the equation—

$$\Sigma mv^2 = \Sigma m \int (Xdx + Ydy + Zdz),$$

the integral being taken for each molecule over the whole path which it has described since the beginning of the motion.

Presuming a knowledge of the article cited, we may describe the vis viva thus:—Dividing the whole motion of the system, from the beginning to the time under consideration, into an infinite number of infinitely small changes of place, each of those changes is one of the virtual motions which come under consideration in the principle of virtual velocities. And each motion has, generally speaking, its contrary; and one of these two the system would tend to take, and to refuse the other, if its motion were for an instant restricted, so that it could only choose between those two. The one which it would tend to take is that for which $\Sigma m\,(X\,dx +$ &c.) is positive. Now, it appears in the preceding equation that whenever the infinitely small motion which is taking place for the time being is that which (when restricted as above) the system would take, the vis viva is receiving increase; when that which it could not take, decrease. And the vis viva is the balance, so to speak, of all the sums of moments, each with its proper sign, added, also with its proper sign, to the vis viva at the beginning of the motion. [PHYSICAL FORCE, CONSERVATION OF.]

The preceding equation is sometimes said to express the principle of the *conservation of vis viva*, which is to be understood thus: the system never acquires nor loses any quantity of vis viva from the action of its parts upon each other, but only from the action of external forces. If after a certain time all external forces cease, from that moment $\Sigma m\,(X\,dx +$ &c.) is $= 0$, or $d\,(\Sigma mv^2) = 0$, or Σmv^2 remains constant.

Another remarkable property of the vis viva is, that in all the cases which occur in nature, the amount of vis viva acquired in passing from one position to another depends only on the co-ordinates which settle the initial and final positions. If X, &c., be functions of co-ordinates only, it generally happens that $X\,dx + Y\,dy + Z\,dz$ is an integrable function, and depends on co-ordinates only. But the force of this result is not easily seen by the beginner.

At the end of the 17th century a remarkable discussion took place on the question of the mechanical interpretation of the vis viva. Leibnitz first gave this name: he considered force when it produces motion as *vis viva*, or living force; but when it is equilibrated, he called it *vis mortua*, or dead force; and he measured the effect of living force by the mass multiplied into the square of the velocity. To take the simple case which was mostly appealed to:—If two equal weights be thrown up in vacuo, the one with a velocity double that of the other, it is well known that the one will rise, not *twice*, but *four* times as high as the other: accordingly, Leibnitz considered that the force which produces the double velocity is four times as effective as the other force. Various other instances were produced in which the duplication of the velocity is the quadruplication of the effect produced. It was accordingly argued that, for a given mass, the square of the velocity is the proper measure of the force necessary to destroy or to create the velocity. But, on the other hand, it was very well known that, whatever might be adopted as the measure of force, it was certain that pressures were, *cæteris paribus*, proportional to the simple velocities produced by them in a given time. John Bernoulli adopted the opinion of Leibnitz, which was opposed by various other contemporaries; and the controversy (the history of which may be seen in Montucla) continued until the publication of D'Alembert's work on dynamics, in which the question was treated as being purely one of words.

It was objected to the opinion of Leibnitz, that though the double velocity would give four times the ascent, it ought not to be forgotten that it required twice the time: so that in a given time double the velocity would produce only double the ascent, one part of the ascent with another. This argument was never satisfactorily answered; and while we cannot help thinking that it ought to have been decisive of the question, we draw from it a conclusion different from that of D'Alembert; we cannot think the dispute a mere question of words. It must be granted that, for all purposes in which time is not an element, the measure of the effect of a force may be the square of the velocity, as exemplified in the instance cited. But when is it that a mechanical effect can be properly estimated without reference to the time in which it is produced? The definition of the words measure and effect may thus without doubt be accommodated either to the idea of Leibnitz or of his opponents; and those who disputed on the question without requiring exact definitions might degenerate into a mere question of words. But it ought to have been a question as to what was the *proper* meaning of the word effect, in the fundamental phrase "effect of a force," the proper explanation of which must precede all good reasoning in mechanics. If pressure be defined as that which produces a certain effect [PRESSURE] on our senses, undoubtedly it is a known fact that uncounteracted pressure produces motion; but it is only when allowed to act for a finite time: consequently, the element of time is as essential to the conception of the phenomenon as that of pressure or motion. Height in a rectangle gives area; but it would not therefore be allowable to measure that area by the height; for there must be a base, or there is no rectangle at all. But if pressure be merely considered as the cause of motion, and called force in that sense, it is very difficult to see why the cause, which is only known by the effect, is to be measured by anything but the simple effect. Probably this discussion gave rise to the chapter of the 'Mécanique Céleste,' in which Laplace speculates upon what the laws of motion would have been if force had been as a function of the velocity, instead of as the simple velocity. We have never met with any one who could give us an intelligible account of the meaning of this investigation.

VISCIN. [BIRDLIME.]

VISCOUNT, the name of a dignity which ranks fourth in the peerage, immediately above that of baron. It is the most recent English title, having, it is said, its origin in the time of Henry VI., who, in 1440, created by letters patent John, Lord Beaumont, Viscount Beaumont. In Scotland the title of Viscount was first granted by James VI.

Camden observes that, although this is a new title of dignity, yet it is an ancient one of office: viscount, *vicecomes*, the deputy of the count or earl, is the Latin name for the sheriff of a county [SHERIFF], an office in ancient times held by persons of the highest rank. Whether the title of viscount was suggested by that office it is difficult to say; but Spelman mentions that William the Conqueror made Baldwin hereditary Viscount (*vice-comitem*) of Devon and Baron of Okehampton; and "he made Ursus or Urso Abtot viscount of Worcester, but Roger his son was deprived of the title by Henry I., because he had killed a certain servant of the king; the office, however, was transferred through his sister to the Beaumonts." Spelman seems in these passages to consider this title as one of dignity before Henry VI.'s time, and as having been distinct from that of sheriff: in the first instance he joins it to the title of baron and gives it precedence; in the second, he treats the Beaumonts, who are usually deemed the first viscounts, as only restored to a title which had been in abeyance or forfeited for three centuries. In the British peerage, in 1861, there were 22 viscounts; and there were 41 Irish viscounts, of whom 10 held British peerages also, with 5 Scotch viscounts, of whom 3 held British peerages.

(Spelman, title *Vice-comes, nomen dignitatis*; Camden's *Britannia* (Gough's), i., cxciv.; 2, 299; 4, 24.)

VISHN'U (from *vis*, "to enter," or "to pervade") occupies the second place in the Trimûrtti, or Triad of the Hindus, and is the

* On this point, and many others connected with the history of mechanics, the reader will find specific accounts and valuable references in Walton's 'Collection of Problems on Theoretical Mechanics.'

personification of the preserving principle. There is no doubt that his worship is of a very ancient date; but at the same time it is evident that it has experienced successive and considerable changes, and that the forms under which Vishn'u is now worshipped in India are far from being authorised by the ancient scriptures of the Hindus. (For his place among Vaidik deities, see VEDA.)

There is no trace of Vishn'u or anything relating to him in the Institutes of Manu, although the allusions which are made to idolaters and the worship of inferior gods (book iii., v. 152, 164) might possibly have some reference to him also. However, we might be led to expect that more notice would have been taken of him by Manu, since the two heroic poems, the Mahâbhârata and the Râmâyan'a, which are generally believed to belong to the same period of Hindu literature as the Dharmma-S'âstra, or Institutes, have for their subjects two of the latest incarnations of this god, who therein assumes the attributes of the one supreme god. He is stated to have appeared before the other celestials, and to have agreed, at their humble request, to become man for the purpose of destroying the demon Râvan'a [SANSKRIT LANGUAGE AND LITERATURE], and to remain incarnate among men for the space of eleven thousand years in order to protect the world after saving it. ('Râmâyan'a,' book i., sect. xiii., s'l. 23.) The Mahâbhârata relates the exploits of Vishn'u as Krishna; and the Hari-Vansa, a sort of supplement to that poem, details his genealogy, and a variety of legends exalting his power and recommending his worship. From the numerous allusions which these poems make to the other Avatâras, descents or incarnations of Vishn'u ('Râmâyan'a,' i., xxiv. 22; xxvii. 2; lxvii. 15, &c.), we may safely conclude that at the time of their composition his history had already been brought into a system, where the miraculous deeds which he performs seem calculated to call forth the special adoration of the Hindus.

The order in which these different Avatâras are supposed to have taken place is by no means fixed, and the discrepancy in the different authorities with regard to Vishn'u's actions on earth is sometimes very great. The 'Vishn'u Purana, a System of Hindu Mythology and Tradition,' translated by the late H. H. Wilson, and published in 1840, contains a full account of them. The last Avatâr is yet to come. These Avatârs, there can be little doubt, represent some physical force or power. Professor Max Müller, in his paper on 'Comparative Mythology,' published in the 'Oxford Essays' in 1856, has shown, from philological deductions, that much of the early mythology of most nations has been formed from "the absence of merely auxiliary words;" and that "there are many mythes in Hesiod, of late origin, where we have only to replace a full verb by an auxiliary in order to change mythical into logical language." But, he observes, the Puranas offer no assistance to the comparative mythologist. "The stories of S'iva, Vishn'u, Mahâdeva, Pârvati, Kali, Krishna, &c., are of late growth, indigenous to India, and full of wild and fanciful conceptions."

Still, as the believers in Vishn'u are numerous in India, it may be interesting to give a slight sketch of the various sects. First, we must state that Vishn'u's heaven is called Vaikun't'a; for a description of which we refer to the first volume of Ward's 'View of the Religion, Literature, &c., of India.'

His names are as numerous as those of S'iva, and may be found enumerated in the Kr'ishn'a-nâmasahasram, or "the thousand names of Kr'ishn'a :", they are also partly given in the Amarakosha (i. i. 1.), and of these we shall adduce those which occur most frequently, and are sometimes the cause of a good deal of confusion. They are Kes'ava, Dâmodara, Hr'ishîkes'a, Mâdhava and Madhuripu, Janârddan'a, Achyuta, Govinda, Padmanâbhi, Vâsudeva, Trivikrama, Purushottama, &c.

By his wife Lakshmî, the goddess of beauty, he had Kâma or Manmatha, the god of love. The Purân'as, which are the text-books for the Vaishn'avas, are the Vishn'u, Nâradîya, Bhâgavata, Gârud'a, Pâdma, and Varâha, which are called Sâtwika, or pure and true.

Sects of Vaishn'avas.—The first authentic records we have of the different worshippers of Vishn'u date from the 8th or 9th century of our era. At that time the two great divisions of Vaishn'avas and S'aivas were in a flourishing condition, and each embraced six subdivisions; those which belonged to the Vaishn'ava faith are the following:—

1. The *Bhâktas*, who worshipped Vishn'u as Vâsudeva, and wore no characteristic marks; their worship was that of the one supreme lord of the universe.

2. The *Bhâgavatas*, who thus called themselves from a name of Vishn'u, and impressed upon their persons the *Vaishn'ava* insignia, representing the discus, club, conch, &c., of their divinity. But they had an admixture of superstition in their religious creed, and reverenced the *Tulasî* plant and the *Sâlagrâma* stone, of which more will be said hereafter. The authorities of both these sects were the Upanishads and the Bhagavad-Gîtâ.

3. The *Vaishn'avas* differed only from the preceding sect by promising themselves a sort of sensual paradise after death in Vaikun't'a.

4. The *Pancharâtrakas*, who worshipped the female personifications of Vishn'u.

Besides these there were, 5, the *Vaikhânas'as*, and, 6, the *Karmmahînâs*, who abstained from all ritual observances.

These six sects, of which some have disappeared, have given rise to about twenty different schools, which for the greater part exist to this day. Amongst other divisions of less importance, the Vaishn'avas are usually distinguished into four principal Sampradâyos, or sects, of which the most ancient and respectable is the S'rî Sampradâya, founded by the Vaishn'ava reformer Râmânuja Achârya, who lived about the middle of the 12th century. The establishments of the *Râmânujîyâs* are still numerous in the Deccan, and the same country comprehends the site of the *Gaddi*, or the pillow-seat of the primitive teacher; his spiritual throne, to which his disciples are successively elevated; and this circumstance gives a superiority to the Achâryas of the south over those of the north of India. The worship of this sect is addressed to Vishn'u and to Lakshmî, and their respective incarnations, either singly or conjointly; and this causes many subdivisions according as these Vaishn'avas adore either Nârâyan'a or Lakshmî, or Lakshmî Narâyân'a, or Râma or Sitâ, or Sitâ-Râma, &c. Images of metal or stone are usually set up in the houses of the private members of this sect, which are daily worshipped, and the temples and dwellings are all decorated with the Sâlagrâma stone and the Tulasî plant. A peculiarity of this sect is that they always cook for themselves, and observe the most scrupulous privacy in eating their meals.

The chief ceremony of initiation in all Hindu sects is the communication by the teacher to the disciple of the *Mantra*, which generally consists of the name of some deity, or a short address to him. It is communicated in a whisper; that of the Râmânuja sect is, *Om* Râmâya namah, that is, *Om* Salutation to Râma!

The Hindu sects are usually discriminated from each other by various streaks (*Bhaktichchheda*) on their faces, breasts, and arms; for this purpose all the Vaishn'avas employ a white earth called *Gopîchandana*, which should be brought from Dwârakâ, it being said to be the soil of a pool at that place, in which the Gopîs drowned themselves when they heard of Kr'ishn'a's death. (This word means the "sandal-wood of the Gopîs," and is nothing but a kind of calcareous clay.) The followers of Râmânuja have for their authorities the *S'rî Bhâshya*, the *Gîta-Bhâshya*, the *Vedâsht'a-Sangraha*, and the eight Sâtwika Purân'as; besides numerous other works which are still current in various parts of India. The doctrine contained in these books is called the "Vis'isht'âdwaita," or doctrine of unity with attributes; for although the Râmânujas maintain that Vishn'u and the universe are one, yet, in opposition to the Vedânta school of philosophy, they deny that the deity is void of form or quality, and regard him as endowed with all good qualities, and with a twofold form—the supreme spirit, *Paramâtmâ*, or cause, and the gross one, the effect, the universe: and in these assertions they are followed by most of the Vaishn'ava sects.

The members of this sect are in the north of India called S'rî-Vaishn'avas, and are decidedly hostile to the S'aivas; nor are they on friendly terms with those Vaishn'avas who worship Kr'ishn'a, although they acknowledge that deity to be an incarnation of Vishn'u.

Towards the end of the thirteenth century of our era, Ramânanda, originally one of the earliest teachers of the tenets professed by the preceding sect, retired from the society, and established a schism of his own at Benares. The principal object of worship of Ramânanda's followers is Vishn'u as Râmachandra: they of course reverence also the other Avatâras, but they maintain the superiority of Râma in the present or Kali yuga; hence they are collectively known as *Râmavats*. They also reverence the Sâlagrâma stone and the Tulasî plant, and their forms of worship correspond with those of the Hindus in general; but some mendicant members of the sect consider all forms of adoration superfluous, beyond the incessant invocation of the name of Kr'ishn'a, and Râma. They are known as *Vairâgis* or *Viraktas*. There are many subdivisions of this school, which it would be tedious to enumerate.

A sect of great influence, to which the most opulent part of the population of India belongs, is that of the Rudra-Sampradâya, or Vallabhâchâris. They attach themselves to the worship of Kr'ishn'a and his mistress Râdhâ, one of the Gopis of Vr'indâvana, either singly or conjointly. There is, however, another form which is more popular still, although much interwoven with the other. This is the Bâla Gopâla, or the Infant Gopâla (Cowherd—a name of Kr'ishn'a), the worship of whom is very widely diffused amongst all ranks of Hindu society, and which originated with the founder of the Rudra Sampradâya, Vallabha Achârya. The worship of Kr'ishn'a as one with Vishn'u dates evidently from the Mahâ-Bhârata, and his juvenile forms are brought pre-eminently to notice in the account of his infancy in the Vishn'u and other Purân'as; but none of these works discriminate him from Vishn'u, nor do they recommend his infantine or adolescent state to peculiar veneration. Eight times a day ceremonial worship is paid, and the procession of Jugganâtha is (or was) held in his honour. The most popular festival at Benares is the Janamasht'ami, the nativity of Kr'ishn'a, on the eighth day of Bhadra (August). Another is the Râsa-yâtra, or annual commemoration of the dance of the frolicksome deity with the sixteen Gopis. This last is a very popular festival, and is celebrated with the greatest solemnity.

The Brahma Sampradâya is a sect instituted in the south of India by Mâdhava Achârya, who was born in the Saka year 1121 (A.D. 1199). The doctrine of the members of this sect is similar to that of the Rudra Sampradâya, with the exception that they deny the Moksha, or final emancipation; they also hold the Yoga to be impracticable: for according to them life is one and eternal, dependent upon the Supreme (Vishn'u), and indissolubly connected with, but not the same with him; they quote the following line from the Mahopanishad: "As the bird and the string, as juices and trees, as rivers and oceans, as fresh water and salt, as the thief and his booty, as man and objects of sense—so are God and life distinct, and both are ever indefinable;" and this one from the Garud'a-Purân'a: "From the difference between omniscience and partial knowledge, omnipotence and inferior power, supremacy and subservience, the union of God and life cannot take place." This division of the Vaishn'avas is however confined to the peninsula, and is altogether unknown in Gangetic Hindostan.

Besides these sects, which are the most conspicuous, the Vaishn'avas comprehend the Khâkis, Maluk Dâsis Senais, Mira-Bais, Nimâvats, Charan'a-Dâsis, &c.

This account of the Vaishn'ava sects has been chiefly derived from Professor Wilson's valuable paper in the fifteenth volume of the 'Asiatic Researches,' to which we refer the reader for fuller information.

Most of these religious sects are divided into clerical and lay members, as it were: the bulk of the votaries, though not always, belong to the latter; while the rest, or clerical class, are sometimes monastic and sometimes secular. Of the cœnobitic members of the different communities most pursue a wandering and mendicant life; indeed all of them at some period have led such a life: but when old and infirm they sit down in some previously existing *math*, or monastery, or establish one of their own.

The Maths, Asthals, or Akâras, the residences of the monastic communities, are scattered over the whole country; they generally comprehend a set of huts or chambers for the Mahanta, or superior, and his permanent pupils; a temple sacred to the deity whom they worship, or the Samâdh, or shrine of the founder of the sect, or some eminent teacher; and a Dharma Sâlâ, one or more sheds or buildings for the accommodation of the mendicants or travellers, who are constantly visiting the Math. Ingress and egress are free to all: and indeed a restraint upon personal liberty seems never to have entered into the conception of any of the religious legislators of the Hindus.

Of the inanimate objects sacred to Vishn'u the Sâlagrâma stone is the principal; it forms a profitable object of traffic, and enjoys the highest veneration of most of the Vaishn'avas. The Sâlagrâmas are mostly ammonites, found in the bed of the Gandhaki river, of the size of an orange. The reasons why this stone is worshipped are very contradictory and by no means satisfactory. We refer to the most plausible ones in the 'As. Res.,' vol. xii.; W. Hamilton, 'Description of Hindostan,' vol. i.; Forbes, 'Oriental Memoirs,' vol. iii.; and Ritter, 'Erdkunde,' vol. iv.

VISIER. [VIZIR.]

VISION. [LIGHT; also EYE, in NAT. HIST. DIV.]

VISITATION. [ARCHDEACON; BISHOP.]

VISITOR. [COLLEGE; USES, CHARITABLE.]

VISUAL DISTANCE. The relative position in which objects are seen is usually expressed by the relative direction of lines drawn to them from the eye; and the angle contained by two such lines is the *angular* or *visual distance* between the objects. [DISTANCE.] *Visual magnitude* may be estimated in a similar way, forming what is called the *visual angle* or *apparent magnitude* of an object.

VITELLIN. A form of albumen found in the yelk of eggs. [ALBUMEN.]

VITREOUS ELECTRICITY. [ELECTRICITY, COMMON.]

VITRIFICATION. [GLASS.]

VITRIFIED FORTS is a name that has been given to certain remarkable stone enclosures existing in parts of Scotland, which appear to have been subjected to the action of fire. Attention was first called to the subject by Mr. John Williams, a civil engineer of the last century, who had examined some of them while conducting certain mining operations in the Highlands under the orders of the Board of Annexed (or Forfeited) Estates in 1773, and who, in 1777, published a disquisition about them, under the title of 'An Account of some remarkable antient Ruins lately discovered in the Highlands and Northern Parts of Scotland: in a Series of [13] Letters to G. C. M., Esq.' 8vo. Edinburgh. Williams gave these piles the name of vitrified forts, unhesitatingly assuming that they were artificial structures. Nevertheless the idea, that the so-called forts were of volcanic origin, which had been previously held by Scottish writers, was soon after started anew by Pennant, who had seen one of them, and was taken up by other speculators; in particular it was attempted to be established by the Hon. Daines Barrington, in a paper read before the Society of Antiquaries in 1781, and published in the sixth volume of the 'Archæologia' the following year. But this notion may be said to be now given up on all hands. The subject has also been discussed by Dr. James Anderson and other writers in the 'Archæologia,' the 'Memoirs of the Wernerian Society,' the 'Transactions of the Royal Society of Scotland,' the 'Statistical Account of Scotland,' and of late years at some length by Dr. John Macculloch in the 'Transactions of the Geological Society of London,' and in his 'Highlands and Western Isles of Scotland;' by Dr. Hibbert, as the result of a series of inquiries set on foot by the Society of Scottish Antiquaries, and published in the fourth volume of their 'Transactions,' and by Mr. D. Wilson, in his 'Archæology of Scotland.'

The original description of the general nature of the vitrified forts given by Williams has not been corrected or contradicted in any material point by subsequent observers. And his views were supported at the time, on chemical and other considerations, by Dr. Black, and also by James Watt, who (apparently before the subject had attracted the attention of Williams) had personally and carefully examined the same fort (that on the hill of Craig Phaidrick, or Craig Patrick, near Inverness) which Pennant had hastily inspected. A description of this fort by Watt and a letter from Black are subjoined to Williams's account.

Every vitrified fort Williams had seen was situated on the top of a small hill, overlooking and commanding a surrounding valley or plain, always having at the summit a level area of greater or less extent, and for the most part inaccessible or very steep, at least on one side. Indeed, he asserts that the hills are always difficult of access, except in one place, which has everywhere been strengthened by additional works, of which he gives a description. What is called the fort consists of a wall enclosing the level summit, generally, in part at least, rectilineal and rectangular, but sometimes having one or more of the sides curved to suit the shape of the area. Exterior to this is sometimes a second circumvallation, which in some instances approaches within a few yards of the first, in others is removed from it to a considerable distance; but this outer enclosure is merely constructed of loose blocks of stone; it is the inner wall only which is entirely or partially vitrified. Williams's account is, that the materials have been "run and compacted together by the force of fire; and that so effectually, that most of the stones have been melted down; and any part of the stones not quite run to glass has been entirely enveloped by the vitrified matter; and in some places the vitrification has been so complete, that the ruins appear now like vast masses or fragments of coarse glass or slags." Generally, however, it would appear that the vitrification is not so complete as this description would seem to imply, though it may be sufficiently applicable to the more perfect specimens: in many cases the fire has only given the wall a coating of glass; in some, only one side of the wall is vitrified. The walls appear to be, in almost all the forts that have been examined, partially thrown down; in some, "the vitrified ruins," Williams states, "are nearly all grown over with heath and grass, and often appear at first sight like the ruins of some earth or sod buildings:" from the instances in which the structure seems to be the most entire, it may be conjectured that its original height was commonly about twelve feet.

Above fifty of these vitrified forts in all have been found, dispersed over the shires of Inverness (in which they are most numerous), Ross, Cromarty, Banff, Moray, Argyle, Aberdeen, Perth, Forfar, Kincardine, and Bute. Two or three have also been discovered in the southern counties of Wigton, Kirkcudbright, and Berwick. The most celebrated are that on the hill of Knockfarril, or Knockfarril na Phian, that is, the Place of Fingal on Knockfarril, on the south side of the valley of Strathpeffer, two miles to the west of Dingwall in Ross-shire; that, already mentioned, on the hill of Craig Phaidrick, two miles west of Inverness; that on the hill of Noth, in Aberdeenshire; that on Dun MacSniochain, in Argyleshire; that on the hill of Dunadeer, in Aberdeenshire; that near Creich, in Sutherland; that near the church of Amwoth, in Kirkcudbright; that on the hill of Dunskeig, at the entrance of Loch Tarbert, in Argyleshire; that on the castle hill of Finhaven, four miles to the east of the town of Forfar; that on the hill of Laws, near the village of Drumsturdymuir, a few miles to the north-east of Dundee; that at the entrance of the bay of Carradale, in Cantyre; that in the parish of Kingarth, in the Isle of Bute; that (very slightly vitrified) on Barryhill, in the parish of Meigle, Perthshire; those on Castle Finlay and Dunevan, in Nairnshire; that called Tordun Castle, about three miles from Fort Augustus; that on the west side of Gleneves, in Lochaber, about three miles south from Fort William.

Setting aside the theory of the volcanic or otherwise accidental origin of the vitrified forts, which appears to be untenable, seeing that they are manifestly artificial structures, we have still two suppositions between which to choose in accounting for the appearance they present. The vitrification may have been part of the process of their erection, and designed as a substitute for the ordinary cement; or it may have been the result of accident afterwards. The latter view was suggested by Lord Woodhouselee so early as 1783, and has since been supported by Dr. Hibbert and Sir George Mackenzie; the former, which was that taken by Williams and other early investigators, has been ably defended in recent times by the late Dr. John Macculloch. It is impossible for us here to enter at length into the considerations which have been advanced on both sides: they amount for the most part to but slight and unsatisfactory probabilities. Dr. Hibbert's notion is that the inclosures were intended for the protection of beacon fires; and he has endeavoured to show that the elevations on which they are erected are so chosen as that one of these signals could always be seen from another. His views are adopted by Mr. Wilson in his valuable 'Archæology of Scotland,' before referred to. Dr. Macculloch, on the other hand, maintains that this is not the fact. Besides, he observes that the extent of most of the enclosures is far beyond what could have been required for any beacon fire: the area of that at Amwoth, for instance, is not less than 2700 square yards. How also, it is asked, should it have happened, as is generally the case, that the walls should be vitrified on both surfaces, the exterior as well as the interior, if the effect was produced merely by the flame of a beacon lighted up within the inclosure? That they were intended for defensive military posts, Dr. Macculloch further contends, is manifest from the whole character of the works—both the vitrified walls and the surrounding defences, all of which, he says, "vary in form and size according to the ground they stand on, and are so contrived, just as a military work would be in the hands of a modern engineer, that they may command all the points of access, and prevent the enemy from advancing anywhere under cover." Macculloch further sought to show that the material of which the walls are built has evidently been selected with a view to its capability of being vitrified. But, as Mr. Wilson observes, his statements "only confirm the fact, already familiar to the chemist and geologist, that there are few districts in Scotland where rocks do not occur more or less capable of being vitrified." The materials that have been commonly used are granite or moorstone, limestone, sandstone, and what is called pudding-stone, all of which have the quality of being more or less easily fusible by fire. None of these forts are found south of the Tweed; they appear indeed to be peculiar to Scotland.

VITRIOL. A name formerly given to the sulphates. Thus the terms green, blue, and white vitriol were applied to sulphate of protoxide of iron, sulphate of copper, and sulphate of zinc respectively. Sulphuric acid is now sometimes termed *vitriol*, or *oil of vitriol*.

VITRIOL, WHITE. [ZINC.]

VIZIR, or VEZIR, is the name of the ministers of the sultan of the Turkish empire, and is also given as a title of honour to several other high functionaries, civil as well as military. The word is of Arabic origin, and means literally "the bearer of a burden," as *vezr* designates "the action of bearing or carrying a burden." Some write *wazír*, or *vazír*; but this is not correct. From *vizár*, a substantive which expresses the action of supporting a prince in the administration of his empire, is formed *vizáret*, the dignity or function of a vizír, which we generally call *vizirat*. There are two plurals of vizír: the Turkish plural, *vizírler*, which is the common; and the Arabic plural, *vuzerá*, which occurs in imperial decrees, as for instance, in "*vuzerái* 'izámi zeví-l-íhtirám," "the illustrious grand vizírs." The post of a prime minister, who directs state affairs when the sovereign either will not or is prevented from doing it, is a very ancient institution in the East; and the lieutenant of a king was called vizír by the Arabs long before this title was adopted by the Turks-Osmanlis. The first Turkish vizír was the celebrated 'Alá-ed-dín, the son of Osman, founder of the Turkish empire, who was appointed to the post of prime minister by his brother, Sultan Urkhan, in A.H. 726 (A.D. 1326). Until the reign of Mahmoud II. the grand vizír was almost the sole minister; but his power was then much circumscribed. He is now only the head of the ministry, and the other ministers have distinct departments and titles, as in European governments. At first there was only one vizír. But Timur-Tash (Ironstone), a general of Mürad I., having gained a great victory over the Turks-Seljuks of Caramania in A.H. 788 (A.D. 1386), his master gave him the title of vizír, and the then vizír, 'Ali Pasha, was created "vizír 'azim,"—that is, the great or illustrious vizír. From this time the number of vizírs was gradually augmented: Mohammed II. had seven; Mürad III., six; Mürad IV., nine; but from the time of Ahmed III. there were only seven vizírs who were real ministers. The title of vizír is likewise given to the Begler-Beys, or governors, of Rumelia, Anatolia, and Damascus, to the four high judges, the grand equerry, the sirdar, or field-marshal, the chief master of the forests, and to several other high functionaries; and in former times it was given to the silihdar, or armbearer of the sultan, and to the agha of the janissaries, two dignities which are now abolished. Sometimes, also, this title is conferred upon governors of Sanjaks, as was the case with the famous 'Ali Pasha of Janina, after his victories over the French in 1798. The title is now considered as ranking next below that of Mushir, or field-marshal. The insignia of a vizír are a splendid dress of velvet embroidered with gold, pearls, and precious stones, a turban with an ornament of diamonds, and a standard, to the top of which are attached three horsetails, and which is carried before them by an officer: hence the title of pasha of three tails, which is identical with vizír. The dress of the grand vizír is still more magnificent than that of the common vizírs, from whom he is distinguished by several privileges: he receives the solemn visits of all the high functionaries, including the common vizírs; he commands the centre of the army in battle; and, except the sultan, he is the only person who is saluted with the "alkish," a kind of benediction pronounced by those who appear in the presence of the grand vizír. The words of the "alkish" are, "Allah ömerler were efendümüze!" (God give a long life to our master!)

(Hammer, *Des Osmanischen Reiches Staatsverfassung*, &c.; *Geschichte des Osmanischen Reiches*; Kieffer et Bianchi, *Dictionnaire Turk-Français*, sub. voc. 'Vizír' and 'Alkish.')

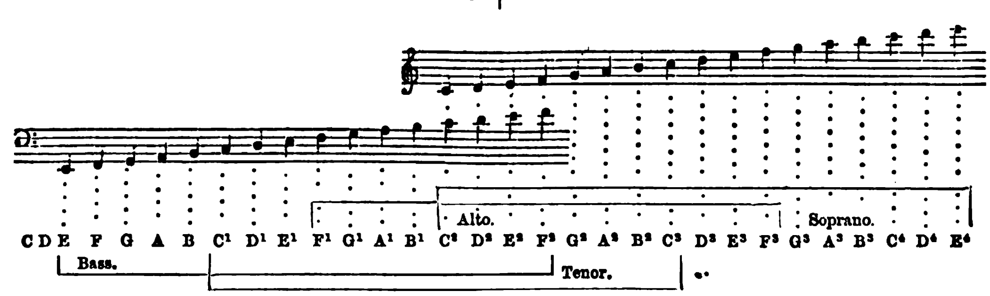
VOICE. The voice (from the Latin *vox*) is an audible sound produced in the larynx. The design of the present article is to treat of the sounds of the human voice in its two great functions of Song and Speech. The nomenclature and notation of music [MUSIC] are here adopted, with such an extension, based upon the same principles, as is necessary for the purpose.

The infinite varieties of sounds heard in the human voice are all embraced under the general terms Pitch, Loudness, Quality, and Duration.

The scale of the human voice, from the lowest note of the bass to the highest note of the soprano, within which limits composers write vocal music, is four octaves in extent, namely, from *mi*, E,  in the bass cliff to *mi*, E^4,  in the treble cliff. There have been instances, but they are very rare, of voices capable of descending lower, and others of ascending higher than those limits. This scale of sounds is divided into *voce matchile* (male voice), which extends from *mi* (E) in the bass to *do* (C^3) in the treble cliff; and *voce feminile*, or *voce biancha* (female voice) which extends from *fa* (F^1) to *mi* (E^4) in the treble cliff.

The lower or male voice part of the scale is subdivided into Bass and Tenor, each containing two octaves: the bass extends from *mi* (E) to *fa* (F^2); and the tenor extends from *do* (C^1) to *do* (C^3).

The upper or female voice part of the scale is subdivided into Contralto and Soprano, each containing two octaves: the contralto extends from *fa* (F^1) to *fa* (F^3); and the soprano extends from *do* (C^2) to *mi* (E^4). These are the four scales within which musicians compose vocal music for each class of voice. The following diagram exhibits the scale of the human voice and the relation of its subdivisions:—



N.B. The terms *Alto*, *Contralto*, and *Counter-tenor* are the same.

Intermediate between the bass and tenor is another male voice, extending from *la* (A) to *fa* (F^2), and termed the Barytone. And between the Contralto and the Soprano is another female voice, extending from *la* (A^1) to *la* (A^3), and termed the Mezzo-Soprano. The voices of eunuchs and boys are classed with female voices.

By reference to the diagram it will be seen that the scales of the several voices overlap each other in the great compass of the human voice; thus the bass overlaps the tenor eleven notes, so that the tenor descends to within five notes as low as the bass; while the bass ascends to within four notes as high as the tenor. Eleven notes are common to both bass and tenor scales, and any music whose variations of pitch are within the range of those eleven notes can be sung either by a tenor or a bass voice. It appears also by the diagram that a tenor voice reaches to within three notes as high as the contralto, and mid-way up the soprano compass; giving twelve notes common to the tenor and contralto, and eight notes common to the tenor and soprano scales, which explains the wide range of music which tenor voices can sing.

The ordinary compass of a voice is about twelve notes. Many singers' voices however extend to two octaves; some even beyond two, and some have reached three octaves. Catalani's compass is said to have been three and a half octaves.

The compass of soprano and some other voices is divided into registers, of which there are two, namely, the natural and the falsetto. The former is termed in the Italian school *voce di petto*, which means chest voice; and the latter *voce di testa*, which means head voice. To these the Italians add another, which joins the two registers, and which somewhat partakes of the character of both; it is named the *mezzo falso*, or middle falsetto. The extreme upper notes of the falsetto are by some termed the *flautino*, or flute register, but this appears to be an unnecessary subdivision. The following table exhibits at a view the voices and their registers:—

Bass . . .	Chest : .			
Barytone . .	Chest .			
Tenor . .	Chest . .	Mezzo-Falso . .	Falsetto	
Contralto . .	Chest .	Mezzo-Falso .	Falsetto	
Mezzo-Soprano .	Chest . .	Mezzo-Falso . .	Falsetto	
Soprano . .	Chest .	Mezzo-Falso .	Falsetto .	Flautino.

In this musical distribution of the registers of the voices there is no falsetto given to the basses. The bass and barytone voices however are both capable of extending their compass by running up into a falsetto, and hence they must each have a mezzo-falso register also. The falsetto is commonly adopted by bass singers to imitate a woman's voice in the opera buffa.

There is also a feigned lower voice by which voices of all kinds are able to descend lower in pitch than in the natural register. The term basso-falsetto has been proposed to designate this voice, but the term lower falsetto is more accurate.

The Quality of the Voice.—Each person's voice has a distinct quality or tone (*timbre* of French authors), by which it is recognised, even when singing in unison with others. The terms which are adopted to describe the qualities of the voice are vague: they are descriptive, such as nasal, guttural; descriptive by comparison with other sounds, as silvery, flute-like, musical; and metaphorically descriptive, as pure, clear, deep, brilliant, flexible, attractive, mellow, &c. Attempts have been made to connect certain qualities of the voice, as fulness with the bass, brilliancy with the soprano, &c., but without success. It is however quite true that those who are accustomed to hear much singing would mostly recognise any voice to be a bass, tenor, &c., although singing in unison with contraltos or sopranos. The essential distinction however between voices, as the bass and tenor, is not the quality, as stated by some physiological writers; for a voice is classed among basses or contraltos, as the case may be, solely in consequence of its compass lying within the limits of the bass or contralto scales.

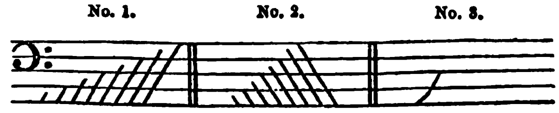
Each voice has its natural and falsetto qualities, which belong respectively to the natural and falsetto registers. Besides these there is in song an improved quality named pure tone, and in speech a corresponding improved quality named the oratorical tone.

Song-voice.—The song-note is a musical sound of some fixed pitch in the musical scale. When a clear resonant voice produces a song-note, the accompanying harmonic sound may be heard just as it is with the sound of a vibrating string. The song-sounds of the human voice are arranged into the diatonic, chromatic, and enharmonic scales. [Music.]

Speech-note.—The speech-note is not a true musical sound, because its pitch varies throughout its duration. These notes are termed slides, accents, and inflexions; and they may be imitated on the violin by sliding a finger up the finger-board while the bow is applied. These notes may have an ascending or descending course in pitch, and sometimes they have both on a syllable. The varying pitch of a speech-note will be illustrated if the reader, with an intense feeling of inquiry utter aloud Hamlet's interrogatory "Pale, or red?" The speech-note on the word "pale" will consist of an upward movement of the voice; while that on "red" will be a downward movement, and in both words the voice will traverse so wide an interval of pitch as to be conspicuous to ordinary ears; while the cultivated perception of the musician will detect the voice moving through a less interval of pitch while he is uttering the word "or" of the same sentence. And he who can record in musical notation the sounds which he hears will perceive the musical interval traversed in these vocal movements, and the place also of these speech-notes on the musical staff.

Speech-notes are of two kinds, namely, simple and compound. The simple consist of a single rising or falling movement of the voice. These movements may be of any extent from a semitone up to an octave. These differences of extent give eight simple rising speech-notes, namely, semitone, tone, third, fourth, fifth, sixth, seventh, octave, and as many simple falling speech-notes, making a total of sixteen distinct simple speech-notes. Mr. Steele accurately represented these notes by diagonal lines on the musical staff. The length of the line indicates the interval or dimension of the note; and its situation on the staff indicates its local pitch, as in the annexed diagram, Nos. 1 and 2, where the eight notes ascending and descending are in accordance with Mr. Steele's notation.

No. 1. No. 2. No. 3.



In these notes the sliding movement of the voice is equable, that is, it passes through equal spaces in equal times. The voice however in some notes is retarded in some part of its course, so that it passes through unequal spaces in equal times. Mr. Steele noted this retardation of the voice by slightly curving the diagonal line at the part, as in the above diagram, No. 3. Now the voice may be retarded at the beginning, at the middle, or at the end of a speech-note. And the voice may be accelerated in each of those parts. It will be seen that these modifications of pitch greatly multiply the number of speech-notes. And this number can be again greatly increased by successively giving to each note all the various forms of loudness of voice of which it is capable.

The compound speech-notes consist of both the simple vocal movements combined in a variety of circumflexes. They were first noted on the staff by Mr. Steele, from whose 'Prosodia Rationalis' the following diagram is copied:—

Numerous as are the varieties of circumflexes, they admit of classification, of which the following, partly taken from Dr. Rush, is adopted:—

The number of constituent vocal movements.

1. Simple circumflex consists of two movements.
2. Compound circumflex consists of three movements.
3. Continuous circumflex consists of more than three movements.

The direction of the first vocal movement.

1. Direct circumflex has the first an upward movement.
2. Inverted circumflex has the first a downward movement.

The dimensions of the vocal movements.

1. Equal circumflex, each movement of equal dimension.
2. Unequal circumflex, each movement of unequal dimension.

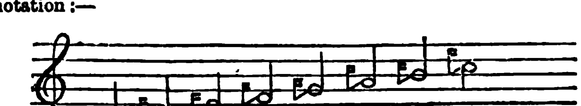
In forming a circumflex speech-note, the voice may be retarded or accelerated in parts, as well as move equably through its course. The possible varieties of circumflex are almost infinite, and the number in ordinary use is far beyond what would be anticipated. This will account for the immense variety of sounds which are heard in human utterance, and which has been more a subject of declamation than thoughtful inquiry.

The Compass of the Speech-voice.—Several of the rhetoricians of antiquity speak of the changes of pitch of the voice seldom exceeding a fifth on any one syllable. Observations conducted for twenty years on the leading public speakers of the period have convinced the author of this article of the accuracy of this ancient statement. It is true that higher intervals are used, even up to the octave, but very sparingly, and the fifth itself is of less common occurrence in oratory than the third.

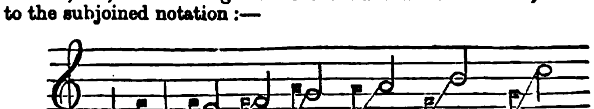
Speech melodies seldom exceed the limits of an octave and a half. Whatever the speaker's key note may be, he seldom rises more than a fifth above it, or descends more than a fifth below it in pitch. A person's key note is generally somewhat below the middle of his compass, which circumstance enables most speakers to ascend an octave if required for the purpose of expression. The following notation of Mr. Steele's speaking compass, taken from the 'Prosodia Rationalis,' is interesting:—

The voice of song (that is, a song-note) has been described as continuing throughout its duration on one level line of pitch. This description was necessary at the outset in order to state the essential distinction between song (musical) sounds and speech sounds.

Close observation however of the song-notes of singers, especially in dramatic music, will show that many of the notes are not of uniform pitch, but that the voice rapidly slides through some interval, commonly of a tone, and the song-note is produced at its summit. Let the slide be equal to a semiquaver, and the song-note a minim, or rather to a minim minus the semiquaver slide, which is stolen from the quantity of the song-note: many singers reach the several degrees of the scale by these slides according to the subjoined notation:—



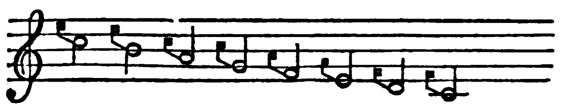
In taking the intervals from a fundamental note, it is not uncommon to hear a rapid slide through the entire interval, producing slide thirds, fourths, &c., and the song-note at the summit of the slide, according to the subjoined notation:—



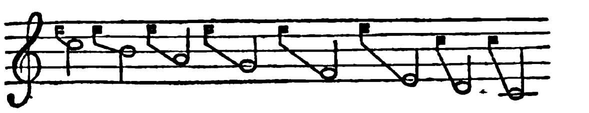
Similar notes often occur in the passionate intonation of the wide intervals of operatic music.

These song-notes closely approximate to those speech-notes in which the movement of the voice is retarded at the upper part of its ascent; and the approximation is the nearer in proportion to the greater retardation.

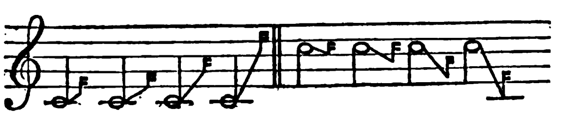
Sometimes the song-note is preceded by a rapidly descending slide, which may be of the interval of a tone, as in the subjoined diagram:—



The slide is however frequently heard of greater intervals, especially in the musical expression of high excitement of feeling, as in the subjoined diagram:—



In song a rapid slide is occasionally heard after the song-note. The slide may either rise or fall in pitch, and it may be of a tone or of a higher interval. The subjoined diagram is a notation of such notes, with a tone, 3rd, 5th, and 8ve, respectively, ascending and descending:—

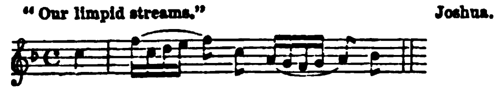


Ascending. Descending.

The after-note of song (*Nachschlag* of the Germans) being always on the weak part of the measure, the slur from its principal to it produces a slide as above noted. These however are rarely heard.

A slur in song binds two or more notes into one continuous sound by a rapid slide of the voice, and thus approximates to a speech-note. In the following illustration taken from Callcott's 'Grammar of Music,' p. 83, the effect of the first slur is similar to a circumflex speech-note, of equal intervals and inverted flexure; and the second slur is in effect similar to an unequal inverted circumflex:—

"Our limpid streams." Joshua.



The preceding illustrations are given with a view of indicating, and not of exhausting, the subject.

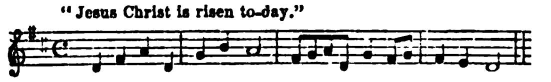
Of Recitative.—The notes of song, of speech, and the mixed notes above described, are all to be heard in recitative. The speech and the mixed notes predominate over the pure notes of song.

Of Chant.—In chant also are to be heard the notes of song, speech, and the mixed. The rapid part of the chant consists of speech-notes, and the concluding syllables of the clausular divisions are sung on song and mixed notes.

Of the kinds of Melody in Song, Speech, Recitative, and Chant.

Song.—A succession of single sounds forms a melody or tune. [MUSIC.] A melody is said to proceed by *degrees* when its successive notes are in proximate degrees of the scale; and a melody proceeds by *skips* when it omits or leaps over one or more degrees of the scale. In general, degrees and skips are intermixed, as in the melody of the Easter Hymn, taken from Callcott's 'Grammar:'—

"Jesus Christ is risen to-day."

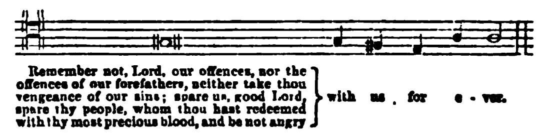


In the incantation scene of the opera of 'Der Freischutz,' Weber has produced an effective melody, consisting of a repetition of the same sound. For the rhythmical arrangement of the sounds in song, see MUSIC, RHYTHM, and PROSODY.

Speech.—In speech, as in song, a succession of single sounds constitutes a melody. A speech-melody formed of speech-notes may proceed in all the varieties above described of song. [ELOCUTION.] In vocal music the rhythmus of the language bends to that of the music. It is musical rhythmus. In speech-melodies however the rhythmus is that of the language.

Recitative.—Recitative melodies also proceed in all the varieties of song. In accompanied recitative, although the musical rhythmus takes the lead, yet the singer has much latitude, and in a great degree controls the musical rhythmus. In unaccompanied recitative the musical rhythmus entirely yields to the singer's ideas of what is appropriate to the required expression.

Chant.—Chant melodies also proceed in all the varieties of song. The ordinary melody however consists of a rapid iteration of the same note through a clause to the concluding four or five syllables, which are set in an appropriate succession. The following notation from the Litany, as arranged by the Rev. P. Penson, of Durham Cathedral, is quoted from the Leeds Church-Service, edited by Mr. Hill, the choir-master:—



The first note, *sol*, G, is rapidly reiterated on each syllable to the last five. The rhythmus is left to the taste and feeling of the chanter. In both recitative and chant the words are more distinctly uttered than in song. This arises from the structure of the notes, which are chiefly either speech-notes or those song-notes which approximate to them, in both of which distinct utterance is infinitely easier than in the notes of song.

Of the Voice as a Natural Language of the Emotions.—The voice, whether it be or be not united with verbal language, is expressive of the feelings. The voice is the language of the feelings, by which they manifest themselves to the ear without previous teaching; and when heard, are recognised and felt without teaching. The scream of terror, the shout of joy, the laugh of satisfaction, the laugh of sarcasm, the laugh of ridicule, are made by man and understood by his fellow-man, wherever the one may be born and whatever may be the speech of the other. The voice is a natural, a universal language. Each mental attribute has its voice, which is in relation to that attribute; and whether that attribute form part of the mind of man or brute, it instantly recognises the voice. The piercing cry of pain, the affrighting scream of terror, the voice of joy, are common to all, and recognised by all. The voices of the feelings, so far as pitch, duration, and loudness are concerned, are capable of notation. Dr. Colombat has attempted the notation of cries arising from various pains: and Dr. Burney has noted the song of several birds. The changes of pitch present the most remarkable changes in the voice; and on these mainly depend the voices of the feelings. The mind adopts changes of pitch to express its condition, and the interval of music is but a means of measuring, and thence imitating, that expression. A higher intensity of feeling increases the interval. Composers know this fact, and avail themselves of it in dramatic music. The pages of Handel, Mozart, Beethoven, Weber, and Rossini are full of illustrations of it. The "Messiah," the greatest of all musical compositions, abounds with degrees of intensity of the same feeling.

On the Improvement and Preservation of the Voice.—In the improvement of the song-voice the great objects to accomplish are, 1. To improve its quality in clearness and resonance. 2. To make every note in its compass equally pure. 3. To extend its compass both above and below. 4. To obtain power to produce a prolonged note on each degree of its compass. The accurate intonation of the scales is presupposed, for without that all training is musically useless. To effect these objects, various systems of discipline are proposed, but none would be successful without the governing ear and voice of a master. The work, however, of Signor Crivelli stands in the foremost rank.

For the preservation of the song-voice the two great principles are, 1. To be temperate in all things, as eating, drinking, &c.; and, 2. Daily practice in the scales of music.

In the improvement of the speech-voice, the first great requisite is so to produce voice that it may not be injurious either to the general health or to the throat in particular. 2. To improve its quality in clearness and resonance throughout its compass. 3. To extend its compass both above and below. 4. To produce a prolonged speech note on each degree of its compass. These have seldom been systematically attempted, and not only have many orators been limited in their success by the defects of their voices, but many have been obliged to discontinue their avocations, especially the clergy, either from the injury to the throat or to the general health which public speaking produced. The primary object of elocutionary science, like that of physical, is to produce the greatest possible effect with the least expenditure of power; but, as in song-training, no system can be successful without the governing ear and voice of a master. The work entitled 'Cull on Public Reading' contains an outline of speech-voice training which has been eminently successful.

For the preservation of the speech-voice, as for the song-voice, temperance in all things is required; also daily practice in the several forms of speech-note. By this means public speaking may become a pleasurable and healthful exercise.

The ancient orators were accustomed to exercise their voices daily in preparatory declamations, and to ascend and descend through the compass of their voices by repeating about 500 lines of verse from memory. The ancients adopted various medicaments and diets as beneficial to the voice, and certain nostrums are recommended at the present day; but let the orator depend more on a proper exercise of his organs, as the singer does on his, and he will be rewarded with cheerfulness and health.

VOID. [VACUUM.]

VOLATILE OILS. [OILS.]

VOLCANO. The situations on the globe where subterranean fires have made or found channels to the surface of the land or to the bed of the sea, are termed volcanoes. A volcano is merely the channel of upward communication from the subterranean fires; the mountain in which the volcano acts, and the extensive mounds and masses of ashes, lava, &c. (substances hereafter described), which surround it, are the effect and the measure of the expansive mechanical forces which are relieved by the pouring forth of the streams of melted or flowing and plastic rocks, the showers of ashes, torrents of steam mingled with gases, and of water, which constitute the eruptions. By considering the nature of these solid, liquid, and gaseous substances, their mutual relations and respective functions in volcanic phenomena, and the circumstances of their ejection, some progress may be made towards a chemical theory of the nature and origin of the subterranean fires; but to gain a proper notion of the mechanical forces set in action during volcanic excitement, we must enter upon a larger inquiry:—the connection of earthquakes and volcanic eruptions, the relations of one volcanic district with another, especially as to coincidence or reciprocity in the times of their violent activity or remarkable repose; and the history not only of volcanic phenomena which are now in progress or have formerly happened in particular situations, but the general history of the effects of the disturbance of the internal heat during all geological periods and over all parts of the globe. Those mechanical forces, it must be remembered, are simply the correlates of this heat, and come into action, primarily, in consequence of the antagonistic action of the sun's rays upon the surface of the earth, and its more immediate results in changing the position of the matter constituting that surface.

Has this extensive inquiry been followed out so completely and methodically as to justify a belief that the true theory of volcanoes is reduced, as several other branches of the great theory of nature have been, to a plain process of induction? That many geologists suppose so is evident from the decision with which their general speculations are advanced; but the student who desires to possess clear and systematic inferences without being troubled with contending hypotheses will find it necessary to class the phenomena as if the inquiry were very far from completion. The following views may aid his researches into this large and interesting subject:—

Succession of Volcanic Phenomena.—A complete history of any one volcano, by showing us its origin, its alternations of rest and activity, its progress to decay, and its final extinction, would furnish a sufficient base for a general theory of volcanic action; for the analogies among all burning mountains, as to form, structure, composition, and associated phenomena, are such as to warrant the application of a few general laws and one theory to them all. But we know not completely the succession of phenomena which have happened in any one volcano. We have indeed examples in abundance of new islands and new mountains being raised in our own days and giving forth fire; we have the history of Vesuvius as an intermitting volcano for nearly eighteen hundred, and that of Ætna for above two thousand three hundred, years; and we may contemplate on the banks of the Rhine, in Hungary, and in Auvergne, the aspect of a country from which the subterranean fires appear to have withdrawn their forces before (though in the country last named probably not long before) the origin of history. The birth, continued activity, decay, and extinction of volcanoes are phenomena seen in separate parts of the earth's surface, and acquire unity and consistence only by being rightly combined into a correct general view of volcanic action.

Earthquakes.—Previous to volcanic eruptions generally, whether these happen in old craters or burst up in new situations, earthquakes prevail, sometimes for a considerable period, in the vicinity of the volcano, and extend their terrors to considerable distances from it. Near to the centre of future violence springs have been known to fail and others to burst forth, and unusual noises have been heard. Previous to the year 1538 the Neapolitan shore had been disturbed by earthquakes for two years; and these symptoms of subterranean disturbance were succeeded by the production of the Monte Nuovo (on and over the ancient site of the Lucrine Lake) in the space of forty-eight hours.

Among the effects of great earthquakes are fissures in the crust of the earth, both in volcanic regions and in distant situations. In 1811 and 1812 the movements of the ground in the valley of the Mississippi and in Caracas caused vast depressions and elevations, some of which remained, so as permanently to affect the drainage and change the form of the surface. Some of the numerous fissures produced in Calabria by the earthquake of 1783 assumed a radiating form, and it is conjectured by Lyell that in these situations the ground was permanently raised. In 1669 the flanks of Ætna were fissured, and through the opening the Monte Rossi was raised, by ejection of ashes, &c., to the height of 450 feet. In 1759 the new volcano of Jorullo was formed on the plains west of Mexico by the accumulation of ejected materials (as is now known) into a mountain 1695 feet high.

By these instances, taken from situations far from other volcanoes (Jorullo), at points in the vicinity of active and extinct volcanoes (the Monte Nuovo), and on the slopes of a frequently burning cone (the Monte Rossi), it appears that generally the earliest observable fact in the history of volcanic phenomena is the opening of the ground,—

a. Along a line of fissure. *b.* In a system of intersecting fissures. Such openings, when happening on land, constitute subaërial volcanoes; and when occurring in the bed of the sea they produce submarine volcanoes.

The preceding statements relative to the connection of earthquakes and volcanoes, and the alleged elevation of land by the former, are in agreement with the inferences generally drawn from both classes of phenomena prior to the publication of the recent inductive researches on earthquakes, of which, and of their results, we have given some account in the articles EARTHQUAKE and SEISMOLOGY. Seismic and volcanic energy are evidently the same in origin, manifested in the former in a manner purely mechanical, and in the latter in a thermal (if not chemical) and also mechanical manner. But we must now admit that these phenomena are not related as cause and effect. Earthquakes do not produce or commence volcanoes, or initiate, though they may be simultaneous with, volcanic eruptions; nor do volcanoes cause earthquakes, though there is a common cause, or chain of causes, for both. Mr. R. Mallet has shown that fissures even are never produced by the direct passage of the wave of shock in an earthquake, but are a mere secondary effect, conformed to and determined by the dip or slope of the subjacent beds of rock, and are no more than incipient landslips. The movements of the ground in Caracas and in the valley of the Mississippi, mentioned above, were in all probability of this description. In like manner, having deduced from theory, as well as inferred from observation, that earthquakes cannot produce elevations (although the latter have been known to have taken place about the same time as earthquakes and in the same region), he examined with care more than 150 miles of sea-coast, as well as river-courses, for evidence of any permanent elevation of land having taken place even concurrently with the earthquake of the 16th of December, 1857,—the greatest that has occurred in Italy since that of 1783, referred to above,—but found none.

The production of elevations and true fissures appears in fact to be a third great effect, or class of effects, of the common chain of causes of earthquakes and volcanoes,—to be a distinct consequence from them of "the tendency of the globe to swell into froth at the surface," to use the emphatic and comprehensive expression of Sir J. F. W. Herschel. That a volcano begins by the production of a fissure, through which the ejections constituting an eruption are subsequently to be discharged by the continuance of the force originating the fissure, is most probable; though it may often happen that the elevation of such materials from below falls short of an eruption, and merely fills the fissure (afterwards to be observed as a dyke), or that the materials elevated are of a different description, and are not otherwise related to volcanic phenomena than as being effects of a common primary cause—subterranean heat. We shall again have to notice the light thrown upon the philosophy of volcanoes by the recent investigations of earthquake-phenomena.

Eruptions.—When by some movement of the ground a channel is opened from the interior to the surface of the earth, a paroxysm of volcanic excitement follows, and an eruption happens through the new opening. There may be a slow outpouring of melted rock, pressed upwards against gravity by an internal force; or a violent upburst of clouds of scoriæ and ashes, mixed with larger stones; or a torrent of the same materials mixed with water, and constituting mud; or volumes of steam and gases of different sorts; but permanently gaseous matter appears to be much inferior in quantity to aqueous vapour, and frequently, if not generally, to be the least important product or educt of an eruption. These are exactly the products, singly or in combination, which are delivered by long-established vents, and, as far as we can judge, the same have been yielded by volcanoes which probably became extinct before the historic era of the human race; moreover, the volcanoes of all regions agree generally in this respect. Evidently, therefore, the condition of the interior parts of the earth, which are under the influence of volcanic excitement, is of a general and continuous nature, and must be supposed capable of interpretation by examination of the products and the circumstances of their extrication.

The enormous flashes of lightning which accompany volcanic eruptions, issuing from the ascending column of steam and solid ejections, and which are equally characteristic of eruptions originally submarine, when they rise into the atmosphere, have been celebrated from the time of Pliny; but they had not been accounted for in any satisfactory manner, having only been vaguely referred to an evolution of electricity connected with the intense actions of various kinds taking place in the eruption. After Mr. (now Sir William G.) Armstrong had observed the electricity of effluent steam, Mr. Brayley pointed out the precise analogy of the sparks given by it, to this volcanic lightning. ('Phil. Mag.,' Series 3, vol. xviii. p. 94.) Dr. Faraday subsequently ascertained that the electricity of effluent steam is produced, in reality, by the friction of the globules of water, resulting from its partial condensation, and of particles of foreign matter, both merely driven onward by the steam as a mechanical agent, upon the substance of the tube from which it issues. In the eruption of a volcano we have all these elements in perfection, and on an immense scale, the foreign particles being supplied by the volcanic ashes, and we may therefore conclude, that the enormous evolution of electricity accompanying it arises from their friction, as in the hydro-electric machine. It is probably the greatest example in nature of the production of frictional electricity.

Mass of Volcanic Products.—Now the first thing which arrests the attention in regard to the circumstances which accompany the products of volcanic eruptions, is the enormous mass of materials ejected at particular points. In 48 hours, in 1538, the Monte Nuovo, 440 feet high and 8000 feet in circumference, was thrown up in a place which may be regarded as a new vent of the Neapolitan volcanic region. In 1759 a new vent was opened west of Mexico, a new volcanic mountain (Jorullo) was thrown up to the height of 1695 feet, and an area of three or four miles was covered with its lavas. (See col. 670.) Between July and August, in 1831, Graham's Island had been raised from the sea-bed, 100 fathoms deep, to a height of 107 feet above the sea, with a circumference of 3240 feet; in September its height was 100 to 230 feet, and its circumference 2300. In the winter of 1831-2 the whole vast heap of ashes had been dispersed by the waves, and nothing remained of this short-lived volcano but a dangerous shoal. Subsequently this has been lowered, and a comparatively slight elevation above the average level of the neighbouring sea-bed is now under deep water. The lava currents from many volcanoes are of the same gigantic proportions. In 1737 Vesuvius poured forth 33,587,058 cubic feet; in 1794, 46,098,766 cubic feet; and Ætna, in 1669, gave forth 93,838,950 cubic feet, which would make a considerable hill; for it would cover a space of ground one-quarter of a mile across with a conical mound 180 feet high. The accumulated effects of two years' eruptions of Skáptaa Jokul, in Iceland, appear to have filled valleys and lakes and broad plains with floods of melted rock. The lava is said to have flowed in one direction 50, and in another 40, miles, with breadths of 15 and 7 miles respectively, and with a depth averaging about 100 feet, but in places reaching 600 feet. If these data have any claim to be regarded as fair approximations (they are so regarded by Lyell and other writers), the mass of lava poured out in two years by this *modern* volcano exceeds a hundredfold that of the Plutonic rocks which appear in the chain of the Malvern Hills. It would cover all the coal-fields of the British Islands with a plateau of basaltic rock 20 feet thick, or bury London under a mountain rivalling the cone of Teneriffe. In the eruptions of Tomboro, in Sumbawa, in 1815, ashes and scoriæ were thrown out sufficient to form three mountains equal to Mont Blanc, or to cover the whole of Germany two feet deep. The volume of muddy and watery eruptions from volcanoes can seldom be accurately measured. Humboldt speaks of mud eruptions, called "Moya," as frequent in the volcanic system of the Andes, and they are abundant enough to fill valleys and stop the channels of rivers.

From such data as can be collected there appears no sign of any general decay in the magnitude of the volcanic eruptions taken generally, though in respect to any particular volcano the contrary may be inferred.

Eruptive Forces.—If the quantity of matter ejected by volcanoes be taken as a measure of the *amount* of unbalanced pressure which required and obtained relief, the *force* with which it was ejected may be regarded as a measure of the *intensity* of this pressure. Accurate observations on this point are needed. If, as recorded by Sir W. Hamilton, stones were thrown so high above Vesuvius as to occupy 11 seconds of time in falling to the level of the crater, this gives an upward velocity of 350 feet in a second at the level of the crater, and a height of about 2000 feet; but the mountain being above 3000 feet high, we must estimate the pressure at the level of the sea as competent to sustain a column of matter of the ordinary weight of lava (say twice and a half that of water) nearly a mile in height. This would equal the pressure of between 300 and 400 atmospheres.

Lava which had flowed in 1798, was traced by Humboldt to the summit of the Peak of Teneriffe, and must therefore have been sustained (unless the lava were, as is probable, of a lighter kind) by double the pressure. These pressures appear great, but in no degree improbable if judged by the well-known effects of steam. A temperature of 800° Fahr. would give the steam pressure for a height 2000 feet above the cone of Vesuvius; and so rapidly does this power augment with additional heat, that less than 1000° Fahr. may be sufficient to give steam a force equal to balance the whole column of lava in the Peak of Teneriffe. Now these are temperatures which appear to fall within the observed heats of some of the lava currents, for these have been found to melt silver and to perform heating effects greater than those of red-hot iron. Steam-power, generated by the admission of water to the hot interior parts of the earth, appears entirely adequate to the "eruptive forces" actually witnessed in volcanoes. It is much in favour of this being really the agency employed, that we find in explosive eruptions such considerable bodies of aqueous vapour erupted during most parts of the paroxysm; that some eruptions have yielded little else than steam, and others chiefly hot water. Moreover, on considering attentively the distribution of volcanoes over the globe, we find the active volcanoes most frequently by the side of the sea, or by other considerable bodies of water; and the extinct volcanoes in the vicinity of ancient lakes, or desiccated branches of the ancient ocean. Why they should be in the immediate proximity of the ocean or of lakes, will appear in the sequel. But while such proximity undoubtedly facilitates the operation of water in volcanic phenomena, that operation appears not to depend upon it; volcanoes may receive water on account of their vicinity to it, but that vicinity is not occasioned by the necessary agency of water in their eruptions.

The general type of a volcanic eruption appears to be as follows:—The ground is rocked by frequent earthquakes; special movements and noises happen in and about the volcanic mountain; clouds of steam rise from the crater, followed and mixed with showers of ashes and scoriæ driven up by the exploding and expanding vapour; the tube of the crater becomes filled by melted, or at least flowing matter, which undulates upward and downward with the irregular pressure of the vaporous or gaseous matter; these burst in large bubbles through it, scattering it into granular dust and ashes, till the lava overtops or breaks through the loose conical walls of the crater, and flows abundantly, so as partially or wholly to relieve for a time the unbalanced internal pressure.

Volcanic Products.—The substances thrown out during volcanic eruptions, whether stony, liquid, or gaseous, disclose more or less completely the nature and condition of the interior masses of the globe, at depths greatly exceeding the dimensions of the greatest volcano or mountain known, but still very small in comparison to the earth's radius, and belonging to the mere outer crust of the globe. The lava or melted rock is generally referrible to a very small number of aggregations, in which felspar, augite (or hornblende), and oxide of iron are the most important ingredients, the mass being modified by additional minerals, as leucite, idocrase, olivine, garnet, epidote, stilbite, heulandite, and many others. Combinations of sulphur, and of uranium, copper, lead, arsenic, and manganese, also occur in various proportions; but these metallic bodies do not play an important part in volcanic phenomena. The so-called ashes and scoriæ consist of the same substances as the lava, the most prolific repositories of the rarer minerals being always in cavities of the lava or scoriform aggregations. [The characters of these mineral substances have been described under their respective names in NAT. HIST. DIV.]

In these particulars modern lava will bear comparison with ancient Plutonic rocks, for they are composed of similar mineral aggregates, modified by many of the same rarer crystallisations, which mostly occur in the cavities of their mass. The difference of most importance between Plutonic rocks (granite, &c.) and volcanic rocks (trachyte, &c.) is in the degree of their consolidation; and this difference appears quite intelligible by a comparison of the various appearance and character of lava which has cooled and become solid under different circumstances. Lava cooled in air under slight pressure is often cellular; cooled under the pressure of water (as in the case of the current which passed through Torre del Greco into the sea), it is more compact; when vitreous, and much distended by steam, it becomes vesicular pumice. We may therefore believe that lavas which remain and grow solid under great pressure about the internal base of the volcano are of a more dense nature than those which come to the surface, and may thus closely resemble, or be even identical with, some of the older Plutonic rocks, which thus regarded, and from other evidence, appear to be in fact *unerupted lavas.*

The foregoing account of volcanic rocks applies, principally, to one class only of lavas, the stony or common lavas, the most abundant product of volcanoes; but there is a second, the vitreous or glassy lavas, of which the mineral called obsidian, or volcanic glass, is the type, and of which pearlstone and pitchstone and a few other minerals are examples, but partly in a different condition. While the lavas of the greater number of volcanoes belong to the former class (though mingled we believe in those of every one with some glassy lava), those of certain volcanoes are exclusively vitreous, of which that of the volcano in the Island of Bourbon is an example. In the flowing state the nature of these two classes of lavas is very different. The vitreous lavas are then essentially in a state of dry igneous fusion, comparable to that of artificial glass, or of metals; but the stony lavas, even while fresh erupted and flowing, are not properly in a melted state, being in fact as truly aggregates of distinct mineral substances while in that state as they are when they have ceased to flow, acquired the character of ordinary solids, and become cold. They are, while they retain the flowing property, as Mr. G. Poulett Scrope first observed and maintained (in his work referred to below) more than a third part of a century since, a sort of mud, consisting of the crystalline grains of the minerals found to constitute them, allowed to slip or glide over each other by the intervention of water or of aqueous vapour in a peculiar condition of condensation and adhesion to the surfaces of the solid particles, though at a red- or even at a white-heat. Mr. Scrope's views, though almost contemptuously rejected at the period of their enunciation, have received great support from the subsequent discovery of the possible existence of water in a liquid state at high temperatures (as they might have received it from a contemporary one of its convertibility into vapour of its own volume), and from the now admitted necessity of the agency of water in the production of all the crystalline aggregates constituting the Plutonic rocks, including granite itself, which has been referred to by Mr. Scrope in a confirmatory paper communicated to the Geological Society in 1856. A remarkable proof, among many others, that the stony lavas are not really in a fused condition, is afforded by the fact urged by Mr. Scrope, that the radiation of heat by them is comparatively so slight, evincing that they cannot possess that intensely high temperature which would be requisite to impart to their mineral and chemical elements a truly liquid state, independently of the agency of water.

The views of this consummate volcanic geologist, however, are now probably to be regarded as forming only a first approximation to a true theory of the nature of lava. The researches which have been subsequently pursued in the chemistry of geology, and in the artificial synthetic production of minerals, as well as in the geology of the metamorphic rocks, and respecting the action of the igneous rocks upon the sedimentary strata, tend to modify the original conclusions of Mr. Scrope, but still only in the manner which has characterised the progress of all great discoveries in science. The necessary agency of water, together with intense heat, in the production of the crystalline rocks, has been urged by Scheerer and E. de Beaumont. Its operation through a great range of temperatures, both in producing and in altering rocks, has been demonstrated or illustrated by Bunsen and Delesse, and more recently by a remarkable series of experiments by Professor Daubrée of Strasburg. He has shown "that the molecular state of the water in lavas, 'be it what it may,' has had a great effect in the formation of silicates, even when anhydrous. It causes them to separate, and to crystallise at a temperature much below their point of fusion; it enables them to crystallise in an order of succession different from that of their fusibility; thus, for example, leucite, an infusible silicate of alumina and potash, occurs in lavas in well-formed crystals, often of large size. To this, Ludwig, in his German translation of Daubrée's essay, adds that the crystals of leucite often contain fragments of lava, and even small crystals of the very fusible mineral augite." * These results are most apposite to, and beautifully elucidatory of, the true nature of lava as originally observed by Mr. Scrope. His views, perhaps, would have sooner been entertained by other geologists, had he more explicitly distinguished between the vitreous and the stony lavas when flowing. The former when in the purest and most characteristic condition present us with the state of igneous fusion in its most perfect form; solidifying into glass when rapidly, and crystallising when very slowly, cooled. Taking volcanic phenomena as a whole, there doubtless exists every gradation between this and the hydroplastic condition of lava such as that of Vesuvius and Etna, which, however rapidly cooled, does not solidify into glass, but into an aggregate rock or stone, identical with that resulting from its slow cooling in nature. It is important to observe that the glassy lavas are converted by slow cooling not into stony lava, but merely into the crystalline state of the combination of silicates of which they consist. The stony lavas, however, when truly fused, whether naturally or artificially, become the glassy lavas if quickly cooled, or the corresponding vitrite or crystalline substance if allowed to cool slowly. Such also is evidently the origin of the vitreous lavas in volcanoes, their observed transitions from the glassy to the crystalline or stony form depending partly on their mineral constitution and their condition when in the flowing state, and partly on the circumstances and rate of their refrigeration. Of all this we now possess ample evidence, both geological and experimental. For some of the former we may refer to the facts detailed by Mr. Darwin in his 'Geological Observations on the Volcanic Islands,' &c.; and as an example of the latter, to the results of fusing basalt, which is an ancient lava, and when melted and rapidly cooled becomes a glass scarcely distinguishable from obsidian, but when gradually cooled does not return to its original condition of a stony lava, an aggregate rock consisting of several mineral substances, but becomes a kind of pearlstone—the peculiar crystalline condition of the glass. The importance of these latter facts in reference to the acceptance and right understanding of Mr. Scrope's views has already been urged by Mr. Brayley [WATT, GREGORY, in BIOG. DIV.], and been frequently adverted to by him in lectures on igneous geology.

Water undoubtedly is second only in quantity among the products or educts of volcanic action, to the solid earthy matter, oxides, like it, some of non-metallic combustible, some of metallic bases. Its functions in the origination of Plutonic and volcanic action were first suggested, as we shall find, by the discoverer of the chemical nature of that earthy matter, Sir H. Davy. Those which it possesses in volcanic phenomena themselves, partly in the condition of vapour, and partly it is probable in a peculiar intermediate condition not yet understood, were first truly discovered by Mr. Scrope, and established in his 'Considerations on Volcanoes.' The liquid products of volcanoes also contain, though rarely, the sulphuric and muriatic acids; and among the substances of most interest in aiding to complete the theory of chemical actions, are sublimations of common salt, and muriate of ammonia. The origin of these where the volcanoes are situated by the sea-side cannot be doubtful. Boracic acid is another product of this kind occurring in the crater of volcanoes (Daubeny); but this we now know is an abundant element of the earth's crust, widely disseminated, though but rarely in great quantities in a single locality. Compounds of boron, however, do not appear to play an important part in the history of volcanoes.

The gaseous products of volcanoes are important in the investigation of the chemical theory of the igneous action. Besides the clouds of vapour of water (so abundant in eruptions, and so often productive of local rains), chlorine, azote, sulphuretted hydrogen, sulphurous acid, and carbonic acid, are the most common. The evolution of sulphuretted hydrogen (depositing sulphur) continues under various circumstances after other signs of activity have ceased in particular volcanic regions; and even after the craters have fallen in and become full of water, mineral springs and springs rich in carbonic acid flow with little variation for centuries (many such have been flowing from before the commencement of history to the present day), while azotised waters, rising to the surface along the lines of fissures more ancient than any known volcanic systems, concur with them in demonstrating the almost interminably slow process by which subterranean heat rises to the surface of the earth.

* Leonard Horner, F.R.S., Anniversary Address to Geological Society of London, 1861. 'Quart. Journ.' vol. xvii. pp. xlviii—xlix.

Chemical Hypothesis of Volcanic Action.—The nature of these various products, and the order in which they successively make their appearance, have been the bases for speculations as to the chemical processes going on in the interior of volcanic regions. Sir H. Davy's discovery of the metallic bases of the earths and alkalies, and of the extraordinary appetency for oxygen of several of these bases (potassium, sodium, &c.), suggested to that great chemical philosopher a new and ingenious hypothesis of volcanic action. Water admitted to some of the metallic bodies alluded to is instantly decomposed, and its oxygen absorbed, with an immediate and very remarkable evolution of heat and light, while the metals become earths or alkalies. The substances most abundant in volcanic products contain these earths, and these alkalies,—namely, potash, soda, lime, silica, alumina, &c.,—in various combinations, evidently the result of successive crystallisations from a fluid mass. In this hypothesis it is assumed that the interior portions of the earth consist in part of the metallic bases of the earths and alkalies; that water is from time to time admitted to these; that violent combustion and great heat follow; that the oxides generated are melted together, constituting lava, while the hydrogen, and some of the water undecomposed, go off to form new combinations with sulphur, chlorine, carbonic acid, &c., which are liberated from previous states by the heat and the various chemical agencies set in activity. The power which raises the lava, and throws out the clouds of ashes and scoriæ, is the undecomposed and confined steam.

Whoever looks carefully at this hypothesis will find in it much that is admirable, and little that is open to strong objection, if it be regarded merely as a *theory of the eruption of volcanoes*, not as a theory of the changes in the condition of the interior parts of the globe, of which volcanic action is one of the visible exponents.

It is some recommendation of this view that it seems to unite itself with a general and not improbable speculation regarding the origin of the more ancient Plutonic rocks, which certainly must be supposed to have passed through a very similar series of changes to those which lava has undergone. Those rocks have the same bases as lava; it is the natural result of chemical reasoning, that the elements which are now combined in them existed at some earlier time in a separate state; the oxidated and melted granite crust of the earth is formed by the union of these elements, and, according to the hypothesis of Davy,* the new rocks which volcanoes yield are produced by a somewhat similar process of oxidation and fusion.

But this hypothesis was nevertheless neglected by its author for reasons which do not appear to have been fully stated by himself. It was taken up by Dr. Daubeny, and has been maintained by him with much perseverance and ingenuity of research as a sufficient 'Chemical Theory of Volcanoes.' We may call it the 'Hypothesis of Subterranean Oxidation,' and develop it, according to Dr. Daubeny, as follows:—

Below the surface, at a depth of a few miles, the interior of the earth is assumed to contain the earthy and alkaline metalloids, iron and other metals, sulphur and sulphuretted salts. Slow combustion happening amongst them, even under the continents, by slight additions of moisture and air, generates particular gases (nitrogen, carbonic acid, sulphuretted hydrogen, &c.); these rise and combine with springs which issue along lines of natural fissures, or are discovered in artificial wells, often giving to them a temperature higher than that of the country where they occur. Under the sea or large bodies of water, and especially along lines of sea-coast (where fissures may be supposed more numerous than elsewhere), water may be admitted to the interior more easily and in greater quantity, and may occasion phenomena of the same order, accompanied by other effects more powerful, rapid, and characteristic, until the process ceases for awhile by the choking of the passages which admitted the water.

The water, decomposed by contact with the metalloids, yields its oxygen to them; the hydrogen is liberated, but not allowed to escape in great quantity alone, for it readily, under the influence of heat, combines with sulphur into sulphuretted hydrogen, or, with the oxygen of atmospheric air (if any be present), reconstitutes water. Nitrogen is thus liberated, and may be conceived to pass off partly free, partly combined with hydrogen, so as to constitute ammonia, which again unites with chlorine (derived from the sea-water), and constitutes sal-ammoniac. While oxygen (derived from atmospheric air) is plentiful in the volcanic channels, the hydrogen will not unite with sulphur, which accordingly combines with oxygen into sulphurous acid. When the oxygen is consumed, sulphuretted hydrogen is formed in abundance,

* 'Phil. Trans.' 1828.

and predominates towards the close of the eruption, and even, by the aid of the residual internal heat operating on sulphur, is evolved for centuries after the volcanic violence is spent.

The evolution of chlorine is easily traced to a double decomposition of sea-salt; carbonic acid is supposed to rise from calcined limestone rocks; and specular iron-ore (*fer oligiste*) is a product of sublimation. Thus, in the opinion of Dr. Daubeny, all the main phenomena concomitant upon volcanic action seem to admit of explanation if we suppose, first, sea-water, and afterwards atmospheric air, admitted to considerable masses of metals, metalloids, sulphur, &c., the basis of the whole speculation being the abundant decomposition of water at a moderate depth below the surface of the earth. The views of Dr. Daubeny have been controverted by very eminent writers (as Dr. Davy, Prof. Bischof, and others) on particular points; but we are not aware of any attempt upon other assumptions quite so satisfactory as this of Dr. Daubeny, to explain generally the *chemical products* of volcanic eruptions in the order of their occurrence.

Perhaps, therefore, we may concede to this hypothesis the probability that in the interior of the earth the metalloids exist in quantity sufficient to cause an abundant decomposition of water, and thus originate a given series of chemical changes such as are witnessed in volcanic eruptions. But before we accept it as a *general explanation* of volcanic disturbances, other classes of data than those furnished by chemical analysis must be brought into the reasoning.

An important circumstance in the general theory of volcanoes is the connection and reciprocal activity which exists underground between volcanic regions entirely separated on the surface, as between Sicily and Naples; between the Mediterranean volcanic region, taken generally, and the region of extinct (or long suspended) volcanic action in Asia. To this we must add another and larger series of facts regarding the extent and distribution of volcanic action on the surface.

Volcanic Regions and their Connection.—Volcanic regions, if estimated by the area over which the lava and ashes have been dispersed, constitute but a small portion (perhaps less than $\frac{1}{100}$th part) of the surface of the globe, but in a survey of these regions we must include not only the active vents and extinct craters, but also "large intermediate spaces where there is abundant evidence that the subterranean fire is at work continuously, for the ground is convulsed from time to time by earthquakes; gaseous vapours, especially carbonic acid gas, are disengaged plentifully from the soil; springs often issue at a very high temperature, and their waters are usually impregnated with the same mineral matters as are discharged by volcanoes during eruptions. (Lyell, 'Princ. of Geology,' book ii., ch. ix.)

To describe these districts would be entirely foreign to the purpose of this essay, but we may by a simple classification show how much of the grandest features of physical geography is due to volcanic disturbance.

European Volcanic Districts.—The Icelandic volcanoes, remarkable for abundant lava streams; the Azores, amongst which new islands have been thrown up; Sicily, including Ætna and the vanished Graham's Island, often called Sciacca, which is properly only the name of the opposite point of Sicily; the Lipari Isles, with Stromboli always burning; the Neapolitan tract, including Vesuvius; Ischia and the Ponza Isles; Santorini and some neighbouring islets. The above are all considered as *active* volcanic centres, and have been subject to eruptions in historical times. The *extinct* volcanic systems of Europe are the trachytic domes in the centre of France (Auvergne, [AUVERGNE, in GEOG. DIV.] the Vivarais, &c.), the Eifel country, the Seven Mountains, and other trachytic and basaltic parts along the Rhine; the Westerwald, Vogelsgebirge, Rhöngebirge; together with the Kaiserstuhl, and many other scattered basaltic hills in the middle of Germany; Hungary, Transylvania, both remarkably rich in trachytes and the vitreous lavas called pearlstones; the Gleichenberg in Styria. In Italy, the Euganean hills and other smaller points appear in the north of Italy; while between Rome and Naples large ancient craters occur, and connect Mount Albano with Vesuvius. (Daubeny.)

Asiatic Volcanic Districts.—Mixed active and extinct volcanic mountains occur about the Persian Gulf, the Red Sea, and the Dead Sea, in the vicinity of Smyrna, in the Caucasus (especially in Mount Ararat), and in the Elburz Mountains, including Demavend. These are, or appear, detached points of more or less decayed, though once powerful, action, fed by inland seas. On the southern and eastern shores of Asia the subterranean energies are still unsubdued, and constitute a long chain of lofty islands and promontories from Barren Island, in the Bay of Bengal, through the length of Sumatra and Java, by Bally, Sumbawa (already noticed), Flores, Celebes, Sangir, Mindanao, Fugo, Luçon, Formosa, Loochoo, Japan, the Kurilian Isles, the magnificent mountains of Kamtchatka, examined by Erman, and the line of the Aleutian Isles, to Alaschka, on the western coast of North America.

African Volcanic Districts.—The African islands are nearly all volcanic, though, as in St. Helena, the action has long been extinct; or, as in the Canary Isles, the localities once devastated now enjoy immunity through the great safety-valve of Teneriffe. (Von Buch.) On the continent, traces of volcanic action appear in the chain of the Atlas; while in the northern as well as in the equatorial portions of the "Mountains of the Moon," now known through Dr. Beke to be a meridional range parallel to the coast, and extending from the north-eastern to the south-eastern regions of the continent, are many active volcanoes. An account of an eruption of one of these, Jebel Dubbeh, in May last (1861), by Captain R. L. Playfair, R.N., was recently communicated to the Geological Society.

The late M. Daussy, geographer to the French Board of Longitude, collected observations of earthquake-shocks received by vessels at sea at various periods, but all within a given limited area, which, according to Mr. Mallet, render the existence almost certain of a vast active volcanic suboceanic area in the basin of the Atlantic, nearly midway between Cape Palmas on the west coast of Africa, and Cape St. Roque on the east coast of South America, or in the narrowest part of the ocean between these continents. This vast disturbed and perhaps partially igneous ocean-floor can be no less than nine degrees, or above 620 miles, in length from west to east, and from three to four degrees, or between 200 and 300 miles, in breadth from north to south. We have thus a submarine volcanic tract in activity beneath the Atlantic, as large in area as Great Britain, and where the bottom of the ocean is rendered uneven in the extreme, immense protrusions, that is, elevations of land, whether persistent or temporary, taking place in deep water.

American Volcanic Districts.—"Along the north-west coast of the American continent," Sir John Herschel states, "the chain of newer igneous formations is almost continuous, and in Oregon attains an immense development; nor are active volcanoes of great magnitude wanting, *but only those parts of the volcanic zone which lie upon the coast-line* contain such, namely, Mount Regnier and St. Helen's, at the mouth of the Columbia river." The Rocky Mountains show many marks of ancient volcanic action, and serve incompletely to connect the long Asiatic line just described with another enormous volcanic system running through California and Mexico, interrupted at the isthmus of Darien, but continued through Pasto, Popayan, Quito, Peru, and Chili, to Tierra del Fuego; in the last locality, however, though there are trap-rocks, there are no active volcanoes. This mighty range of mountains is everywhere parallel to the sea, being only crossed by the line of Mexican volcanoes, which includes the new mountain of Jorullo, and passes perhaps from the West Indies to the Revillagigedo Isles. The volcanic vents are unequally distributed along the great Cordillera: one in California, five in Mexico, and above twenty between this and the isthmus of Darien. South of this point the volcanoes are few, but mostly of prodigious grandeur and frequent activity, the fire issuing from one or other of the mountains, which, according to Humboldt and Darwin, are all parts of one grand swollen-up mass—supporting Cotopaxi, Antisana, Tunguragua, and other huge cones. Only one active volcano occurs in Peru, but nineteen are active at frequent intervals in Chili, and one (Villarica) burns almost uninterruptedly. Here also is the highest volcano in the world, Aconcagua, measuring 23,910 feet. Most of the West Indian islands are volcanic, or partly volcanic and partly calcareous, the limestone being mostly due to the growth of corals, perhaps on the craters or round the slopes of volcanic mounds. A similar view appears applicable to the numerous groups of islands in the Pacific Ocean, in some of which, as the Ladrone Isles and Hawaii, are lofty and active volcanoes.

In general the Banda Isles, New Guinea, New Britain, Norfolk Island, and St. Philip, the Society, and the Sandwich Islands, are principally of volcanic origin. The low lagoon islands, described by Mr. Stutchbury ('Journal of the Bristol Institution') as deriving this form from the growth of coral, have been thought to be so many points of volcanic mounds; but it has been suggested by Darwin ('Trans. Geol. Soc.') that they are points of subsided land, on which the zoophyta attached themselves. Western Australia contains basaltic and other volcanic accumulations.

"The east coast of Australia offers no active volcano, but is marked along its whole extent, from north to south, with evidences of former igneous activity, occurring (in striking resemblance with what prevails on the opposite coast in South America) among the crystalline and transition [primary and palæozoic] rocks which constitute the general seaboard. But the subterranean fires would seem here to have shifted their ground, and taken up a new line of action to seaward, at an interval of from 1000 to 1200 geographical miles from the coast, but still conforming to its curvature, prolonging the series through the Solomon Islands, New Hebrides, and Friendly Islands, to New Zealand. (Herschel, 'Phys. Geog.')

On comparing this synopsis of the geographical distribution of volcanoes with a good map of the world, two remarkable features of that distribution will be obvious: these are, in the words of the philosopher last cited, "Their tendency to a linear arrangement when insular," and "their constant association with coast lines."

In reference to these features, and to the phenomena described in the preceding review of volcanic regions and their connection, Sir J. Herschel resumes: "It seems impossible to disconnect this obviously systematic arrangement with the general evidence we have, from other sources, of the tendency to continued elevation of the coast line of the Andes, and, indeed, of the whole continent of South America, on the one hand, and of the depression over a large portion of the bed of the Pacific on the other—alternations which would naturally result from a change in the incidence of pressure on the general substratum of liquefied matter which supports the whole. The bed of an ocean supported on a yielding substratum may be depressed without a corresponding depression of its surface, by the simple laying on of material, whether abraded from the land, or chemically abstracted from the sea itself. That matter *is* in process of abrasion and transportation from the land into the ocean at every instant, and along every coast line, we know as a matter of fact. We know, too, that all existing strata, however enormous their thickness, *have* been formed at the bottom of the sea, and it is, therefore, no hypothesis, but a perfectly legitimate assumption, that the same process is still in progress, no matter how slowly, from this cause, at least in the vicinity of coast lines; and when we look at the vast amount of organised exuviæ which constitute so large a portion of many of the secondary and tertiary beds—the secretions of mollusca, infusoria, and zoophytes—and bearing in mind the large proportion of continental substance which has been so formed, look to the evidence afforded by deep-sea soundings, and by coral formations, that the same process is going forward in open sea, far out of the reach of coast washing and river deposit (the material being *taken up chemically* by the river and coast waters, and *chemically extracted from them*, when diffused by currents, by the processes of organic life), we shall at once perceive that any amount of pressure on the one hand and relief on the other, which the geologist can possibly require to work out his problem, and any law of distribution of that relief and that pressure, is available without calling in the aid of unknown causes."

In apposition with these views of the physical geographer, taken, as it were, from an eminence based on all science (and to which we shall return), we may appropriately place the most recent view of the relations of earthquakes and volcanoes, regarded on a cosmical scale; that taken by Mr. Mallet in his fourth report, the following portions of which embrace the principal points of the subject, as resulting from his own seismological researches and those of M. Perrey.

"Should it ultimately prove a fact, as rendered probable from the beautiful investigations of Darwin, that there are great areas of gradual subsidence now in motion beneath the Pacific, it may still happen (though it is not probable) that seismic, or even volcanic bands may traverse such areas of subsidence, without materially affecting their general downward movement. Although many portions of the earth's surface now show evidences of vertical instability, either slowly or *per saltum*, occasionally rising or sinking, these effects are all comparatively insignificant in extent. The great formative forces, whatever they were, upon which the elevated land of the great continents and the depression of the ocean-beds depended, have ceased sensibly to act. The function of the volcano and the earthquake in the existing cosmos is not creative, but simply preservative; and vast as they appear to the eye and sense, their effects are very small in relation to the totality of the great terrestrial machine. If, however, such large areas of oceanic subsidence as have been supposed really exist, they will most probably be found situated almost centrally within the oceanic sub-basins, and hence surrounded, but not traversed, by seismic bands [or lengthened tracts subject to earthquakes].

"There is one fact, which is shown by the relative positions of the greatest volcanic areas upon our globe (and these the most active) and of the areas of probable subsidence, that is worthy of fixing our attention.

"It will be observed that the bands of probable subsidence are tolerably adjacent to the greatest seats of volcanic activity, and that the latter generally have subsiding areas at more than one side. Thus, in the Pacific, the band of subsidence is along the great volcanic girdle from Celebes to New Zealand, and thence stretches between (and at one point may cut through) the line of sub-oceanic volcanic girdles, from the New Hebrides to the Marquesas.

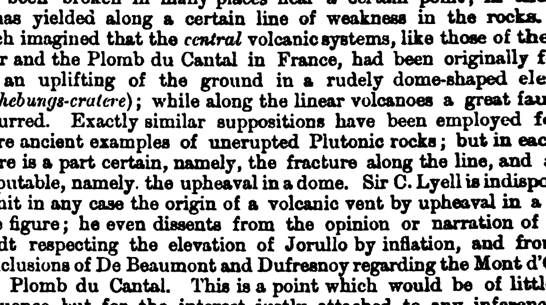
"Again, the great volcanic horseshoe girdle of Sumbawa is between the subsiding area in the China Sea, north of Borneo, and the coral bands north of Australia, which whole continent, or at least its western and northern parts, may probably be subsiding also. Lastly, in the north we have Iceland and its volcanic system, between the sinking coasts of Greenland and those of the Baltic.

"If we admit then, as certain, that these vast tracts are subsiding, we can scarcely withhold our belief that the subsidences are due to, and are the equivalent in bulk of, the solid ejecta and exhalations of these various great volcanic areas respectively. The assumed area and extent of subsidence of those supposed subsiding tracts are, however, I apprehend, greatly overrated.

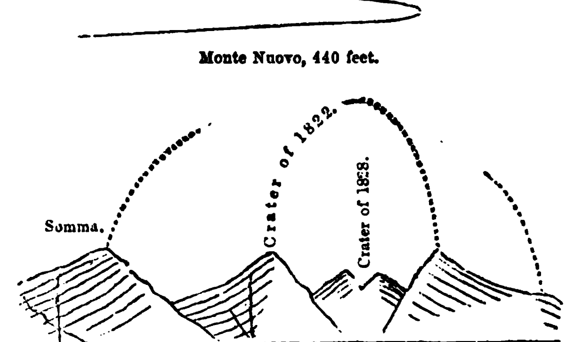
"The seismic intensity in any part of the world, so far as originating impulse is concerned, does not seem to be connected with the superficial character, to the greatest known depth, of the geologic formations, beyond what connection is necessarily inferential from the seismic bands (where they exist), following, on the whole, the lines of mountains and ridges that separate the surface-basins of the earth, whether volcanic or not. While, therefore, the seismic waves diverge from axial lines that are generally of the older rock formations, and often of crystalline igneous rocks, or actively volcanic, they penetrate thence formations of every age and sort, even to plains of the most recent post-pleistocene clay, sands, and gravels; and occasionally, by the secondary efforts of great shocks, these loose materials are shaken or caused to slip, and gather up into new forms (as in the Ullah Bund at the mouths of the Indus, &c.), and so the earthquake has come to be mistakenly viewed as a direct agent of elevation. Its true cosmical function is the very opposite: it is part of the dislocating, degrading, and levelling machinery of the surface of our globe, while the part of the volcano is restoration and renewal. Both are, however, not creative, but conservative (strange as it may sound), and suited to the period of man's appearance and possession of the earth."

The philosophic investigator of the volcanic system of the Canaries (Von Buch) has arranged the groups of volcanoes, which have thus been briefly sketched, into two systems. 1. Central Volcanic Systems, where the vents are grouped round some principal cone, as Ætna, or arranged in an expanded area, as Iceland. 2. Linear Volcanic Systems, as the grand chain of Asiatic Isles and the lofty range of the Andes; and this view is perhaps of the more importance, because it is applicable to the ancient Plutonic rocks, which, from other considerations, we have inferred to be of the nature of unerupted lava. Thus the Sienitic *line* of the Malvern Hills may be contrasted with the scattered *groups* of traps about Charnwood Forest and the country north of the Cheviot Hills.

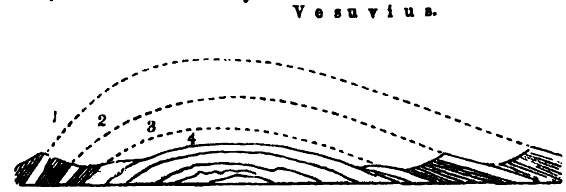
In the one case the crust of the earth has yielded to pressure, and has been broken in many places near a certain point; in the other it has yielded along a certain line of weakness in the rocks. Von Buch imagined that the *central* volcanic systems, like those of the Mont d'Or and the Plomb du Cantal in France, had been originally formed by an uplifting of the ground in a rudely dome-shaped elevation (*Erhebungs-cratere*); while along the linear volcanoes a great fault had occurred. Exactly similar suppositions have been employed for the more ancient examples of unerupted Plutonic rocks; but in each case there is a part certain, namely, the fracture along the line, and a part disputable, namely, the upheaval in a dome. Sir C. Lyell is indisposed to admit in any case the origin of a volcanic vent by upheaval in a dome-like figure; he even dissents from the opinion or narration of Humboldt respecting the elevation of Jorullo by inflation, and from the conclusions of De Beaumont and Dufresnoy regarding the Mont d'Or and the Plomb du Cantal. This is a point which would be of little consequence, but for the interest justly attached to any inference concerning the *origin* of volcanic phenomena. That there have been some rudely dome-shaped elevations in the older strata, in connection with disturbances of the interior of the globe, is evident to any one who has



Monte Nuovo, 440 feet.



Vesuvius.



Woolhope elevation.

1, Line of the Aymestry limestone; 2, line of the Wenlock limestone; 3, line of the Woolhope limestone; 4, line of the Caradoc sandstone [now termed the Upper Llandovery Rock.]

studied the strata in the vicinity of Woolhope, described by Sir R. I. Murchison, of which the subjoined cut gives a cross-section. That the structure of such stratified domes of elevation is entirely different from that of a volcanic cone of eruption is evident by contrasting with the former figure the section across Vesuvius and the profile of the crateriform Monte Nuovo. Some further information on this head appears under the article STRATIFICATION, in NAT. HIST. DIV., and upon the whole it is certain that in respect of a volcanic mountain or region, whose internal structure is sufficiently exposed, there are characteristic marks by which the existence of "craters of elevation" can be affirmatively proved, if any such craters exist. Von Buch, De Beaumont, Professor James D. Forbes, and others agree in ascribing this origin to some of the mountains in central France, and apparently on sufficient evidence. It is, however, not a phenomenon admitting of frequent citation.

Now, the districts thus classed together are not only related by geographical proximity, but have some real subterranean as well as apparent superficial connection. Humboldt and Darwin speak confidently of the great volcanic regions of the Andes as one grand system of subterranean activity; though the manifestations of this at the surface offer local peculiarities, both as to time and circumstances. Mr. Darwin has been led, by the investigation of the volcanoes and earthquakes of the Cordilleras of the Andes, to regard them all as depending primarily on the disturbance of a vast internal sea of melted rock, spread below a large part of South America.

Other conclusions, equally on a large scale, which have been drawn by M. de Beaumont from other classes of phenomena, have a direct bearing on this subject. M. de Beaumont has inferred that the principal mountain-ranges throughout the world have their several geological dates determinable by comparing the positions of the disturbed and the undisturbed strata in and around them: that to each great period of fractures in the earth's crust belongs a certain prevalent direction in which those fractures happened; and though this view may be subject to particular objections and restrictions, there is this great truth in it, that the several systematic fractures which it professes to refer to one certain geological date have each an assignable date. This date being assigned, we find that the earth's crust has in ancient geological times been broken by lines of fracture or bent into flexures, 10, 50, 100, or several hundred miles long, and this often (there are many examples in the British Isles) with no unusual exhibition of really volcanic rock on the line, and even with little appearance of unerupted granite or sienite. These great fractures traverse nearly all regions, with no special reference to active or extinct volcanoes, and it is clear that they are due to a general cause, which has been in operation through all past geological periods, and which produced effects exactly comparable in kind, if greater in degree, to those now performed by modern earthquakes. But if we consider the account of the effects of the great Lisbon earthquake in 1755, which extended over Europe, changing momentarily the level of the land, raising waves 60 feet high at Cadiz, and 18 feet at Madeira, and causing sensible disturbance in the West Indies and Loch Fyne; or the narratives of the Chilian earthquakes in 1822 and 1835, the former of which raised the sea-shore for 100 miles, and the latter rent and shattered the entire provinces of Cauquenes and Concepcion in every direction—it will remain very doubtful in our minds whether the internal power to which earthquakes owe their force has really decreased, or the violence of the earthquake been moderated and relieved by the intermitting action of volcanoes. Mr. Darwin speaks confidently of earthquakes and volcanic eruptions in South America as parts of the same phenomenon, now one and then the other, or both together, but at different points, relieving the pressure on the "internal sea of molten rock;" and this view, which is the largest, appears at the same time the simplest and best founded of all the postulates for a general theory of volcanoes.

This able writer has indeed by a simple inference brought us at once to the basis of this theory. He has inferred that the primary shock of an earthquake is caused by a violent rending of the strata, which on the coast of Chili and Peru seems generally to occur at the bottom of the neighbouring sea.

Here then we take our basis of a general theory of volcanic actions. The earth's crust is subject to fractures, and has always been subject to fractures on a great scale: below the surface of the earth is now, and was in ancient geological periods, an internal sea of molten rock; this sea is agitated and thrown bodily from its place by the rending of the strata: *a wave of translation* (not an ordinary undulation) is generated in the liquid mass [WAVES AND TIDES], which passes rapidly onwards and moves the land on its crest, in a given direction: this is the earthquake. A portion of the melted rock is forced by the general pressure into cavities of the rocks, or spread out in irregular sheets on the bed of the sea; these are the dykes and interposed beds of Plutonic rock: to some part of the internal hot fluid, water finds access, and the steam which is generated and confined supports local columns of melted rock, in particular fissures of the earth's crust, till the lava finds vent and flows to the surface, or is driven up in dust and scoriæ by the violent extrication of the vapour: this is the local volcanic action. As to the composition of that internal sea of melted rock, we may admit it to contain unoxidised metalloids, if by this means we can better explain the peculiar chemical nature of the products which come to the surface; and thus we find at last only one condition remaining to be satisfied, namely, the condition of a continual and progressive destruction of the equilibrium of the internal masses of the earth, which causes the violent rending of the strata antecedent to earthquakes and volcanoes. On this point we need not enlarge. The general progress of geological and physical science has rendered it very probable that the disturbance of the equilibrium of the earth's internal masses, which has at so many geological epochs been exalted to an intensity equal to sink and raise hundreds of miles square, and to fold into complicated contortions the seemingly solid crust of the globe, is due simply to a slow change and gradual diminution of the earth's internal heat. Great fractures, Plutonic rocks, and volcanic accumulations, are of all geological ages; but as our existing land is, in respect of a very large part of its surface, of very recent date, and volcanic cones of loose materials cannot withstand the wasting action of the sea, it is no wonder that the antiquity of volcanoes, if judged only by the relation of volcanic products visible on the land to the stratified crust of the earth, appears much inferior to that of the Plutonic rocks, which were formed among the strata of every age, under circumstances which admitted of their being preserved. But if we more closely study this matter, and compare marine volcanic sediments, such as have been spread by the waves round the base of Sciacca, or Sabrina, with the "trappean" sandstones described by Sir R. I. Murchison interposed amongst the Silurian strata, we shall perceive that local volcanic excitement consequent on general changes in the internal condition of the earth is a phenomenon of all geological periods.

The subject of the production of volcanic cones, whether by eruption or by elevation, or partly by both, has been adverted to in the preceding considerations, and the remarkable example of Jorullo, repeatedly mentioned in the descriptive part of this article, cited from Humboldt as one of elevation. Since their original publication, much research, in which have been observed numerous facts explicatory of the subject, and much reasoning and discussion relating to it, have been instituted and made public, especially by Mr. Scrope, in continuation, or rather resumption of his arguments in support of the reality of the production of volcanic cones exclusively by eruption, by Sir C. Lyell, and by M. Abich, all on the same side.

The most recent view of the subject, in relation to these researches and discussions, taken by Professor John Phillips, F.R.S. ('Anniv. Address to Geol. Soc.' 1859), which it is just to him to quote in this place, is as follows: "In general, it appears probable that cones of elevation are at least of rare occurrence, while cones of eruption are numerous; but as vertical movement of the ground is an essential condition for volcanic excitement at the outset, we must be prepared to admit the possibility of its occurrence as a part of volcanic history: and the only questions which remain for calm and serious study in reference to a given volcano are—How much? and at what epoch? Questions not to be answered hastily." On this point, however, we submit that, however theoretically probable it may be, that vertical movement of the ground is essential to the beginning of volcanic excitement, no proof that it is so has yet been adduced, beyond that required to produce fissures, and ceasing with their production; while induction from the late observations of earthquake-phenomena already noticed, is opposed to it, and some of the results obtained by Mr. W. Hopkins, in his researches in physical geology, appear to indicate that the theory is itself defective, if not erroneous.

Mr. Scrope's recapitulation on this question ('Quart. Journ. of Geol. Soc.' vol. xv. p. 545), states its present aspect in these terms: "My argument then is, that the 'elevation-crater' or 'upheaval' theory, as applied to volcanic action by MM. de Humboldt, De Buch, de Beaumont, and Dufresnoy, and to some extent by Dr. Daubeny and Professor James Forbes, as well as in several popular geological compilations, is an assumption irreconcilable with the appearances it professes to account for, and wholly hypothetical—such a process never having been witnessed; while there is nothing in the form, structure, or composition of any of the cones or craters to which it is applied by its advocates inconsistent with the supposition that they owe their origin to the simple, ordinary, normal, and perfectly intelligible phenomena of volcanic eruptions, as witnessed repeatedly by competent observers as well in the present day as through all past historical times."

Subsequently to the promulgation of these arguments, evidence of the most precise nature, proving that the volcano of Jorullo is truly a cone of eruption, as contended long ago, even on the evidence of Humboldt himself, by Mr. Scrope and Sir C. Lyell, and that it was formed in no degree by upheaval—of which process it had been brought forward by Humboldt as almost a crucial instance—has been given by M. H. de Saussure, a geologist of Geneva, the third in descent, we presume, of a name dear to science. He communicated this evidence to the 'Société Vaudoise des Sciences Naturelles,' in 1859, exactly a century after the surface of the fertile valley of Jorullo had been transformed into a barren sheet of lava, by a catastrophe, having "for one of its results a perfectly characterised volcanic mountain, which suddenly sprung up on the surface of the globe, with unexampled rapidity and grandeur of proportions." Described about half a century after its formation by the great traveller under the influence of an imposing hypothesis, it became one of the subjects, for another half-century, of a controversy among the most eminent investigators of the globe's physical structure. This controversy, we think, as respects Jorullo, must now cease. M. de Saussure states that the sheets of lava surrounding the mountain, called Malpais,—which Humboldt regarded to be the result of a softening of the pre-existing surface soil by gases, and its inflation by them from beneath like a bladder,—are nothing else than vast outflows of incandescent matter, which have lined the whole valley, filling its cavities and forming promontories, just as a mass of molten lead would spread when poured on an uneven surface. The edges of the Malpais are not a section or broken edge of an elevated tract, but only the lateral or terminal borders of currents of lava. The cone which forms the mountain of

Jorullo itself is the simple result of the heaping up of cinders and scoriæ ejected by gaseous explosions from the principal orifice of eruption, after the outbursts of lava had ceased. The eruption took place originally from an axial fissure running north and south, but there is no trace of the elevation of the beds along this axis. The volcanic pressure from beneath had only forced an exit through this fault for the escape of the liquid and aëriform matters erupted. In short, the phenomena of Jorullo show that the most powerful volcanic outbursts can take place without the slightest derangement of the superficial beds. ('Quart. Journ. of Geol. Soc.' vol. xvii.; 'Translations,' &c., p. 13, 14.)

The subject of subterranean heat and its consequences is so vast, and its ramifications in science are so unlimited, that the preceding view of reasonable explanations of Plutonic and volcanic action is far from having exhausted the catalogue. Not merely geologists, mineralogists, and chemists, but astronomers and mathematicians have attempted the solution of the problems involved; the former directing their attention chiefly to special structures, products, or phenomena, the latter to such probable causes as point to hypotheses of wide generality, embracing the entire system of the relations between the earth as a planet to the heat of its interior regions, and to that which it receives from the solar radiation.

While Dr. Daubeny was engaged in perfecting what has been called the chemical theory of volcanoes, originated by Davy, other inquirers gave their attention to that subject under different aspects. Sir C. Lyell, as a uniformitarian in geological speculation, and the advocate, not only of the sufficiency of existing causes, but of their persistence without the trace of a beginning, or the prospect of an end, naturally sought for elements of chemical causation, by which a perpetual circulation of cause and effect returning through effect to cause might be supposed to be maintained; and the late Professor Daniell, of King's College, London, suggested to him hydrogen, with its continual separation from water by means of oxidable bodies and its re-union with oxygen effected by high temperature, as such an element.

Two mathematicians concurred, though independently, in enunciating a theory of Plutonic and volcanic action, dependent on that of the secular variation of the isothermal surfaces within the globe. The foundation of this was the observed augmentation of temperature as we descend from the surface of the earth towards its interior; of which subject we adopt from Mr. W. Hopkins the following condensed statement. A considerable number of observations have been made to ascertain the temperature of the earth at considerable depths beneath its surface, and the law according to which that temperature increases in descending. This law, in a considerable number of localities, may be considered as approximately determined to be—that the increase of temperature above that of the mean temperature at the surface in any proposed locality, is proportional to the depth beneath the surface. The results of observation also lead to the conclusion that the rate of increase of temperature in descending beneath the earth's surface is nearly uniform in each locality, and nearly the same in different localities, being equal to about 1° Fahr. for 60 feet of depth. At all depths, therefore, there will be, mathematically speaking, spheroidal concentric surfaces of the same temperature throughout, or *isothermal surfaces*.

The upward migration of heat from the interior towards the surface of the globe, in consequence of the deposition of fresh matter upon its surface, had been indicated as a cause of geological phenomena by Mr. Poulett Scrope; but the theory of the secular variation of the isothermal surfaces of the interior of the globe considered as so caused was proposed by Mr. Babbage, in a paper read before the Geological Society, in 1834, and by Sir J. F. W. Herschel, in letters communicated to that Society three years afterwards, and eventually printed by Mr. Babbage, together with his own paper, in the appendix to his work entitled 'The Ninth Bridgewater Treatise,' published also in 1837. His application of the theory to volcanic phenomena, properly so called, had been announced, however, in terms of extreme generality, and the main object of his paper was to explain by its means the pyrometric expansion of rocks as the cause of elevation. From these circumstances, apparently, it happened that his views remained comparatively unregarded until the subsequent promulgation by Sir John Herschel of views identical with them in their leading features, but more explicitly developed in their application to those phenomena.

Almost every article in this Cyclopædia which relates to any subject of geological science describes facts, whether structural or dynamical, which involve the truth, that solid materials derived from the land are perpetually being distributed over and accumulated upon the bed of the sea; this having been the process also of the formation of the sedimentary strata of which, mainly, the present land consists. We have seen that it is also true that the temperature of the globe below the surface, and to the greatest depth with which we are acquainted, increases as we descend, the heat communicated to the surface at last escaping from it by radiation into space. By the continued deposition, therefore, of the new sedimentary strata, which are necessarily bad conductors of heat, on the bed of the ocean, the interior heat, instead of being permitted to escape, will be accumulated, and the original surface will acquire the temperature before possessed by some isothermal surface below, at a depth equal to the thickness of the matter deposited upon it, the amount of the accumulation, or the increase of the temperature, augmenting with the increase of this thickness; and consequently, by the necessary extension of this process, the temperature of every isothermal surface vertically below the mass of accumulating matter, to an indefinite depth, will rise in the same proportion. If the temperature at which water boils at the surface, for example, originally existed at the depth of two miles, the deposition of strata of that thickness would cause the temperature of the original sea-bed to rise to that amount; and if the isothermal surface at a certain other depth, of six or seven miles, perhaps, had the temperature of ignition, the deposition of a thickness of sediment equal to that depth would cause the original sea-bed to become red-hot, and, by the continuance of deposition, it would eventually "*become actually melted*," however refractory its materials, "*and that without any bodily transfer of matter in a liquid state from below.*" This process, to use a familiar illustration given by Sir J. Herschel, "is precisely that by which a man's skin grows warmer in a winter day by putting on an additional great coat: the flow of heat outwards is obstructed, and the surface of congelation carried to a distance from his person, by the accumulation thereby caused beneath by the new covering." In the case of the human body, however, we cannot carry the illustration further: a succession of great coats would not now raise the temperature of the skin, because the heat of the body is limited; whereas the succession of external coverings of the earth will indefinitely exalt the temperature of the original surface of deposition, and successively that of all the isothermal surfaces below, because the heat of the interior, by the theory, is conceived to be, and, so far as we know, is actually, unlimited.

The removal of matter from above to below the sea, in the production of sedimentary strata, produces a subversion of the equilibrium of pressure, and, as we have seen, and which is the most important effect, a subversion of the equilibrium of temperature. But the process, as described, by which this is effected, *must be excessively slow*, and it will depend, "1st, on the depth of matter deposited [as already explained]; 2ndly, on the quantity of water retained by it under the great squeeze it has got; 3rdly, on the tenacity of the incumbent mass, —whether the influx of caloric from below, WHICH MUST TAKE PLACE, acting on that water, shall either heave up the whole mass as a continent, or shall crack it, and [the results of the action of the heat upon the sedimentary matter and the water] escape as a submarine volcano [or a linear series of such volcanoes, afterwards to become subaërial and insular], or shall be suppressed until the mere weight of the continually accumulating mass breaks its lateral supports at or near the coast-lines, and opens there a chain of volcanoes." For a further account of these and other consequences of the rise of the isothermal surfaces, the reader must consult the original papers of the authors of the induction, or of what, for the sake of convenience, we have termed the "thermotic theory of Plutonic and volcanic action." But we may now refer to Sir J. Herschel's account of the facts of the local distribution and systematic arrangement of volcanoes, cited in a previous column (666), as evincing their entire agreement with his theoretical views here given.

Such being the position of the subject, an effort was now made to deduce from the thermotic theory, in the most general, but also in the most explicit, manner, the chemical theory of Plutonic and volcanic action, and to show that the latter, as originated by Davy, adopted by Gay-Lussac, and explicitly advocated by Daubeny (though Davy's speculation had been rejected by one of the authors of the thermotic theory), was in reality a simple and necessary consequence of the theory of the secular variation of the isothermal surfaces, explained by Babbage and Herschel, and applied by them to account for the same phenomena. This was done by Mr. Brayley, in a Friday evening discourse at the Royal Institution (where, thirty years before, Sir H. Davy had announced his theory), deliverd May 11th, 1838, and published in the 'Philosophical Magazine,' series 3, vol. xii., pp. 533–536.

Viewing the subject in the most general approximate manner, agreeably to the amount of our actual knowledge at the time, and unavoidably disregarding a multitude of modifying considerations which must enter into the discussion of the problem, in order to obtain an exact solution of it, Mr. Brayley first pointed out, on the one hand, how great a thickness of deposited matter would be required for the original surface to attain even a moderate temperature above that due to its geographical position; but, on the other hand, at how insignificant a thickness (or depth), compared to the earth's radius, adequate temperatures for Plutonic action would occur,—all these inferences being founded on the observed law of the increase in temperature in descending of one degree of temperature (1° Fahr.) for every fifty (more accurately sixty) feet of depth. The depths at which the temperatures of boiling water and of ignition respectively would be found, are stated above. At the depth of 26 miles, less than $\frac{1}{153}$th part of the earth's radius, cast-iron would melt, or the temperature of 2786° be attained; at 50 miles depth, a temperature of 5000°; and at 100 miles, only $\frac{1}{40}$th of the earth's radius, one of nearly 11,000°; either of which, from all analogy, would be more than adequate to the effects required; for it cannot be doubted that at such temperatures even the most infusible and fixed bodies known to form the earth's crust would be not only liquified but volatilised.

Davy, after repeatedly advocating his own theory, had finally relinquished it, for reasons which it is remarkable that he should not have seen, were altogether in its support, when the theory was duly followed out—in favour of that of an ignited nucleus of the earth, but admitting at the same time that it was adequate to the explanation of all the phenomena it sought to account for.

After drawing attention to these points, Mr. Brayley proceeded to argue that if the theory of volcanoes dependent on that of the secular variation of the isothermal surfaces were true, then the chemical theory must also be true, as being necessarily involved in the wider generalisation of the former. The grounds of the argument were the following, which, as nearly a quarter of a century has elapsed, we now state in the words of Mr. Brayley's original enunciation of his deduction.

"The new deposits formed at the bottom of the sea by detrital matter must inevitably contain much carbonaceous and other combustible materials derived from organised beings, and these would become distributed sometimes in a finely-divided state, intimately mingled with earthy bodies,—that is, with the oxides of the earthy, alkaline, and common metals. At the exalted temperatures implied in the theory, many of these oxides, including those of the earthy and alkaline bases, would become reduced to the metallic state; the ignited water with which the whole would of necessity be saturated, would be decomposed; its oxygen re-oxidising the bases, and its hydrogen being evolved in an uncombined state. Now one of the most abundant elements in all the detrital matter would necessarily be oxide of iron, which would thus be presented, in a state of minute division, to incandescent, but enormously compressed free hydrogen, by which, agreeably to known results of experiment, it would be reduced to the metallic form, water being re-composed. A new affinity would now come into action: finely divided metallic iron being in intimate contact with the earthy and alkaline oxides, they would be reduced, as in the ordinary method of obtaining potassium and the process by which Davy and Berzelius first succeeded in deoxidising the combustible bases of silica and alumina, and would eventually react upon the water still present. By this constant circulation of affinities, exerted simultaneously in different portions of the heated mass, according to their respective temperatures and to the local distribution within it of the various substances evolved (dependent on their respective properties, as modified by the enormous pressures to which they would be subject), chemical equilibrium would alternately be established and subverted; and all the phenomena and effects of plutonic and volcanic action would ensue."

Mr. Brayley also briefly alluded to Mr. Scrope's "views of the origin and constitution of lava, &c.,"—then and recently considered so anomalous,—"as other probable truths involved in the new [that is, the thermotic] theory," from which indeed they were considered in this discourse to be as necessarily deducible, as, in the present article, they have been advocated as confirmable by known facts.

Unacquainted with Mr. Brayley's views, Professor John Phillips, at about the same time (1838), in his 'Treatise on Geology,' in the 'Cabinet Cyclopædia,' remarked,—"There is not, we believe, any attempt on record to deduce all the *chemical* phenomena of volcanoes from the hypothesis of general heat below the surface of the earth; we must therefore, at present, suppose this is difficult, except upon the admission of that powerful absorption of oxygen from water, which the chemical hypothesis provides." Proceeding to inquire whether the results of the latter "involve the rejection of the hypothesis of a pervading high temperature below the surface of our planet," and replying in the negative, he continues: "It appears to us very clear, that the union of the two speculations here brought into comparison is not only practicable, but reasonable, and even necessary." We have seen, however, that an attempt had been made to deduce all the chemical phenomena of volcanoes from the hypothesis of subterranean heat, by the intervention of the thermotic theory, certain chemical consequences being assigned to the latter. Several years after, Prof. Phillips penned the view of the subject taken in the preceding section of the present article; and his most recent ideas respecting it are stated in the following terms in his first Presidential Address to the Geological Society, 1859.

"That the earth is still fluid within, under the regions of volcanic action, and ever ready to pour out its melted constituents under the pressure of elastic vapour, is evident by all the phenomena of volcanic excitement. Is this fluidity due to the residual heat of the globe, still effective in these regions, or maintained if not excited here by the chemical process of oxidation, by the decomposition of water, and the reunion of one of its elements with the uncombined bases of the earths, alkalies, and metals? The answer, if taken from volcanic phenomena alone, appears ambiguous. The chemical products of volcanoes, indeed, require the admission of water to the roots of the fiery action, and the decomposition of it there; but this seems not decisive of the question, whether the bases of the alkalies and earths and metals exist uncombined with oxygen in these situations, chemists of eminence taking different views of the matter."

"If we take earthquakes for our guide, these tremors appear to follow laws which apply to elastic solids, not undulating fluids, and yet they presuppose a shock or displacement [see col. 669], such as a fluid support for a solid crust might well account for."

All the preceding inductions and speculations, however, will be affected by the conclusions at which we may arrive on a subject of a cosmical nature, and relating to the structure of the planet. This is the probable thickness of the solid crust of the globe, assuming it to consist of a fluid nucleus of high temperature inclosed in a solid shell. The phenomena of the increase of temperature with the depth, and their consequences with regard to the heat to which the bodies composing the crust must be subject at comparatively small depths, as briefly noticed above, have led some geologists to conclude that the crust, or external solid shell, is not of greater thickness than sixty or seventy miles, and others have considered it even less: Mr. Darwin, for example, from his researches on the South American volcanoes, infers a probable thickness of twenty miles only. Mr. W. Hopkins, and Archdeacon Pratt, of Cambridge, Professors Hennessy and Haughton, of Dublin, all mathematicians and physicists, and all having a well-earned right to independent judgment in matters of physical geology, have severally investigated this problem, and the latter two inquirers differ greatly from the former, if not in some degree from each other, in the thickness they respectively assign to the crust. But we are disposed to agree with Archdeacon Pratt, that the result Mr. Hopkins has obtained agrees best with all our knowledge. The numerical result of his refined investigation (1839-1841) is, that the least admissible thickness of the crust must be about one-fifth of the earth's radius; a result which after many years' devotion to physical geology he has recently (1859) confirmed, remarking that, "without assigning any great importance to an exact numerical result," he retained full confidence in the investigation, "as showing that the thickness of the crust could not be so small as 200 or 300 miles, and consequently that no geological theory can be admitted which rests on the hypothesis of the crust being nearly as thin as it has been frequently assumed to be."

This conclusion will necessarily affect all our views relative to the causation of plutonic and volcanic phenomena, on whatever foundation they may rest. The source of volcanoes must be in cavities contained in the solid crust at depths probably not greater than those at which the solidity of the crust had been supposed to terminate, by those geologists who reasoned only from the known increase of heat from the surface downwards. Mr. Hopkins, himself, proposes to explain their phenomena "on the supposition that a portion of matter more fusible than the general mass of the globe, exists in a state of fusion in subterranean reservoirs, forming so many subterranean lakes of determinate extent; in some cases originally distinct; in others, communicating with adjoining lakes by more or less obstructed channels."

The view, however, of plutonic and volcanic action at which we have now arrived, combining the thermotic with the chemical theory, and including also the consideration of the thickness of the earth's crust, will itself require modification, in consequence of Mr. Grove's remarkable observation of the decomposition of water by heat alone, independently of chemical action.* [WATER.]

From this it would appear to follow irresistibly, first, that in the very interior of the globe the elements composing water must exist in a state of separation from each other, as it were rigidly separated by heat; but still, from the immense pressure to which they must necessarily be subject, in a very dense state, so that, upon reduction of temperature—lowering of the heat—they would immediately enter into combination.

Secondly, that even in the superficial lakes of molten or flowing matter, to which, after Mr. Hopkins, as we have seen, we must attribute volcanoes,—universally distributed below the mere surface of the earth,—as shown by Mr. Darwin,—the result of the deposition on the bed of the ocean of new deposits, causing the rise of the isothermal surfaces, as demonstrated by Babbage and Herschel—in the more heated parts of those lakes water will exist, not as steam or as incandescent or ignited water, but as mixed but uncombined oxygen and hydrogen gases. At the same time the mere effect of heat will be modified by pressure, and the chemical action of the bodies present, so that we have here another great result perfectly in harmony with the thermotic theory on the one hand and the chemical theory on the other. But we are not to expect any evidence of the existence of free oxygen and hydrogen below to arrive at the surface, for as the upper parts of the molten flood will be of inferior temperature, in them, or in their ignited solid roof, the gases will reunite into water, and eventually ascend to the surface, as steam, or mingled with the mineral elements of lava, in some state intermediate between those of liquid and vaporous water, to be disengaged as steam in the volcano, and from the surface of currents of lava.

Thus, all the great powers and forces which govern the material elements of the globe mutually act and react upon each other. Pressure and condensation caused by gravity, combination resulting from chemical affinity or attraction, heat, producing alternately rarefaction or condensation, combination or separation, accordingly as it is related to the other forces; the whole being so held in equilibrium between themselves and the antagonistic action of the sun upon the surface of

* It has been doubted whether the decomposition of water in Mr. Grove's experiment is really due to the action of heat; but there is no room for doubt that it is due at least to agencies excited by the temperature obtained, or inseparable from it, so that the argument in the text will remain valid. The decomposition is effected *at* the temperature, whether immediately by its means or not, and will not take place at an inferior heat.

the earth, that the magnitude, figure, order, and beauty of our planet are perpetually maintained.*

VOLTAIC ELECTRICITY. [GALVANISM.]

VOLTAIC PILE. [GALVANIC BATTERY.]

VOLTAMETER. [ELECTRO-CHEMISTRY.]

VOLUME. This word, as meaning a part of a book, is derived from the old form of a book, a roll (of parchment). But our language takes from the French a sense of which the Latin knows nothing; and *volume* means bulk, size, or solid content. Thus the volume of a sphere is two-thirds of that of its circumscribed cylinder: the volume of a cone is one-third of that of a cylinder of the same base and altitude, and so on.

Under the various words, PRISM, CYLINDER, CONE, SPHERE, &c., will be found the modes of ascertaining their volumes. The mode of finding the volume which is contained under a given surface is a process of the integral calculus, which it would be useless to attempt describing within any limits we could afford.

VOLUMETRIC ANALYSIS. *Volumetrical Analysis.* In chemistry, analysis comprehends that series of operations by which a compound body is resolved into its constituents. Analysis may be *qualitative*, and have for its object the mere ascertaining of the number and nature of the constituents, or it may be *quantitative*, which as well includes the determination of the amount of each ingredient. Quantitative analysis is based upon the great chemical law of definite combining proportions, and may be proceeded with either in a gravimetrical or in a volumetrical manner; that is, a body may be isolated and weighed alone in a balance, and its quantity ascertained; or it may be separated by, and weighed in combination with, another body, whose combining proportion is well known: such is the gravimetric method. The balance, the instrument used for measuring the gravitating force of the compound, may, however, be in part or wholly discarded, and the amount of a constituent of a compound be ascertained by noting the volume of a liquid which is required to be added to the compound before a given effect is produced: such is volumetric analysis. Gravimetry is more generally applicable, but requires an exceedingly delicate balance, with perfectly accurate weights, great skill in manipulation, and the expenditure of a considerable amount of time. Volumetric analysis is only applicable to a limited extent; and the liquids referred to, or standard solutions as they are called, sometimes require considerable care in their preparation; but no elaborate apparatus is necessary. The operation is simple, and easy of execution, and may usually be performed in one-tenth or one-twentieth part of the time necessary for a gravimetrical experiment.

Volumetrical analysis seems to have first sprung from Richter's observations on neutral saline solutions, a research which much aided the discovery of the laws of chemical combination. Quantitive estimation by the balance, or restricted gravimetrical analysis, existed prior to that time, and was constantly appealed to in determining the truth of these laws, because the balance was already well known, and its indications could be relied on. Until chemistry began to be applied in the arts and manufactures, there was little or no demand for expeditious analytical processes; even the volumetrical processes of alkalimetry, acidimetry, and chlorimetry, introduced by Descroizilles, and improved by Gay-Lussac, Dalton, and Faraday, for a long time stood alone; and not until within the last ten or fifteen years did the operation of analysis by measure attract any particular attention, or seem likely to aid, much less to any extent supersede, the old method of gravimetry. Since that time, however, the tendency has been in the opposite direction; and now many of the elements, as well as the more commonly occurring proximate principles, can be estimated by volumetric methods. Gases have been almost exclusively analysed volumetrically, but, requiring special and peculiar treatment, their examination is described under GASOMETRIC ANALYSIS, which is generally looked upon as a distinct and separate branch of chemistry.

An enumeration of all the processes of volumetric analysis would require more space than can be devoted to such a subject in this Cyclopædia: nor would such a list be of value for any length of time. The masterly researches of Bunsen and others have already systematised and extended the applications of many of these processes; in a few years, therefore, it is hoped that an approach to classification may be attained, and that the present inconvenience of having to make, and the difficulty of keeping, so many standard solutions, to a great extent will be got rid of. Moreover, several volumetric methods have already been treated of in this Cyclopædia [ALKALIMETRY; ACIDIMETRY; ASSAYING; CHLORIMETRY; COPPER; SOAP-TEST; TANNIN; UREA], so that the subject need only be generally treated of here.

The manner in which the processes involved in volumetric analysis are carried out, will be readily seen on referring to any of the articles above mentioned, or in considering a generally applicable process by Bunsen, presently to be described. The only apparatus necessary are some pipettes and a few accurately graduated measuring-glasses of small and large capacity. One of the latter should be capable of delivering fluid both in a free stream and slowly in small drops. A special measuring-tube, or burette, has been contrived for this purpose by Mohr, and is now generally used for the purpose. *Fig.* 1 is a drawing of the instrument.

Fig. 1.

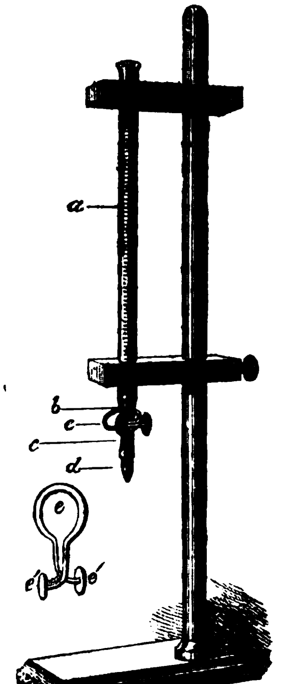

Fig. 2.

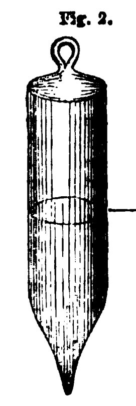

Fig. 3.

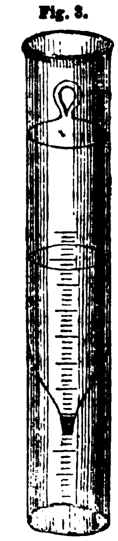

It consists of a glass tube, *a*, from three- to five-eighths of an inch wide, contracted at the lower extremity, *b*, and graduated. To the contracted portion is fitted a small piece of vulcanised caoutchouc tube, *c*, into the other extremity of which a small spout, *d*, made of narrow glass tube, is inserted. A wire clamp, *e*, effectually prevents any fluid from passing out of the burette, unless the knobs, *é*, *é*, are pressed by the finger and thumb of the operator, when the liquid either flows or drops as may be wished. The accurate reading off of the height of the solution in the burette is a matter of great importance; Erdman recommends, for this purpose, the use of a float, *fig.* 2. It is a hollow glass bulb, and is used as indicated in *fig.* 3, which represents the upper part of the burette. It must move freely within the burette, and its specific gravity be so adjusted, by enclosing in it a small quantity of mercury, that the upper edge of the liquid in the burette may cut it uniformly on all sides at a line, *a*, marked round the central portion of it. In order also that the line on the float may be parallel with the graduation on the burette, and that no undue friction may exist between the two glass surfaces, the axis of the float must coincide with that of the tube. In cases where the test-liquid contains anything that may act upon the caoutchouc, the end (*b*, *fig.* 1) of the tube may be more finely drawn out and fluid expelled by gradually compressing an india-rubber ball attached to the upper extremity of the burette. Burettes may be specially graduated for a particular class of operations, as seen under ALKALIMETRY, and ACIDIMETRY; the degrees may indicate measures of ten grains each, as described under SOAP-TEST; or, as now usually adopted in chemical laboratories, the division may be into cubic centimetres.

By classifying the reactions by which reducing or oxidising volumetric determinations are effected, Bunsen has succeeded in preparing three test-solutions, by which any of the following substances can be quantitatively estimated: mixtures and compounds of iodine, chlorine, bromine, chlorites, hypochlorites, sulphide of hydrogen, sulphites,

* This view of the effect of Mr. Grove's observation on the chemical part of plutonic and volcanic theory, formed part of a lecture delivered by Mr. Brayley at the Russell Institution, in 1847, shortly after that observation had been communicated to the Royal Society.

chromates, chlorates, arsenites; the peroxides of iron, manganese, lead, nickel, &c., protoxide of iron, &c. The fact on which the method is based is as follows:—that when iodine is brought into contact with an aqueous solution of sulphurous acid, containing not more than 0·04 or 0·05 per cent. by weight of anhydrous acid, hydriodic and sulphuric acids are respectively formed:—

$$\underbrace{I}_{\text{Iodine.}} + \underbrace{HO}_{\text{Water.}} + \underbrace{SO_2}_{\text{Sulphurous acid.}} = \underbrace{HI}_{\text{Hydriodic acid.}} + \underbrace{SO_3}_{\text{Sulphuric acid.}}$$

The standard solution of iodine is made by dissolving five grammes of perfectly pure iodine in a concentrated solution of pure iodide of potassium, and making up the liquid to exactly one litre with pure distilled water. This solution (=1000 cub. cent.) will obviously contain 0·005 gram. of iodine in every cubic centimetre. The sulphurous acid liquid is made by adding 35 or 40 cub. cent. of a saturated solution of sulphurous acid to 5000 cub. cent. of water, introducing a little starch paste into some of the solution, and then pouring in the standard solution of iodine until after brisk agitation a distinct blue coloration remains. The value of this sulphurous solution having been calculated according to the above equation, it must be diluted till it contains 0·03 gram. of sulphurous acid in 100 cub. cent. The third test-liquid necessary is one containing about one gramme of pure iodide of potassium in 10 cub. cent. of water. In using these standard solutions for estimating an unknown quantity of free iodine in any substance, a weighed quantity of the latter is taken, the iodide of potassium solution added to dissolve the iodine, (if not already in solution) and the sulphurous acid solution then added until the brown colour of the iodine has disappeared. To effect this, an excess of the sulphurous acid is necessary, but that excess is determined by mixing a small quantity of starch paste with the liquid and then adding the standard solution of iodine until the blue colour appears and remains permanent. The quantity of iodine equivalent to the total amount of sulphurous acid used, less the quantity of iodine afterwards added to neutralise excess of sulphurous acid, will be the amount of iodine present in the portion of substance that was submitted to examination. The great value of this volumetric method of Bunsen depends upon the circumstances that so many bodies may be made directly or indirectly to liberate iodine from iodide of potassium, and that the reactions which occur in the processes are constant, accurately defined, and well known. Any body also which is decomposed by iodine in a known manner can be thus estimated. For example, an unknown quantity of sulphuretted hydrogen in any fluid is at once determined on adding to a given amount of the fluid, first a little starch paste and then the standard iodine solution until a permanent blue (iodide of starch) is produced: as the equivalent of iodine is to that of sulphuretted hydrogen, so is the amount of iodine used to the amount of sulphuretted hydrogen sought for. Hypochlorites are valued according to this method, by mixing a solution of a known weight of the salt with the test solution of iodide of potassium; adding hydrochloric acid till an acid reaction is obtained, and then determining the amount of liberated iodine in the manner already described. Besides a large number of substances which directly liberate chlorine,—and indirectly therefore, iodine,—those substances which are readily and perfectly oxidised by chlorine also come within the range of this method: such bodies may be heated with a known weight of bichromate of potash and hydrochloric acid; every two equivalents of the chromic acid yield under these circumstances three equivalents of chlorine, excess of which must of course be used, and that excess determined, as above indicated, by the amount of iodine it will liberate. For other examples of the adaptation of Bunsen's method, see the English translation of Fresenius's 'Quantitative Analysis,' third edition.

Gay-Lussac's volumetric method of estimating silver by a standard solution of chloride of sodium, has already been described under ASSAYING. The converse is of course equally easy, namely, the determination of the amount of chlorine in any chloride by a standard solution of nitrate of silver. Mohr has shown that this method admits of very general application: thus ammonia may be estimated by adding excess of hydrochloric acid, evaporating to dryness, and determining the amount of chlorine in the residue; the resulting chloride of ammonium being a definite salt, it is only necessary to know the amount of chlorine in the residue and then a simple calculation will give the quantity of ammonia experimented on. Nitrogen may be determined in a similar manner after conversion into ammonia by soda lime. Carbonic acid may be absorbed in a mixture of chloride of barium and ammonia, the carbonate of baryta collected on a filter, washed, dissolved in hydrochloric acid, the solution evaporated to dryness, and the chlorine estimated as before; the weight of the latter being, of course, transformed by calculation into an equivalent quantity of carbonic acid. Carbonates or nitrates are converted into chlorides, the chlorine estimated, and the equivalent of nitrate or carbonate calculated. Salts of organic acids may be altered to carbonates by ignition, and the carbonates treated as already described. Chlorates, iodates, and bromates are reduced to chlorides, iodides, and bromides, and also acted upon in the way indicated.

Permanganate of potash is a re-agent of considerable value in the volumetric analysis of substances which readily absorb definite quantities of oxygen. Possessed of an intense purple colour, its solution freely gives up its oxygen and becomes almost colourless. It is best standarised by noting the quantity necessary to be added to a known amount of a definite protosalt of iron, such as the ammonio-protosulphate, before a permanent purple tint is produced: this of course only occurs when the protoxide of iron is wholly converted into peroxide. After the strength of the permanganate of potash solution has been thus fixed, it can be used for estimating an unknown amount of protoxide of iron in a weighed quantity of a mixture of the two salts and for other similar operations.

In all the above described processes of volumetric analysis, as well as in those only referred to, a balance and weights or saturated solutions of definite strength are necessary at some stage of the operations. Quantitative determinations can, however, be made without the use of weights, with volumetric solutions of unknown strength, and the strength of which need not be ascertained or regulated. For example, let it be required to know the amount of carbonate of soda in a specimen of crude soda-ash. Place on one pan of a balance a piece of chemically pure carbonate of soda and counterpoise it by the crude ash; dissolve in separate quantities of water, tinge the solutions by litmus, then add dilute acid from a graduated measure until both are saturated; suppose, now, that twenty-two volumes of acid were required for the pure soda and sixteen for the impure, then as $22 : 16 :: 100 : x$, a calculation that shows the crude ash to contain 72·7 per cent. of pure carbonate of soda. Many other determinations may obviously be made on the same principle. The substance to be determined need not even be available in the pure state; one of its compounds must, however, be attainable in that condition, and both that compound and the impure body must be capable of being similarly acted upon by the test-liquid employed. For instance, in the example above worked out, pure carbonate of lime may be substituted for carbonate of soda, but the number of volumes of test-liquid used must be added to or subtracted from according as the equivalent of the substituting body is higher or lower than that of the body substituted.

VOLUNTARY SETTLEMENT. [SETTLEMENT.]

VOLUTE, a rolling or spiral curve, a name particularly given to the spirals which appear in architectural columns as ornaments of the capitals. The Ionic volute (figured in COLUMN, col. 49) is that which is of most interest. There has been, we believe, some discussion as to what the form of this curve really was. Whether the architect of a Greek temple employed anything but his eye to give an agreeable form, we do not know; but a mathematician would say beforehand that it would be hardly possible to draw such a number of concentric spirals not interfering with each other as are seen in the diagram above cited, unless each of them was tolerably near to a logarithmic spiral, in which the tangent always makes the same angle with the radius. We examined with particular attention a cast made at Athens by Professor Donaldson, and found the following result:—Taking the diagram in COLUMN (col. 52), we found that each spiral, as far as c, or thereabouts, was remarkably true to the logarithmic spiral: but that from c the law of the curve changed, and the acute angle made by the tangent with the radius vector began to increase, until it became a right angle at A.

VOMICINE. [NUX VOMICA, ALKALOIDS OF; *Brucine*.]

VORTEX. The theory of Descartes on the formation and mechanical laws of the universe was first published in 1637, in his 'Principia Philosophiæ.' One part of this theory, namely, the hypothesis of vortices, is almost the only one which generally passes by the name of Des Cartes. But it should be remembered that this is only a part, and a small part, of the system which rendered the Newtonian view of astronomy for a long time unacceptable to the continental philosophers. The metaphysics, the mechanics, and the astronomy, of the once celebrated Cartesian system, combined as they were by one writer, and that writer a most skilful and elegant proposer of his own views, are to be looked at together as that which Newton's philosophy had to meet. Perhaps we should not be wrong in saying that the impossibility of a vacuum, maintained by Des Cartes as self-evident, was a greater obstacle in the way of the theory of gravitation, with which it seemed incompatible, than the theory of vortices, which Des Cartes proposed as an hypothesis, and which did not necessarily contradict Newton's deductions. We shall here present a brief sketch of the system, so far as is necessary, from the third book of the 'Principia Philosophiæ:' this sketch is, as far as it goes, only a table of contents of the work itself.

The human imagination must not either limit the power of God or unduly exalt its own: and it must not suppose that all things were made for man's use only. In enumerating phenomena Descartes prefers rather to deduce them from causes than to make them serve in finding causes. He then describes the relative distances of the planets, and asserts the immensity of the distances of the fixed stars. After the usual statements relative to the light of the sun, planets, and fixed stars, he rejects the Ptolemaic hypothesis, and observes that those of Copernicus and Tycho Brahé differ very little as hypotheses, and explain phenomena in the same manner. He says also that Tycho, though he denies the motion of the earth, yet in reality gives it more motion than the former (with Descartes, relative motion was a most absolute idea); whence, differing from both, he will, with more truth than Tycho, and more care than Copernicus, take away the motion of the earth. To this end he proposes an hypothesis, which will be very fit to explain phenomena; but only as an hypothesis, not as an absolute truth. The fixed stars are exceedingly distant; the sun consists of a fluid and mobile matter, which would carry the circumjacent parts of the heavens with it, but which does not change its place in the heavens: the solar matter does not need aliment. Each one of the fixed stars has an immense space about it, in which there is no other fixed star. The heavens are filled with fluid matter, as astronomers commonly suppose, because they do not see how the phenomena of the planets can be otherwise explained. Each* of the heavens carries with it all bodies therein contained. The earth and every planet is at rest in its heaven, though it may be carried with that heaven: the earth therefore, or any one planet, may be said not to move, but all the others must be said to move. The whole heaven of the sun is moved round it in the manner of a whirlpool, "in modum cujusdam vorticis," the more distant parts moving more slowly than the nearer; and the planets are carried round with this heaven. And as in the larger whirlpool are sometimes seen smaller ones, which are carried round in the larger; so each planet is the centre of a smaller vortex, in which its satellites are carried round their primary. The sun and planets are carried round their axes by the motion of their vortices (the inclinations of the planetary orbits to the ecliptic have an obvious explanation: the inequalities in longitude are mentioned without explanation). It can hardly be that an hypothesis which thus explains phenomena can be false: to say this would seem to be an imputation upon the Deity, namely, the supposition that He made us so imperfect, that a right use of reason might lead us to deceive ourselves (Descartes is not the only one who has used this sort of argument). Nevertheless, he is willing that it should be put forward only as an hypothesis. And though both religion and reason teach that God made the world complete, that not only the seeds of plants were formed, but plants themselves, &c., yet the nature of things will be better explained if it can be shown how, as from seed, the solar system was produced (Descartes here fears the imputation which was afterwards cast upon the author of the *nebular hypothesis* [SOLAR SYSTEM]). All matter originally consisted of particles, forming numbers of fluid heavens, revolving about their several axes. These particles were originally equal in size and motion; they also became spherical, when the corners had been worn down by rubbing against each other. And since no portion of space can be vacuous [VACUUM], the interstices of these spheres must be filled by matter, of form perpetually changing, derived from the parts worn off the angles: this last kind of matter moves more quickly than the other. Besides this there is a third sort of particles of matter, more solid, or else of form more adapted to motion: of this planets and comets are composed. There are three classes of celestial heavens: the first, that of our sun and its system; the second, the various heavens of the fixed stars immediately adjoining; the third, including all which are beyond, and which never can be seen in this life. The *primary* particles, as those are called which are obtained by attrition from the secondary particles, at last become more than enough to fill the intervening spaces (how this could be Descartes does not say), and the residue, as fast as it arises, was forced to the centres of the vortices, where it formed certain very fluid spherical bodies: these are the sun and fixed stars. The secondary particles receded from the centres to make room. The efflux of these primary particles from the fluid bodies just described is light. The centrifugal force of particles in motion round a centre is then dwelt on, and the circular form of the sun and fixed stars is attributed to it. The motion of the vortices must be such that their contiguous parts may have a common motion. The primary particles flow from the poles of each vortex towards the centre, and from the centre towards the other parts. But the same must not be said of the secondary or spherical particles (the reasons given are fanciful in the extreme, consisting entirely in different motive powers given to the two species of particles).

The preceding may give a sufficient idea of the sort of foundation which Descartes builds upon, and his manner of raising the structure. He proceeds through what he supposes to be explanations of all the phenomena of light, of the formation of planets and comets, and of all the varieties of conformation which are seen in the solar system. Why comets have tails and planets none; how the primary particles of other vortices find their way into ours, so that we can see the fixed stars; how the planets obtained their first motions of projection: how the spots on the sun are formed, and so on, are all explained by the powers of the two species of particles: an hypothesis on their nature being always ready when wanted. A reader who has looked into this book of Descartes's 'Principia' begins to understand two things better than before: first, the satire on philosophical explanations contained at the end of Molière's 'Malade Imaginaire,' written a few years after the death of Descartes; next, the declaration of Newton, *Hypotheses non fingo.*

As the hypothesis of vortices is usually represented, it has a certain reasonableness of appearance, which no doubt makes many wonder why it should be so universally contemned. If a fluid mass were whirled round the sun, it would carry the planets with it: and the supposition of minor vortices, one round each planet which has a satellite, is perfectly consistent with the laws of hydrostatics. When Newton proposed to refute the system of Descartes, he was obliged to have recourse to numerical considerations: he could not but admit that a planet, in one of Descartes's vortices, would have an orbit; but he showed, from the nature of fluid motion, that it could not have the orbit which, from the time of Kepler, it was known to have. The quality of a phenomenon is known before its amount is measured; and it is natural to expect, in the history of philosophy, that explanations which serve to account for the nature of a phenomenon, but are irreconcilable with its amount, should precede those which are drawn from consideration of both. The possibility of the planetary motions finding their proximate cause in the rotation of a fluid mass which fills the solar system, is a thing which did suggest itself, and ought to have suggested itself, to the inquirers of the time which elapsed between Copernicus and Newton. Descartes says expressly, "putandum est, non tantum Solis et Fixarum, sed totius etiam cœli materiam fluidam esse: *quod jam vulgo omnes astronomi concedunt*, quia vident phænomena planetarum vix aliter posse explicari." No mechanical difficulty stood in the way in their time; and those who had seen particles of dust whirled about by the air would have no difficulty in imagining the hypothesis of a vortex. Now we find this fault with the common notion of Descartes's system: the disparagement which belongs to it *as a whole*—to the primary and secondary particles which, though obtained from the same original particles, yet have different laws of motion, and to the gratuitous deduction of everything from this fancy—is conveyed to their readers by writers who only present the most rational extract which could be made, namely, the idea of a vortex. This is the sort of syllogism on which such writers proceed: "Descartes's system is ridiculous; all I know of that system is its vortices; therefore I must laugh at the vortices." Yet not only was Newton obliged to have recourse to his most powerful weapons to refute these vortices, but it is not at all a settled point that his refutation is sound; that is, his mathematical refutation. His remark that comets could not find their way through the vortex is much more to the purpose, though Descartes has his way out of this difficulty, as out of every other.

* The matter in the space about a planet, or star, which is under the influence of that planet, is called its *heaven*.

VORTICES. [VORTEX.]

VOUSSOIR, one of the stones of an arch. [ARCH.]

VOW (from the Latin "votum," through the French), a promise to perform some future act, or to pursue some future line of conduct, confirmed by an appeal to the Supreme Being, or at least to some supernatural power, to punish or be propitious to the maker of the promise according as he breaks or keeps his word. Abraham made his steward swear that he would faithfully discharge the mission to seek out a wife for Isaac; this is an example of the vow which is supposed to bind a man to perform one definite act or incur some supernatural punishment; and the oath taken by witnesses, in courts of justice, at the present day, to speak the truth, belongs to the same class. [OATH.] Some vows again are understood to bind those who make them to the performance of certain limited duties for the whole of their future life—such are the marriage vow, as contemplated by the Church of Rome and the law of England, and the coronation oaths of kings. Some vows are even intended to give a particular form and direction to the whole of a man's future emotions, thoughts, and actions—such are the priestly and monastic vows. The view entertained of the character and operation of a vow has differed materially at different periods. The vow originated in a religious conception, in the recognition of some unseen power superior to and exercising a control over visible nature and man's destinies. But as the moral faculties of society expanded, the vow came to be regarded as a solemn form of making a promise, in which the appeal to the Divinity was meant to remind the utterer of the oath of what men are too apt to forget, that the eye of God was upon him, and that His universal and unfailing law punishes crime and falsehood. The operation of a vow is different upon two different classes of minds. To the ignorant and superstitious it affords a motive (their fears) for adhering to a course of action that their fickleness or dishonesty might have tempted them to swerve from. In the more enlightened it awakens a stronger sense of the importance of the act they are about to undertake, renders them more cautious to pledge themselves beforehand, more resolute in performing a promise once made.

The instances in which, in a rude state of society, advantages are derived from vows or promissory oaths, are perhaps not few in number, but they are still exceptional. The bad influence of the superstitious view of the nature of a vow is permanent: it perverts men's moral opinions by leading them to regard actions as vicious and virtuous, not because of their own inherent character, but because of their being consistent or inconsistent with a promise made beforehand. Men have thus been led to see criminality in the non-performance of a crime they had pledged themselves to commit. The danger with regard to vows, understood in the more rational sense, consists in their too frequent use, or in their employment upon trivial occasions. The public promise of a king ascending the throne to govern with equity—the pledge of man and wife to know one undivided interest till death—the promise to give true and faithful evidence where the property, life, or honour of a fellow-being are at stake—are worthily and usefully accompanied by an appeal to the Divinity, that reminds the makers of these promises of the importance of the engagement they have taken upon them, and brings the religious sentiment to strengthen and confirm the dictates of expediency. But custom-house oaths, masonic vows, and such trivialities and mummeries, degrade the vow to the level of a mere theatrical show, or of the thoughtless habit of interjectional swearing in common discourse. The addition of a vow does not render a promise more binding, or alter the reason why it is binding. A promise affords a ground of belief that a man will act in a certain pre-determined manner, instead of being carried away by the whim of the moment. It is of advantage to the individual who makes promises that he should, except in extreme cases, contract the habit of adhering to them, because it imparts consistency and power to his character; and it is of advantage to all with whom he may have dealings that he should contract this habit, for it renders their transactions with him safe. Hence the universal feeling that, except in very extreme cases, promises ought to be kept, even to the maker's disadvantage. Vows are exactly on the same footing: the superadded appeal to the Divinity by its solemnity renders men more cautious in binding themselves, and more earnest and unwavering in the performance of their promise. The danger of making vows frequently and on trivial occasions has been inferred from the nature of the religious sentiment called into play: a further restriction of their admissibility may be deduced from the nature of the simple promise. It limits man's freedom of action, and so far is a disadvantage. It ought to be confined to actions: for a man to pledge himself to feel and think only in a certain manner is to undertake an impossibility. It pledges him to an unhealthy struggle against the order of nature. The promise ought moreover to be restricted to actions meritorious in themselves, and of some consequence. If to commit a crime is bad, to promise to commit one, and deliberately to keep the promise when aware of the criminality of the act, is worse. To tie a man's self up by a promise from the commission of an action indifferent in itself is a wilful waste of the power of self-denial, of which man at the best has no more than barely serves his necessities: the mind worn out with struggling against harmless propensities falls an easy prey to temptation in more important matters. The whole history of the monastic orders, a history attractive from the grandeur of its irregular and imaginative struggles, is an illustration of these views. With regard to simple promises, the rule of action is to make as few as possible, and exert every effort to keep them unless convinced that to do so would be a crime. With regard to vows, the same rule holds if possible with more force, because fickleness in regard to them implies a profane trifling with the most sublime emotions of our nature.

VOWEL. [ALPHABET.]

VOYAGE. [SHIPS; BOTTOMRY.]

VULCAN. [HEPHÆSTUS.]

VULCANISED INDIA RUBBER. [CAOUTCHOUC MANUFACTURE.]

VULGATE. The Vulgate (*Vulgata versio*), or common version, is the name sometimes given by St. Jerome to what he elsewhere calls the *Vetus*, or ancient version, and what St. Augustine calls the *Vetus Itala*, or Old Italian Version, being the most generally received of those early Latin translations of the Scriptures distinguished by biblical critics as the ante-Hieronymian, all which are now lost, with the exception of some parts of this *Vetus Itala*, and such fragments of the others as are quoted in the writings of the Fathers. Jerome's first labours as a translator of the Scriptures consisted in a revision and correction of this original Vulgate, which he completed about A.D. 390. Before this date, however, he had commenced an entirely new translation from the original Greek and Hebrew; and it is this to which the name of the Vulgate is now given. The earlier Vulgate, as revised by Jerome, has all perished, except only the Book of Psalms and the Book of Job, and the apocryphal Books of Maccabees, Baruch, Ecclesiasticus, and Wisdom. The use of Jerome's new version appears to have been gradually introduced; but ever since the 7th century, when it was sanctioned by Pope Gregory I., it has been exclusively adopted by the Romish Church. The Council of Trent, in the 16th century, even conferred upon it an authority superior to that of the original text, by ordaining that "the Vulgate alone should be esteemed authentic in the public reading of the Scriptures, in disputations, in preaching, and in expounding, and that no one should dare to reject it under any pretext whatever." Accordingly, all the Romish translations of the Bible into the modern languages profess to have been made not from the Greek and Hebrew, but from the Vulgate.

The true text of Jerome's version, however, has been at all times matter of doubt and controversy. It very early got mixed with that of the *Vetus Itala*; and the restoration of its purity employed the labours of Alcuin, by direction of Charlemagne, towards the close of the 8th century, of Lanfranc, archbishop of Canterbury, in the 11th, of Cardinal Nicholas and others in the 12th and 13th. After the invention of printing, the Latin Bible was the first considerable work that was sent to the press; but the earliest editions exhibited a very corrupt text. The first critical editions were those produced at Paris by Robert Stephens (Etienne), in 1528, 1532, 1534, 1540, 1545, and 1546. Of these the edition of 1540 is accounted the best. Other corrected editions are those of John Hentenius, a divine of Louvain, first printed at Louvain, in folio, in 1547, reprinted by the Plantins, at Antwerp, in 5 vols. 8vo, 1565 and 1574; and that of Lucas Brugensis, and other divines of Louvain, printed at Louvain, in 3 vols. 8vo, in 1573; and again, both in 8vo and 4to, in 1586.

The first revised edition of the Vulgate promulgated by authority in the Romish Church was issued at Rome from the press of the Vatican, in three volumes, folio, in 1590, under the title of 'Biblia Sacra Latina, Vulgatæ editionis, jussu Sixti V. recognita et edita.' This edition, the preparation of which had been begun under Pius IV., was declared by Pope Sixtus to be the authentic text, and is known as the Sixtine Vulgate, or the Bible of Sixtus V. Yet it had been no sooner published than it was discovered to be full of misprints and other errors, which were very insufficiently corrected by the necessary emendations, printed upon separate strips of paper, being here and there stuck over the original word where the passage had been most grossly disfigured. Gregory XIV., who succeeded Sixtus V., ordered it to be suppressed, and the true Sixtine Vulgate is now of excessive rarity. A new edition of it, in the same form, was brought out in 1592, under the authority of Gregory's successor, Clement VIII., and this is called the Clementine Vulgate, or more frequently by Roman Catholic writers the corrected Bible of Sixtus V. It is now the authorised edition in the Romish Church; the Vulgate as since printed being commonly entitled 'Biblia Sacra Latina, Vulgatæ editionis Sixti V. et Clementis VIII.' Protestant controversialists have, naturally enough, made the most of the variations to be found between the Sixtine and Clementine Vulgates, each published and declared to be the only true edition by an authority professing to be infallible.

VULPE'CULA ET ANSER (the Fox and the Goose), a constellation of Hevelius, situated immediately above Aquila and Sagitta. It does not contain any stars of conspicuous magnitude.

VULPINIC ACID. [LICHENS, COLOURING MATTERS OF.]

W

W is a letter which performs the double office of a consonant and a vowel, the natural order of the vowels being *i, e, a, o, u*. The sounds then of *i*, that is *ee*, and *u*, that is *oo*, are the most remote, and the attempt to pass with rapidity from either of these to the others, more particularly to the other extreme, gives an initial breathing which has the character of a consonant, namely, in the one case *ee-oo*, or *you*; in the other *oo-ee*, or *we*. Hence it is that the letters *y* and *w* appear as the representatives, sometimes of a consonant, sometimes of a vowel. The English character *w* is formed by the repetition of a *v*, which itself is only a variety of the symbol *u*, and that again has in all probability grown out of the letter *o*. [ALPHABET.]* The Anglo-Saxon alphabet employs the symbol ƿ. In Latin the *v* or *u consonans* had probably the power of a *w*, a supposition which at once accounts for the use of a common character for the vowel and consonant. The Greek and Hebrew alphabets had also a single symbol for this consonant, which occupied the sixth place, and is called digamma in the former, *vau* or *waf* in the latter. But in the Greek alphabet the letter went out of use, and is, therefore, commonly omitted in our grammars of that language, although the gap at this point in the alphabetical designation of numbers still bears evidence to the original position of the letter. [DIGAMMA.] Most of the modern languages of Europe are deficient in a symbol for this letter. The French employ what is a sufficient though a clumsy equivalent, the diphthong *ou* prefixed to a vowel, as in the common particle *oui*; the Spaniards prefer *hu*, as in *huevo, hueso*. In this way the map of the New World often gives testimony as to the race of Europeans who originally settled in the country. Thus the Indian tribe which has furnished a name to the territory belonging to the United States now called Wisconsin, in the old maps is written Ouisconsin, that country having been first visited by the French. So again in Mexico, the town Chihuahua (pronounced Chiwáwa) tells us that its name was first written by Spaniards; and the same may be said in the map of Peru of the river Huallaga; and the numerous towns commencing with the same syllable, as Huancavelica, Huancayo, Huanuco, Huancabamba, &c. At other times the Spaniards have employed the letters *gu*, as may be seen in the different rivers of Spain Proper, which have prefixed the Arabic word *guad*, denoting water; and this mode too of representing a *w* is to be traced in Spanish America in Guamanga, Guanca, Guancarama, Guatemala, &c. The ancient Greeks again often prefixed a simple *o* to represent a *w*, as in *oiδa*, &c. [DIGAMMA.] We have hitherto spoken of the consonantal power of the letter; its use as a vowel, so far as our own language is concerned, is confined to the end of syllables; and there is always another vowel prefixed to it, as in *new, law, show*; but in the Welsh language it is employed by itself, and in the middle of syllables with the power of a vowel. The map of Wales will furnish abundant examples, as Pwlheli, Cwmtydr, Bettws, Llwchwr, often written Loughor, &c.

Many nations have a difficulty in pronouncing the consonantal *w*. This is more particularly the case in some parts of Germany, where the people are unable to appreciate the difference between a *w* and a *v*, almost always substituting the latter sound, or what nearly approaches to it. Hence it is important for the philologist to distrust the evidence and criticism of a German scholar when these sounds are in question; and this caution may be more particularly given in reference to German writings upon the Sanskrit language. London too is remarkable for the confusion of the sounds, though this confusion does not seem to arise from any inability to pronounce either a *w* or a *v*, each being substituted for the other with a most amusing perversity.

The other interchanges of this letter have been already given under the preceding letters. See C, § 4 and 7; G, § 6; H, § 7; M, § 5; O, § 11; R, § 8; S, § 11; and DIGAMMA.

WAFER, a small round piece of dried paste, which is used to fasten letters. The host, as given to laymen at the sacrament in the Romish Church, and the piece of consecrated cake given in extreme unction, is also called a wafer, and it is recommended to be swallowed whole if possible. Thin cake formed into a roll, and called wafers, is still sold by pastrycooks. In fact the word was used in England to signify a thin cake long before wafers for sealing letters were invented.

Waffel is the name given by the Germans to a thin cake made with flour, eggs, sugar, &c.; the Dutch call such a cake *wafel*, and the Danes *vaffel*. The French call it *gaufre*. The French name for a wafer is *pain à cacheter*, and wafers are *pains à cacheter*. The Anglo-Saxons also had the name *waffel*.

To make common wafers, a liquid paste is made with flour and cold water, very smooth; and colouring matter is then mixed with it. The baking is done with an instrument similar to that which is used to make *gaufres* and *waffeln*. It consists of two thin plates of iron; the upper plate closes upon the lower, which is made with a ledge, and thus forms a mould for the paste. Both plates having been warmed and greased to prevent adhesion, some of the liquid paste is poured into the lower plate, and the upper plate is then shut down, which forces out any superfluous paste and forms the rest into a thin and even layer. The instrument which is held by a handle like that of a frying-pan, is placed for a few moments over a fire, and the sheet of baked paste is then taken out and dried in the air, when it becomes firm and brittle, and is cut with a suitable instrument into wafers.

Gelatine or *transparent wafers* are thus made. Good gelatine or glue is dissolved in warm water. The mixture, while still warm, is poured on a warm and slightly oiled glass plate, having a bordering formed of slips of cardboard; another warm plate is laid on it, and pressed. When cold, the gelatine is removed in a very thin, semi-transparent sheet, and is cut into small pieces of the proper shape by means of a punch. Sometimes a little sugar is added to the gelatine.

Medallion wafers have a device in cameo or relief. The device is first engraved in intaglio on a metal plate. A paste is then made of any convenient powder mixed with gum-water or size; a background is formed of melted coloured gelatine; and the two are so applied to the engraving as to lead to the production of a sheet of medallion wafers, which are separated by cutting or punching.

WAGER. In a wager or bet, two parties stake money against each other on the happening or failure of a certain event: A is to pay a certain sum to B if the event happen one way; and B is to pay a certain sum to A if the event happen the other way. Thus, if John bet Thomas three to one (in pounds) that he will win the game, and it turn out that he does win the game, he (John) is to receive one pound from Thomas; but if John should not win the game, Thomas is to receive three pounds from John.

The principle of a wager exists in a great multitude of transactions which do not bear the name: in fact, every commercial affair in which money is risked upon a possibility of receiving more than legal interest in consideration of that risk, is a wager. Thus, if John lend Thomas 100*l.* to engage in an adventure, knowing that he can receive nothing if it fail, and in consideration of 150*l.* if it succeed, it is a wager of the following kind. If the money be out a year, and John could safely make five per cent. of it, he risks 105*l.* in case of loss, and is to receive 45*l.* in that of gain; so that in fact it is as if John bet Thomas 105 to 45, that the speculation would succeed. For if we were to suppose that John lends Thomas 100*l.* for a year at five per cent., on good security, and makes the above wager besides, they will be found to be in exactly the position originally described.

A fire insurance is a simple wager between the office and the party; and a life assurance is a collection of wagers. There is something of the principle of a wager in every transaction in which the results of a future event are to bring gain or loss. And in every game of chance, we have a wager or a collection of wagers, whenever money is staked.

Much has been written and said upon the morality of wagers, in which the word is understood in its common acceptation, namely, that there is nothing but a stake of money, made in a manner which has no reference to commercial advantage, and no tendency to promote the physical well-being of the community. It is however exceedingly difficult to draw the line between the pure wager, which is nothing else, and the commercial wager. The loan of John to Thomas, above described, may be a useful transaction: it may give the country a new mine or a new market. But it does not follow that the pure wager, or a case which is generally so considered, may not be also useful. It were to be wished that, in considering this matter, the right and wrong of the transaction itself should be always carefully seperated from the tendency of the collateral circumstances connected with it. One or two instances will explain our meaning.

A horse-racer and a stock-jobber are two of the characters which are set down in public opinion as mere gamblers, and so are a billiard-player and a hazard-player. All four are considered to belong to the same class. Now it is true that the occupations of all but the second are generally connected with much that is objectionable, and which, though not necessarily attached to their mode of life, are so frequently consequent upon it, that the strength of the tendency is sufficient to justify the warning which writers upon morals give against the pursuit of gambling. And among all the four descriptions of characters are to be found the full proportion of those whose society is not coveted by a very respectable minority of the nation. But though many a man born to better things has been ruined by each of the four pursuits, it would be unjust to say that there is no distinction between them. We doubt whether billiards or hazard ever were the cause of any benefit to society; the wager which ends in a wager seems to be the proper description of both. But horse-racing has at least improved the breed of horses; and, as business is now transacted, it is due to the stock-jobber that funded property can be turned into money, or *vice versâ*, at any moment of the year. We do not mean to say that the money which changes hands on the course might not be much more effectively employed in the improvement of horses, or that it might not be practicable to effect modes of rapidly realising or investing without the concomitant of gambling. All we wish to illustrate is the fact, that innumerable classes of wagers are mixed up with the transactions of society, from those which are essential to its existence, through those which are of mixed harm and good, up to those which are but dubious in their very best cases.

A wager is fairly laid when the odds are proportional to the probabilities of the event happening or failing. Thus if it be four to one against the happening of an event, the better who bets that it will not happen should offer four to one. In the long run such an event will fail four times where it happens once, and the better will receive a pound four times for every occasion on which he pays four pounds once. But suppose a person should continually offer only three to one upon a contingency on which it is four to one he wins. In the long run he will, upon every five bets, receive one pound four times, and pay three pounds once: he will therefore win one pound on every five bets. Algebraically thus:—let the odds for his winning be a to b, while these which he offers are m to n; in $a+b$ trials, one set with another, he will win n pounds a times, or £na, while he will lose m pounds b times, or £mb. If na equals mb, the wager is fair on both sides; if na be greater than mb, it is unduly favourable to the better; if na be less than mb, it is unduly against him.

There are many cases in which doubt may arise as to whether a wager is fair, and also as to how it is to be interpreted. With respect to the latter it is or ought to be clear, that if both parties understood the wager in one sense, that one sense is the fair interpretation: but that if either of the parties understood the wager in one certain sense, and the other party knew that he understood it in that sense, no subsequent attempt at a different interpretation should be admitted on the part of that other party. We are told that this rule is widely departed from; and that under cover of adherence to literal signification of words, interpretations are permitted which offer inducements to what we must call attempts at fraud. Thus, it is said, that when the better undertook to run across a bridge in an incredibly small time, and had his bet accepted, he was permitted to win by running from one parapet to the other, which was held to be crossing the bridge, in the same manner as going from one footpath to the other is held to be crossing a street. Here it is clear that the party accepting the bet understood that the other was to cross the water upon the bridge, which is the true meaning of going across a bridge; and it is also clear that the better knew he was taken in that sense. An adherence to the literal meaning of a wager is, of course, necessary in all cases of doubtful meaning, but there is no language in which the literal meaning of a sentence is always made up of those of the words put together.

A wager is not fair unless the point in doubt be clearly the same to both parties, and unless there be no concealed knowledge in the possession of either. The latter is included in the former, as an instance will show. John bets Thomas that the ship Hope is arrived in dock from Jamaica before the time at which the bet is laid; his manner implies that he has formed the conclusion from his knowledge of the time at which the Hope was to sail, of the properties of the vessel, of the prevailing weather, &c.: if his manner tell truth, the wager is fair Or his manner implies that he may be in possession of particular information, that he may have seen the captain, &c.; it says, "Mind, I do not tell you what my reasons are, all I tell you is the fact:" still the wager is fair. If Thomas dispute, he knows in either case what he disputes, be it the question of the Hope's rate of sailing, or the goodness of John's inference from his particular knowledge. But if John, actually knowing of the Hope's arrival, should lead Thomas into a wager on the probabilities of the ship having arrived, when he knows that it actually has arrived, the wager is unfair. In all matters of skill, indeed, the mere offer of the wager is an assertion of skill, and the acceptance of the wager is the denial of this assertion: this is understood, so that there is no occasion for the party who offers the wager to make any declaration of skill, other than is implied in the wager itself.

There is one case, and that a common one, in which the immorality of the wager is not easy to expose, though it is, we think, sufficiently certain; it is where a person, by offering different wagers to different people, secures himself a certainty of gain, let the event happen which way it will. Thus one of three things must happen, A, B, C; a person bets 4 to 4 against A, 5 to 4 against B, 6 to 4 against C, with three different persons; he must win 8, for two of his opponents must lose: he cannot pay more than 6, for one only can win; he is therefore, on the most unfavourable supposition, a gainer of 2. As against each of his opponents the wager may be fair: these may not be known to each other, and each one may consider that he has the best of the wager. Whom then does he injure? If it be admitted that a man has a right to lay any bet which he can get taken provided the event betted on be perfectly understood, he can then injure no one, and no exception can be taken to the proceeding. But if it be not allowed that a man has a right to lay any odds, except those which, to the best of his knowledge and belief, represent the state of the chances, he must then offer a bet which he believes to be unfair, to some one or other of the preceding persons. By betting 4 to 4 against A, he declares his belief that the chance of A's arrival is $\frac{1}{2}$: similarly by betting 5 to 4 against B, he declares his belief that the chance of B's arrival is $\frac{4}{9}$. Consequently he implies a declaration that his belief of the chance of C's arrival is—

$$1-\frac{1}{2}-\frac{4}{9} \text{ or } \frac{1}{18}.$$

Consequently he ought to lay 17 to 1 against the arrival of C, whereas he lays 3 to 2, or 6 to 4. He is then telling contradictory stories to different people, and is saved from conviction only by the fact of each party not knowing what he has stated to others. If there were a possible mode of fighting in which the weapon of each opponent should be armour against those of the rest, we imagine it would not be considered either brave or honest that a man should provoke the combat with several enemies, in such a manner that he should be sure to kill, and sure not to be killed; and we suppose that if wagering be permitted at all among men of honour, it is under the idea that he who makes another risk his money also risks his own.

This possibility of securing certain gain by betting against belief (for against belief it must be) seems to us to be enough, were there no other reason, to show that a wager is not right, unless the odds really represent the opinion of the better: for to maintain that such a wager is a fair one, is also to maintain that it is fair to make others meet risk without sharing it.

It may indeed be asserted that each better has his own book, which he endeavours to make up in such a way as to win in every event; so that the whole is an admitted trial of skill. But this excuse breaks down when it is remembered that it is impossible a society of gamblers can make a set of books which will give a balance of gain to all, without *taking in* a number of persons who do not belong to the society: and the question is whether the words in italics have not two real meanings.

WAGER (in Law.) [GAMING.]

WAGER OF BATTLE. [APPEAL; TRIAL.]

WAGER OF LAW was a mode of trial where the defendant was permitted, as it was said, "to make his law," that was, "to take an oath (for example) that he oweth not the debt demanded of him upon a simple contract, nor any penny thereof;" "but he ought to bring with him eleven persons of his neighbours that will avow upon their oath that in their consciences he saith truth; so that he himself must be sworn *de fidelitate*, and the eleven *de credulitate*." This form of trial was not allowed save when the debt arose by word only, and might have been satisfied in secret without witnesses. It was not permitted as to any debt arising on specialty, or where a contempt, trespass, deceit, or injury was supposed in the defendant; but only in some cases, in debt, detinue, or account; and also in a real action where the tenant alleged that he was not legally summoned. Neither was it permitted to an infant, nor to a person outlawed or infamous, nor in a suit on behalf of or for the benefit of the crown, nor to executors or administrators in matters relating to the debts of their testator. Where admitted, however, it was conclusive, and barred the party for ever. This mode of trial seems to have existed at a very early period in the history of nations. It was part of the law of Moses, that "If a man deliver unto his neighbour an ass, or an ox, or a sheep, or any beast to keep, and it die, or be hurt, or driven away, no man seeing it; then shall an oath of the Lord be between them both, that he hath not put his hand unto his neighbour's goods, and the owner of it shall accept thereof, and he shall not make it good." (Exod., xx. 10.) The practice of trying by the oaths of the parties to a suit prevailed in the civil law, where either of the parties might refer the matter to the oath of his adversary; and if he did not accept it, or justify his refusal of it, the judge decided against him. The whole proceeding is prescribed at length in 'Cod. Justin.,' iv. 1, 12. The clergy, also, in the earlier ages were generally admitted to this mode of defence. It was also one of the customs of London in the sheriffs' court. But in this country it ultimately gave dissatisfaction. "Men's consciences," as Lord Coke says, "grew so large," that the presumption of law that no man would forswear himself ceased to be much relied on. Other forms of actions were brought, such as assumpsit and trover, in which the wager of law could not be had; and eventually, by 3 & 4 Wm. IV., c. 42, s. 83, the whole proceeding was abolished.

WAGER-POLICY is a name given to a policy of insurance made by persons having no interest in the event about which they insure. Such insurances, formerly common, were found to be "productive of many pernicious practices," and therefore the statute 19 Geo. II., c. 37, was passed, by which it was enacted that no assurances should be made on any ship belonging to his Majesty or any of his subjects, or on any goods, &c., laden on board, "interest or no interest, or without further proof of interest than the policy, or by way of gaming or wagering, or without benefit of salvage to the assurer; and that every such assurance shall be null and void to all intents and purposes."

WAGES are the price paid for labour. The labour of man, being an object of purchase and sale, has, like other commodities, a natural or cost price, and a market price. Its natural price is that which suffices to maintain the labourer and his family, and to perpetuate the race of labourers. The rate of wages cannot be permanently below this natural price, for if in any country labourers could not be maintained, they must cease to exist: they must be exterminated by famine, or be removed to some other country. If the price paid were only sufficient to maintain the labourer himself, without any family, he would be unable to marry, or his children would die of want. By these distressing causes the supply of labour would be reduced until the competition of employers had raised the price of labour to its natural level. But although the natural price would thus appear to be that which only wards off starvation, there is, happily for mankind, a principle which tends to raise it to a much higher standard. Every man desires to improve his condition, to enjoy more of the comforts and luxuries of life than have fallen to his lot, and to raise himself in the estimation of others. If he has accomplished this, he acquires habits of living which it is painful for him to forego. He endeavours to bring up his children with the same views and habits as his own, and feels it a degradation if they fall below the standard which he has himself attained. The necessary consequence of this tendency to social improvement is to cause prudence and forethought in marrying, and undertaking the support and settlement of a family. A labourer cannot well have too many wants. He should desire good food, good clothing, a cleanly and comfortable home, and education for his children. If the standard of wants could be universally raised, the natural price of labour would rise in proportion; for if each labourer were determined not to render himself unable to gratify these wants, all could command the wages that would supply them. The degree in which this principle operates determines the natural rate of wages and the condition of the working classes. Where it has no influence, as in many parts of Asia, the wages are only sufficient to support life upon the commonest food, and to provide the most squalid clothing and habitations. In more civilised countries, the wants and prudence of the middle classes extend lower in the scale of society, and the labourers want more and enjoy more of the comforts and decencies of life.

The general market-rate of wages depends upon the ratio which the capital applied to the employment of labour bears to the number of labourers. If that ratio be great, the competition of capitalists must raise wages; if small, the competition of labourers amongst each other, for employment, must reduce them. Whenever the accumulation of capital is proceeding more rapidly than the increase of population, wages will be on the increase, and the condition of the working classes will be continually improving, until some check has been given to the increase of capital, or until the growth of population (which is naturally encouraged by high wages) has altered the relative proportion of capital to labourers, and reduced the market-rate of wages to the natural rate. While the general rate of wages is regulated by these causes, there are various circumstances which, by increasing or decreasing competition for employment, tend to raise or depress the wages paid to persons engaged in particular occupations. Some of the principal of these are—

1. The agreeableness or disagreeableness of the employments.
2. The easiness or cheapness, or the difficulty and expense, of learning them.
3. Their constancy or inconstancy.
4. The small or great trust that must be reposed in those who carry them on.
5. The probability or improbability of succeeding in them.

It is not uncommon to hear these circumstances stated as the direct and immediate causes of high or low wages in particular employments; as if in some cases employers voluntarily gave high wages, or the labourer could command them merely on account of the nature of the employment. But the relation of supply to demand will influence wages in particular employments, as it does the price of labour generally, and of other commodities; and the circumstances stated above will obviously tend to increase or diminish the number of competitors for particular employments. More will naturally seek an agreeable trade, easily learned, than one of a disagreeable character and difficult to learn. All descriptions of skilled labour bear a higher price than unskilled labour. The expense of acquiring the knowledge of any art or trade would not be incurred at all, unless the person who had incurred it were better remunerated than others who have nothing to offer except their natural strength and intelligence, which is common to all men; but many cannot incur the expense of learning a trade if they would; others are too indolent, too careless, or too awkward; and thus skilled workmen are not open to the same unlimited competition as other classes of labourers, and are in a condition to command higher wages. Wherever uncommon skill, talent, or other advantages are required, the number of persons actually practising and living by an employment must be comparatively limited. Most persons are deterred from attempting to learn it by the fear of failure, and many who attempt it do not succeed in gaining their livelihood by it. The few who are really successful can then command an extraordinary reward for the exercise of their peculiar talents or acquirements. The world will enjoy the advantage of them at any price, not being satisfied with any less degree of excellence. Even if an unusual influx of skilled labourers into any employment should lower the rate of wages, this lower rate is not likely to continue very long, as the superfluous number would seek other employments which offered a higher reward. This result is facilitated by the fact, that the ordinarily high price of skilled labour causes a much more expensive mode of living, and thus raises the natural rate of wages of skilled labourers; or, in other words, induces them to regard as necessaries a variety of comforts which are beyond the reach of common workmen.

Wages are usually calculated in money, and are called high or low according to the money price actually paid; but the condition of the labourer is obviously affected by the price of commodities as well as by the amount of his wages. If the necessaries of life be cheap, low money wages will maintain him in comfort; if they become dearer, higher wages will not improve his condition, but will leave him as he was. Hence it becomes a most important object to inquire whether the price of provisions affects the rate of wages. The disputes which have arisen upon this question would seem to be chiefly caused by attempts to apply a universal law to countries and employments under totally different circumstances. Some contend that as wages are regulated by supply and demand, the price of provisions cannot affect them; while others maintain that the average prices of labour and of food must always, for long periods of years, conform one with the other. It is evident, at the outset, that the former are speaking of the market rate of wages, and the latter of the natural rate; and if this distinction be borne in mind, the two propositions may easily be reconciled. If the market rate of wages be high, it is because the demand for labour is greater than the immediate supply. A fall in the price of provisions could not then lower the rate of wages, because the supply of labour would still be the same; but if the fall were permanent, the condition of the labourer would become so easy, that population would increase, and the supply of labour would be more abundant. The market rate would thus be brought down to the natural rate, unless capital should be increasing in the same proportion as the supply of labour; and any increase in the price of food must then check the growth of population, limit the supply of labour, and ultimately raise wages. There is the same tendency in the market price of labour to conform to the natural price as there is in the market price of commodities to conform to their real value. Both labour and commodities are equally capable of increase and diminution, and the varying causes which encourage or check production adjust the proportion between the natural or cost price and the market price. But in some countries the market rate of wages may be very much above the natural rate, and in others nearly the same. In one country capital may be increasing more rapidly than population, and in another not so fast. It is clear that a rise or fall in the price of food cannot influence the rate of wages alike in all these countries. Where the wages are high, and capital is rapidly accumulated, any reduction in the price of food and other commodities is a clear gain to the labourer, and can have only a very remote, if any, effect in lowering wages; but where wages are already reduced to the natural rate, and capital is not increasing faster than population, wages will undoubtedly rise and fall with any permanent increase or diminution in the cost of subsistence.

The question is further affected by the differences which exist in the natural rate of wages in various countries. Where the natural rate is so low as only to afford the bare means of existence, the least rise in the price of food must be fatal to numbers of the labouring population, and, by thus limiting the supply of labour, must raise its price; but where the natural rate is high, the labourers suffer indeed from a rise in the price of food, but their existence is not endangered, the supply of labour is not diminished, and their wages consequently do not rise. From these circumstances, it is evident that the precise condition of a country in respect to capital, population, and wages must be ascertained before it can be determined whether the price of food will affect the money rate of wages. It may, however, be generally affirmed, that in proportion as the market rate approaches to the natural rate, and the latter to the mere cost of the commonest subsistence, will the price of the necessaries of life affect the rate of wages.

When the causes which regulate the price of labour are understood, the folly and injustice of any legislation to fix the rate of wages are obvious. The seller of an article will always endeavour to obtain a high price for it, which the purchaser will only give if he be unable to obtain it for less. Labour is the most important object that man has to buy or to sell. Each will make the best bargain he can, and in this no law ought to restrain him. Laws may purpose to affect wages either directly or indirectly. Direct interference with the rate of wages has been frequently resorted to. By several acts of parliament a legal rate of wages in particular employments was ordered to be settled, from which any deviations either on the part of the employer or labourer were punishable. (See 25 Edw. III., stat. 1; 34 Edw. III., c. 11; 13 Rich. II., c. 8; 11 Hen. VII., c. 22; 5 Eliz., c. 4; 1 James I., c. 6.) Unless all the causes of high or low wages already explained be visionary, it is plain that no law can overrule them and establish a legal rate different from that which natural causes would have produced. It may embarrass the operations of trade, and mischievously disturb the freedom of the labour market; but it cannot attain its immediate end—a compulsory rate of wages. The experience of this fact has long since put an end to any such legislation in this country. The most pernicious interference with wages ever effected by the indirect operation of a law resulted from the mode of administering the laws for the relief of the poor. Before these laws were altered in 1834, it was the practice in most parishes, especially in the south of England, to give relief from the poor-rate to labourers in proportion to the number of their children. The natural rate of wages was continually undergoing depression, because, marriages being encouraged without reference to the sufficiency of wages to support a family, population was extraordinarily promoted. At the same time, the property destined to support it was suffering diminution, by being taxed heavily for the payment of comparatively unproductive labour.

The only sound mode of raising wages and improving the condition of a people is to promote and encourage the increase of the general wealth of a country [WEALTH], by every means which legislative science points out as best suited to that end, and at the same time to remove obstructions, and give facilities to the moral and intellectual improvement of the working classes. By these means capital will be increasing with the natural growth of population; while the labourers, with better habits, will be less prone to reckless improvidence, and consequently not so likely to outrun the increase of capital.

It is not unusual for persons in particular employments to desire higher wages, and to enter into combinations against their masters in order to obtain them. Such combinations were formerly prohibited both by the common and statute law of this country; but since the 5th Geo. IV., c. 95, if unattended with violence or intimidation, they are not unlawful. Unless he has bound himself by a contract, every man has a right to give or withhold his own labour as he pleases; but he has no right to prevent others from disposing of their labour. But the only mode of rendering a combination effectual is to exclude fresh workmen, which frequently can only be done by molestation and threats, which are subversive of the freedom and peace of society. Strikes, temperately conducted, cannot in principle be condemned, being often a necessary protection to the working classes. When masters are not dealing fairly with their workmen, the fear of a strike may often control them, especially as, when acting unjustly, they would find a difficulty in obtaining new hands. But where the cause of a strike or combination is not an occasional dispute concerning wages, but an attempt to limit the number of workmen by compulsory regulations and bye-laws, and to dictate to their employers, it is injurious to trade, and ultimately to the parties themselves. To the labouring classes at large such combinations cannot be beneficial. Whenever they are successful it is by excluding many competitors, who are, of course, injured by the exclusion. The labour market must become clogged by a mass of exclusive trades, which render it difficult to find employment. The injury suffered by trade in consequence of the artificial limits to the supply of labour and the unnaturally high wages must also have the effect of diminishing capital, and consequently the means of employing labour.

WAHHABIS or WAHABEES, is the name of the adherents of a Mohammedan sect in Arabia. The origin of this sect is intimately connected with the following circumstances. When Sultan Selim I. had conquered Egypt and deposed the last khalif of Cairo, Al-mutawakkel in A.H. 922 (A.D. 1517), he was acknowledged as successor of the khalifs by Berekiat, the grand sherif of Mecca, who presented him with the keys of the Ka'bah. From this time the sultans of the Osmanlis were the protectors of the Mohammedan faith, though only recognised as such by the Sunnites; they were the guardians of the holy cities, Mecca and Medina; and they had the privilege and the duty of protecting the numerous caravans of hájis, or pilgrims, which annually travel to Mecca. A Turkish pasha resided at Jidda, and sometimes also at Mocha, and while the fertile provinces of Hejaz and Yemen in Western Arabia seemed to obey the Sultan, the pashas of Baghdád and Basrah made frequent attempts to establish the Turkish authority in the province of El-Hassa in Eastern Arabia. The Mohammedan religion had generally departed from its primitive purity, and was particularly corrupted among the Turks. The Mohammedans had introduced novelties into their religion, which were rather calculated to please the senses, and which found favour among people who have always loved to follow the bent of their imaginations. Mohammed gradually received honours like God himself; virtuous men became saints, and the miracles they were said to have performed were eagerly believed by the people; many austere rules of the Korán were forgotten or left to the extravagances "of a few derwishes and fakirs;" and the places of worship were adorned by the princes and the rich with the arts and luxuries of the East, while the poorer Mohammedans indulged their passion for religious buildings by erecting a rude tomb to some unknown saint, surmounted by a cupola of painted brickwork. To this we must add that the Korán ceased to be the sole source of religious knowledge, and that traditions concerning Mohammed were considered by his disciples as pure and trustworthy as the Korán itself. Although the Arabs had deviated from the rule of the Korán, there was a striking difference between them and the Turks. The Turks used opium and wine; not satisfied with polygamy, they had intercourse with prostitutes; they were addicted to practices against nature, which are strictly prohibited by the Korán, and more than once holy hájís of the Turkish caravans had polluted the sacred cities with their scandalous conduct. The caravans especially, those congregations of pious men assembled for the purpose of performing one of the most sacred duties of their faith, presented a revolting aspect to the simple and uncorrupted believers among the Beduins of the desert. Their leaders gave full licence to debauchery, and although it was generally their riches which tempted the Beduins, and excited them to predatory attacks, it often happened that the Son of the Desert unsheathed his sword indignant at the pride and vices of men who, from the moment they reached Mecca, proudly assumed the holy title of *hájí*.

Such was the state of the Islám, when, in the beginning of the last century, a Mohammedan sheikh conceived the project of reforming the religion of Mohammed, and restoring it to its primitive purity.

This sheikh was 'Abdu-l-Wahháb ("the servant of Him who gives (us) every thing"), who was born at El-Hauta, a village five or six days' journey south of Der'aiyeh, the capital of the province of Nejd, on the road from this town to the district called Wádi Dowásir, or as some say at 'Al-Aynah, in Nejd, or Aiyineh, which seems to be El-Ayeyneh, near Der'aiyeh. 'Abdu-l-Wahháb was born at the beginning of the 12th century of the Hijira, which corresponds to the end of the 17th century of our æra. His father was the sheikh, or chief, of the Beni Wahháb, a branch of the great tribe of Temim, which occupies a considerable part of Nejd. 'Abdu-l-Wahháb received his education in the schools of Basrah, where he studied divinity. He made the usual pilgrimages to Mecca and Medina, and lived several years at Damascus, where he had frequent disputations with the divines on religion, but displaying great zeal in the abolition of abuses, his doctrine was considered as schismatic, and being exposed to persecutions, he fled to Mosul. After some time he returned to Arabia, but the doctrines which he preached to the natives, and his violent attacks on Turkish tyranny and vice, became so many causes for new persecutions, and he led a wandering life till he settled at Der'aiyeh, the residence of the sheikh Mohammed Ibn Sa'úd. This intelligent chief listened to the words of the reformer. He became his disciple; he married his daughter; and soon drew his sword to propagate the new doctrine among the tribes of Arabia. Mohammed Ibn Sa'úd thus laid the foundations of a powerful empire on theocratical principles, of which his descendants remained masters for nearly a century.

When Sa'úd, the grandson of Mohammed Ibn Sa'úd, conquered Mecca, he ordered a kind of confession of faith to be published, the substance of which is as follows:—

'Abdu-l-Wahháb's doctrine teaches the salvation of mankind. It is divided into three parts: I., the knowledge of God; II., the knowledge of religion; III., the knowledge of the prophet. In the first part, God, it is said, is one Almighty, and we acquire the knowledge of him by adoring him. The second part, knowledge of religion, is threefold, and contains—1. The Islám, or resignation to the will of God; 2. Faith; 3. Good works. The Islám contains five things: 1. The belief that there is only one God, and that Mohammed is his prophet; 2. The five daily prayers; 3. Alms, one-fifth of the annual income; 4. Fasts during the month of Ramazan; 5. The pilgrimage to Mecca. The Faith contains six things, namely: 1. The belief in God; 2. In his angels; 3. In his Holy Scriptures; 4. In his prophets; 5. In his divine and perfect qualities; 6. In the day of judgment. Good Works are only the consequence of the rule that we should adore God as if he were present to our eyes; and though we cannot see him, we must know that he sees us. The knowledge of the prophet, which is the most important part of Wahhábism, is based on very positive principles. Mohammed, the prophet, was a mortal like all other men, and he preached for all the nations of the world, and not for one only, the Arabs; no religion is perfect and true in all its parts except his, and after him no other prophet will come; Moses and Jesus were virtuous men, though inferior to Mohammed, notwithstanding he was not of divine nature. Those who do not fulfil their religious duties are to be severely punished. The reformed religion shall be propagated with the sword, and all those who refuse to adopt it are to be exterminated. 'Abdu-l-Wahháb not only forbade the adoration of Mohammed and of saints, but he also ordered their splendid tombs to be destroyed, and he declared tradition to be an impure source. He made several other prohibitions concerning social and religious abuses, such as the habit of using wine, opium, and tobacco, the use of the rosary for prayers and he preached strongly against those unnatural practices which were and are still so frequent among the Turks.

The doctrine of 'Abdu-l-Wahháb was no new religion: it was Mohammedanism reduced to a pure deism, and so little did it deviate from the Korán, that even to the present day many theologians of Syria and Egypt do not venture to say that it is schismatic. Yet this reformer maintained that there had never been any man directly inspired by God, and that there was no scripture or book whatsoever which was entitled to be called divine. Hence it follows that according to 'Abdu-l-Wahháb there is no revealed religion; and if he calls the Mohammedan a divine religion, it is not because he believed that it had been transmitted directly from God to man, but merely on the ground of its perfection.

The reformed Mohammedanism made rapid progress, especially among the nomadic Arabs, or Beduins, who had never adored Mohammed as a divine person, nor viewed the Korán as a divine book, although they considered themselves to be as orthodox Mohammedans as any of the other nations which have adopted the Islám.

The inhabitants of the towns were less inclined to adopt Wahhábism, but Mohammed Ibn Sa'úd nevertheless succeeded in conquering the greater part of Nejd, of which he was the temporal chief, while 'Abdu-l-Wahháb was the spiritual chief. The system of government established by these two men was strictly conformable to the political prescriptions of the Korán, and very like that of the first khalifs. The chief authority lay in the hands of the temporal chief, but this authority was confined to the direction of important affairs; the governors of the provinces and the under-governors were kept in strict obedience to the orders of the prince, but their authority over the Arabs was not very great. The ulema of the capital, Der'aiyeh, who generally belonged to the clan or family of Sa'úd, formed a council or ministry for religious and legislative affairs, and in time of war the governors used to assemble in Der'aiyeh for the purpose of concerting the plan of the campaign. Trade and agriculture were well protected. The revenues of the Wahhábi empire were composed of:—1. One-fifth of the booty taken from heretics; the four remaining fifths were for the soldiers. 2. The tribute, called "alms" in the Korán: it was a certain part of the property, which varied according to the nature of the property: for fields watered by rain or rivers it was one-tenth of the yearly produce; for fields watered artificially, one-twentieth only; merchants paid one and a half per cent of their capital. The Beduins, who had always been tax-free, disliked these "alms" very much, but they were indemnified by the frequent occasions of plunder. 3. Revenue from the chief's or prince's own estates, and from the plunder of rebellious towns. The punishment for a first rebellion was a general plunder, one-fifth of which belonged to the fiscus; in case of a second rebellion, all the grounds belonging to the town were confiscated, and became the property of the reigning chief; and as such rebellions were very frequent, the chief acquired immense estates. The greater part of them were afterwards confiscated by Mehemet 'Ali, the pasha of Egypt. Except a few hundred men who formed the prince's life-guard at Der'aiyeh, the Wahhábis had no standing army, but assembled when the prince designed some expedition. Two or three great expeditions were made every year.

The name of the Wahhábis soon became known in the Turkish provinces adjacent to Arabia. The Turkish government was not aware that this sect had as much warlike and religious energy as the Arabs under the first khalifs, and employed little activity in their efforts to coerce them. The Wahhábis were successful in their resistance. They gained several battles, and even possessed themselves of Mecca. At length their subjugation was entrusted to Mehemet 'Ali. [Mehemet 'Ali, in Biog. Div.] He commenced his preparations in 1809, but active hostilities only began in 1811, and continued for several years. By 1818, however, their power was completely broken, and 'Abdullah, the successor of Sa'úd, was captured, sent to Constantinople, and there beheaded. The sect, however, though subdued, was not exterminated. They have more than once risen again in arms, but have been repressed; but still their tenets are understood to have numerous adherents throughout Arabia.

(Burckhardt, *Notes on the Bedouins and Wáhabys*; Mengin, *Histoire sommaire de l'Egypte sous le Gouvernement de Mohammed Aly*; Corancez, *Histoire des Wahabis*.)

WAHLENBERGIA, a genus of plants belonging to the natural order *Campanulaceæ*, of which the botanical characters are given in the Nat. Hist. Div. To this genus belongs the Wall Pellitory of Great Britain; and some of the numerous foreign species are cultivated on account of their blue and red flowers. For this purpose the seeds of those which are annual should be sown on the hot-bed, and when the plants are of sufficient size they may be placed out in the open border in a warm sheltered situation in the month of May. The hardy perennial species may be grown in pots in a mixture of peat and loam, and should be kept rather moist. They are easily increased by division.

WAIF. If the goods of any person were stolen, and the felon, thinking that pursuit was made after him, fled, and during his flight waived or abandoned the goods, they became waif, and were forfeited to the crown, or to the lord of the manor, if he were entitled to waif. No goods could become waif which were not in possession of the felon at the time of his flight. Therefore, if he concealed the goods, or placed them in a house, or, for instance, left a horse at an inn in pledge for his meat, and afterwards fled, the goods did not become waif.

It was necessary, in order to complete the title of the crown or lord of the manor to waif, that it should be taken possession of by some one on his behalf; otherwise the original owner was not barred from recovering his goods at any period of time, and if he seized them first, they remained his property. The forfeiture of goods waived was instituted for the purpose of stimulating the person robbed to make fresh pursuit after the felon, and so, if possible, catch him with the goods upon him. And in further encouragement of such pursuit, it was part of the law, that if the owner succeeded, within a year and a day, in attainting the thief, he was entitled again to recover his goods from the crown or the lord of the manor, even though they had been reduced into possession. The restriction of the character of waif to goods waived during the flight was because goods which had been concealed by the felon would afford no track of his course, and might very possibly escape the search of the owner, even though he did make fresh pursuit. It is said also that the goods of foreign merchants could not become the subject of waif, because a foreigner, ignorant of our language and usages, could not be expected to act with the same despatch and effect as a native. Lord Coke distinguishes between waif which was stolen property, and the goods which were the property of a person who fled for a felony. These latter were always forfeited on proof and finding by a jury of that fact, even though the party were acquitted of the felony. Part of the inquiry, therefore, on the trial of a prisoner for felony, was whether or not he fled for it. If the jury found that he did, his goods were forfeited, whatever might be the verdict as to his guilt. This was either because of the presumption which his flight raised, that he really had committed the offence, though it could not be legally proved against him; or, according to Mr. Justice Foster, because his flight tended to stop or embarrass the course of justice against the real offender. If he was killed during his flight, the coroner's jury inquired as to his flight as well as respecting the cause of his death. By 7 & 8 Geo. IV., c. 29, s. 57, the court before whom a prisoner is convicted has power in all cases, without restriction as to time, to order restitution of stolen property to the owner, except as to negotiable instruments in the hands of parties who, without notice, have given value for them: and by 7 & 8 Geo. IV., c. 28, s. 5, the jury are no longer to be charged to inquire whether a prisoner fled for treason or felony. The consequence is that no forfeiture can now be incurred by such flight.

WAIN, CHARLES'S. [URSA MAJOR.]

WAITS is a name now applied only to those itinerant musicians who, in most of the large towns of England, especially London, go round the principal streets at night for some time before Christmas, play two or three tunes, call the hour, then remove to a suitable distance, where they go through the same ceremony, and so on till four or five o'clock in the morning.

The word, which was formerly spelled *wayghte* or *waighte*, is common to all the Teutonic languages (German, *wacht;* Dutch, *wagt;* Danish, *vaght;* Swedish, *wakt;*) and the root is the same as the Anglo-Saxon *weccan*, to wake, and *wacian* (pronounced wakian), to watch, and the English *wake* and *watch*.

The wayghte, or wayte, was originally a minstrel watchman, and the kings of England, as well as the mayors of large corporate cities and towns, seem to have employed them in preference to common watchmen. By a document in Rymer's 'Fœdera,' vol. ix., "De Minstriellis propter Solatium Regis providendis," it appears that in the reign of Edward IV., "a wayte that nightelye from Mychelmas to Shreve Thorsday pipethe the watche within this courte fower tymes, in the somere nyghtes three times, and make the bon gayte at every chambere doare, and office, as well as for feare of pyckeres and pillers; he eateth in the halle with the mynstrielles;" it then goes on to state his allowance of bread, ale, coals, and so forth, for each night.

The waits seem to have been always distinct from the common watch, which was called the marching watch, and never, we believe, the waits. At a later period, the term waits seems to have been restricted to the band of minstrels kept by the city of London and other large cities and towns. We read of the City waits frequently, from their attendance on the City pageants, and of the waits of Southwark and other places. In 'The Tatler,' No. 222, a writer from Nottingham complains that the young men of fashion there "make love with the town music," and that "the waits often help him through his courtship." The waits, or stipendiary town-musicians, have for many years, we believe, ceased to exist in every corporate city and town in England, though there are yet town-bands, who, at least in some cases, are stipendiary musicians.

(Brand's *Popular Antiquities*, by Ellis; Strutt's *Sports and Pastimes*, by Hone.)

WAIWODE. [WAYWODE.]

WAKES, holiday festivals which are kept once a year in some of the rural districts of England. They are the remains of certain religious wakes, wakings, or vigils, followed by a festival, which were once held in all the country parishes. Previous to the Reformation in England, every church, when it was consecrated, was dedicated to some particular saint or martyr, and every rural parish had its wake every year, and most of them had two wakes, one on the day of dedication, the *dies dedicationis*, and another on the birth-day of the saint, the *propria festivitas sancti.* These church festivals seem to have been established by the early popes and bishops soon after the introduction of Christianity into England, in the place of the heathen festivals to which the people had been accustomed.

In the Saxon times the church method of reckoning the day was from sunset to sunset, so that the Sunday and festival and fast days began about six o'clock on the evening preceding the day itself, and the eve was in fact the commencement of the sacred day, when the people were accustomed to repair to the church and to join in the religious exercises. These night devotions were called in Anglo-Saxon *wæccah*, wakes, and the night itself was called the eve (the Anglo-Saxon *æfyn*, or *æven*), which explains why Christmas-eve and other eves of sacred days precede the day itself. On these occasions the floor of the church was strewed with rushes and sweet-smelling herbs [RUSH-BEARING], the altar and pulpit were adorned with green boughs and flowers, and tents were erected in the churchyard, which were supplied with provisions and ale. The eve was dedicated to devotion; the following day to festivity. These festivals gradually deviated in most parishes from the original purposes for which they were instituted. The inhabitants of neighbouring parishes attended each other's festivals, and others came from a distance, especially if the saint was of high reputation; hawkers and pedlars frequented them with their wares, and the religious wakes were converted into fairs and scenes of dissolute indulgence. The wakes continued to be kept in this way till 1536, when Henry VIII., by an act of convocation, ordered the festival of the saint's day to be abolished, and that of the dedication of the church to be kept on the first Sunday in October in all the parishes. But the saint's day was the favourite festival of the people; they gradually ceased to attend the festival of the dedication, and it has long been entirely discontinued, while the saint's day festival still subsists in the altered form of a country wake.

(Strutt's *Sports and Pastimes*, by Hone; Brand's *Popular Antiquities*, by Ellis.)

WALES, PRINCE OF, is the title usually borne by the eldest son, or heir apparent, of the British king or queen. This title originally distinguished the native princes of Wales; but after the entire conquest of Wales and its union with England, the title was transferred to the sons of the kings of England. Henry III., in the 39th year of his reign, gave to his son Edward (afterwards Edward I.) the principality of Wales and earldom of Chester, but rather as an office of trust and government than as a special title for the heir apparent to his crown. There is a tradition that Edward, when he became king, to satisfy the national feelings of the Welsh people, promised to give them a prince without blemish on his honour, a Welshman by birth, and one who could not speak a word of English. In order to fulfil his promise literally, he had sent his queen, Eleanor, to be confined at Carnarvon Castle, and he invested with the principality her son, Edward of Carnarvon, then an infant, and caused the barons and great men to do him homage. Edward was not at that time the king's eldest son, but on the death of his brother Alphonso he became heir apparent, and from that time the title of Prince of Wales has ever been borne by the eldest son of the king. The title, however, is not inherited, but is conferred by special creation and investiture; and has not always been given immediately after the birth of the heir apparent. Edward II. did not create his son Prince of Wales till he was ten years old, and Edward the Black Prince was not created until he was about thirteen.

The eldest son of the king is by inheritance Duke of Cornwall. Edward the Black Prince was first created duke of Cornwall on the death of John of Eltham, his uncle, who was the last earl of Cornwall; and by the grant under which the title was then conferred, in the 11th Edward III., the dukedom is inherited by the eldest living son and heir apparent. If the duke succeed to the crown, the duchy vests in his eldest son and heir apparent; but if there be no eldest son the dukedom remains with the king, the heir presumptive being in no case entitled to it. The Black Prince was also created by his father earl of Chester and Flint. By the statute 21 Richard II., c. 9, the earldom of Chester was erected into a principality, and it was at the same time enacted that it should be given only to the king's eldest son. Although that statute, with all the others in that parliament, was repealed by the 1st Henry IV., c. 3, the earldom has ever since been given together with the principality of Wales.

The antiquity of the title of Prince of Wales and its regular succession are, as it were, a confirmation of the parent's present right and of the prince's own nearness in succession to the crown. Thus on the death of Edward the Black Prince, Edward III. immediately made his grandson Prince of Wales. Richard III., as soon as he came to the throne, created his son Prince of Wales, in order to strengthen his usurpation. Henry VII., again, on the death of his son Arthur, created his next son, Henry, Prince of Wales. Henry VIII., having no son, created his daughter Mary, Princess of Wales; and after her illegitimation, his next daughter, Elizabeth. Each of them in succession had only been heiress presumptive, yet they bore the title, being then next in succession to the crown.

The titles now borne by the eldest son of the sovereign as heir of the crowns of England and Scotland, are "Prince of Wales and Earl of Chester, Duke of Cornwall and Rothsay, Earl of Carrick, Baron of Renfrew, Lord of the Isles, Great Steward of Scotland."

(Selden's *Titles of Honour*, part ii. c. 5; Connack's *Account of the Princes of Wales*, 8vo. 1751.)

WALKING-WHEEL. A mechanical contrivance by means of which the dead weight of men, or animals, acting upon one side of a wheel by walking upwards, is made to act as the motive power of the machine to which it is applied. It is frequently used in quarrying operations, or in agricultural districts, where labour is cheap; but in large towns it is rarely the case that the wheel-cranes can be advantageously employed, because in those localities artificial sources of power, or the more complicated adaptations of machinery, are found to be more economical than the employment of the dead weight of human beings. The walking-wheels were, however, much used in engineering and architecture in the last century, and they are retained at the present day in the quarries around Paris; but the tendency of modern practice is unquestionably to lead to their abandonment in favour of more perfect mechanical contrivances.

The walking-wheel used by Peyronnet at the bridge of Orleans is a good illustration of this class of engines. It consisted of an upright post, or pivot, supported by a strong framework of timber, bearing, upon a metal pivot at its head, an inclined beam, projecting on one side to form the arm of the pulley, and on the other to support the windlass and the walking-wheel. The weights upon either side of the pivot were arranged in such wise that they balanced one another as nearly as possible when the machine was in work; and the motion was given by the movement of the men walking in the interior of the wheel. The power exercised, therefore, in these engines depends upon the ratio of the radius of the men's path to the radius of the axle, and upon the weight of the men employed; and as in quarrying operations it is possible to increase the diameter of the walking-wheels to almost any dimension which may be desired, they are usually made of great size. Peyronnet made his wheels about 12 feet 9 inches in diameter; near Paris they are sometimes made of from 16 feet to 18 feet in diameter. Generally speaking the men walk on the inside of the wheel; but occasionally they tread upon, and hold by, rounds placed upon the periphery of the wheel; in either case it is essential to provide means by which the motion should be regulated and the men may be prevented from making false steps. If the load at the extremity of the arm should at any time, for instance, exceed the weight of the counterbalancing machinery, there would be a danger of its overpowering the men and of causing the wheel to run backwards; the consequences of such an accident would be, in all probability, fatal to the men employed; and it is therefore essential to bear in mind that the useful range of the use of walking-cranes must be limited to the narrow bounds of the weights on the respective sides of the machinery. Walking-wheels are seldom used, even in rude districts, when the weight to be raised exceeds four tons.

Animal power is occasionally applied to walking-wheels by making horses, donkeys, and even dogs, move in them; but all these animals exercise so much greater power when pulling against a collar in a horizontal direction, that they are more commonly and more advantageously employed in horizontal mills than in the vertical walking-wheels. The old-fashioned turnspit wheels formerly in use in mediæval kitchens afford familiar illustrations of this class of machinery.

The tread-wheels used for the punishment of offenders are, in fact, walking-wheels; but in them the wheels are designedly so balanced that the mere weight of the prisoners placed upon the boards causes the wheels to revolve, and thus to bring in succession the various boards under the feet of the men, who are compelled to tread upon each of these boards, unless they prefer receiving very heavy and painful blows. No use is made of the power thus exerted, and it seems to be one of the most painful considerations connected with this mode of punishment, that the men feel and know that they are working in vain.

(Peyronnet, *Nouvel Architecture Hydraulique*; Borgnis, *Traité complet de Mécanique*.)

WALNUT, ECONOMICAL USES OF. The walnut tree, though not so valuable as many other trees growing in this country, subserves a great number of useful purposes. The majority of timber trees do not yield fruit palatable to man; the majority of fruit trees do not yield timber of any considerable size; but the walnut yields both.

Walnut-wood is white in young trees; but in the older varieties, the wood is solid, compact, veined, and of a brownish colour, slightly shaded with lighter brown and black. It was the wood most highly valued for the best kinds of furniture before the introduction of mahogany; and many old mansions contain fine specimens of the work thus produced, exhibiting great beauty of grain, polish, and pattern. Walnut-wood is found very useful for press screws, wooden shoes, clogs, musical instruments, gun-stocks, turnery ware, coach-making, wheel-making. It is preferred to all other kinds of wood for the stocks of muskets and rifles: in 1806 no less than 12,000 walnut trees were required for musket-stocks for the British army; this led to a great rise in price, which in its turn led to a great increase in the planting of walnut trees in England.

Of the use of the fruit of the walnut as food, little need be said here. In some countries the nuts are regarded as a food, in others as a luxury. In a young and green state the whole fruit is pickled, the pulpy husk as well as the undeveloped nut or kernel. Besides the pickling, the French adopt a mode of preserving the green fruit; they also make a prepared dish from the very young kernels, and a *conserve brûlée* of kernels in a dried state. Large quantities of walnut oil are obtained from the fruit. The fruit is gathered, the husk removed, and the kernels are kept dry throughout the winter. The mucilage has by that time been converted into oil. The nuts are cracked with a small mallet; the fragments of hard shell are carefully removed, and the soft kernels are crushed under a millstone into a kind of oily paste. This paste is put into strong linen bags and pressed; the best walnut oil is obtained from it. The residue is taken from the bags, moistened with warm water, heated in a copper, replaced in the bags and pressed a second time; oil of an inferior quality is thus obtained. Walnut oil, largely made in France and Italy, is used as a substitute for olive oil at the table, for almond oil in medicine, and for whale oil in lamps. Artists employ it in the preparation of white and delicate colours, on account of its limpidity and quick drying. It is used in France as an ingredient in copper-plate printing ink; and some authorities state that the backs of prints for which this kind of ink has been employed do not turn yellow so quickly as under the influence of the ordinary English ink. The *marc*, or oil-cake, remaining from the oil-pressure, is used in some country districts as a material for candles, and in more as a fattening diet for sheep, swine, and poultry. The husks of the unripe fruit readily yield a dark dye—a fact rendered evident by the state of the hands of walnut-peelers. Sometimes the flooring of rooms is dyed to a dark colour, by boiling walnut husks to a paste, strewing this paste in a layer on the floor, and allowing it so to remain till dry.

The walnut tree in spring will yield, by incision of the trunk, a sap, which in some parts of Asia is evaporated into a cheap substitute for sugar; and a kind of wine may also be distilled from it. A liquor, obtained by boiling the roots of the tree before the rising of the sap, is used as a brown dye for the face by gypsies and theatrical performers. The leaves, and the bark of the young shoots, may in like manner be made to yield a brown dye.

Considered in reference to fuel, walnut-wood ranks almost on a level with sycamore; it burns with a violet flame. It does not take a high rank as a material for charcoal. Potash may be obtained by burning the leaves. Nearly all parts of the tree—the fruit, the bark, the root, the wood, the sap—have been brought into requisition for medicinal purposes.

WALTZ (from *Walzen*, Germ. *to roll*), a gay dance, in triple time, and executed by two persons, who almost embracing, rapidly turn round on an axis of their own, while moving quickly in a circle whose radius is from ten to twelve feet, according to the dimensions of the room.

WAPENTAKE (from the Saxon *waepen*, arms, and *tac*, touch, or *betach*, yield) is a term which prevails in Yorkshire, and indicates a territorial division like the hundred of other counties. [SHIRE.] The word is derived from the habit which our Saxon ancestors had of attending with their weapons the meetings of their tribes, whether convened for the administration of justice or to decide on peace or war. This circumstance, inseparable from the assembly, gave a name to the meeting and to the district whose inhabitants were convened. Various explanations, all however connected with this habit, are given to the last syllable. By some it is supposed to mean the *touch* or rustling of their arms, by which the assembly was wont to signify its opinion of the matters submitted to it; by others the *acceptance* by the lord of his tenants' arms in token of their submission to him. These are the two solutions quoted by Spelman. Others, however, say that the word denotes the custom which the vassals had of *touching* the spear of the lord as a mark of homage; and this seems to be the explanation most usually adopted. (Spelman, *Wapentachium et Wæpengetachium*; Cowell.)

WAR, SCIENCE OF. The science of war has been divided by military writers into Strategy and Tactics, and sometimes into Grand and Elementary Tactics. Under STRATEGY and TACTICS we have defined what are the limits of those divisions, and given the general principles which govern strategic operations; as also some of the principal definitions, such as Base of Operations, Lines of Operations, Interior Lines, &c. It is, therefore, unnecessary to recur to these further than to recapitulate the main principles which are or should be the basis of all military operations, and which, though often neglected when stated, appear self-evident truisms. These general principles are: to bring the mass of the forces successively into collision with portions of the enemy; to operate as much as possible on his communications without exposing your own; and, thirdly, with a view of being superior at the point of collision, to act on *interior* lines. [STRATEGY.] These principles must be borne in mind in making all military combinations, whether for a campaign or on the day of battle; and such combinations will be more or less good as these principles are more or less carried out.

In Europe, an army while in the field can draw much of its support from the country in which it is acting, and therefore it does not wholly depend upon its magazines for its means of subsistence; yet even in this part of the world the supplies of provision and forage which can be obtained in an enemy's country are often precarious, and an army without regular communication with its depôts is in danger of being reduced to the necessity of surrendering in order to avoid being starved. Such a disaster is still more likely to overtake an army in the East, if unprovided with the means of support in itself, since there the military force of the enemy consists largely in swarms of light cavalry, who, avoiding regular engagements, hang continually upon the flanks and rear of the army, both preventing supplies from arriving and cutting off all parties who may be beyond the protection of the main body. In fact, an army is in all cases dependent on its communications with its depôts and base of operations for receiving its supplies, not only of provisions, but also of ammunition and reinforcements, and also in getting rid of its sick and wounded. And, further, such is the moral or psychical effect on an armyof its communications being interrupted, that it has always been held by the greatest generals, not only of our own time, but of antiquity, that such an event is the sure prelude to disorganisation and defeat. Now a base of operations may be a single fortress or sea-port town; but, as a general rule, it is a long strip of country, and in this latter case a slight consideration of its object and of the general principles which should guide all military combinations indicate what is the best form for a base of operations, namely, that it should form two sides of an angle approaching more or less to a right angle, so situated with respect to the theatre of war that one side is parallel and the other perpendicular to the enemy's base of operations. For it is evident that, supposing the enemy to have advanced into the theatre of war, a great power of acting on his communications is afforded by employing the end of the most advanced portion of the rectangular base for entering the theatre of war; for it places the army on the enemy's communications in his rear without at the same time exposing its own. It is not necessary that the base should be right-angled to give this advantage; for, in fact, a base of any other form is good when, by projecting into the theatre of war, it gives the power more or less of acting from an advanced point on the communications of the enemy. Napoleon's theatre of war at the commencement of the Austerlitz campaign was bounded on the north by the Mayn and northern boundary of the Austrian dominions, on the west by the Rhine and western boundary of Piedmont, on the south by the Gulf of Genoa, Romania, and the Adriatic and Illyria. The base formed by the Rhine and the Mayn, supposing the country north of the Mayn to be in possession of the French, is a base of the best kind. The Rhine is parallel and the Mayn at right angles to the Austrian base. Supposing, then, an Austrian army to advance into the theatre of war west of Bamberg, the French, advancing from Bamberg and Bareith, would cut off their communications, that is, their supplies of all descriptions, and in case of defeat, which is therefore probable, their lines of retreat, and, driving them into the angle between the Mayn and Rhine, utterly destroy them, while at the same time the communications of the French would be secure, and they could receive supplies and reinforcements, and, if defeated,—which, with these advantages in their favour, would not be probable,—they might with ease retreat into some fortified portion of their base of operations.

Again, the campaign of Moreau, in 1800, is a good example of a base of this kind, the base being formed by the High Rhine and the Lake of Constance and the line of the Lower Rhine, the French being in possession of Switzerland. Napoleon wished Moreau to pass the Rhine at Schauffhausen with his whole army, and thus to cut Kray off. As he had a *tête-de-pont* at Bâle, however, he was content with making certain of a lesser success, and, ordering Lecourbe to pass at Schauffhausen, he himself, with half the army, crossed at Bâle, effected a junction at Enghen, and occupied Stockhack, which was a very important point on the Austrian line of retreat. Kray, finding himself cut off in the angle of the high and low Rhine, with 60,000 men, endeavoured to retreat, but was met by Moreau and defeated at Enghen.

If we consider Spain roughly as a rectangle, three of the sides of which are formed by the sea and in possession of the English, whilst the fourth is in possession of the French, it will be seen what immense advantage the maritime base of Torres Vedras, at the extremity of one of the sides, conferred.

Lines of operations, as has been before stated, should at all times be interior [Strategy], so that the portions of an army moving on them may at any time be massed in superior numbers to the enemy at any point where a collision may occur; but at the same time a single road or strategic line, or indeed a single line of operations, may often be unfavourable, as it does not give so great security against the enterprises of the enemy, and in the presence of the enemy is extremely bad, as it necessitates the column being of great length on the line of march, rendering it unwieldy and liable to be overwhelmed by an attack in front, or cut in half at the same time. Lines at a distance from one another are objectionable, in so far as they may become exterior, and the troops on them be attacked in detail and overwhelmed before they can support each other. When it is said that a commander should always endeavour to operate on interior, and make the enemy operate on exterior, lines of operations, it must be understood that mere distance apart on the map is not the only criterion of lines being exterior or interior. Lines which appear exterior from their distance apart on the map may be really interior from their advantage of cross roads, &c., and more especially from the superiority in the rate of marching of the army moving on them. There is always an immense advantage in maintaining as large a strategical front as possible, for by so doing the enemy is kept in doubt and suspense as to the point on which it is intended to strike a decisive blow; but the length of this strategical point must of course be limited by the necessity of maintaining interior lines. Superiority in the rate of marching is then of immense importance. The divisions of an army which can march twice as fast as another are on interior lines, when 80 or 90 miles apart, to their enemy, when his divisions are 50 miles apart.

Napoleon said that if two armies are equal in all things except numbers and the rate of marching, the relative values of the two armies will not be found by comparing their numbers, but by comparing the products of their numbers and rates.

These considerations will show the immense superiority some rapid means of transit along the strategic front may give; for instance, a railway. It was by availing himself of a railway in this manner, that the Emperor Louis Napoleon made that splendid movement at the commencement of the late Italian war, when, by suddenly concentrating his forces, which had been extended along the whole line of the Ticino, on his extreme left, he crossed, and attacking the Austrian army before it could concentrate, won the battle of Magenta.

With respect to converging and diverging lines of operations. Diverging, or, as they are sometimes called, excentric lines, proceeding from any one point or more in a base, may perhaps occasionally be found advantageous for offensive operations, since by them bodies of troops may be rapidly moved up at once to different points in an enemy's line, and, if compelled to retreat from such points, they will gradually approach each other, and be able to unite at some point in their rear; but they are only admissible when the marches have been so ordered that interior strategical lines are observed, so that the divisions, by falling back or repassing the central point, may be in superior force at the point of collision. It is evident, therefore, that such lines should not have a great degree of divergence, especially when there are few or no cross roads of communication, since then the columns in their advance may become so far separated as to be in danger of being cut off in detail.

Diverging or excentric lines of retreat are eminently wrong. As an instance may be given Wurmser's retreat before Bonaparte. Bonaparte having directed his whole force on one division, overthrew it at Trent; then getting in rear, and on the communications of the other division, destroyed it at Bassano and Mantua; he, Bonaparte himself, having by a concentric retreat just previously been enabled to beat Wurmser.

The retreat of the Russian armies in 1812, under Barclay de Tolli and Prince Bagration, before Napoleon, is an example of the grea advantages of concentric retreats. Though Napoleon made repeated attempts to intercept them, he was unable to prevent their retiring on, and joining at, Smolensko, whence they retired on Moscow; and though they were beaten at Moskwa, the battle was not very decisive; and their armies, by keeping together, were enabled to menace Napoleon's communications. This, according to Jomini, was the commencement of Napoleon's disasters.

Concentric lines of retreat require care in using them, that the divisions joining do not get intermingled, which may lead to inextricable confusion and disaster, as was the case with the Prussians after Jena, by which they suffered a severe augmentation of their disasters. Lastly, when an army employs converging or concentric lines of operations, it is necessary to organise the marches so that the divisions may arrive at their place of assemblement before the enemy can reach it, so as to intercept and defeat the divisions separately.

In the campaign of 1809, the British and Spanish armies were compelled to act on what are called double excentric lines of operations; for Lord Wellington was on the line of the Tagus, having Lisbon for a base, while Venegas with a Spanish army was employed in La Mancha; and there were besides the forces in Gallicia and Leon. The armies, being thus separated from each other, were quite unable to co-operate for one object, even had the Spanish generals and armies been capable of executing any combined operations.

Having thus far slightly considered the main principles of strategy, which space only permits us to touch on, we must for a further elucidation of them refer our readers to the various works, such as Jomini's, on this subject; and we cannot recommend a better work than the 'Elementary Treatise on Strategy,' by Edward Yates, B.A., as an introduction to the works mentioned at the end of the article, and to general military history, by the close study of which alone can a clear knowledge of the principles of war be obtained in the cabinet, the full knowledge and power of applying which must be obtained by experience in the field. Yates's 'Elementary Treatise on Tactics' cannot be too strongly recommended as an introductory work to the study of the other branch of the science of war.

The manner of reconnoitring ground and performing the details of military manœuvres, has been described under Reconnaisance, and Evolutions, Military. We will now proceed to a consideration of military positions and the principles of tactics with relation to the marches of armies, and the general movements on a field of battle and in a retreat.

Military positions are the sites occupied by armies either for the purpose of covering and defending certain tracts of country, or preparatory to the commencement of offensive operations against an enemy.

A position is considered as advantageously chosen when it is on elevated ground; when it is not commanded by eminences within the range of artillery; and when, from the existence of natural obstacles, as rivers or marshes, on the wings, it is incapable of being turned, that is, the enemy cannot, without making an extensive movement, get to the rear of the army by which the position is occupied. In the event of such points of support being wanting, the position, whether it be a plain or an eminence, should have its flanks protected by villages, or by redoubts raised for the purpose; for the flanks being the weakest points of the line, since the troops there are only defended by their own fire, they particularly require to be strengthened by the impediments of the ground, or by fortifications, in order that the enemy, in any attempt to turn the position, may be retarded till reinforcements can be brought up to oppose him.

The advantages possessed by an army on commanding ground consist in the troops being able to see the manœuvres of the enemy while their own are concealed; the fire, also, being directed downwards, is more effective than that of the enemy, which is made upwards from a lower level. The existence of woods or hollow ways in front of a position is considered as an unfavourable circumstance, since an enemy might there place divisions or parties for the purpose of attacking the line by surprise; but, on the other hand, a wood in the rear, if it should not be such as to create an impediment to the passage of the troops through it, might become advantageous in the event of a retreat, as it would afford a temporary cover for the retiring columns. A village or even a single building on the ground occupied by the army may become the key of the position; and, as frequently on the preservation of this point depends the possession of the field of battle, such point should be well supported by troops and artillery. At the battle of Corunna, in 1809, the village of Elvina was twice contested by the opposing armies; and on the field of Waterloo, the Château d'Hougoumont was the object about which the action raged with the greatest violence. The highest point of ground, particularly if near the lines of operation (the roads leading to the magazines), may also constitute the key, and it is usually strengthened by one or more redoubts. It would evidently be advantageous if such key were near the centre of the line, because, on any change in the disposition of the latter, the key might still be retained, and if the wings are separated from each other, it might prevent either of them from being cut off by the enemy; whereas, if situated at one extremity, it might, on a wheel of the army taking place, become so remote as to be incapable of being supported.

The elevated ground which constitutes the position should be able to contain all the troops who are to occupy it; but it should not much exceed the extent necessary for this purpose, lest, not being able to defend the whole, the army should be deprived of the advantages arising from a superiority of command, in consequence of the enemy gaining some part of the height.

However favourable a position may be with respect to the elevation of the ground, that circumstance will be of small value if the troops and artillery cannot be conveniently placed on it. It is indispensable that the ground afford ample room for the manœuvres of that species of troops in which the strength of the army chiefly lies; and at the same time it may be observed that, in making choice of a position, the ground in front should be as much as possible disadvantageous in that respect for the enemy. The Spanish general, Cuesta, is blamed for having, previously to the battle of Rio Seco, in 1808, placed his army in such a situation that the ground before it was in the highest degree favourable for the action of the French cavalry, which was particularly numerous. Artillery should always be placed where it can act with most effect; and when the ground occupied by an army presents alternately salient and retired points along the front of the line, the batteries should be placed at all such points. At the former, in order that the lines of fire may effectually command the approaches by which the enemy's columns may advance; and at the latter, that they may defend the descending ground immediately in front of the others. Infantry may occupy any kind of ground, but should, if possible, always form a close line. It is usually placed between the batteries; and, if exposed to a distant cannonade, the troops may be drawn up in a trench, the earth from which will serve to cover them, without preventing them from marching out in line to meet the enemy. Cavalry must be posted on a level plain, over which it may advance with regularity when a charge is to be made; if compelled to act on broken ground, it is formed in small detachments behind the infantry, through whose intervals it may pass at proper opportunities. It may be observed, that every disposition of an army for defence should correspond to that of the works which constitute a fortified place. The batteries at the advanced points of the line serve a purpose similar to that of the guns in the flanks of bastions; and the intermediate line of troops forms a sort of curtain.

In the choice of positions for offensive operations, such should be taken as have no rivers or broken ground in front since these would impede the contemplated movements towards the enemy: small inequalities, behind which infantry or cavalry may be concealed, are, however, advantageous, as they afford the means of occasionally making attacks by surprise. On the other hand, when an army is on the defensive, the front as well as the wings should be protected by every obstacle to the progress of the enemy which nature may present or art can devise; among those afforded by the latter may be mentioned the blocking up of roads by abatis or traverses; preparing countermines by which, on the enemy's advance, the roads may be destroyed; rendering fords impassable and even forming inundations by constructing dams across the streams. It should be observed, however, that when a defensive position is covered by a river, the line of troops should be at 800 or 1000 yards in rear of the latter, in order that sufficient space may be afforded for the troops to act against the enemy in the event of his forcing a passage across; and, in all cases, every obstacle in the way of a free communication within the position ought to be removed, that the troops may easily succour each other when attacked. Whatever be the nature of the obstacles opposed to the enemy, they should be within the range of the artillery of the line; and then the position may be considered as impregnable, since an enemy would find it scarcely possible either to form or deploy his columns of attack on broken ground and under a destructive cannonade. Good roads, on the other hand, should exist, or should be formed, in the rear, both to facilitate the arrival of supplies from the magazines or depôts, and to favour a retreat, should the latter step become necessary. An army always retires in disorder under the fire of the enemy, and its danger is greatly increased when the retrograde movement is embarrassed by walls, ravines, streams, or other impediments; the divisions then become separated from each other, and some of them are generally cut off by the enemy before they can be supported. It would be advantageous that the ground in rear should command that of the position itself; for then the army, in retreating, would obtain a superiority of elevation over the pursuing enemy; and it might even have an opportunity of renewing the action with a prospect of success.

A knowledge of the art of choosing military positions is an important qualification in the staff-officers of an army; and these officers should continually exercise themselves in forming correct judgments concerning the fitness of ground for such positions. They should be able to ascertain at once, by the eye, its extent and the stations it may afford for troops of the different arms, so that those of all kinds may act with the greatest effect and duly support each other; and, consequently, they should be able to determine the order of battle which is the most advantageous for the ground to be occupied. They are also to judge of the facilities which the roads may present for an advance or a retreat, or for the conveyance of supplies from the magazines; and, finally, of the obstacles which the ground in front may oppose to the movements of the enemy. The power of readily appreciating the character of ground in all these respects is what is called, by foreign writers, the military coup-d'œil; and this can only be acquired by a profound knowledge of the tactics of war, joined to much experience in the practice of executing military surveys, and of contemplating the appearance of ground from all possible points of view. These points being the supposed stations of the enemy, the staff-officer should accustom himself to observe from thence how the latter might make his attack; for then only can he judge in what manner an attack ought to be opposed; that is, what disposition of troops and artillery would be the most favourable for resisting it when made.

The main principles which have been laid down at the commencement of this article as the guides to the conduct of strategical operations, are equally the principles in tactical combinations; the following observations, then, are simply with a view of showing how these may be carried out.

Marches comprehend all the movements by which an army transports itself from one place to another: when they are made at the opening of a campaign, and at a considerable distance from the enemy, they are called *routes;* and on such an occasion the object generally is to invade a country, to seek subsistence, to surprise the enemy or force him to make counter-movements, in executing which he may be advantageously attacked. During a campaign, and in the enemy's sight, marches are made in order to attack some important position which he may occupy, or succour some post which he may threaten, or in order to fall back on the magazines of the army. At the end of a campaign an army marches to the quarters which it is to take up for the winter.

When an army already encamped in order of battle is to advance towards the ground directly before it, the march is said to be to the front; and if it is to proceed to ground on the right or left of the line, the movement is called a flank march. In the former case it would be advantageous if there were several roads nearly parallel to one another, and all tending to the position which is to be occupied; and it would even be proper, should there not already exist a sufficient number, to make such, by cutting through woods or walls, forming causeways over marshes, or bridges over streams. The army might then be divided into several short columns, so as to be able with facility, if suddenly attacked, to deploy into line at any moment either during the march or on arriving in the new position: the intervals between the lines of route should therefore be, as nearly as possible, equal to the extent which the columns moving in those lines would occupy when formed in order of battle. The advanced guard, consisting both of infantry and cavalry, may march before the head of the centre column at the distance of about a mile; and these troops should be accompanied by the pontoons and the sappers who are to remove the obstacles, or form the bridges. When the French army advanced into Russia in 1812, it marched in three great columns nearly abreast of each other: the centre column proceeded along the main road; and the country being one vast plain, the others with their artillery moved over the ground on both sides.

On a flank march along nearly parallel roads, since the heads and rears of the columns are where the extremities of the wings of the army would be if in order of battle, the several lines of route should be as near together as possible, that the troops may readily move into their proper places in re-forming the line; and it is obvious that, in such marches, the divisions in each column should be well closed together; for should they become separated by rivers, marshes, or any other obstacles, the enemy might seize the opportunity to attack a division before it could be supported by the others.

The difficulty of returning rapidly to the order of battle when attacked, is the reason that flank marches in the presence of an enemy are dangerous, particularly when the ground offers no impediment to his approach: they however become necessary when a position is to be taken up on either extremity of an enemy's line; and in order that they may be executed with safety, the columns should be protected in flank by a corps appointed for the purpose. In general an effort is made, by false demonstrations, to deceive the enemy, for a time at least, respecting such movements: these consist in opening roads in different directions through woods or enclosures, in laying bridges over streams, in sending provisions and stores, and even bodies of troops, to various points; and, while the enemy is in a state of uncertainty concerning the object of the demonstrations, the columns secretly commence their march: care however is to be taken that detachments, when sent out as feints, do not proceed so far from the army as to be cut off, or compelled to retire with great loss.

In the usual order of march the artillery should be formed in divisions corresponding to those of the troops, in order that each column may have a portion attached to it, and ready to act with it in the event of being obliged suddenly to come to action independently of the rest of the army. A few pieces of artillery generally accompany the advanced-guard in order to protect the deployment and commence the action; and a division composed of the heaviest pieces may move with the cavalry for its support. During the march, the place of the artillery is in rear of the column to which it belongs, that it may not impede the movement of the troops; that of the reserve artillery being behind the centre column, in order that it may readily move up to the position in which it is to be employed. If some point of attack has been previously decided on—if, for example, it is intended to commence an engagement by assailing a village or an intrenchment —a considerable division of the artillery must accompany the columns destined for that purpose; and if the army while making a flank-march is likely to be attacked on the road, some artillery proceeds at the head of each division of the troops. Should an attack in such circumstances take place, the troops must form as quickly as possible, and the artillery must be placed where it may serve to repel the assailants by its fire.

If an extensive movement is to be made in order to arrive at the position of the enemy, it is necessary to be careful that the latter may not, by short routes, attack the army on the march. This manœuvre was successfully performed by the Prussians at Liegnitz in 1760: the king, being surrounded by the Austrians and Russians, and in danger of being overwhelmed, on learning that the corps of General Loudon was moving to turn his left and fall on his rear, while other troops were to attack him in front, suddenly decamped, leaving troops and artillery to occupy the attention of Marshal Daun in front, and defeated Loudon on his march: by this action he opened a communication with Breslau, and caused the siege of Schweidnitz to be raised.

In all marches the breadth of a column must depend upon that of the road, and space should be afforded for the officers and orderlies to pass by the side of the troops without inconvenience: care should be taken when any change is made in the breadth of a column previously to entering a defile, that the formations be made without allowing the troops to fall into confusion.

To force a defile which is occupied by an enemy possessing artillery, and covered by epaulements, is an undertaking which is likely to be attended with some loss: but if it is necessary to attempt it, the troops which guard its entrance should be dispersed by a fire of artillery; and then the infantry of the army may enter the defile protected by light troops and artillery placed on the slopes or summits of the heights, in situations where their fire may act with effect against the enemy's position, or against the posts which he may occupy. These detachments must be followed by reserve troops, by whom they may be strengthened, or on whom they may retire if repelled. The enemy is thus, if possible, to be driven from every post by which the defile, with its parallel or transverse passes, if such there be, is flanked; when the main body of the army may dispose itself in the position which shall appear most favourable for maintaining possession of the ground while the enemy remains in the neighbourhood: strong detachments must also be placed in situations which may command every approach to the flanks of the defile.

In the event of having penetrated into the enemy's country, some strong posts should be secured, in order that they may serve to protect the succeeding operations. Fortified places are usually on rivers, or in situations from whence cross roads diverge into the country; and the possession of even one such place would be advantageous, as a depôt for artillery and stores, while the rivers or roads would facilitate the conveyance of supplies to the army.

On the other hand, in order to defend or cover a country, an army should be posted so that by short movements it may reach the enemy; and it must be understood that, in acting on the defensive, the corps of troops should not be stationed at great distances from each other, in the expectation of being able to defend every point which may be menaced by the enemy. This error was committed at the opening of the campaign in 1809, on the advance of the Austrians in great force towards the frontiers of France; when General Berthier so separated the divisions of the French army, that all of them might have been separately defeated, had the movements of the Archduke Charles been more rapid than they were.

When two armies are in the neighbourhood of each other, an engagement, either general or partial, may take place: the latter usually consists in an attack on one wing, or on some advanced part of the enemy's line, in order, by driving it back, to obtain a more advantageous position, or to secure some line of communication. A general action may become necessary when an invasion of a country is to be prevented, when a besieged fortress is to be relieved, when the position occupied is to be defended, or when that which is occupied by the enemy so far obstructs the communications as to deprive the army of the means of subsistence. A battle may also be hazarded if the position of the enemy be disadvantageous, if the divisions of his army are ill supported, or if his force is weakened, either from some part being badly covered, or from considerable detachments having been made.

An army drawn up for parade is usually disposed in two lines, with the infantry in the centre of each, and the cavalry on the wings; but this is far from being the case on service, since the nature of the ground will frequently render a contrary disposition necessary: in some parts of the field the troops may be in a single line, in other parts in two, or even in three lines.

The order of battle immediately previous to an engagement depends so much on the facility which the ground may afford for disposing and moving the troops, that it is scarcely possible to assign any rule for the formation; yet it is usual among military writers to class all the different dispositions of an army under two kinds, which are designated the *parallel* and the *oblique* order. The first comprehends all dispositions in which the troops of both armies may be engaged at once along the whole of their fronts: it was very generally employed by the Greeks and Romans, and during the middle ages: but it is now seldom adopted, since the weaker army is in danger of being outflanked; and should any part of it be driven back, the rest of the troops would either be turned and thus cut off, or be also compelled to retire. The battle would therefore be lost; and, being closely pursued, the defeated army incurs the risk of being entirely ruined. At the battle of Talavera, July, 1809, the two armies were drawn up in parallel order, and the attack was made by the French at the same time on the centre and on both wings of the allies.

The oblique order of battle may be said to have been employed by the ancients when it was intended to break the enemy's line: on such occasions the phalanx was drawn up in the form of a wedge, and it advanced with an angle in front against the centre of the line. At the battle of Arbela, the army of Alexander attacked only the right wing of the Persians; and at the battle of Cynoscephalæ, the consul Flaminius, ordering one of his wings to remain on the ground which it then occupied, advanced with the other against the army of Philip. (Polyb., ex. 3, lib. 17.) But this order of battle was first employed on sound military principles by Frederick III. of Prussia.

It does not always consist in drawing up an army in a straight line, which, if produced, would meet the line of the enemy; for this, on account of the inequalities and accidents of the ground, is seldom possible: nor are the two wings of an army always placed at unequal distances from those of the enemy, though this is frequently the case. The principle of the oblique order consists in such a disposition of the troops as may enable a portion of the army to engage at some one point in the enemy's line, while the rest, protected by the obstacles of the ground, is stationed so as to be able to support the troops engaged, or prevent the enemy at other points of his line from attacking those troops in flank; and a great commander will always manœuvre so that his army, even though inferior on the whole to that of the enemy, may be superior in strength at the point of attack.

The attack is generally directed against one of the enemy's wings in the hope of being able to turn it, that is, to get beyond its extremity, or in its rear, and thus to cut off its retreat or intercept its supplies; but if the wings are well protected by the ground, or by intrenchments, or by strong reserves being posted there, and if at the same time the centre has been weakened by troops having been drawn away, or by those which form it being widely disseminated, the attack may be advantageously made against that part of the line. At the battle of Corunna, January, 1808, the British and French armies were in oblique order, the right of the former being near the left of the latter; while the opposite extremities were, by the nature of the ground, kept at a considerable distance from each other. The French made a charge with two strong columns, one of which advanced towards the British centre, and the other attempted to turn its right: in order to take this last column in flank, a part of the British army was placed obliquely to the line; and its fire, together with that of the reserve, which was moved up to the support of the right wing, prevented the success of the manœuvre. At the battle of Eckmühl (1809), Napoleon with his right wing attacked and defeated the left of the Austrians: by this success he cut them off from Vienna, and compelled them to retire towards Bohemia. Again, at the battle of Borodino, in 1812, the French attacked the Russian army at its centre and on its right wing, and succeeded in gaining the heights in that part of the position, after having suffered immense loss in storming a redoubt which protected them, and which was gallantly defended by the *élite* of the Russian nfantry.

Whatever be the order of battle, a strong reserve of troops is necessary, in order that any part of the army may be succoured by it when weakened by losses, or when in danger of being overpowered by numbers. At the battle of Albuera, the timely bringing up of the reserve, when the first line was destroyed, was the means of the victory being gained; and at the battle near Bayonne, December, 1813, two British regiments having been improperly withdrawn from an important position, that position was in danger of being lost, when General Hill brought up the reserve and maintained the action. Strong reserves are particularly necessary when armies engage on a plain, as then the whole line may be forced into action, and in the event of being defeated, its ruin would be inevitable without the support of a numerous body of troops.

When cavalry commence an action, its charge should be preceded by a fire of horse-artillery placed on one of its wings. The fire of that artillery should at first be directed against some part of the enemy's line which is at a distance from the point to be attacked; and if the latter point should be weakened by troops being withdrawn from it to strengthen that point against which the fire is directed, the artillery and cavalry immediately move rapidly forward: the former, having discharged some rounds of grape-shot, retires, and the cavalry is left to execute its charge. Should the artillery become mixed with the combatants, it would be in danger of being taken by the enemy, whereas, being kept in reserve, it may after the charge either join in the pursuit or protect the retreat.

Infantry generally commences an attack by a fire of light troops; and these are accompanied by a part of the artillery, which joins in the firing, the rest remaining in reserve. If the skirmishers retire in order to allow the first line of the army to engage the enemy, the reserve artillery is brought up with that line, and it disposes itself by the side of that which had previously been in action, or it goes to one of the wings. Should the enemy's line become disordered, the horse-artillery gallops up to within range of grape-shot and completes the victory.

The stations of artillery in position should, if possible, be such that the fire of the guns may converge towards some battery of the enemy, in which case the fire of such battery against those guns is necessarily divergent. In general, when an army acts on the offensive, the lines of fire from batteries in position should form nearly right angles with the front of the position, in order that the attacking columns may have room to form in the intervals between those lines of fire; but if the enemy be the assailant, the lines of fire may form acute angles with the position, in order that he may be thereby annoyed when nearly in contact with the troops; the fire of the artillery being directed against the points where the enemy's troops are in masses, as against the heads and flanks of the columns of attack. The guns should not, however, be placed in position till they are wanted, in order that they may be as little as possible exposed to the fire of the enemy; and if any battery is subject to a heavy cannonade, another should be immediately placed in a situation where its fire may cross that of the first battery on the ground occupied by the enemy's guns. When placed on elevated ground, the guns in a battery should be able to defend all the slope of the height up to them; and when that is not possible without bringing them so near the brow as to be exposed to the view of the enemy, other guns should be placed where their fire may flank the ascending ground.

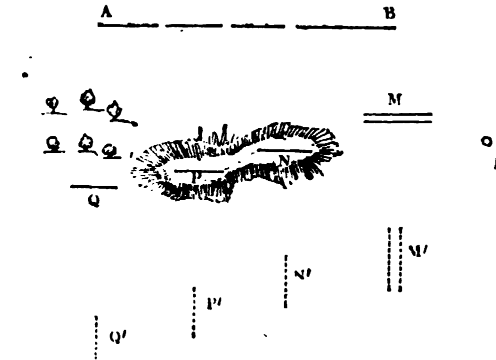
Artillery consisting of 9-pounder guns is found most convenient for the batteries which are placed with the troops: such guns are capable of serving to defend the position, and they may be employed to destroy walls, displace abatis, or ruin field intrenchments. Howitzers are also used in the field for the purpose of throwing shells into redoubts or villages, or among troops protected by hedges, hollow ways, &c., where the shot from gun-batteries could not take effect. To these must now be added rifled guns. [Ordnance, Rifled.] Horse-artillery should be kept with the reserve, and be ready to advance wherever it may be required, either to support a part of the line which is likely to be forced, or to gain the flanks or rear of the enemy; and when it is required to get possession of a position before the enemy can arrive at it, the horse-artillery, on account of the rapidity of its motion, may be employed for the purpose.

The batteries by which an army is protected in its position constitute a sort of bastions, being usually placed a little in advance of the infantry of the line. If the army receives the attack of the enemy, the artillery commences the action by a cannonade while the enemy is at a distance; and if the army acts on the offensive, the artillery supports the columns of attack. It is usual, when guns are fired in position, to direct them so that the shot may strike the ground in front of the enemy's line, and afterwards, by rebounding, make a series of grazes among his troops. When the ground is hard and even, these ricochets are very destructive; but if soft, or much broken by inequalities, the shot plunges in the ground and does comparatively but little execution. It is doubtful if ricochet fire is practicable or likely to be efficacious with rifled ordnance.

The best proportions for the quantity of artillery in an army is one gun for every 500 men (infantry), and one gun of the horse-artillery for every 250 men (cavalry); but this will vary much with the country in which it is to be used, hilly country requiring much less artillery than level country.

Armies, whether on the offensive or defensive, are generally kept in columns till the proper moment for deploying has arrived; for by this disposition both parties are enabled to conceal their projects from each other till one of them has determined to commence the action, and each is in a condition to make such movements as may be necessary in order to give him an advantage over his opponent. The Spanish general, Cuesta, is blamed for having, at the battle of Medellin (1809), in which he was defeated, advanced towards the French army in one weak line three miles long, when, by keeping the troops in columns, he might have moved them between the enemy's divisions, and thus, by separating them from each other, have destroyed them in detail. If a position is such that the army occupying it is exposed at several points to be attacked, those points should be occupied by small bodies of troops, the bulk of the army being kept behind in columns ready to march to any point where their services may be required. Thus the enemy will be embarrassed from the impossibility of determining the force of the army at any one point, and his only chance of success will lie in the quickness of his movements. The circumstances which may determine a general to attack a position at any particular point are, the appearance of that point being weak on account of troops or artillery being withdrawn, from the ground being there more easy of access than elsewhere, or from its capabilities of affording cover to troops in their advance.

If an army, as A B, in position on level ground, is to be attacked on its left wing, B, the army acting against it is usually placed *en échelon*, as at M, N, P, Q, each division consisting of a battalion or a brigade;

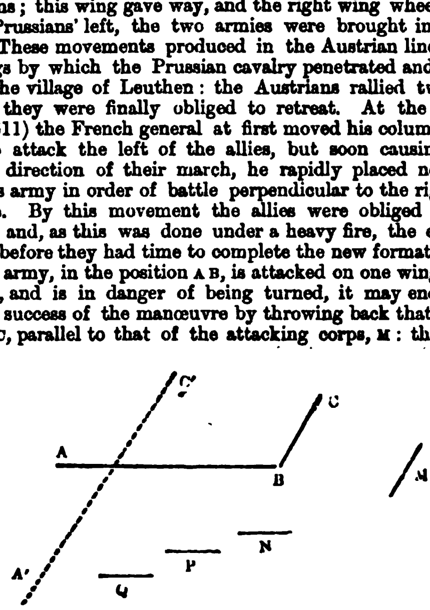


and this formation may be accomplished by moving up the different columns, as at M', N', P', Q', to the places which, when deployed, they are to occupy during the engagement. It would be advantageous, however, that the heads of the columns should remain till the moment of deployment in a line parallel to that of the enemy, in order to keep the latter as long as possible in suspense respecting the real point of attack. A favourable moment is then chosen for bringing the greatest mass, as M', to the wing at B, which is supposed to be the weakest part of the line; but it should be observed that this intention will succeed only when the different columns can be moved to their stations with great rapidity, for if the enemy has time to perceive the manœuvre he will not fail to take measures to counteract it. The échelons must always be so near one another as to allow them to be mutually supported, yet not so near to the enemy as to be in danger of being forced into action. In order to explain the process of turning an enemy's position, let it be supposed that the left wing (B) of his line is in a plain, and not well protected by works, and, consequently, that it may be turned, while the right wing (A) is covered by woods. Strong columns are formed at M in order to perform the manœuvre of turning the flank B. The divisions at N and P constitute the centre, and may be supposed to be on elevated ground, so as to be refused to the enemy; while Q may consist of a small division extended along the skirts of the wood merely to keep the enemy in check.

Should the enemy reinforce his left, B, by drawing troops from his right, A, and should this circumstance become known after the troops M have set out on their march towards B, the infantry of the column M may then change their route and proceed towards N and P, concealing their strength as much as possible by passing through woods and hollow ways, if such there be, while the cavalry, supported by some infantry in a village, as at I, move towards M as before, in order to deceive the enemy. The central columns P and N then move towards their left, and unite with the trooops Q to attack the wing A. Thus the disposition of the army is completely changed: and if the change is effected with rapidity, the enemy might not have time to reinforce the wing A before it would be turned. If the troops in the wing B were to advance to attack the central columns at P and N, and these were to retire, those troops would be unable to produce any effect, as it would be necessary to recall them in a short time on account of the danger then threatening the right wing.

This is nearly what took place at the battle of Leuthen (1757), when the king of Prussia advancing against the Austrian army, made demonstrations as if he would attack their right wing. Marshal Daun, though for a time he suspected the feint, was at length deceived, and sent all his reserves to strengthen that wing: the king observing this, proceeded immediately to execute an oblique attack; for which purpose his columns moved rapidly to the right and deployed on the left wing of the Austrians; this wing gave way, and the right wing wheeling up to attack the Prussians' left, the two armies were brought into parallel positions. These movements produced in the Austrian line disorder, and openings by which the Prussian cavalry penetrated and took possession of the village of Leuthen: the Austrians rallied twice afterwards, but they were finally obliged to retreat. At the battle of Albuera (1811) the French general at first moved his columns as if he intended to attack the left of the allies, but soon causing them to change the direction of their march, he rapidly placed nearly two-thirds of his army in order of battle perpendicular to the right of the British line. By this movement the allies were obliged to change their front, and, as this was done under a heavy fire, the enemy was upon them before they had time to complete the new formation.

When an army, in the position A B, is attacked on one wing, as B, by the corps M, and is in danger of being turned, it may endeavour to prevent the success of the manœuvre by throwing back that wing in a direction B C, parallel to that of the attacking corps, M: this is called



forming the army *en potence;* the angle B is, however, weak, for the troops in B C by falling back may become crowded and disordered; A B may become exposed to a raking fire from M, and B C to a like fire from troops at N. It is evident, however, that M cannot now turn the flank B C without making a circuitous movement, by which it may become separated from the rest of its line: and if the army A B is strong enough, it may form a line parallel to the direction of C B. By such a movement the parallel order would be restored, and the wing A might even be made to turn the left, Q, of its opponent: this should of course be attempted, as the return to a parallel order of battle leads to no useful result. In order to effect it, the division B C should retire gradually, while the brigades in A B wheel back, in order to keep in connection with it; at the same time the brigades at A wheel to their front so as to form the new line A'C', in a direction oblique to that of Q, P, N.

An attack on an enemy's line is often made by a strong division drawn up in one column for the purpose of forcing its way through the line at some point where it appears to be weak, and thus compelling the different corps to retire that they may not be separately overwhelmed. This is the mode of attack which was practised with so much success by Napoleon against the Continental armies, but which failed when attempted against the British troops, both in Spain and at Waterloo.

It is adopted when an attack is to be made on an enemy behind retrenchments, in which case the troops move as much as possible towards the salient angles of the work in order to avoid the direct fire; it is also necessary when the ground only permits the troops to advance on a narrow front, as in defiling through a ravine; in fact, if an enemy's position have obstructions in its front, it must necessarily be attacked in columns if at all. The columns should be connected with each other by bodies of light troops, and the attack should be made with a view of separating a wing of the enemy from his main body.

The attack in column possesses some advantages over one made by troops deployed in line while the men remain steady in the column; for the enemy is intimidated by the sight of a vast body coming against him, while the assailants feel confidence from their union. A rapid succession of efforts directed against troops in a slender line will also, in general, succeed in breaking their order; but there are several circumstances which more than counterbalance these advantages: during the advance over uneven ground the men lose their ranks and fall into confusion; the flanking fire of the enemy's artillery makes great havoc among the crowded masses, and the columns can only oppose this fire by an irregular fire from its sides; disorder then ensues, the commands of the officers are no longer regarded, and an attempt to deploy for the purpose of making an attack in line only completes the disorganisation. An attack in column can indeed, scarcely succeed unless it were preceded by a heavy fire of artillery: this will put the enemy's line in disorder; and in the event of forcing it, the column may then be deployed in order to secure its advantages.

If a line, nearly equal in strength to that of the opponent, on being attacked in column, were to stand firmly, it is probable that the attack would fail; and even if the line were penetrated, the troops, by forming themselves in hollow squares, disposed chequer-wise, so that their fires may cross on the ground in their front, have invariably been found capable of resisting the efforts of the assailants. This last manœuvre was recommended by General Jomini, and was for the first time employed at the battle of Aspern, in 1809. In that action Napoleon, perceiving the Austrian line to be weakened in the centre, ordered it to be attacked by the whole corps of Marshal Lannes, which for this purpose was drawn up in one great column. The column, preceded by artillery, advanced rapidly, and succeeded in penetrating the line. The troops in that part gave ground, but forming themselves in squares, they resisted all the efforts of the French cavalry to disperse them, while the wings of the army closing upon the flanks of the column, poured into it a destructive fire of artillery, which at length forced it to retire in confusion between the two fortified villages which supported its wings. The attack of the French at the battle of Wagram had, however, complete success: the Austrians, being doubtful of the precise spot at which Napoleon would cross the Danube, had very widely dispersed their troops; the centre of their line was particularly weak, and against this part the French emperor determined to direct a dense column. This was composed of the reserve of the army, and the charge was preceded by a heavy cannonade, which still further dispersed the Austrian troops. The army, being thus broken, was compelled to retreat. At the battle of Talavera (1809), the French in strong columns attacked, at the same time, the centre and both wings of the British line. The latter was drawn up three deep, and its fire of musketry and artillery, directed against the heads and flanks of the columns, aided by charges of cavalry, drove the enemy back with great slaughter. An indiscreet pursuit made by the Guards was the cause of much disorder in the centre; and the enemy returning to the charge, that part of the line was completely broken; but fresh troops being ordered up to the spot, their fire kept the enemy in check till the disordered troops rallied, and the artillery continuing to play on the flanks of the enemy's columns, the latter at length gave way.

The success of an action is often promoted by sending out a detachment with directions to fall on the flanks or rear of the enemy during the engagement. The sudden appearance of a body of troops in such a situation cannot fail to produce embarrassment in the army which is attacked, and to diminish the energy of its operations towards the front. On the other hand, there is some danger in sending out large detachments from an army, as it is seldom possible to afford them due support; and therefore they may be cut off by the enemy. The distance which the detachment has to march, together with the state of the roads on which it must move, should be ascertained with precision, in order that it may be at the appointed post at a seasonable moment; and such determinations are very uncertain, particularly if the corps has to make a great circuit. It almost always happens that the detachment arrives too late for the accomplishment of the object; and this was the case with a detachment sent by the king of Prussia during the action at Torgau (1760), with a view of turning the left of the Austrians, and cutting off their retreat.

Detachments are however constantly sent out to protect the parties reconnoitring a country, to guard a convoy, or to support a foraging party. In these cases its object is less to fight than to cover a retreat; therefore the troops advance with circumspection, and retire when the enemy appears in superior force. During the war in Spain (1813), Colonel (Sir Frederick) Adam having been detached to occupy a post at Ordal, ten miles in advance of the army under Lord William Bentinck, in Catalonia, was suddenly attacked by the French army, and his troops dispersed. This misfortune is ascribed to neglect in not having placed outposts, by which warning might be obtained of the enemy's approach.

An army which gains an advantage over its adversary is always more or less deranged by the action, and it is necessary that it should endeavour to recover its order preparatory to receiving the second line of the enemy, should the latter advance to renew the combat. On the enemy retiring, the first line of the victorious army advances, and then the second line follows it in order to support it, sending, if necessary, battalions or squadrons to replace such as have been most disordered during the action. In the event of the second line, or reserve, of the enemy being defeated, since then there is no apprehension that the action will be continued, companies of troops may be detached in pursuit of the retreating army; but every precaution should be taken to keep them within the support of the main body, and particularly to prevent the troops from dispersing for the purpose of plundering the country. The advance of the whole army in pursuit should continue so long only as it can be conducted with order, and in masses strong enough to oppose the enemy if his troops should rally in a good position. If disorder should take place among the pursuers, the latter should be made to fall back on the reserves: the pursuit of a retreating army can, indeed, be seldom continued beyond the first elevated ground at which the latter may arrive; since, however little discipline it may preserve, it may there rally and return to the order of battle. The consequences of the actions at Jena and Waterloo are exceptions to this rule, because the vanquished armies were at those places too completely disorganised to allow them to make any attempt to rally.

When the success of an action begins to be doubtful, and it is apprehended that the army must retreat, some of the heaviest artillery should be drawn off to a good position on heights, or behind streams or hollow ways, while the lighter artillery remains engaged. The first line of the defeated troops is then made to pass through the intervals of the second, or of the reserve, while the latter continues the action. The first line should remain in order of battle in rear of the second, till the latter is enabled to retire; and this alternate retreat of the lines should be continued till the army can be thrown into columns of march, when the retreat may be protected by detachments of light troops. In general the retreat should be made in one body, as thus it can more easily protect itself against the enemy in pursuit. If, however, the centre is broken, the army may be obliged to retire by different and even by diverging routes; and, provided there are in the rear strong posts by which it may be protected, the risk of being cut off during such a retreat is small.

When there are narrow defiles in rear of the field of battle, the retreat through them becomes extremely dangerous, for the army may be overtaken before it can get through; and if they are already occupied by the enemy's detachments, the retiring army may be annihilated or compelled to surrender. It has been observed that the situation of the British army at Waterloo would have been very critical if it had been compelled to retreat; this criticism, however, is hardly just. The British army had good roads to retire by, and the open forest in rear would have been an admirable position for defending the rear of the retreating columns. In order to pass a defile in safety, it ought to be previously occupied by troops: artillery and a reserve corps should also be stationed so as to defend the approaches on the advance of the enemy towards them.

If, when not in action, an army is to retreat from a position which it occupies, the movement is usually concealed from the knowledge of the enemy, and, for this purpose, it frequently takes place at night. On such occasions the outposts remain at their stations as long as possible; and fires are left burning on the ground, as if the army were still in the position: after it is dark the main body moves off, and the rest of the troops follow by degrees.

The approach of winter, and the necessity of taking repose after the fatigues of a campaign, render it necessary for armies, whether on the defensive or otherwise, to take up positions where they may remain during the season of inaction. These positions, called winter-quarters, should be chosen by the commander of the army on the offensive, so that he may be able to preserve the ground which he has gained; and by him who is on the defensive, so as to be secure against the attacks of the enemy. The principles by which a choice of quarters is determined are the same as those which regulate the occupation of ground for a field of battle. The quarters should be covered in front and on the flanks by rivers or other natural impediments to the approach of an enemy, or by forts constructed for defence.

A great extent of ground in front is therefore a disadvantage, as some part may be ill-guarded, and liable to be surprised, and the troops will be too much disseminated. If it is traversed by great roads perpendicular to its front, it is also disadvantageous, as the enemy may then easily march into the quarters.

Several battalions of infantry and squadrons of cavalry are quartered in villages along the front of the position; the whole or a division of a company or of a squadron at each place: these posts may be strengthened by redoubts, palisades, or abatis; retrenchments also should be executed, to defend roads by which the enemy may approach, and bridges over the streams should be destroyed. The troops in each of these stations furnish the men necessary to constitute the advanced posts of the chain. A stronger force should occupy villages and towns within the first chain, and from these are sent such bodies of troops as may be requisite to support those in their front. The great body of the troops ought to be near a central point of the position, in order that succours sent from that body may easily reach any part that may be threatened.

When an army is in quarters, there are established alarm-posts, at which the troops should be appointed to assemble. These are frequently in the vicinity of a fortress, that the corps may be protected by the latter till all have assembled; but they should be in commanding situations, that, in the event of the enemy attempting a surprise, his movements may be easily seen. Each division, or corps of the army, should have its own alarm-posts, and there should be, besides, the general place of rendezvous for the whole army: the latter place should be so situated that all the divisions may be drawn up there before the enemy could arrive at it, and it should be protected by a fortress which may contain the provisions for the support of the troops.

A system of signals, for day or night, is determined on, by which intelligence may be conveyed to all the different posts, of the approach of the enemy. Should an alarm be given by any outpost of the chain, the bodies of troops which are appointed to support that post take arms, attach the horses to the artillery, and prepare to march immediately to the point of danger; but the judgment of the commander, and the information which he may receive from spies or deserters, must enable him to form an opinion whether a demonstration made by the enemy is true or false.

WARD, WARDEN, that is, "guard" and "guardian." Ward is the name used in the counties of Durham, Westmoreland, and Cumberland, instead of the hundred of the midland counties or the wapentake of Yorkshire, to denote a subdivision of those shires. The neighbourhood of those border counties to the Scots rendered it essential that the military preparation of the inhabitants should be constant; and hence the subdivision of the county took the warlike appellation of ward, rather than the more peaceful one of hundred. The great officers whose duty it was to defend the northern borders from the Scots, and the north-western from the Welsh, were called lord-wardens of the marches [MARCHES]; and we still have the lord-warden of the Cinque Ports, the lord-warden of the Stannaries. To descend to a lower class of functionaries, a castle or tower was heretofore often called a ward; and it served as a place not only of defence, but also for the safe keeping of malefactors: hence the keepers of some jails are called wardens; for example, the keeper of the Fleet prison, until it was abolished, was called warden.

Forests were divided into wards. By the Municipal Reform Act (5 & 6 Will. IV., c. 76,) cities and boroughs are divided into wards, each of which has the right of electing an alderman and a certain number of council-men. [MUNICIPAL CORPORATIONS.]

WARDS, COURT OF. The Court of Wards and Liveries was established by the statute 32 Henry VIII., c. 46, to superintend the inquests which were held after the death of any of the king's tenants by knight's service, for the purpose of ascertaining what lands the tenant died seised of, who was his heir, whether the heir was an infant; and thus what rights accrued to the king in the shape of relief, primer seisin, wardship, or marriage.

By the famous statute passed in the first Parliament of Charles II. (12 Charles II., c. 24), the Court of Wards was abolished, together with the feudal rights out of which that court arose. The preamble of the statute states that it had been intermitted since Feb. 24, 1645. [GUARDIAN.]

WAREHOUSING SYSTEM is a customs' regulation, by which articles of import may be lodged in public warehouses at a moderate rent, not being chargeable with duty until they are taken out for home consumption, and being exempt from duty if re-exported. It affords valuable facilities to trade, is beneficial to the consumer, and ultimately to the public revenue. Where no such system exists, the merchant must either pay the duty on every article immediately it is landed, or must enter into a bond with sureties for payment at a future time. If he pays at once, he is obliged to advance a large capital, on which interest must be charged to the consumer until the goods be sold; or he must effect an immediate sale, perhaps at an inadequate profit, or even at a loss, in order to raise the funds necessary to pay the duty. If he wishes to defer the payment until the market shall offer an advantageous sale, he may find it difficult to induce persons to become his sureties, and, when he has succeeded, he may involve them in ruin. The natural result of these difficulties is, that none but wealthy capitalists can import articles on which heavy duties are charged, and a monopoly is thus established, to the great injury of the consumer. The immediate payment of customs' duties also obstructs the carrying trade of a country, by making the re-exportation of articles more troublesome as well as expensive.

The first British statesman who proposed a remedy for these evils was Sir Robert Walpole, in his celebrated Excise scheme, in 1733. His object was to unite the Excise laws with those of the customs as regarded wines and tobacco, and to charge a small duty immediately on importation, and the remainder on being removed from the Excise warehouses for home consumption. Speaking of tobacco, he thus explained his proposal:—"If the merchant's market be for exportation, he may apply to his warehouse-keeper, and take out as much for that purpose as he has occasion for, which, when weighed at the custom-house, shall be discharged of the three farthings per pound with which it was charged upon importation; so that the merchant may then export it without any further trouble. But if his market be for home consumption, that he shall then pay the three farthings charged upon it at the custom-house upon importation; and that then, upon calling his warehouse-keeper, he may deliver it to the buyer, on paying an inland duty of 4*d.* per pound to the proper officer appointed to receive the same." Walpole clearly foresaw the advantages of his scheme to the carrying trade. "I am certain," he said, "that it will be of great benefit to the revenue, and will tend to make London a free port, and, by consequence, the market of the world." This wise plan, unfortunately for English commerce, was not permitted to be carried into effect.

The advantages of the warehousing system were most forcibly pointed out by Dean Tucker in 1748, in his 'Essay on the Advantages and Disadvantages which respectively attend Great Britain and France with respect to trade,' and afterwards by Adam Smith, in his 'Wealth of Nations;' but it was not established before 1803 (43 Geo. III., c. 132). The acts by which warehousing is now regulated are the 3 and 4 Will. IV., c. 57; 4 and 5 Will. IV., c. 89; and 6 and 7 Will. IV., c. 60.

The main objection to Sir Robert Walpole's scheme was that the warehousing was compulsory, but, under the existing law, it is at the option of the importer. Amongst other privileges enjoyed by the merchant, he may remove any merchandise from one port to another, either by sea or inland carriage, to be warehoused again. A committee of the House of Commons reported, in 1840, "that the privilege of having bonding warehouses may be conceded to inland towns, under due restrictions and regulations, with advantage to trade and safety to the revenue. An Act (7 & 8 Vict., c. 31) conferred this privilege upon Manchester. Since then the power of appointing warehousing ports has been conferred on the Treasury by the Customs Consolidation Act of 1833; and a similar power as to inland towns by the 23 & 24 Vict., c. 36.

The advantages of warehousing have been understood in various foreign countries as well as in England. So long since as 1664, M. Turgot established it in France; but it was discontinued in 1668, except for merchandise imported from the East and West Indies and Guinea, or exported thereto. In 1805 the system was re-established in a more extensive manner, but was confined to certain sea-ports, until 1832, when it was extended to several of the principal cities in the interior. Warehousing both at the ports and at certain inland towns is permitted in Holland. In Belgium, Denmark, and most other commercial countries the system has also been adopted.

WARMING AND VENTILATION. References having been made from SMOKE, STOVE, and VENTILATION to the present article, it will be desirable here to glance rapidly at the principal modes employed for warming and ventilating buildings generally.

Open fire-places.—A "cheerful English fire" is associated with so many ideas of comfort and social enjoyment, that we are apt to forget how dearly we pay for it. Dr. Franklin and Count Rumford did something to call attention to the subject, but Dr. Arnott has done more. In order to understand this matter, it will be necessary to bear in mind that, while some fire-places or stoves give out heat by *conduction* chiefly, others do so mainly by *radiation*. Open fire-places are of the latter kind, and a serious loss of heating-power results from the arrangement. The burning coals radiate heat into the room, and another portion of heat is reflected from the metallic portions of the grate; but the heated air, which ought to contribute to the desired effect, is mainly allowed to escape up the chimney with the smoke and other results of combustion.

Dr. Arnott enumerates about a dozen evils which are more or less inseparable from the familiar open fires of our apartments. Among these are: *Waste of fuel.*—There is, first, the heat which escapes with the smoke; then the current of warmed air from the room, which ascends the chimney; and, lastly, the valuable fuel contained in the smoke itself. From all these causes Dr. Arnott estimates a loss of seven-eighths of the whole heating-power, while Rumford estimated it as high as fourteen-fifteenths—each basing his conclusions on the kind of open fire-place chiefly in use in his own day. *Unequal heating.*—In a cold wintry day, when seated near a large fire, we may frequently hear persons complain of being scorched on one side and frozen on the other. This arises from the circumstance that, as most of the heat received from an open fire is radiated from the burning fuel, instead of being conducted by the air, this heat, diminishing in intensity as the square of the distance increases, is very unequal, being too great at a small distance, and too weak at a greater; while the draught, or current of cold air which feeds the fire with oxygen, acts like a chilling blast against the side of each person or object which is turned away from the fire. *Strata of air unequally heated.*—Besides the inequality just alluded to, there is another, arising from this circumstance—that the entering current, being colder and specifically heavier than the air previously in the room, occupies the lowest stratum, and subjects the feet to a cold bath, which is frequently attended with bad consequences. Other objections are—the *smoke and dust* arising from the use of open fires; the *loss of time* attendant on the care which they demand; the *danger to property and to person* which accrues from them; the *necessity* (until lately supposed to be indispensable) *of employing climbing boys;* and many others.

Many contrivances have from time to time been brought forward to obviate one or other of these inconveniences. Count Rumford suggested the register-stove, the peculiarity of which consists in narrowing the entrance or throat of the chimney by a plate which can be moved to vary the size of the aperture; by this means, particularly if the opening be near the fire, the very hot air directly from the fire enters before it can mix with much colder air from the room, and thus the draught is increased so as to lessen the chance of smoking. But the very circumstance which constitutes the excellence of this stove, namely, the rapid ascent of heated air up the chimney, illustrates the waste of the method generally by showing how much of the heating agent is lost. The almost interminable variety of open fire-places, both in the form of the grate itself and in that of the opening in which it is placed, have been introduced either for an ornamental purpose or for the prevention of smoking; the other evils enumerated are almost inseparable from the system.

Dr. Arnott, in 1855, published a volume "On the Smokeless Fire-place, Chimney-valves, and other means, old and new, of obtaining healthful Warmth and Ventilation." His chief object was to describe a kind of open stove which he had invented, as the result of combining many principles long known, but only in part acted on. In this, as in other cases, he generously threw all patent privileges aside, and sought how best he might serve the public generally. The chief faults of open fire-places being the production of smoke, waste of fuel, unequal heating, and troublesome management, he devised a plan for lessening, if not preventing, all these evils. One day's charge of fuel is supplied at once, in a box beneath the grate. The coal is borne upwards, when wanted, by a moveable false bottom in the box, which is raised easily by the poker as a lever, with notches and ratchets to retain the false bottom at any height. The box is from 8 to 18 inches deep, and contains from 20lbs. to 30lbs. of fuel. In warm weather, the fire is kept dull by not raising the bottom so high or so often as in cold weather. To light the fire, paper and wood are laid on the coal; and on this three or four inches of cinder or partially coked coal. The wood soon kindles the cinder, and the pitchy vapour from the coal rises through the wood-flame and cinder-flame, ignites, and adds to the heat, without producing smoke. It is important that no air should pass up through the coal-box; to insure this, the false bottom moves up tightly. The coal only burns at the top, but it keeps a-light with great tenacity. Even if no fuel were left in the grate, the coal in the box would burn gently downwards, and endure through a whole night. The grate is accompanied by an improved form of chimney-valve, &c. Any kind of coal, culm, or coke will do. A room may be kept warm all night, by leaving the valve and throat of the chimney only a little open, and thereby drawing away only a little of the warmed air. Dr. Arnott, having tried his new open smokeless fire-place in many ways, has found that it saves one-third of the fuel, cures a smoky or ill-drawing chimney, ventilates the room through the valve, diffuses the heat about the room, requires no tending for twelve hours together, renders chimney-sweeping unnecessary, and calls for very little personal attendance. We may add that Dr. Arnott combats an opinion, now very prevalent, that a modern *low* grate warms the floor of a room better than one of greater height. In the usual position of a hearth-rug, more heat comes down upon it if the grate be moderately high. If the grate be low, hardly any heat *strikes* it; it merely passes horizontally *over* it, while cold air rushes along the floor in the opposite direction, on its way to feed the fire.

Close Stoves.—The common Dutch stove is one of the simplest examples of a close stove. It generally consists of a cylindrical case of sheet iron, within and near the bottom of which is a grating for containing the fuel. There is an ash-pit beneath the grating, and three openings to the interior—one to the ash-pit, one for introducing the fuel above, and one leading to a flue or chimney. When the fuel-door is closed and the ash-door open, there is then one aperture by which cold air can enter to feed the combustion, and another by which the smoke can escape. In this form of stove the heated iron case warms the air of the room by *conduction* rather than *radiation*, and all this air becomes much more nearly equalised in temperature than by a common fire. There is also great economy of fuel, and an absence of smoke and dust. On the other hand, inconvenience arises from the highly heated iron, the temperature of which is so great as to decompose many of the heterogeneous particles always floating in the air. The air acquires a burnt and sulphureous odour; it exercises a dry and shrivelling effect on objects in the room; and it often gives headache and giddiness to those who are exposed to it. In Germany the stoves are made on this principle, but are often more ornamental in their character.

The Russians contrive their close stoves on a different principle. Earthenware and brickwork are largely used, instead of metal, as a means of making the heat less intense near the stove, and of keeping up a reservoir of heat after the fire is extinguished. The stove is built in a massive style, and consists of a series of chambers, of which the lowest serves as the fire-place, and the upper ones as flues; and being composed almost entirely of brick and porcelain, the outer surface remains at a moderate temperature for a very long period.

Within the last thirty years many forms of stove have been devised, with the view of obviating some of the objections urged against those used on the Continent. Where, as in a common German or Dutch stove, the burning fuel comes in contact with the metal of which the stove is formed, this metal becomes so highly heated as to produce upon the surrounding air the deleterious effects before alluded to. Dr. Arnott has the merit of having drawn attention in a particular manner to this subject. The problem which Dr. Arnott sought to solve was, to obtain a considerable extent of surface heated not much above 200°, as a means of warming apartments. He first caused a kind of water-stove or tank to be constructed, having a fire-box in its centre; and by certain arrangements for the admission of air and the emission of smoke, he kept the water always nearly at the boiling temperature. This apparatus being however both expensive and difficult to manage, he dispensed with the water, and surrounded the fire merely with a body of air. In the new form of stove, the fuel is put into a small fire-box, enclosed within a larger case of sheet-iron; the only openings in the outer case being a door at which the fuel is introduced, an air-hole beneath the grate, and a chimney for the exit of smoke, which chimney, being merely a metallic tube three or four inches in diameter, can be easily arranged in position. The interior of the outer case is nearly divided into two parts by a partition so adjusted as to cause a continued circulation of the heated air within, and hence an equable heating of the outer case. The air-vent leading to the fire is provided with a valve, by which the admission of air is rendered more or less abundant according as the fire within is less or more intense. It was one point in Dr. Arnott's system to make the stove a "self-regulating" one, by providing apparatus whereby the valve would open and shut at the proper times to maintain any required temperature; and he suggests six or eight different modes of arrangement, from which the maker of the stove may select one. Dr. Arnott states:—"During the winter, 1836-7, which was very long and severe, my library was warmed by the thermometer-stove alone. The fire was never extinguished, except for experiment, or to allow the removal of pieces of stone which had been in the coal; and this might have been prevented by making the grate with a moveable or shifting bar. The temperature was uniformly from 60° to 63°. I might have made it as much lower or higher as I liked. The quantity of coal used (Welsh stone-coal) was, for several of the colder months, six pounds a day; less than a pennyworth, or at the rate of half a ton in the six winter months." This kind of stove possesses many advantages; but it is not free from defects. It is liable to the objection already stated with regard to the unpleasant feeling consequent on the use of all stoves of the kind, and indeed with it more than others; for owing to the very slight expenditure of fuel, there is little or no change in the atmosphere.

Numerous varieties of the close stove, bearing more or less on the above construction, have been brought forward since the publication of Dr. Arnott's first book on this subject in 1838. Each professes to possess some peculiar merit; but all present these features in common: that the air-hole, by which the combustion is fed, is very small, and capable of adjustment; that there is a body of air to be warmed, external to the grate or fire-box itself, but confined within an outer case; that the consumption of fuel is much smaller than in any variety of open fire-places; and that the flue for carrying off the smoke and gases is small in diameter, and capable of being carried in any direction. In one variety, called the Vesta stove, there is a very ingenious arrangement whereby the ashes can be raked from the grate into an ash-receiver, and new fuel thrown into the grate, without any dust rising into the room, or any air entering the stove except through the customary air-vent. In the different forms of kitchen-ranges the open fire-place is combined with what may be deemed a close stove; for the oven and hot-closet are representatives of the heated space within the outer case of a close stove. The stoves often employed in shops, halls, &c., are adjusted not so much for the economising of fuel as for the consumption of their own smoke.

Gas-Stoves.—In addition to the use of gas for lighting, described in its proper place, gas is now extensively employed for heating, by means of stoves of various kinds. The stoves are mostly cylindrical in form, with openings at the top and bottom. At the lower end, a few inches above the floor, is a ring-burner pierced with numerous minute jet-holes. The top has frequently a sliding valve or damper to regulate the heat. The details vary greatly in different kinds. Edwards's gas-stove has bulbous-shaped burners of fire-resisting clay, pierced with numerous small holes. Air enters through a lower row of holes and mixes with the gas. The bulb becomes gradually covered with a thin yellow flame. Several such bulbs are combined in various ways, and arranged to form cooking and heating stoves. One form of this stove, the so-called *Atmopyre*, consists mainly of small cylinders of pipe-clay. Each cylinder is from two to four inches long, and perforated with holes $\frac{1}{25}$th of an inch in diameter. One end of the cylinder is fixed upon a gas-burner; the gas, being turned on, mixes with the atmospheric air in the cylinder; the little jets which penetrate the minute holes are ignited, the cylinder becomes red-hot, and presents the appearance of a solid red flame. By placing many such cylinders within another of larger size a very intense heat may be produced, applicable to manufacturing purposes.

Whatever form a gas-stove may present, its assumed advantages are: a comparative freedom from dust and dirt; a saving of time and labour; facility for adjusting the temperature of a room; and economy in cost and maintenance. The disadvantages are alleged to be: a diffusion of aqueous vapour, nitrogen, and carbonic acid gas; these ought to be carried off by a chimney or flue, which however is seldom provided for gas-stoves. Moreover, all the bad gases are given off near the floor (in gas-stoves, though not in gas-lights), so as to mix with the whole of the air in the room; and any defect in the burning of any one of the numerous small jets leads to the production of an offensive odour. To lessen these evils, it has been recommended that the stove should have two or three concentric cylinders; that the heated air should be allowed to circulate between them; that there should be no opening at the top; that a flue of two inches diameter should be placed at about mid-height, to carry off vapour, dust, and deleterious gases; that there should be an increased amount of metallic and reflecting surfaces to receive the heat; that only the *radiative*, not the *ascensive*, heat should be allowed to combine with the air of the room; that the size of the stove ought to bear some well-ascertained proportion to the size of the room; that care should be taken not to overheat the stove, for fear of producing an empyreumatic odour; and that the gas-jets should never exceed three-quarters of an inch in height. If the flue be long enough to allow the stove to stand near the middle of the room, nearly all the heat will be rendered practically available. In a well-arranged gas-stove seven-eighths of all the heat may be economised. A more equable heat can be maintained by such a stove than by any mode of using coal or coke, on account of the jet-holes remaining constantly of the same size. So far as regards safety, the flue of a gas-stove is not so likely to be highly heated as that of other stoves. Whether such a flue could be made conformable to the decorations or furniture of a room, instead of being an eyesore, is a question worthy the attention of architects and upholsterers. In relation to economical use, it has been calculated that a gas-stove will boil one gallon of water by the expenditure of gas to the value of one farthing; while a pennyworth of gas will bake three quartern loaves or six pounds of meat. On this subject, the application of gas to cooking, see COOKING APPARATUS.

Warming by Heated Air.—In all the arrangements yet described, the stove or fire-place is in the room which is to be warmed, and its heating effects are calculated with respect to that room alone. A notable advance, carried to a great extent in the present day, is to have the fire in an outer or lower apartment, and to carry the heated air from thence in a pipe to the apartment to be heated. The Chinese have been beforehand with us in this matter. In the better class of Chinese houses there are hollow flues extending beneath the floors, and connected with a fire-place constructed either against the exterior wall of the apartment to be heated, or else in an inferior room adjoining. The flues are perforated with numerous holes, through which they give out the heated air and smoke to the whole of the under side of the flooring. This flooring consists of flat tiles or flag-stones nicely imbedded in cement, so as to prevent the escape of the smoke or heated air from the flues beneath into the room. After circulating beneath the tiled floor, the smoke escapes by a chimney into the open air. In this arrangement it is obvious that the apartment is warmed by the conduction of caloric from the warm tiled floor to the air of the room; and as this conduction proceeds slowly, the tiles retain heat enough to warm the room many hours after the fire has been extinguished.

Before the improved methods of warming factories came into use, Mr. Strutt, of Derby, devised a form of stove which, under various modifications, was called the "cockle stove," the "Derby stove," and the "Belper stove," for warming his cotton-factories. In these stoves the fire was contained in an iron receptacle, shaped sometimes cylindrically, sometimes rectangularly; and at a certain distance from it, encompassing it on every side, was a brick casing or envelope, so that a body of air existed between it and the fire-box. The fire-box had three openings to the exterior, one to introduce the fuel, one for an ash-pit and air-vent, and one for a chimney; the exterior envelope had two openings, wholly distinct from the others, one to carry off heated air to the various rooms of the factory, and another to admit a renewed supply of fresh air. Dr. Fyfe describes an arrangement adopted in a church, which may perhaps be taken as a fair example of a numerous class of instances. The body of the church is warmed by two stoves about four feet high, made of cast-metal, and shaped nearly like a bell. A square ash-pit, about a foot high, rests on four balls, and supports a fire-box or furnace. Concentric with this fire-place is an outer case; the space between the two containing the air which is to be warmed. The usual adjustments are provided for the introduction of fuel and of air to feed it, for the exit of smoke, for the entrance of fresh air to the air-chamber, and for the exit of the heated air to perform its wonted office. The air-tubes, communicating with the air-chamber of the stove, are conveyed along the lower edge of the gallery of the church; and small branch pipes opening from them at regular intervals give out a stream of hot air which mingles with the cold air of the building. The fires are lighted early on the Sunday morning. From this time till the congregation assembles the fires are constantly supplied with fuel, and a supply of heat is thus kept up sufficient to warm the whole interior of the church during the time of divine service. A stove such as this is likely to give a tainted and offensive character to the air, like the common German stoves, unless a rapid current be kept up. Hence a change has been occasionally introduced, by having the outer casing made of brickwork, instead of metal, and by making its dimensions much larger, an arrangement which heats the outer case less intensely, and provides a larger body of air heated to a lower temperature.

Very numerous varieties of the hot-air apparatus have been brought into use; but the principle on which they all act can readily be understood. When the nave and dome of St. Paul's cathedral were recently fitted up for Sunday evening services during the winter, six stoves, constructed on a plan devised by Mr. Goldsworthy Gurney, were placed in the crypt. Gratings admitted the heated air from these stoves into the body of the cathedral. The vitiated air escaped by openings at the top of the dome. Each stove was a cylinder, with radiating wings all round. It stood in a vessel of water. The hotter the stove, the more the water evaporated, so as to keep the air in a proper hygrometric state. The steam generated from this water also carried off the heat from the iron quickly, and thus aided in warming the building.

Warming by Steam.—The employment of steam-boilers in large establishments where steam-engines are worked, is one of the circumstances which have led to the very extensive adoption of the method of warming by steam. A marked difference is observable in the principle of this method, as compared with that of hot-air warming. The heated agent, that is, the steam, is not permitted to mingle with the air of the room which is to be warmed, but acts through the medium of the metallic tube which confines it, and which it raises to a temperature sufficient to warm the room, without imparting a burnt quality to the air.

The general arrangements of a steam-heating apparatus, as suggested by Mr. Scott Russell, are somewhat as follows:—At a convenient part of the building, and as low as possible, there is to be placed a close steam-boiler of the ordinary construction. From this boiler a small steam-pipe is to be carried to the part of the building which is to be warmed. This small pipe should be pretty thick, and carefully rolled round with a bandage of flannel to the thickness of a quarter of an inch, and the boiler should be wholly covered with bricks and plastered over to keep in the heat. This smaller steam-pipe should have an area of one square inch for every six gallons of water that the boiler can boil off in an hour. Pipes of a larger size are to be laid round the room above the floor; or under the floor, if apertures be left to allow a free circulation of warmed air to enter the room. Into these larger pipes the steam is to be conducted, and in them the steam will be condensed into water, giving out its heat to the colder air of the room which is in contact with the outside of these pipes. Small leaden or tin pipes must be provided, for the purpose of bringing back this condensed water into the boiler, for which movement a gentle slope is given to the pipes. The water thus returned, being again heated in the boiler and converted into steam, is again made to ascend and give out its caloric to the room which is to be warmed.

The efficacy of this mode of heating depends on the great capacity for heat which steam possesses, a capacity equal to 1000°; that is, a pound of water at 212° will absorb a thousand degrees of heat in becoming a pound of steam. Steam will thus communicate as much heat as a mass of red-hot iron; and it will have this advantage over the iron, that it can carry this heat to a distance without a similar loss, because the heat, being latent, will not be given out until it arrive at its destination and become condensed, when the whole of its 1000° will be usefully applied.

Tredgold, Mr. Scott Russell, Dr. Arnott, and other writers on this subject have given the results of their calculations as to the quantity of steam and steam-pipe thus required. Dr. Arnott, after taking into account the loss of heat through the thin glass of windows, through the thick walls of buildings, and through various openings and crevices, arrives at the following result:—In a winter day, with the external temperature at 10° below freezing, to maintain in an ordinary apartment the agreeable and healthful temperature of 60°, there must be of surface of steam-pipe, or other steam-vessel, heated to 200° (which is the average surface-temperature of vessels filled with steam of 212°), about one foot square for every six feet of single-glass window of usual thickness; as much for every 120 feet of wall, roof, and ceiling of ordinary material and thickness; and as much for every six cubic feet of hot air escaping per minute as ventilation, and replaced by cold air. A window with the usual accuracy of fitting is held to allow about 8 feet of air to pass by it in a minute; and there should be for ventilation at least 3 feet of air a minute for each person in the room. According to this view, the quantity of steam-pipe or vessel needed, under the temperatures supposed, for a room 16 feet square by 12 feet high, with two windows, each 7 feet by 3 feet, and with ventilation by them or otherwise at the rate of 16 cubic feet per minute, would be—

For	42 square feet of glass,	requiring	1 foot for 6	= 7
,,	1238 feet of wall, ceiling, &c.,	,,	1 foot for 120	= 10⅓
,,	16 feet per minute ventilation	,,	1 foot for 6	= 2⅔
				20

that is 20 feet of pipe 4 inches in diameter, or any other vessel having the same extent of surface.

Mr. Scott Russell's calculations had relation to the quantity of water and of fuel required, as well as that of the steam-pipe; and he arrives at the conclusion that a room containing 500 cubic feet of air, and exposing 400 feet of surface, may be maintained at a temperature of 20° above that of the air without—that is to say, at 60° in the inside of the room when the atmosphere is at 40° without—for a space of twelve hours, by the evaporation of two gallons of water, and at the expense of about three pounds of coal. This calculation rests on the maintenance of the required temperature so far as the room and its contents are concerned; but the change of the air requisite for a person living in the room disturbs the formula, and brings into it many new elements.

This mode of heating buildings is adopted to a large extent in Lancashire, Yorkshire, and Cheshire, in the steam-power factories. In the cotton-mills, woollen-mills, flax-mills, power-loom factories, dye-works, bleach-works, print-works, &c., the facilities for producing an uninterrupted supply of steam are so great, that the steam-heating system becomes by far the most economical that can be employed. Orrell's cotton-mill at Stockport may be taken as an exemplification of a large class of such buildings. This mill is situated on the banks of the Mersey, and occupies a ground area of 280 feet by 200 feet. It is six stories in height, and has several distinct apartments 280 feet in length each. All the preparatory processes are effected in the upper stories; while the weaving and finishing are conducted below; but all the rooms and galleries are alike heated by large steam-pipes, running the whole length of the rooms, and conveying steam from one end of the building, where the boilers are situated, which furnish not only this supply of steam, but also that required by four steam-engines employed in the mill. The steam is admitted to the heating-pipes in quantity proportionate to the coldness of the weather.

A very large structure at New York, presented to the city as a museum and lecture-room, and called the Union Building, affords a good example of the steam-heating system. There are no less than eight miles of small pipe arranged in the basement, filled with high-pressure steam. A fan-blower, twelve feet in diameter, sends a vast body of air rapidly through the pipe-rooms; and the air thus warmed finds its way into spaces beneath every floor. A hole of one inch diameter is made through the floor under every chair or seat in the lecture-hall, 2300 in number; up these holes warm air is sent in winter, and cold air in summer.

Warming by Hot Water.—The principle on which the hot-water method is founded is different from all the others which have passed under our notice. When a vessel of water is heated, the water does not become hot by the *conduction* of caloric from particle to particle, but from the ascent of heated particles from the bottom, where we suppose the heating agent to be applied, to the upper strata. This is proved from the circumstance that if heat be applied only to the surface of the water in a vessel, it is by extremely slow degrees that the lower strata becomes heated. Heat being applied to the bottom of a vessel, the lower strata of particles, becoming specifically lighter than before, ascend, while the colder particles at the surface descend to supply their place; and hence a series of ascending and descending currents is formed. Now, if, instead of having the, heated water only in a vessel, it ramify also through closed tubes connected with the vessel, the ascending and descending currents may be passed through different parts of a building, besides the room where the vessel itself may be placed. The heated water, rising to 212°, or to any temperature depending on the fire to which it is exposed, gives out heat to the metallic pipe through which it passes, and this pipe again communicates heat to the air of the room. Hence the operation of this method of warming depends on the circulating, or ascensive and descensive property of heated water, by which the portions of pipe farthest removed from the fire become as much heated as those in its immediate vicinity.

Where all the apartments to be warmed are on one level, an open boiler may be used; but where it is necessary to carry the pipes to different floors of a building, some of them much above the level of the boiler, the boiler must in that case of necessity be closed. When an open boiler is employed, a pipe branches out from the upper part of the side, extends horizontally through the rooms to be warmed (without in any case rising above the level of the water in the boiler), and returns again to the boiler, which it enters at a lower level than the other. Under this arrangement a current of heated water will flow from the boiler at the upper orifice, and, after traversing the tube, return to the lower orifice. A closed boiler is, however, more extensively useful, since it enables all the stories of a building to be warmed by one apparatus. The whole system, including both tubes and boiler, is filled with water at a valve at the highest point; and when heat is applied to the boiler, a circulation ensues which speedily causes the whole length of tubing to become hot. In this form of the apparatus the temperature of the water is kept down to a moderate pitch, in order to avoid danger; but in a modification of it, called the "high-pressure" method, the boiler consists of a coil of pipe forming part of the circulating pipe, and is capable of being safely heated to such a degree that the pressure of the water within equals 1000 lbs. on the square inch. The whole system of water circulation is brought to so high a temperature, that the metal of the pipes warms the air of a large building very speedily.

Many large and important buildings are warmed on one or other of these two hot-water systems—mostly on that with the closed boiler. The hot-water apparatus put up by Mr. Perkins in the British Museum, for warming the rooms formerly used by readers, suggested the plan which is adopted for warming the present magnificent reading-room. This room is warmed by three boilers, the furnaces of which consume their own smoke. Main pipes conduct the hot water from these boilers to smaller pipes, which bring it into the room, and the water then returns by other pipes to the same boilers. There is an air-shaft which reaches the full height of the building, having windows in it to admit fresh air. There is a fan, or blower, at the bottom of the shaft. Air is forced from the shaft through valves into arched brick chambers, whence it cannot return. This air is filtered through a wire sieve, and is then conveyed up into the reading-room—not to warm it, but to keep up a supply of pure air. The doors of the room are made double, insomuch that nearly all the air that enters it comes from this shaft. There are pipes under each table, and valves above the tables to admit warm or cold air according to the season of the year. The new Houses of Parliament are also warmed by a modification of the hot-water system.

Another large structure, the warming of which may be adduced as an example of this system, is St. George's Hall, at Liverpool. Furnaces and boilers send hot water through about a mile of 4-inch pipe. A fan, worked by a 10-horse power steam-engine, draws in the external air, and drives it past the hot-water pipes. The warmed air enters the halls and courts by apertures in the walls and floors. The temperature of the pipes rarely exceeds 90°. There are 120 fire-places and flues of various kinds; but there are no chimney-pots, and no smoke is made. There are open fire-places in many of the rooms, in which coal is used that has been partially burned, but not actually coked, previously. What little smoke there is escapes, together with the vitiated air, up flues at the four corners of the hall; these flues have curved deflectors outside, and louvres inside, to shield the ascending currents from eddies of wind. There are vast air-chambers between the ceiling of the hall and the outer roof, to carry off the respired air and the products of the combustion of the gas lights.

Ventilation.—There is an important, but often neglected circumstance attending the artifical warming of buildings: namely, that the amount of fresh air, requisite under any condition for animal respiration, must be more and more increased in proportion to the fuel burned in the room; or, more correctly, there must be one portion of air to feed combustion, and another portion to aid respiration. Now, under the common arrangements of an English apartment, the open fire-place and the tall chimney draw air so rapidly in that direction, that the whole body of air in the room becomes speedily changed, provided there be an average amount of open doors, windows, crevices, &c. to yield the supply. Until modern inquirers set themselves to solve these two questions, or others analogous to them—" How many cubic feet of air are requisite for the combustion of a pound of coal?" and, " How many cubic feet of air are respired by an average man in an hour?"—there were no means of determining the proper amount of air necessary to be supplied in a building where *close* stoves are used, or where the methods of warming by heated air, by steam, or by hot water are adopted.

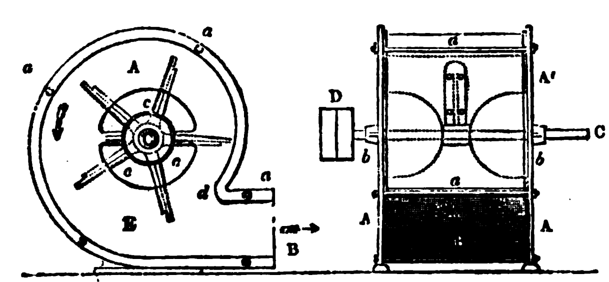
Dr. Arnott places the matter under the following form, so far as respiration alone is concerned:—" In respiration or breathing a man draws into his chest at one time about twenty cubic inches of air, and of that air a fifth part is oxygen; of which again there is converted into carbonic acid gas nearly a half. The carbonic acid, if afterwards inhaled, would be noxious to the individual. About fifteen inspirations are made in a minute, vitiating, therefore, three hundred cubic inches, or nearly one-sixth of a cubic foot, of atmospheric air, but which, mixing as it escapes with several times as much, renders unfit for respiration at least two cubic feet under common circumstances." Tredgold makes a very different estimate of the quantity of air respired in a minute, and introduces other items into his calculations. In the first place he reckons the average number of respirations per minute twenty, and the number of cubic inches of air inspired each time forty; so that the air directly vitiated amounts to eight hundred cubic inches per minute. He next takes into consideration the vapour mixed with the respired air, and the insensible perspiration always going on from the skin, and assumes that three cubic feet of air per minute will be requisite to remove these causes of impurity. Lastly, he supposes a room to contain persons in the evening, when candles, lamps, &c. are lighted, and in lieu of the air vitiated by this combustion he assumes (on what data does not clearly appear) that one-fourth of a cubic foot of fresh air per minute for every individual will be necessary to purify the atmosphere of the room on this ground. Taking all these results together, Tredgold comes to the conclusion, that when a room containing several persons is lighted to the average and customary degree, it will be necessary to supply four times as many cubic feet of fresh air per minute, as there are persons in the room; that is, four feet for each person.

This supposition, of four cubic feet of fresh air per minute for each individual in a room artificially lighted, of course involves the condition that an equal quantity of vitiated air per minute must be allowed to escape; and the inquiry naturally follows, How does this escape take place? Carbonic acid gas is heavier than atmospheric air; but there are three circumstances which render respired air rather lighter than the general air of a room: namely, the existence in it of nitrogen and vapour, both of less specific gravity than air, and the higher temperature of the respired air than the air of a room. From all these circumstances combined, it is found that respired air ascends to the upper part of the room; and it follows that the ceiling, or some neighbouring part, is the proper place for an outlet.

In the majority of buildings erected, there is no account whatever taken of the means for insuring ventilation. The fire-places are constructed, the windows fixed, and the doors hung without a thought being paid to the means of effecting a constant change of the air contained within the apartments. But it is probable that in most English rooms, provided as they are with tolerably large open fire-places, and with doors which are frequently opened, the ventilation is sufficiently complete. The fresh air enters the room by the open window, the lower part of the open door, and any crevices which may exist at a small height from the floor; while the vitiated and specifically lighter air escapes partly up the open fire-place and chimney, partly near the upper extremity of the open doors, and partly by crevices around the doors and windows generally. In crowded rooms, however, where the amount of vitiated breath bears a much larger ratio to the cubical contents, and where the doors are generally small compared with the height of the room, the impure air cannot escape by these means, and some arrangements must be made near the ceiling for the removal of the air. These methods are chiefly of two different kinds; the one by the use of a *revolving wheel* or *fan*, and the other by the action of a *chimney* or *tube*.

We sometimes see one of the upper panes of glass removed from a window, and its place supplied by a revolving fan, as a means of ventilating the appartment. This fan or wheel is provided with radii formed like the sails of a windmill, or the blades of a screw-propeller, so that any force which sets the wheel in motion will cause a current of air to pass obliquely between them. But in this case the fan is made to revolve merely by the impulse of the air itself, and is not under the control of the inmates of a building. A more complete exemplification is presented by the arrangement of the large cotton-mills of the North. A fan-wheel, fan-ventilator, or wind-fan (for by all these names the contrivance is known), being placed in any convenient position, is set in motion by the steam-engine of a factory, and by its rotation draws out the vitiated air from a series of rooms with great rapidity. The following is one variety of wind-fan used in the factories. It consists of two cast-iron end-plates, A A, having a central circular opening, *c c c*, from the circumference of which the outline of each plate enlarges spirally, the point nearest the centre being near *d*, and that farthest off being under E (*Fig.* 1). These two parallel plates are connected by bolts, *a a a*; a mantle of sheet-iron being previously inserted into grooves cast in the edges of the end-plates so as to enclose a cavity with an elongated outlet at B, to which a pipe is attached for

Fig. 1. Fig. 2.



carrying off the vitiated air in any direction. Within this cavity a shaft, C, revolves, in bearings, *b b*, placed centrally in the frame-plates, A A, and cast in the same piece. On this shaft a boss is wedged fast, bearing five flat arms, *c c c*, to which are riveted five flat plates or wires, of the shape shown between *a* and *a* (*Fig.* 2), having a semicircular piece cut out of them on each side, about the size of the end opening. On one end of the shaft, C, beyond the box-bearing, the loose-and-fast pulleys, D, are fitted for receiving the driving-band, and for turning the wings in the direction shown by the arrow. Thus the air is driven before them out of the end orifice, B, while it enters by the side openings at *c c c* (*Fig.* 1). By the centrifugal force of the revolving wings, the air is condensed towards their extremities, and makes its escape from the pressure through the orifice, B, while it is continually drawn in at the sides by its tendency to restore the equilibrium.

At the Reform Club-house a steam-engine works a revolving fan, capable of throwing 11,000 cubic feet of air per minute into a subterranean tunnel under the basement story; and the steam of condensation, from the small steam-engine which works the fan, supplies three cast-iron chests with the requisite heat for warming the whole building. A plan of ventilation has been adopted at the General Post-Office, in which the fan is used. The fan, worked by a steam-engine, draws fresh air down a shaft; the air is filtered through fine wire-gauze, and then sent up into all the rooms through pipes pierced with small holes.

The second mode of effecting ventilation, namely, by the use of a tube or chimney opening into the air from the upper part of an apartment, depends for its action on the ascensive power possessed by a lofty aërial column. As the " draught" of a furnace-chimney carries up the smoke, &c., more rapidly if the chimney be very lofty, so does a lofty chimney exceed a low one in carrying off vitiated air: and for the same reason, even if no chimney, properly so called, be provided, a lofty room, furnished with appropriate openings in its ceiling, will furnish a draught to carry off impure air more rapidly than a low room; and in many of our public buildings this arrangement is deemed sufficient.

Dr. Reid, when the temporary House of Commons was being prepared, introduced the system of an *artificial* draught. A circular shaft was built, 120 feet high, and from 8 to 11 feet in diameter. A large fire was maintained at the bottom of this shaft, which caused a powerful draught; and the draught sucked out all the vitiated air from the building, by a tunnel connecting the basement story with the shaft. The vitiated air in the House ascended by apertures into a space above the ceiling, and thence descended by pipes to the tunnel which conveyed it into the shaft. The experience derived from this arrangement led to many improvements in the ventilation of the present Houses. Mr. Goldsworthy Gurney here employs mechanism, by which fresh air is drawn in from some of the open courts, and after being filtered through a wire-gauze screen, is made to pass over steam-heated boxes; it is moistened by jets of spray, and enters the floors of both Houses through holes covered with horsehair cloth. In summer the air is cooled by the wet spray, and does not come into contact with any heated surfaces. Besides this mode of warming the two principal chambers, there are steam-pipes to various parts of the building. A large coke fire produces a draught, which drives the vitiated air out of openings near the ceiling.

The modern application of the two main principles of ventilation—the production of a current by a rotating fan, and by the ascensive force of heated air—are very varied. We can only notice a few of them. One of the simplest and best known is Dr. Arnott's chimney valve, for ventilating ordinary sitting-rooms. The air of a room, vitiated by breathing, smoking, &c., ascends, but cannot easily escape, because there are no openings near the ceiling; it contaminates all the air above the level of the chimney opening. A chimney valve corrects this. A hole is made from the side of the room into the chimney, near the ceiling. An iron door or valve is fixed in the opening, so nearly balanced as to open or close with great ease. When opened, the air in the upper half of the room enters by virtue of the draught in the warm chimney.

Lesure's method of ventilation, introduced in 1857, draws in cold air from the atmosphere, warms it, discharges it near the ceiling, and sends off the impure air from a room without mixing with the pure warm air. To effect this, a fire is lighted in a small stove or furnace; the products of combustion are carried at once through pipes into the chimney; and air enters through a hole in the outer wall, by a channel to a receptacle beneath the fire-place, into the interior of a casing surrounding the stove, but not in contact with any part of the fire or stove. The air becomes heated during its passage, and at the same time moistened by steam from a basin of water placed within the case; it escapes through an opening into the room, by *lateral* apertures parallel with the ceiling. As the upper parts become filled with warm air, the foul air finds its way to the fire and the chimney. In Wemyss's plan, introduced in 1859, an adjustable gridiron slide is fitted up in the wall near the ceiling, the inner side flush with the wall. The slide governs a passage into a metal chamber, fitted into a hole in the wall behind the slide. The chamber has two passages, one to admit the passage of fresh air, the other of foul. There is a ventilating fan at the outer end of the chamber. A cord easily moves the sliding valve, so as to make it open or close; and the chamber is made telescopic, to suit it to the thickness of the wall. M'Kinnel's patent ventilator, introduced in the same year, is intended to ventilate carriages and ships as well as houses and public buildings. It is planned to obviate certain evils arising from having the abduction tubes, to draw off foul air, near the roof or ceiling, and the induction tubes, for admitting fresh air, near the floor; in all such arrangements there is a cold current in the lower part of a room, productive of many inconveniences. To remedy this defect, Mr. M'Kinnel proceeds as follows. Two concentric tubes rise from the ceiling of the room to be ventilated, the inner one to a greater height than the outer. Both have access, in various ways, to the outer atmosphere. The vitiated air of the room escapes through the inner tube, while the pure air from without descends through the annular space between the two tubes. Both passages have wire gauze screens to ward off rain, soot, &c.; and valvular mechanism to regulate the currents. A lower apartment may be ventilated in a similar way, by having the ascending and descending flues in the outer walls, and a horizontal tube between the ceiling of the room and the floor of that next above it.

The ventilation of hospitals has received much attention in France and other parts of the Continent. Dr. Van Ecké introduced a system in Belgium, which has been copied in some of the French hospitals, on the recommendation of a commission presided over by Dr. Grassé. A stove called a *calorifère* is placed in the basement story. Air from the garden of the hospital descends a shaft, passes horizontally into the basement, and thence through the stove. The air warmed in the stove passes over a pan of water to imbibe moisture, and then ascends to the wards above. In warm weather the air from the garden is made to pass up into the wards without passing through the calorifère, by simply turning a regulating valve. Thus all the air admitted to the wards is derived from the garden. The warmed air enters each story at the centre of the floor, through small holes. Some of the warm air is in an *inner* tube, and ascends to the next highest story; and so on, up to the top range of rooms. The foul air rises from the four corners of each ward, up pipes to the loft, and then to a central drum or shaft. A small steam-engine works a fan to draw out the foul air more quickly. The smoke from the engine fire and from the calorifère is made to warm a mass of air carried up to the drying-room of the laundry. In England, Dr. Arnott has ventilated the York County Hospital in a peculiar way. There is an air-cylinder with a capacity of 125 cubic feet, moving up and down eight times in a minute, and connected with a beam having a central pivot. A column of water, 60 feet high, produces a pressure which forces air into the cylinder, and from the cylinder 2000 cubic feet per minute is forced into the building.

This subject, the ventilating of hospitals, is connected medically with a recent proposition by Dr. Stenhouse, to use charcoal as a ventilating filter for ships and sick rooms. The antiseptic properties of charcoal are well known. Dr. Stenhouse proposes to employ two sheets of wire-gauze, enclosing a thin layer of powdered charcoal; and to place this apparatus wherever foul air is likely to pass. In some cases it would be well to employ a ventilating fan, to force a passage of the air through the filter. Dr. Stenhouse remarks, that if a layer of coarsely-powdered charcoal were placed under the floors of kitchens and basement rooms, it might prevent, by a sort of filtration, the ascent of offensive sewer odours from beneath.

We may advert, lastly, to an inquiry made in 1859, at the instance of the General Board of Health, by a commission consisting of Mr. Fairbairn, Mr. Glaisher, and Mr. Wheatstone. Dr. Lyon Playfair was also appointed; but as he could not assist in the investigation, he did not sign the report. The inquiry was generally into the modes of warming and ventilating buildings. Experiments were made in the board-room of the General Board of Health, on the temperature of the air, walls, and floor, and on the hygrometric state of the air. Then at the Wellington Barracks, in different soldiers' rooms, heated by different kinds of open fires. Other experiments were made to determine the effect of duplicate panes of glass; and to determine the chemical and general state of the air.

Among the results at which the commissioners arrived were the following:—Smoke from almost all fires for warming rooms may be avoided. All fire-places ought to be constructed to prevent the formation of smoke at all. The ventilation of rooms ought *not* to be attempted by any peculiar form of grate; the grate ought to be devoted to the due burning of the fuel, leaving the ventilation to be achieved by other means. In all open fire-grates reflecting surfaces should be used, to increase the amount of heat radiated into the rooms. Chimney-flues should be of much smaller dimensions than is customary. The flue should not be situated in the outer wall of the house, so as to become chilled by the external air; it should be provided with a closing aperture, placed far back to increase the intensity of the combustion. Fire-brick linings should be used. Sunken ash pits and hidden ash should be provided. The grate is best placed when visible from the greatest number of places in the room; and the burning mass in it should be broad rather than deep. The commissioners agreed with Dr. Arnott, that the grate should not be so near the floor as is now customary in the better kind of houses.

The ventilation of mines is noticed under MINING.

To those who wish to study this subject in detail, we refer to the volumes on Warming and Ventilation by Tredgold, Hood, Richardson, Arnott, Sutton, Jebb, Lloyd, Burn, Bernan, Reid, and Perkins. The parliamentary Blue Books relating to the new Houses of Parliament, and to the proceedings of the Board of Health, also contain much information on the matter. A cheap, useful, and well-illustrated compendium of the whole subject will be found in Tomlinson's 'Treatise on Warming and Ventilation,' forming part of Weale's Rudimentary Series.

WARPING, a mode of producing a deposition of the earthy matter which is suspended in rivers. This causes a stirring of the water, which prevents the finer particles from being deposited. It is only necessary to produce a stagnation of the water for a few hours to have a copious deposit, leaving the water clear over it.

On the low flats which border the mouths of rivers, occasional inundations often cause a deposit which is highly fertilising. Thus the polders in Holland and Flanders have been formed of the mud of large rivers, and, being drained and kept dry by dykes and sluices, have formed the most fertile soils.

Warping is an imitation of this natural process:—A bank of earth is raised along the course of the river, so high that the floods cannot pass over it. In some part of this dyke is a sluice for the double purpose of letting in the water and letting it out at pleasure. When the tide is setting in and counteracting the natural current of the river, the sluice is opened and the water flows in by one or more channels made for the purpose of conveying it over the lower land, and covers it to the depth of high-water. The sluice is now shut, and the imprisoned water, becoming stagnant, deposits all the mud which it held suspended before. The sluice is opened at low-water, and the water is allowed to run out slowly; it leaves a coating of mud or sediment, which hardens and dries rapidly. This operation is repeated until a thickness of several inches of new soil has thus been warped, when it is allowed to dry, and is then ploughed and cultivated like any other field. It takes some time before any corn will grow on the new warp: at first it looks like barren mud; but it soon dries to a better texture, and ultimately produces very extraordinary crops. If its fertility decrease, and its surface is still below high-water mark, a slight warping, like the inundations of the Nile, immediately restores the fertility. What is curious, is the almost total absence of organic matter in the warp-soils, or rather, its intimate combination with the earths, so that it is not readily separated from them. It is neither like clay nor sand, but something between the two, soft to the touch, but not hardening into lumps when dry: neither very porous nor very retentive of moisture. The principal earth is silica, in a very fine state. It generally contains a portion of calcareous matter, probably from comminuted shells. It produces beans, oats, potatoes, and wheat in abundance, without any manure. It is admirably adapted to the growth of flax, especially when the warp is of a good depth.

The principal expense in warping is the sluice, and the canal through which the water is conducted over the land; the longer this latter is, the slower the process, as much warp is deposited in the canal, which has sometimes to be dug out. Accurate levels must be taken, or much expense may be incurred uselessly, if the water will not cover the surface to a sufficient depth.

It is of little consequence what the soil was originally; for a new soil is deposited over it. It should, however, not be too wet nor marshy: a porous soil is best, as this becomes the subsoil. All the inequalities which existed before, are obliterated by the warping, which fills up all cavities, and leaves a perfectly level surface. The fertility of warped land naturally leads to the conclusion that silica, in a very comminuted state, becomes best adapted for the roots of plants to shoot in, and to supply them regularly with the moisture necessary to their vegetation, and that their chief nourishment is derived from the atmosphere, since very little organic matter can be detected in warp, and few mineral substances besides the earths.

WARRANT. A warrant is a delegation by A, who has power or authority to do some act of that power or authority to B. Thus, a man having, of course, power to act in and manage his own concerns, may give a warrant of attorney to another to act or manage on his behalf. A sheriff who has power to arrest, &c., may give a warrant to his bailiff to act for him. A landlord who has power to make a distress upon his tenant, may give a warrant of distress to another for that purpose. A magistrate who has power to bring before him persons who are within his jurisdiction, and reasonably suspected of having committed certain offences, may make a warrant to others to do that act. A warrant, which should be in writing, ought to show the authority of the person who makes it, the act which is authorised to be done, the name or distinct description of the party authorised to execute it, and of the party against whom it is made; and in criminal cases the grounds upon which it is made. The sense in which the word "warrant" is more generally known relates to criminal matters. A justice of the peace has power within his own jurisdiction to apprehend a person whom he has seen commit an offence over which he has jurisdiction. He may also verbally direct, that is, give a verbal warrant to others to arrest such person in his own presence. He may also give a warrant in writing to apprehend in his absence such person, or any person against whom he has reasonable cause of suspicion from the information of others. The warrant should always be under the hand and seal of the justice. It should be addressed to the constable or constables, or to some private person by name, and the constable or the private person acting within the justice's jurisdiction will not be liable for any of the consequences of obeying a proper warrant. The warrant should name the person against whom it is directed. A warrant to apprehend all persons suspected, or all persons guilty, &c., is illegal; for the discretion as to pointing out the individual person to be apprehended is vested in the justice, not in the officer. The law as to this was expressly laid down by Lord Mansfield in the case of Money *v.* Leach, 3 Bur. 1742, where the warrant, being of the form called a general warrant, and which had been in use since the Revolution down to that time, directing the officers to apprehend the "authors, printers, and publishers" of the famous No. 45 of the 'North Briton,' was held to be illegal and void. The warrant should also set forth the time and place of making it, and the cause for which it is made. A warrant may be to bring the party before the justice granting it, or before any justice of the same county. A warrant of a justice of one county cannot be executed in another until it has been backed, that is, signed by some justice in that other county, and the same provision has been also enacted with respect to warrants granted in any one of the three kingdoms, and requiring to be executed in any other. But a warrant granted by one of the judges of the Court of Queen's Bench is tested in England, and may be executed in any part of the kingdom. A warrant is in force until it has been executed, if the justice granting it be still alive. An officer to whom it is addressed is indictable if he neglects or refuses to act upon it. He is justified in apprehending the party at any time, and in breaking open the doors of a house, but he ought first to make known to those within the cause of his coming, his authority, and to request their assistance. After the party is apprehended, the officer ought forthwith to carry him wherever he is directed by the warrant authorising the apprehension. Much of what has been said as to a warrant of apprehension is equally applicable to a Warrant of Commitment, which is the document by which a justice authorises a commitment of a party to prison, either to suffer a summary punishment or to await his trial. The same matters are essential as to showing the authority, the parties, the cause, and the purpose of the warrant, and these latter should appear distinctly, be lawful, and not be in the disjunctive. A Search Warrant is a document which authorises a search to be made for stolen goods.

A Warrant of Attorney is an authority by which a man authorises another to do an act for him, on his behalf, or as his agent or deputy. [LETTER OR POWER OF ATTORNEY.] But the term is most commonly applied to cases where a party executes an instrument of that name authorising another to confess judgment against him in an action for a certain amount named in the warrant of attorney. It is generally given as a security by one who is, or is about to become, the debtor of another. The advantage of it is, that, by putting it into effect, the creditor obtains a judgment against his debtor at once, and has all the advantages of a judgment creditor, without the risk, delay, and expense of an action. There is frequently a condition attached, that it shall be defeated and become void upon the making of certain payments, or the doing of certain acts. In all such cases it is necessary that the defeasance, or condition, shall be written on the same paper or parchment as the warrant of attorney, and a copy of the whole filed in the Court of Queen's Bench within twenty-one days after the execution. Otherwise, in case of bankruptcy or insolvency of the party making the warrant of attorney, it will be void as against his assignees.

WARRANT OFFICERS are a class of important subordinate officers in the Royal Navy. They are divided into three grades,—gunners, boatswains, and carpenters—and each grade into three classes. We have already explained the duties of a gunner [GUNNER, NAVAL], and of a boatswain [BOATSWAIN]. The duties of a carpenter are multifarious and onerous. He has the general charge of the ship's hull and spars, &c., and is supposed to be an able shipwright, and a well-informed mechanic. The heaving down and repairing (by shifting part of the keel) of H.M.S. Formidable of 80 guns at Malta, some years since, under the suggestion and directions of a carpenter's mate, which elicited the special thanks of the Board of Admiralty, may be quoted as an instance of the nature of what is at times required of those who bear the inappropriate designation of ship-carpenter, as well as of the talent and resources to be found amongst them.

WARRANTY. 1. The doctrine of *warranty of lands* was formerly one of the most important parts of legal learning, but the effect of warranties having been gradually reduced within very small compass, the subject has now become of little practical use; still it is necessary for those who would properly understand the English law of real property to pay some attention to this difficult subject.

Warranty existed in the civil law, and was defined to be the obligation of the seller to put a stop to the eviction and other troubles which the buyer may sustain in the property purchased. By eviction is meant the loss of either the whole or a part of the property by reason of the right which another has to it. The other troubles referred to are those which, without affecting the property of the thing sold, diminish the beneficial interest of the purchaser, such as a claim to a usufruct, or a rent issuing out of the lands. This warranty was either *in law*, being that security which every seller is bound to give to a purchaser for the maintenance of his title to the property sold, though no stipulation to that effect was made at the time of the sale; or *in deed*, being that kind of particular warranty on which the seller and buyer agree. (Domat., l. 1, t. 2, s. 10.)

Warranty of lands in the English law is of feudal origin, and is derived from the obligation of the lord to defend his tenant's title against all claimants. If the tenant was evicted, the lord was bound to make him a recompense by giving him other lands of equal value. Every tenant holding of his lord time out of mind, by what was termed *homage ancestral*, was entitled to this warranty. The statute of the 18th of Edward I., commonly called the statute of Quia Emptores, which prohibited the practice of subinfeudation, and authorised the free alienation of property, put an end to the homage ancestral, and consequently to the implied warranty annexed to it. To avoid the effect of this, when the lord aliened, the tenants, before they attorned to the new lord, required a new warranty from him; and when the tenant aliened, it was with an express clause of warranty from himself. These express warranties were introduced even prior to the statute of Quia Emptores, in order to evade the strictness of the feudal law as to non-alienation without the consent of the heir; for though he might, on the death of his ancestor, have entered upon any lands aliened without his consent, the covenant of warranty descending upon the heir operated as a confirmation of the title of the grantee by obliging the heir who evicted him to yield the grantee a recompense in lands of equal value. This doctrine, it is said, was founded on the supposition that the ancestor would not wantonly disinherit his heir, who therefore was presumed to have received a recompense either in land or money which had purchased land, and that this equivalent descended to the heir, together with the ancestor's warranty.

This doctrine of warranty was the foundation of the assurance by way of common recovery [RECOVERY]; but the use of warranties in conveyances had long been superseded in practice before they were practically abolished by the statute 3 & 4 Wm. IV., c. 27 & 74.

All the learning upon this subject will be found in 'Coke upon Littleton,' with Hargrave and Butler's notes.

2. *Warranty of things personal.*—By the civil law an implied warranty as to the vendor's title was annexed to every sale, and in our law also a purchaser of goods and chattels may have satisfaction from the seller, who sells them *as his own* and whose title proves deficient. But the vendor is not bound to answer for the quality of the wares purchased (except in the case of articles of food, for human consumption), unless

he expressly warrants them to be sound and good, or unless he knew them to be otherwise, and has used art to disguise them, or has misrepresented them to the buyer.

No particular form of words is necessary to constitute a warranty, and a bare representation or description of the quality may amount to a warranty if there be nothing to negative such an understanding. The custom of any particular trade may establish an implied warranty between parties transacting business therein, it being presumed that the dealings of the parties were regulated by the custom in the absence of evidence to the contrary; but when there is express warranty, it cannot be affected by the custom of the trade. A sale of goods by sample is in effect a sale by warranty. A promise or warranty that the goods sold shall be of a merchantable quality is implied when the vendee had not at the time of the sale an opportunity of inspecting them, and when of course the general maxim of *caveat emptor* cannot apply. Also it seems that when a commodity is sold for a particular purpose, the seller must be understood to warrant it reasonably fit and proper for such a purpose, though at the time of sale the purchaser had an opportunity of inspection. Where there is an express warranty, written or, it seems, even verbal, the vendee is not at liberty to avail himself of representations not embodied in the contract and made by the vendor without fraud. A general warranty will not extend to defects that are plain and obvious to the senses, and require no skill to detect, it being presumed that the purchaser knew of and bought subject to them. It seems to be settled that when goods are sold expressly "with all faults," the seller is not liable in respect of latent defects, though he knew of them, unless some artifice be practised to prevent the buyer from discovering them; but even in the case of a sale with all faults, the vendor will still be liable on an express warranty against a particular defect. It has been said that there cannot be a warranty against future defects, but there seems to be no good foundation for the doctrine. It seems that a warranty ought to be given during the treaty for sale or at least before it is substantially completed, and that a warranty given after the completion of a sale is not binding for want of consideration. It has been decided that in actions upon warranty it is not necessary to offer to return the goods before bringing the action, nor even to give notice of the breach of warranty to the seller, though of course the not having done so would be a suspicious circumstance in the plaintiff's case. If there has been no offer to return the goods, the measure of damages will of course be the difference between the sum given and the real value, as ascertained either by sale or estimation. If the warranty be accompanied by an express condition to take back the goods, if found defective, and return the price, the buyer ought to return the goods within a reasonable time in order to maintain his action: and if, after an offer is made to do so, the seller refuse to receive them, they remain at his own risk.

There are certain rules which have been laid down with respect to sales of horses, one of the most common subjects of actions on warranty. The fact that what is termed a *sound* price is given for a horse, does not imply any warrant of its soundness. If at the time of the sale the horse has any disease, or has met with any accident which either does, or in its progress or results will diminish the usefulness of the animal, such a horse is unsound, and, therefore, a cough or temporary lameness which, though it may be curable and not permanently injurious, diminishes his present usefulness, is unsoundness. So any organic defect is unsoundness, and, therefore, a nerved horse cannot be considered sound. Roaring is unsoundness if it proceed from disease or organic defect; but crib-biting, it seems, does not amount to unsoundness, though it is within a warranty that a horse was free from vice. A warranty of soundness is broken if the disease or defect existed at the time of the sale, though it could not then be detected, and did not appear till some time afterwards. The question of the soundness or unsoundness of horses is one peculiarly within the province of a jury to determine, and, therefore, a court will not set aside a verdict on account of the mere preponderance of contrary evidence, nor on the ground of any peculiarity in the nature of the unsoundness proved.

WARREN. A Free Warren is a franchise which gives a right to have and keep certain wild beasts and fowls, called game, within the precincts of a manor, or any other place of known extent, whereby the owner of the franchise has a property in the game, and a right to exclude all other persons from hunting or taking it. It is laid down by Blackstone, that originally the right of taking and destroying game belonged exclusively to the king, and it is certain that this franchise, like that of a chace or park, must either be derived from a royal grant, or from prescription, which supposes a grant. The law is thus settled in the Case of Monopolies, 11 'Rep.' 87, b.

It does not appear that the crown ever had the right of granting free warren to one person over the lands of another, though such a right might be enjoyed by prescription. The right of free warren over the land of another might also arise under other circumstances, as when a man, having free warren over certain lands, aliened them, reserving the warren. (8 'Rep.' 108.)

A warren may lie open, and there is no necessity of enclosing it, as there is of a park. (4 'Inst.' 318.) The beasts of warren appear to be only hares and rabbits; and the fowls of warren are partridges and pheasants, though some add quails, woodcocks, and water-fowl. ('Terms de la Ley,' 589.) The grantee of free warren acquired thereby the right to appoint a person to watch over and preserve the game, called a warrener, who is justified in killing dogs, polecats, or other vermin which he finds disturbing or destroying the game (Cro. Jac. 45), and by 21 Edw. I., s. 2, entitled *De Malefactoribus*, every forester, parker, or warrener was authorised to kill persons trespassing in forests, parks, or warrens, who resisted and refused to render themselves.

The franchise of free warren has nearly fallen into disuse since the enactment of the modern statutes with respect to game.

WARREN, FREE. [WARREN.]

WARTS, the name of small tumours or excrescences which occur on the cuticle. Like all other epidermoid tumours, they are unorganised in their origin and course. They are generally of a conical form, embrace only a small extent of surface, are hard, insensible, and in colour are usually darker than the surrounding surface. In structure they have a radiated character. Their growth is slow, and they derive their nutriment from the cutis over which they lie. The parts of the body on which these excrescences most frequently occur are the hands and face, although they are by no means confined to these localities. They are of an innocent character, and produce no ill consequences, except by pressure, when they occur in such parts as between the fingers and toes or on the eyelids.

When stimulated strongly, they generally get smaller or disappear altogether. Hence the best mode of treatment is the application of stimulants. It is however a curious fact that they often disappear under the use of the simplest remedies, when more violent ones have failed to affect them. The most effectual remedy is cutting them away. When this may be objected to, the caustic applications recommended are nitrate of silver, strong acetic acid, muriated tincture of iron, or a powder composed of subacetate of copper and sabine in equal parts, or the application of a hair-pencil dipped in sulphuric or nitric acid.

The thin integuments situated near the anus are often found to be the seat of excrescences having the character of warts. They are of all sizes, from a pea to an orange. When small, they may be removed by the application of the stimulants recommended above; and when large, they should be cut away with the knife.

WASHING-MACHINES were originally employed in connection with textile manufactures; but the Americans have effected much towards rendering them also applicable to domestic use.

In the bobbin-net district around Nottingham, washing-machines are employed in great variety; for the delicacy of the fabric renders much more care necessary than in the washing of the woven goods made in Lancashire and the neighbouring counties. The dash-wheel, in which centrifugal force is employed to wash and then to dry the goods, is much used, requiring steam power to work it. A kind of thumping machine called a *dolly* is sometimes employed; but it is almost too coarse in its action for delicate fabrics; and so likewise are those machines in which fluted rollers work in contact. One mode adopted is that of forcing a current of air through the ley or washing liquid, and thus blowing out the dirt from the cloth without any rubbing. To effect this, a vessel is provided to contain the goods; a pipe connects it with a blowing apparatus, which may consist of any kind of fan or wind-producer. The goods, slightly soaped, are steeped in soft water at a temperature of about 90° Fahr.; the vessel is covered over, and a current of air sent in from the blowing apparatus.

Mr. Cottrill's patent relates to a sort of triangular prism, two of which rotate on horizontal axes in a direction opposite to that in which yarns or woven goods are drawn through a tank; the angles of the prisms strike the goods as they pass, and thus wash them. In another machine by the same inventor, instead of prisms, two arms or cranks are employed, vibrating about an axis. Many washing-machines are modifications of the cylindrical dash-wheels described under BLEACHING, and call for no detailed notice here. Some of the dash-wheels now used in the dye works, bleach works, and print works of Lancashire and Glasgow will wash 4000 pieces in a day. At the St. Nicholas Hotel in New York, washing is conducted for the visitors on a scale of surprising magnitude and completeness. A cylinder is half filled with soap and water; three or four hundred garments of linen and cotton are thrown in; the cylinder is made to revolve by a steam-engine; steam is admitted to the bottom of the cylinder, rises through the water, and escapes at the top. In doing so, the garments in the cylinder are forcibly driven up, and then a current of steam in the opposite direction forces them down again. By this process, repeated several times, and combined with the rotatory movement of the cylinder, the garments are very quickly washed. They are then gently dried in a centrifugal machine [DRYING-MACHINES], and finally exposed to a current of hot air. The linen is said in this way to be washed in ten minutes and dried in seven, very cheaply, and without injury to the material. The Hampstead Board of Guardians adopted, in 1860, a new washing-machine, consisting chiefly of two ridged boards; the linen is pressed between the boards, slightly rubbed, turned over, slightly rubbed again, and so on about fifty times, the soapy water passing through the pores every time; no hand-rubbing is needed. After several weeks' trial, it was found that five shillings' worth of fuel, soap, and soda sufficed for the washing of one thousand articles.

Among the many curious American washing-machines recently introduced, one is the *ball* machine, in which a number of wooden balls are set in motion by a handle worked by a lever. The linen is so placed that the balls rub against it and against each other, and it is thus washed without the hand being applied to it. The credit claimed for this machine is, that the pressure being slight and temporary, fine fabrics are not injured; moreover, "it tears off no buttons." Another American machine has wooden contrivances intended to represent, in action if not in appearance, the knuckles of a laundress; the theory of the machine is, that the proper result can be obtained without wearing away human fingers.

WASTE, says Coke (Co. Litt., 53), "vastum dicitur a vastando, of wasting and depopulating;" but he gives no further definition. The notion of waste seems to be when a tenant for years, by the courtesy, by dower, or for life, so deals with land, or such things as are attached to the soil, as to destroy them or greatly damage them. Accordingly, the old action of waste lay against such tenants by him who had the immediate estate of inheritance.

Waste is either *voluntary*, which is an act of commission, or *permissive*, which is a matter of omission only. Voluntary waste chiefly consists in felling timber-trees, pulling down houses, or permanently altering any part of a house, in opening new mines or quarries, in changing the course of husbandry, and in the destruction of heir-looms. Permissive waste consists chiefly in allowing the buildings upon an estate to go to decay. It is a general rule that the waste which arises from the act of God is excuseable, as if a house falls in consequence of a tempest. But if the destruction of the house by the tempest has been owing to its being out of repair, the tenant is guilty of waste; and so he will be if he do not repair a house which has been uncovered or damaged only by a tempest. In the same manner, if the banks of a river, while in a state of proper repair, are destroyed by a sudden flood, the tenant is not answerable. (1 'Inst.,' 53 a, b.) The rule applies also to the case of a house burnt down by accident. But in these and all similar cases the tenant will still be bound to repair or rebuild, if he has entered into a general covenant to repair.

Tenants in tail, as they have estates of inheritance, are entitled to commit every kind of waste; but this power continues and can be exercised only during the life of the tenant in tail. When it is said that a tenant in tail may commit every kind of waste, the meaning is that he can do those acts to the land which tenants who have not an estate of inheritance cannot do. A mortgagee in fee in possession has a right at law to commit any kind of waste, being then considered as the absolute owner of the inheritance; but he will be restrained by a court of equity, which will direct an account of timber cut down, and order it to be applied in reduction of the mortgage debt. (2 Vern. 392.) Copyholders cannot, unless there be a special custom to warrant it, commit any kind of waste, and every species of waste not warranted by the custom of the manor operates as a forfeiture of the copyhold. (13 'Rep.,' 68.)

The original remedy for waste was that under the statute of Marlbridge, 52 Henry III., c. 24, which gave to the owner of the inheritance an action of waste against the tenant for life, in which he was entitled to recover full damages for the waste committed. But as this remedy was often found inadequate, it was enacted by the statute of Gloucester, 6 Edw. I., c. 5, that the place wasted should be recovered, together with treble damages for the injury done to the inheritance. No person was entitled to an action of waste against the tenant for life under these statutes except him who had the estate of inheritance immediately expectant on the determination of the estate for life; so that if there were an existing estate of freehold interposed between the estate for life and that of inheritance, the right of action was suspended. (1 'Inst.,' 53, b.) The action of waste had long given way to the much more expeditious and easy remedy by an action of trespass on the case in the nature of waste, which may be brought by the person in reversion or remainder for life or for years, as well as in fee, and in which the plaintiff is entitled to costs, which he could not have in an action of waste (2 Saund., 252, n. 7); and the writ of waste is now finally abolished by the 3 & 4 Wm. IV., c. 27, s. 36. It seems that there was formerly no remedy for mere permissive waste after the death of the tenant, though if the estate of the tenant was benefited by the injury inflicted, as if money was derived to it from the sale of trees cut down, an action for the value of the property might have been sustained against the executor. (Cowp. 376.) Now, however, by the 3 & 4 Wm. IV., c. 52, s. 2, remedies by action of trespass or trespass on the case are given against the executors of any deceased person for any wrong committed by him in his lifetime against the real or personal property of another within six months of his death, provided the action be brought within six months after the personal representatives have taken upon themselves the administration of the estate.

But the most complete remedy in cases of waste is that in the Court of Chancery, which, upon application to it by bill, will not only direct an account to be taken and satisfaction to be made for the damage done, but will interpose by way of injunction to restrain the commission of future waste. A court of equity will grant its assistance against the commission of waste wherever the case appears to require it, even though the plaintiff is not in a condition to maintain an action at law. The court will also grant an injunction against waste *pendente lite*; and in such cases it is not necessary that the plaintiff should wait till waste is actually committed; it is sufficient if an intention to commit waste appears, or if the defendant insists upon his right to do so.

It has long been usual, when estates for life are expressly limited, to insert a clause declaring that the tenant shall hold the lands "without impeachment of waste." These words were originally intended merely to exempt the tenant from the penalties of the statute of Marlbridge, though it has long been settled that they enable him to cut down timber and to convert it to his own use; but he may be restrained in equity from committing malicious waste so as to destroy the estate, or cutting down timber which serves for shelter or ornament to a mansion-house, or timber unfit to be felled. This is what is called the doctrine of Equitable Waste. The privileges of the tenant for life under the words "without impeachment of waste" are annexed in privity to his estate, and determine with it. Thus it seems that if a lease were made to one for the life of another without impeachment of waste, with remainder to him for his own life, he would become punishable for waste, the first estate being merged in the second. (11 'Rep.,' 83, b.)

Ecclesiastical persons, who hold lands in right of a church, are disabled from committing waste, though, like other tenants for life, they have the right to take from the land materials for necessary repairs. They may not only fell timber and dig stones for that purpose, but have even been allowed to sell timber or stone, when the money was to be applied in repairs; also, though they cannot open mines, they may work those already open. (Amb. 176.) Ecclesiastical persons may be proceeded against for waste in the civil as well as the ecclesiastical courts, as an action will lie against them for dilapidations, and may be brought by the successor to a benefice either against his predecessor or his personal representatives. And the Court of Chancery will grant an injunction against any ecclesiastical person whatsoever to stay waste in cutting down timber, pulling down houses, or opening quarries or mines on the glebe. An injunction has, indeed, been granted against waste by the widow of a rector during the vacancy of the living. (2 Bro. cc. 5, 62.) By the 56 Geo. III. c. 52, the incumbents of benefices are enabled to cut down timber on the glebe-lands for the purposes of the statute (55 Geo. III.) enabling them to exchange their parsonage-houses or glebe-lands.

Tenants in tail and tenants in fee have the inheritance in the land, and they are the real owners. Those who have less estates are in the situation of the Roman Usufructuarius. [USUFRUCTUS.]

WASTE LAND. [BURREN LAND.]

WATCH. [HOROLOGY.]

WATCH AND WARD is the ancient provision for the maintenance of the public peace and of property in towns: *watching* relates to the night, *ward* to the day.

The duty of keeping watch and ward no doubt prevailed in Anglo-Saxon times, although it is usually stated to have been imposed by the statute of Winchester (13 Edward I., c. 4). The words of the statute are:—"And henceforth it is commanded that watches be made as formerly they were accustomed to be; that is to say, from Ascension-day to Michaelmas-day, in every city, by six men at each gate, in every borough by twelve men, in every open town by six or four men, according to the number of inhabitants; and that they watch all the night from sunset to sunrise. And if any stranger pass by them, he shall be arrested until morning; and if [no cause of] suspicion be found, he shall go quit." Then follow provisions for delivering him to the sheriff if the watch find cause of suspicion, and for raising the hue-and-cry on him from town to town if he escape. A subsequent act (5 Edward III., c. 14) extends to the day these powers of arresting suspected persons; and in reciting the previous act, this later statute treats it as applying to the country generally; but seems to limit the power of arrest to constables. The statute 5 Henry IV., c. 3, extends to the sea-coast the provisions of the statute of Winchester, and (like it) seems only to revive an ancient custom which had fallen into disuse.

The duty of keeping watch is imposed upon every inhabitant of a town in turn, at the call of the constable. The watchman must be suitably armed, and women or infirm persons must find substitutes. Not to keep watch in his turn, or not to find a sufficient substitute, is an offence for which the party may be indicted at the sessions of the peace, and may be punished by fine and otherwise.

Another class of watchmen, having like powers and duties to the former, is that appointed for the preservation of the peace. [CONSTABLE, POLICE.]

WATER (HO). (*Chemistry.*) Water, as it occurs in nature, has already been treated of in the NATURAL HISTORY DIVISION of this Cyclopædia; its physical properties in the three states of gas [STEAM; VAPOUR, OPALESCENT]; liquid [WATER, following article]; and solid [ICE]; have also been separately described in the present Division; so that it is now only necessary to consider it from what may be termed a chemical point of view.

Water is a chemical combination of the two elements oxygen and hydrogen. When a jet of hydrogen is burnt in an atmosphere of oxygen, or *vice versâ*, water is formed, and condenses on and trickles down any cool surface that may be near. A compound of hydrogen, when burned in the air, also eliminates that element in the form of aqueous vapour. A cold plate held for a few moments in or over the flame of a candle, oil-lamp, or gas-jet, is soon bedewed with moisture, which may be collected and proved to be water. Conversely, water may be made to yield up its elements. Exposed to a temperature above the melting point of platinum, it is resolved into its elements. Passed in the state of steam over red-hot iron, it parts with its oxygen to the metal, and its hydrogen is evolved as gas. Submitted to the action of the electric force, its two constituents are respectively evolved, and may be collected in quantity, from the two terminals of the battery; that from the negative pole, hydrogen, occupying twice the bulk of that from the positive pole, oxygen. A given bulk of hydrogen being only one-sixteenth the weight of an equal bulk of oxygen, it follows from the fact just mentioned that the respective proportions by weight of hydrogen and oxygen in water are one of the former to eight of the latter. Many other experiments might be described demonstrating both synthetically and analytically that water is the protoxide of hydrogen; that it contains one equivalent of hydrogen ($H = 1$) and one equivalent of oxygen ($O = 8$).

Water acts upon other bodies with four different degrees of intensity. Chemically, it unites to form, first, *hydrates;* in these the water is most intimately combined, and can only be separated in many cases by a temperature approaching redness: slaked lime is such a hydrate. Secondly, water combines with crystalline bodies, as seen in sulphate of magnesia, which contains six equivalents ($MgO, SO_3, HO + 6Aq.$), carbonate of soda, which has ten ($NaO, CO_2 + 10\ Aq.$), &c. This water is generally termed *water of crystallisation*, to distinguish it from the former, or *water of hydration*. Thirdly, water, acting chemico-mechanically, is a more or less powerful solvent for most bodies. On its uses in this respect it is scarcely necessary to enlarge. Its capacity for dissolving oxygen and carbonic acid enables it to support the life of fishes and sub-aquatic plants, and without which it would be unpleasant and mawkish as a beverage. Chlorine, sulphurous acid, and sulphuretted hydrogen gases are re-agents whose chemical value would be much restricted if they could not be obtained in the state of solution in water. Its property of dissolving solids enables it to be used as a vehicle for the conveyance of organic and inorganic matter to the tissues of animals and plants, and as an indispensable medium in nearly all arts and manufactures. When water has taken up as much of a body as it can dissolve, it is said to be saturated; and if at this point some of it be removed by spontaneous or artificial evaporation, the dissolved solid is again deposited, either in an amorphous state or in beautiful geometrical forms called *crystals*. The fourth action of water is purely mechanical; it is seen in the gradual wearing away of solid insoluble matter, and is largely concerned in the formation of the channels of streams, &c.

From what has been said regarding the solvent powers of water, both upon gaseous and solid matter, it is obvious that pure water is never met with in nature. If we trace water from the moment when it assumes the liquid condition to the time when it finally makes its way to the ocean, we find it gradually accumulating impurities of various kinds. At the moment of condensation it exerts its solvent power and absorbs gases from the air. When it falls to the earth it percolates through strata more or less soluble and more or less pervious to water, and dissolves, according to circumstances, various quantities of the solid matters which it there meets with. If the surface of the earth where it falls be very hard and insoluble, the water becomes only very slightly contaminated with solid matter. Loch Katrine, for instance, contains only 2¼ grains of solid matter in a gallon of the water; the Dee, at Aberdeen, contains 4 grains; and the Tay, at Perth, contains 5 grains. Frequently, also, when the strata through which the water percolates are pervious, supposing they are at the same time comparatively insoluble, very little solid matter gets into solution. Such is the case with the green sand formation, where the water is very free from mineral matters of a solid kind. Generally, however, water meets with more constituents than those just indicated, and the quantity varies from 5 to 50 grains per gallon. When the latter quantity is exceeded, the water frequently acquires a taste, and may be regarded as *abnormal* water. The water of the ocean is in this condition. The rivers which flow into the sea carry with them matters dissolved, and leave them there, for the solid matters are not carried back by evaporation. Therefore, the sea contains a larger proportion of these substances than is contained in the water of rivers; and we get this effect on a still more exaggerated scale when, in hot climates, rivers empty themselves into lakes which have no outlet. This is the case with the Dead Sea. The river Jordan, which is constantly flowing into it, contains 75 grains of solid matter in the gallon; and none of this matter is returned again into the atmosphere, or no practical amount: therefore, there is a constant accumulation of the saline matters going on there, and in this Dead Sea we have no less than 2600 grains of solid constituents to the gallon of water. The same effect takes place in a lake in the north of Australia, discovered a few months ago. It is highly charged with saline matters, and is known to possess no outlet. There is a similar instance in the celebrated Elton Lake in Russia, which is 11 miles long, 8 miles broad, and on an average only 15 inches deep. In summer it appears to be covered with snow, in consequence of the evaporation of the water forming a crust of saline matter. No less than 200,000 tons of salt are yearly extracted from this lake.

In addition to these mineral and saline constituents, water also dissolves certain organic substances, so that we may classify the impurities contained in water as *mechanical*, or those that are merely suspended in the water mechanically, and not dissolved, *saline* impurities, and *organic* impurities. We will consider these separately.

First, as regards *mechanical* impurities. They consist, in the first place, of mineral substances which are usually innocuous, and have no effect upon the drinker. Next we have vegetable or animal matters, which are generally of an exceedingly noxious character; and then we have living organisms, which perhaps attract the attention of the water-drinker more than the other substances contained in the water. These organisms consist of animalcula and animals of a larger size. We have in the New River water twenty-six species of these animals, in the Thames water twenty-nine species; twenty-four species have been detected in the West Middlesex water, and so on, varying in number in different waters. It has been stated that some of these little animals are very deleterious to health, but this has not been at all clearly made out. Looked at from a chemical point of view, they are exceedingly useful in the water, especially if it be at all impure. Each little animal is a small furnace, which occupies itself in consuming the organic matter, and converting it into its ultimate inorganic compounds—carbonic acid, water, and ammonia, or nitric acid. They feed upon the dead organic matter in the water, and remove it far more readily than it would be removed by the oxidising property of the air. It is, of course, desirable to remove them before the water is used as a beverage, and this can be done by filtration. The animals themselves cannot pass through the filter, but the ova can. This fact has an important bearing upon the storing up of water, and will be alluded to again presently.

We come now to the *saline* impurities. The nature of these will be readily seen by an inspection of the following diagram.

SOLID CONSTITUENTS CONTAINED IN ONE GALLON OF VARIOUS WATERS SUPPLIED TO TOWNS.

The Farnham water is from the green sand: it has been suggested as a supply for London. That from Loch Katrine is perhaps purer than the water supplied to any town in the United Kingdom. The Manchester water can always be drawn from the pipes, the supply being continuous, instead of intermittent, and this is now the case in nearly all large towns except London.

Some of these constituents are termed *earthy salts*, and some of them are *alkaline salts*. Carbonate of lime, sulphate of lime, and nitrate of lime, carbonate of magnesia, and, occasionally, chloride of calcium and chloride of magnesium, are salts of the alkaline earths; others are alkaline salts.

The property of "hardness" in water is due to the first of these classes of constituents—to the alkaline earths—the lime and magnesia salts present in the water. Hard water may be defined as a water capable of decomposing a considerable quantity of soap, and forming with the soap an insoluble precipitate. These salts of lime combine with the stearic acid, and form an insoluble stearate of lime, the curdy matter which is produced by washing in such waters. This stearate of lime is of a greasy nature; it is precipitated in, and fills up, the pores of the skin; no amount of washing in hard water can thoroughly remove it; and hence the skin can only be perfectly cleansed in rain-water, in softened hard water, or, in fact, in water that does not contain soap-decomposing matters.

Of the above constituents, the carbonates of lime and magnesia are the only ones not soluble in pure water: they are kept in solution by free carbonic acid [CALCIUM, *Carbonate of*]. The amount of hardness possessed by waters varies considerably: it is readily ascertained by the SOAP-TEST. The mode of softening waters is referred to under CALCIUM, *Carbonate and Sulphate of*. The only perfect method of removing fixed matter from water is, of course, distillation; indeed, this process is carried out on board some of our ships, the water being subsequently aërated for drinking purposes. On land, however, other less expensive processes are available.

The *organic* impurities contained in solution in water are of animal and vegetable origin, the former being most objectionable. The animal matter contains nitrogen, and is constantly undergoing a fermentive change. Water in this state is highly dangerous to health, and should be carefully avoided. Unfortunately, no test, short of rigid analysis, can be relied upon for detecting this animal matter. Solution of permanganate of potash is decomposed and decolourised by it, and therefore water that discharges the colour from much of that reagent should be viewed with suspicion.

One other possible contamination of water must be noticed: it is lead. Fortunately for most reasons, but unfortunately for some others, water that contains an appreciable quantity of salts does not, as a general rule, act upon lead. Pure distilled water acts very rapidly upon it, but water that is in any degree hard does not usually affect it. Lead can be easily detected in water by the blackening which occurs on passing sulphuretted hydrogen gas through the water. This effect is not, however, produced if only a very small quantity of lead be present. In that case the water, after the passage of the gas, should be set aside for twenty-four hours, when the sulphuretted hydrogen will have become decomposed, and the deposited sulphur will have a dark-brown or black colour if lead be present. It has been suggested to tin the inside of lead pipes—water not acting upon tin; but wherever water comes in contact with both metals, as at a joint or flaw, a voltaic action is set up, and the solution of the lead is facilitated instead of prevented.

Estimation of Water.—This is accomplished either by noting the loss which a body suffers on being heated, or by expelling and weighing the water evolved. If the constitution of the body is well known, the former method is sufficient; if not, the latter process is had recourse to.

Analysis of Normal and Abnormal Waters.—Of all special chemical operations this is one of the most tedious and difficult. Usually a large number of acids and bases are simultaneously present, and being all in solution, cannot be so readily separated as those of perhaps a less complex substance containing both soluble and insoluble matters. Gaseous constituents must generally be determined at the source of the water. The total amount of fixed matter is ascertained by evaporating a known bulk of the water, and weighing the residue after drying at 212° Fahr. If organic matter be present, the residue, dried at 300° Fahr., will char on being ignited; air having access, the carbon will burn off, and the difference in weight, before and after ignition, will give some idea of the amount of that organic matter. The residue may then be quantitatively analysed in the same manner as any other mixture of solids, or separate portions of the water may be used for the purpose. The arrangement of the results of a water analysis depends upon the judgment of the operator. The actual amounts of each ingredient, without reference to arrangement, should first be given, inasmuch as the state in which they naturally exist is liable to alteration from change of temperature and dilution after rain, &c. Moreover, as there are at present no data by which to determine the normal condition of the acids and bases, several systems of arrangement exist; and if the amount of each acid and base were not given, the analyses of a water by two different chemists would appear to differ widely when, perhaps, they closely agree.

WATER, IN ITS PHYSICAL RELATIONS. In the preceding article the chemical history of water is briefly reviewed, and such of its properties are described as depend, primarily, on the nature and activity of the molecules of which it is constituted. We now proceed to treat of some of those properties of water which are exhibited by masses of it, whether in its liquid, aëriform, or solid state; those which render it a subject of physics or natural philosophy; omitting, however, of course, such properties as it possesses in common with other bodies in the corresponding states of aggregation, respectively, and which have been considered in the articles HYDRODYNAMICS; HYGROMETRY; MECHANICS; PNEUMATICS, &c.

The three states of aggregation in which water, like all kinds of ponderable matter, as we have reason to believe, can exist, are all equally natural; though, as in the case of every other substance also, we are inclined to regard that condition as the most natural in which it is most commonly and obviously subject to our observation. This, with respect to water, is the liquid, as with all metals but one it is the solid, and with chlorine, ammonia, and other elementary as well as compound substances, it is the aëriform state; omitting here any reference to those gaseous bodies which have not yet been reduced to another state of aggregation.

We begin with the physical properties of water in the solid form, considering, first, those which it manifests to sensible observation.

In the article ICE the property is described, in virtue of which two portions of that substance in a moist state, when brought into contact, become one. That such is the fact has of course been known from time immemorial, but it had always been referred, without inquiry, to the freezing effect upon water of ice at a lower temperature [HAIL], and had never been made a subject of scientific investigation until Dr. Faraday called attention to its nature and philosophical importance on the 7th of June, 1850, at one of the Friday evening meetings of the members of the Royal Institution of Great Britain (Albemarle Street, London); assemblies in which, from the year 1825 downwards, so many new facts and applications in science and new interpretations of facts have for the first time been publicly made known, or first publicly demonstrated by experiment. To this property of ice the term regelation was afterwards applied by Professor Tyndall, in a paper 'On the Structure and Motion of Glaciers,' by himself and Professor Huxley, read before the Royal Society on January 15, 1857 ('Proceedings,' vol. viii. p. 331), and published in the 'Philosophical Transactions' for that year. In this paper Professor Tyndall describes some experiments illustrative of the practical consequences of regelation, and of their manifestation on the great scale in nature. The entire subject forms so important a part of the history of water in its solid condition, that it is requisite to return to it here.

In the article ICE we noticed Professor Tyndall's conclusion that the plasticity of ice at 32°, in mass, arising from fracture and regelation, in continued and indefinite succession, imparts to it a deceptive semblance of viscosity, which it really does not possess. By virtue of this process, in his experiments, spheres of ice were flattened into cakes, and squeezed into transparent lenses. A straight prism six inches long was passed through a series of moulds augmenting in curvature, and finally came out bent into a semi-ring. A lump of clear ice placed in a hemispherical cavity, and pressed upon by a protuberance not large enough to fill the cavity, was converted into a hard transparent cup. In the experiments with the prism, four moulds, gradually augmenting in curvature, were made use of in succession. In passing suddenly from the shape of one to that of the other the ice was fractured, but the pressure brought the separated surfaces again into contact, and caused them to (regelate) freeze together, thus restoring the continuity of the mass. The fracture was in every case both audible and tangible—it could be heard and it could be felt. A series of cracks occurred in succession as the different parts of the ice-prism gave way, and towards the conclusion of the experiment the crackling in some instances melted into an almost musical tone.

These facts have been applied by Professor Tyndall to explain the phenomena of the motion of glaciers. [GLACIERS, in NAT. HIST. DIV.] This is a most important subject: the very introduction into the philosophy of glaciers of the principle of regelation, "without which," Professors Tyndall and Huxley remark, "it may be doubted whether the existence of a glacier would be at all possible," and the relation of which to glacier action the former was the first to discover, opens in itself a new field of investigation. For the details of this application we must refer to the original paper; but the following is a summary view of the subject, derived partly from that and partly from a more brief account given in the 'Proceedings' of the Royal Institution, vol. ii. p. 322.

All the phenomena of motion in glaciers, on which the idea of the viscosity of ice has been based, are brought by such experiments as those recited above into harmony with the demonstrable properties of ice. The glacier valley is a mould through which the ice is pressed by its own gravity, and to which it will accommodate itself, while preserving its general continuity, as the "hand-specimens" (to use a term familiarly applied to rocks) do to the moulds made use of in the experiments. Two confluent glaciers unite to form a single trunk, by the regelation of their pressed surfaces of junction. Crevasses are closed up, and the broken ice of a cascade, such as that of the Talèfre or the Rhone, is recompacted to a solid continuous mass. "But if the glacier accomplish its movement in virtue of the incessant fracture and regelation of its parts, such a process will be accompanied by a crackling noise, corresponding in intensity to the nature of the motion, and which would be absent if the motion were that of a viscous body. It is a well-known fact that such noises are heard, from the rudest crashing and quaking up to the lowest decrepitation, and they thus receive a satisfactory explanation.* It is manifest" also "that the continuity of the fractured ice cannot be completely and immediately restored after fracture. It is not the *same* surfaces that are regelated, and hence the coincidence of the surfaces cannot be perfect. They

* The sounds sometimes heard during the appearance of the Polar Lights, and supposed to be produced by them [TERRESTRIAL LIGHT], have been referred by Humboldt to the mechanical changes continually going on in the ice-fields and packs of the regions in which those lights, in their most extensive and brilliant development, have been principally observed. Many of these changes must be identical with those of glaciers; and in the facts and reasoning adduced by Professor Tyndall, as above, we probably have the final explanation of this disputed subject.

will inclose for a time *capillary fissures*, and thus the above theory accounts satisfactorily for the known structure of glacier-ice. Professor Tyndall made an experiment on this point in which, by a gradually increasing pressure, he produced in ice fissures of this description accurately resembling those made evident by the infiltration experiments of M. Agassiz in the glacier of the Aar.

Since the publication of Dr. Tyndall's researches, and that of the papers by Principal (late Professor) James D. Forbes and Professor James Thomson, the contents of which were stated in the former article, Dr. Faraday has entered into a new experimental investigation of it, which has appeared in the 'Proceedings' of the Royal Society, vol. x. p. 440–450, under the title of 'Note on Regelation,' in which he has also more fully described that property than in his previous papers. Of the new facts he has observed, and of the conclusions he has founded upon them, the following are the most important.

"Two pieces of thawing ice if put together adhere and become one; at a place where liquefaction was proceeding congelation suddenly occurs. The effect will take place in air, in water, or in vacuo. It will occur at every point where the two pieces of ice touch, but not with ice below the freezing point, that is, with dry ice, or ice so cold as to be everywhere in the solid state."

"Though some might think," Dr. Faraday resumes, "that Professor [J.] Thomson, in his last communication [ICE, col. 816], was trusting to changes of pressure and temperature so inappreciably small as to be not merely imperceptible, but also ineffectual, still he carried his conditions with him into all the cases he referred to, even though some of his assumed pressures were due to capillary attraction, or to the consequent pressure of the atmosphere only."

In order to exclude all pressure of the particles of ice on each other due to capillary attraction or the atmosphere, Dr. Faraday prepared to experiment altogether under water, arranging a bath of that fluid, maintained at 32° Fahr., which by the method he employed it could be for a week or more. [THAW.]

Two similar blocks of good Wenham-lake ice were placed in the water with their opposed faces about two inches apart, each being moored to a particular place by woollen thread attached to pieces of lead, so that they were sunk entirely under the surface of the ice-cold water. If brought near to each other and then left unrestrained, they separated, returning to their first position with considerable force. If brought into the slightest contact, regelation ensued, the blocks adhered, and remained adherent, notwithstanding the force tending to pull them apart. They would continue thus, even for twenty-four hours or more, until they were purposely separated, and would appear (by many trials) to have the adhesion increased at the points where they first touched, though at other points of the contiguous surfaces a feeble thawing action went on, causing a dissection of the ice, developing its mechanical composition, and showing it to consist of layers of greater and less fusibility, horizontally disposed in the ice whilst in the act of formation. "In this case, except for the first moment, and in a very minute degree, there was no pressure, either from capillary action or any other cause. On the contrary, a tensile force of considerable amount was tending all the time to separate the pieces of ice at their points of adhesion;" where still the adhesion went on increasing. Arrangements were next made to ascertain whether anything like soft adhesion occurred, such as would allow slow change of position without separation during the action of the tensile force. It was found that not the slightest motion of the blocks in relation to each other took place in the thirty-six hours during which the experiment was continued. "This result, as far as it goes, is against the necessity of pressure to regelation, or the existence of any condition like that of softness or a shifting contact."

Torsion force was then employed as an antagonist to regelation. The ice-blocks being separate, were adjusted in the water so as to be parallel to each other, and about $1\frac{1}{4}$ inch apart. If made to approach each other on one side, by revolution in opposite directions on vertical axes, a piece of paper being between to prevent ice-contact, the torsion force set up caused them to separate when left to themselves; but if the paper were away, and the ice pieces were brought into contact, by however slight a force, they became one, forming a rigid piece of ice, though the strength was, of course, very small, the point of adhesion and solidification being simply the contact of two convex surfaces of small radius. It was found, also, that there was no more tendency to a changing shape than in the case before examined. If the separating force were increased, but unequally, as respects the two pieces, then the congelation at the point of contact would give way, and the pieces of ice would move in relation to each other. Yet they would not separate, though the torsion force employed was constantly tending to separate them. If a slip of wood, applied to change the mutual position of the two pieces of ice without separating them, were retained for a second undisturbed, then the two pieces of ice became fixed rigidly to each other in their new position, and maintained it when the wood was removed, but under a state of restraint; and when sufficient force was applied, by a slight tap of the wood on the ice to break up the rigidity, the two pieces of ice would re-arrange themselves under the torsion force of their respective threads, yet remain united; and, assuming a new position, would in a second or less again become rigid, and remain inflexibly conjoined as before. By managing the continuous motion of one piece of ice, it could be kept associated with the other by a flexible point of attachment for any length of time, could be placed in various angular positions to it, could be made (by retaining it quiescent for a moment) to assume and hold permanently any of these positions when the external force was removed, could be changed from that position into a new one, and, within certain limits, could be made to possess at pleasure and for any length of time either a flexible or a rigid attachment to its associated block of ice. In observing these states, convex surfaces of contact are necessary, so that the contact may be only at one point. If there be several places of contact, apparent rigidity is given to the united mass, though each of the places of contact might be in a flexible, and, so to say, adhesive condition. "It is not at all difficult to arrange a convex surface, so that, bearing at two places only on the sides of a depression, it should form a flexible joint in one direction, and a rigid attachment in a direction transverse to the former."

The following are Dr. Faraday's inductions from these results, which cannot be abridged:—"So regelation includes a flexible adhesion of the particles of ice, and also a rigid adhesion. The transition between these two states takes place when there is no external force like pressure tending to bring the particles of ice together, but, on the contrary, a force of torsion is tending to separate them; and, if respect be had to the mere point of contact on the two rounded surfaces where the flexible adhesion is exercised, the force which tends to separate them may be esteemed very great. The act of regelation cannot be considered as complete until the junction has become rigid, and therefore I think that the necessity of pressure for it is altogether excluded. No external pressure can remain (under the circumstances) after the first rigid contact is broken. All the forces which remain tend to separate the pieces of ice; yet the first flexible adhesions and all the successive rigid adhesions which are made to occur are as much the effects of regelation as those which occur under the greatest pressure."

"The phenomenon of flexible adhesion under tension looks very much like sticking and tenacity; and I think it probable that Professor Forbes will see in it evidence of the truth of his view. I cannot, however, consider the facts as bearing such an interpretation; because I think it impossible to keep a mixture of snow and water for hours and days together without the temperature of the mixed mass becoming uniform; which uniformity would be fatal to the explanation. My idea of the flexible and rigid adhesion is this:—Two convex surfaces of ice come together; the particles of water nearest to the place of contact, and therefore within the efficient sphere of action of those particles of ice which are on both sides of them, solidify; if the condition of things be left for a moment, that the heat evolved by the solidification may be conducted away and dispersed, more particles will solidify, and ultimately enough to form a fixed and rigid junction, which will remain until a force sufficiently great to break through it is applied. But if the direction of the force resorted to can be relieved by any hinge-like motion at the point of contact, then I think that the union is broken up among the particles on the opening side of the angle, whilst the particles on the closing side come within the effectual regelation distance; regelation ensues there, and the adhesion is maintained, though in an apparently flexible state. The flexibility appears to me to be due to a series of ruptures on one side of the centre of contact, and of adhesion on the other,—the regelation, which is dependent on the vicinity of the ice surfaces, being transferred as the place of efficient vicinity is changed. That the substance we are considering is as brittle as ice, does not make any difficulty to me in respect of the flexible adhesion; for if we suppose that the point of contact exists only at one particle, still the angular motion at that point must bring a second particle into contact (to suffer regelation) before separation could occur at the first; or if, as seems proved by the supervention of the rigid adhesion upon the flexible state, many particles are concerned at once, it is not possible that all these should be broken through by a force applied on one side of the place of adhesion, before particles on the opposite side should have an opportunity of regelation, and so of continuing the adhesion."

The changes of temperature and pressure in the process of regelation, as here investigated, Dr. Faraday thinks, are too infinitesimal to go for anything; and in illustration of this opinion, he describes an experiment. For this, however, as well as for the manipulation of the experiments in general, we must refer to his paper; but an addendum to it we now cite, as it details an easy method of examining the various phenomena of regelation which have been ascertained. "Take a rather large dish of water at common temperatures. Prepare some flat cakes or bars of ice, from half an inch to an inch thick, render the edges round, and the upper surface of each piece convex, by holding it against the inside of a warm saucepan cover, or in any other way. When two of these pieces are put into the water they will float, having perfect freedom of motion, and yet only the central part of the upper surface will be above the fluid; when, therefore, the pieces touch at their edges, the width of the water-surface above the place of contact may be two, three, or four inches, and thus the effect of capillary action be entirely removed. By placing a plate of clean dry wax or spermaceti upon the top of a plate of ice, the latter may be entirely submerged, and the tendency to approximation from capillary action converted into a force of separation. When two or more of such floating pieces of ice are brought together by contact at some point under the water, they adhere; first with an apparently flexible, and then with a rigid adhesion. When five or six pieces are grouped in a contorted shape, as an S, and one end piece be moved carefully, all will move with it rigidly; or, if the force be enough to break through the joint, the rupture will be with a crackling noise, but the pieces will still adhere, and in an instant become rigid again. As the adhesion is only by points, the force applied should not be either too powerful or in the manner of a blow. I find a piece of paper, a small feather, or a camel-hair brush applied under the water very convenient for the purpose. When the point of a floating wedged-shaped piece of ice is brought under water against the corner or side of another floating piece, it sticks to it like a leech; if, after a moment, a paper edge be brought down upon the place, a very sensible resistance to the rupture at that place is felt. If the ice be replaced by like rounded pieces of wood or glass, touching under water, nothing of this kind occurs, nor any signs of an effect that could by possibility be referred to capillary action; and finally, if two floating pieces of ice have separating forces attached to them, as by threads connecting them and two light pendulums, pulled more or less in opposite directions, then it will be seen with what power the ice is held together at the place of regelation when the contact there is either in the flexible or rigid condition, by the velocity and force with which the two pieces will separate when the adhesion is properly and entirely overcome."

In Dr. Faraday's second published notice of regelation ('Exp. Res. in Chem. and Phys.,' pp. 380, 381), he had adduced the growth of crystals of camphor and of iodide of cyanogen, by the deposition of solid matter upon them from an atmosphere unable to deposit like solid matter upon the surrounding glass, except at a lower temperature; and that of crystals in a solution, by the deposition of solid matter upon them which is not deposited elsewhere in the solution, to illustrate the extension of the principle of action which is manifested in regelation. In his reasoning on the nature of that principle, he also rested on the fact, that ice has the same property as camphor, sulphur, phosphorus, metals, &c., which cause the deposition of solid particles upon them from the surrounding fluid, that would not have been so deposited without the presence of the previous solid portions.

But the further experimental inquiry to which he has now subjected the phenomena of regelation, appears to have conducted him to a view of them which is not altogether reconcileable with his previous inferences respecting the extension of the principle. He now asks, "Is this remarkable property peculiar to water, or is it general to all bodies? In respect of water, it certainly seems to offer us a glimpse into the joint physical action of many particles, and into the nature of cohesion in that body when it is changing between the solid and liquid state. I made some experiments on this point;" which he proceeds to relate.

The metals bismuth, tin, and lead did not present the slightest trace of an action corresponding to regelation. Melted nitre appeared at times to show traces of the power; but, on the whole, Dr. Faraday is inclined to think that the effects observed resulted from the circumstance that the solid rods experimented with had not acquired throughout the freezing temperature. Nitre, however, he remarks, "is a body which, like water, expands in solidifying; and it may possess a certain degree of this peculiar power." Glacial acetic acid, he finds, is not merely without regelating force, but actually presents a contrast to it.

"Many results were tried (without much or any expectation), crystals of them being brought to bear against each other by torsion force, in their saturated solutions at common temperatures. In this way the following bodies were experimented with:—Nitrates of lead, potassa, soda; sulphates of soda, magnesia, copper, zinc; alum; borax; chloride of ammonium; ferro-prussiate of potassa; carbonate of soda; acetate of lead; and tartrate of potassa and soda; but the results were all negative."

Dr. Faraday's "present conclusion, therefore, is that the property" of regelation "is special for water, and that the view" he has "taken of its physical cause"—"that a particle of water, which could retain the liquid state whilst touching ice only on one side, could not retain the liquid state if it were touched by ice on both sides, but became solid, the general temperature remaining the same"—"does not appear to be less likely now than at the beginning of this short investigation, and therefore has not sunk in value among the three explanations given," namely, his own and those of Professor James Thomson and Principal Forbes, respectively, which have been stated in our former account of this subject.

In the 'Proceedings of the Royal Society' for May 2, 1861 (vol. xi., pp. 198–204), appears a note by Professor James Thomson, in which he states that he still adheres to the explanation of Principal Forbes's experiment, cited from a former paper by him in our article Ice, as mainly correct, though admitting of modification in reference to a point which seems to him to be as yet rather obscure:—"the influence, namely, of the tension in the ice due to its own weight, which makes it *not* be subject internally to simply atmospheric pressure." Professor Thomson also points out some additional conditions, almost necessarily present in the experiment, which, under his view of the plasticity of ice, would act in conjunction with those originally adduced, and would increase the rapidity of the union. But his principal object in this communication is to dissent from the interpretation given by Professor Faraday of his recent experiments, as above, and to express the opinion that they are in perfect accordance with, and tend to confirm, his own theory, and its application to the various observed cases of the union of two pieces of moist ice when placed in contact. This he does, after describing Faraday's results, in these terms:—"My view of the phenomena of these experiments is as follows: the first contact of the two pieces of ice cannot occur without impact, and consequent pressure; and, small as the total force may be, its intensity must be great, as the surface of contact must be little more than a geometrical point. This pressure produces union by the process of melting and regelation described by me in previous papers. On the application of the forces from the two feathers, at one side of the point of contact, tending to cause separation, the isthmus of ice formed by the union of the two pieces, comes to act as a tie or fulcrum subject to tensile force; and, consequently, a corresponding pressure will occur at the side of the isthmus far from the feathers, and that pressure will effect the union of the ice at the side where it occurs. The tensile force, it may be readily supposed, tends to preserve the isthmus, internally at least, in the state of ice, whatever may be its influence on the external molecules of the isthmus, and to solidify such water as, having occupied pores in the interior during previous compression, may now, by the linear tension or pull, be reduced in cubical pressure or hydrostatic pressure, because the melting-point of wet ice is raised by diminution of pressure of the water in contact with it. The pull applied to the isthmus thus appears to put it out of the condition in which my theory has clearly indicated a cause of plasticity, and, I presume, makes it cease, or almost entirely cease, to be plastic. I believe no plastic yielding of ice to tension has been discovered by observation in any case, and I think there are theoretical reasons why ice should be expected to be very brittle in respect to tensile forces. The isthmus then being supposed devoid of plasticity at its extended side, ultimately breaks at that side when the opening motion caused by the feathers has arrived at a sufficient amount to cause fracture; and the ice newly formed on the compressed side comes now to act as a tie, instead of the part which has undergone disruption, and holds together the two pieces of ice, or serves as a fulcrum under tension to communicate a compressive force to the points of the two pieces of ice immediately beyond it; and so the rolling action with a constant union at the point of contact goes forward. It is to be observed, that the leverage of the forces applied by the feathers is so great, compared with the distance from the fulcrum or tensile part of the isthmus, to the compressed part in process of formation at the other side as that the compression may usually be considered almost equal to the tension; and the tension in the extended part cannot be of small intensity, being sufficient to break that side of the isthmus. In the experiments which gave flexible adhesion *seemingly* under tension, it is not to be admitted that tension was really the condition under which the ice existed at the places where the union was occurring. To apply a simple disruptive force to the whole isthmus of ice, it would be necessary to take very special precautions in order to arrange that the line of application of the disruptive forces should pass through the point of contact of the two pieces. If that were done, and the forces were gradually increased till the cohesive strength of the isthmus were overcome, it is clear that the two pieces of ice would separate altogether, and there would be no flexible adhesion; but the flexible adhesion, when it occurs, is essentially dependent on the existence of an intense pressure at the side of the isthmus remote from the line of the externally applied disruptive forces, or of the single force applied in some of the experiments to one only of the pieces, and resisted by the inertia of the other."

While Dr. Faraday was engaged in the experimental corroboration of the cause to which he had originally assigned regelation, and in the limitation of the inferential views of its extension which he had first taken, a less conspicuous inquirer had been led to found upon those views and upon a known fact in the physical history of glass, a theory of the universality of regelation. This had been indicated, and the fact in question stated, at the end of our former account of the subject in the article Ice. In the 'Proceedings of the Royal Society' (vol. x., pp. 450-460), Dr. Faraday's 'Note on Regelation' is followed by Mr. Brayley's 'Notes on the Apparent Universality of a Principle analogous to Regelation; on the Physical Nature of Glass; and on the Probability of the Existence of Water in a state analogous to that of Glass.'* In the first of the three 'Notes' of which Mr. Brayley's paper consists, the view of the subject taken in Ice (col. 817) is resumed in greater detail, the facts there mentioned being regarded as "indicating the existence of a condition of matter which may be termed arrested liquidity, but yet is not, in the most perfect sense, solidity." It is assumed also to be highly probable that the process by which two plates of polished plate-glass become one is, in reality, analogous to that of regelation in ice, and finally dependent on the same principles, whatever their true character may be conceived or shall ultimately be determined to be. Facts are stated, from which it is inferred that the state of the interior portions of a plate of plate-glass is similar to that of glass in general at certain temperatures much below its fusing point, when it presents such remarkable characters of plasticity, tenacity, and ductility. These facts are stated to recall the view taken by Person, and adopted by Principal Forbes [Ice, col. 816; Thaw], of the simi-

* These notes were received by, and read to, the Royal Society on the 26th of April, 1860, after Dr. Faraday had given an oral account, experimentally illustrated, of the contents of his own 'Note,' which had been received in the preceding month.

larity of the liquefaction of ice to that of fatty bodies or of the metals, "which in melting pass through intermediate stages of softness or viscosity;" and it is remarked, also, that Sir J. F. W. Herschel, when he terms regelation "a sort of welding" [HAIL, col. 603], appears to concur in this view. Mr. Brayley asks, in conclusion of this part of the subject, "Are all cases of the union of two apparently solid surfaces of the same substance by cohesive attraction cases of melting and regelation, an infinitesimally thin film of liquid being momentarily produced and as instantly solidified?"; and having in discussing the philosophy of the union of two surfaces of glass followed the reasoning of Professor J. Thomson, on the cause of regelation, he states, notwithstanding, that he wishes to be understood as not adopting, exclusively, any existing theory on the subject. Admitting the operation of cohesive attraction and consequent pressure in the first instance, the phenomenon, with respect to glass, it is shown, readily admits of explanation by the original view of Mr. Faraday with respect to ice. [ICE, col. 814.]

The object of Mr. Brayley's second 'Note' does not, strictly belong to the subject at present before us, but to preserve the sequence of the whole inquiry in its bearing on the physics of water, we may mention that he finds reason to regard the molecular constitution of glass as being analogous to that of "water cooled below the freezing point, but still remaining liquid, until by a tremor, or the percussive contact of a solid body, or the mere contact of a crystal of ice, its temperature rises to 32°, and it becomes ice," or to that of a saturated solution of salt in hot water. "If so," he remarks, "glass will be a substance in which this state of arrested liquidity, or potential solidity, is permanent." Instructive parallels are also noticed between the crystallisation of water and that of glass and some other bodies, which are presented by the experiments of Gregory Watt, and Faraday.

It is observed in the concluding 'Note,' that "No crystalline body has been longer or more extensively subject to human observation than crystallised water, or ice. Its natural history and properties, as science has advanced, have been investigated with increasing generality and precision; and they have finally become objects of that systematic and exact research which characterises the present era of physical inquiry. . . . . A most remarkable deficiency, however, still remains, apparently, in our knowledge of this substance: *water in the vitreous condition—Ice glass—has never been observed.* While we know the antithetical vitreous state of so many different crystallised substances, —minerals produced by heat, salts deposited from aqueous solution, neutral bodies of organic origin,—and have great reason to believe that that antithetical condition to crystallisation is universal, we have no knowledge of it in relation to water or ice. My own attention has been awake to the subject, without success, for many years. It would seem to be scarcely within the bounds of possibility that the glassy state of water, if possessing what we term solidity, should not, ere now, either have been observed in nature, or have occurred and been recognised in experimental research."

Mr. Brayley inquires, "Does this apparent deficiency in our knowledge exist because—to use language recently introduced into physical science—the *homologue* of the glassy state of water is not what we ordinarily term solid—because the state of water cooled below 32°, but still liquid, is in fact the state which corresponds to the vitreous condition of other bodies, and to the physical nature of perfect ordinary glass? Is the one simply a case of potential solidity, and the other of the confluent or equivalent state of arrested liquidity?"

In reply to the anticipated objection that the homology sought to be established between liquid water below 32° and glass, is a forced one, and after admitting that, in relation to each other, these are extreme cases, he proceeds to show that intermediate terms of the series are not wanting, some of them being supplied by sulphur and phosphorus, and others, in a remarkable manner, by selenium, various conditions of all three appearing to be homologues, at once, of both the extreme terms here alluded to. Mr. Brayley suggests, finally, "Should this hypothesis be verified, water below 32°,—or rather, perhaps, from the temperature of maximum density downwards through that of freezing,—may have to be regarded as the vitreous condition of matter; and the causes of the peculiar characters of that condition, its effects on the transmission of the vibrations of sound and light, the conchoidal fracture, &c., may have to be discovered by researches on its molecular nature."

In expositions, whether of the progress or the actual condition of any branch of science, the student is perpetually reminded of the lesson which teaches the indissoluble and universal connection of every part of nature with every other part. Subsequently to the enunciation of all the views on the subject of regelation, and the molecular relations of ice and water, of which an account has been given in the preceding columns, this truth has been exemplified in a striking and instructive manner, which may eventually make it requisite to modify all existing conclusions on that subject and its applications to natural phenomena.

In the 'Proceedings of the Royal Society' for June 13 of the present year (1861), vol. xi., pp. 243-247, appears the abstract of an elaborate paper (itself to be published in the 'Philosophical Transactions') on 'Liquid Diffusion applied to Analysis,' by Mr. Thomas (late Professor) Graham, V.P.R.S., Master of the Mint. In this he shows the value of the process of diffusion and of the principle of diffusibility in water, as affording the means of bringing out clearly the distinctive properties of what appear, in his judgment, to be two great divisions of chemical substances. Mr. Graham's former researches on DIFFUSION have been noticed in the article on that subject. As this will be the only opportunity the near completion of our work will allow of giving an account of his new results, we shall cite so much of his abstract as, in addition to what is required for the subject of the present article, will suffice for that purpose. The entire subject of diffusion, we may add, illustrates in a remarkable manner the importance of that perfect neutrality as a chemical agent, which has been shown to characterise water in the preceding article on its chemical history.

"The first, or *diffusive*, class of substances are marked by the tendency to crystallise, either alone or in combination with water. When in a state of solution they are held by the solvent with a certain force, so as to affect the volatility of water by their presence. The solution is generally free from viscosity, and is always sapid. Their reactions are energetic, and quickly effected. This is the class of *crystalloids.*"

"The other class, of low diffusibility, may be named *colloids*, as they appear to be typified by animal gelatine. They have little, if any, tendency to crystallise, and they affect a vitreous structure. The planes of the crystal, with its hardness and brittleness, are replaced in the colloid by rounded outlines with more or less softness and toughness of texture. Water of crystallisation is represented by water of gelatination. Colloids are held in solution by a feeble power, and have little effect on the volatility of the solvents. The solution of colloids has always a certain degree of viscosity, or gumminess, when concentrated. They appear to be insipid, or wholly tasteless, unless when they undergo decomposition upon the palate, and give rise to sapid crystalloids. They are united to water with a force of low intensity. Although chemically inert in the ordinary sense, colloids possess a comparative activity of their own, arising out of their physical properties. While the rigidity of the crystalline structure shuts out external impressions, the softness of the gelatinous colloid partakes of fluidity, and enables the colloid to become a medium for liquid diffusion, like water itself. The same penetrability appears to take the form of a capacity for cementation in such colloids as can exist at a high temperature. Hence a wide sensibility on the part of colloids to external agents."

"Another eminently characteristic quality of colloids is their mutability. Their existence is a continued metastasis. A colloid may be compared in this respect to water while existing liquid at a temperature below its usual freezing point, or to a supersaturated saline solution. The colloidal is, in fact, a dynamical state of matter; the crystalloidal being the statical condition."

"For the separation of unequally diffusive crystalloids from each other, jar-diffusion was had recourse to. . . . The separation of a crystalloid from a colloid is more properly effected by a combination of diffusion with the [osmotic] action of a septum composed of an insoluble colloidal material. . . . This separating action of the colloidal septum is spoken of [in Mr. Graham's paper] as *dialysis.*"

"*Ice* at or near its melting point appears to be a colloidal substance, and exhibits a resemblance to a firm jelly in elasticity, the tendency to rend and to redintegrate on contact." Regelation, according to this view, is the form in which the property of *redintegration*, belonging to all colloids, is exhibited by ice.*

The truth of the view of the nature of ice, at or near its melting point, thus taken by Mr. Graham, will require to be tested by optical means, by which it must be ascertained that, at those temperatures, it really is not a crystallised body. A further verification may be obtained by determining whether the alleged colloidal ice resists the passage of electricity as crystalline ice is known to do, and what changes the non-conducting power of the latter undergoes, during the reciprocal conversion of the crystalloid into the colloid state, until it becomes the conducting power of liquid water. (Faraday, 'Exp. Res. in Elect.' par. 403.) Should its truth be established, Mr. Graham will probably be admitted to have discovered the key to the explanation of all the conflicting statements and theories respecting the nature of regelation and of the motion of glaciers. Ice, together with many other bodies, and perhaps all, will be both a colloid and a crystalloid. That which Dr. Faraday, in his recent experiments, found to have the flexible adhesion, will prove, in this case, to be the colloidal or vitreous form of that substance (*ice-glass*, in fact; almost identical with Mr. Brayley's homologue of that hitherto hypothetical body, as evinced by facts recorded by Mr. Graham, which will presently be adverted to), while the rigid adhesion will be found to characterise its crystalloidal form; and the circumstances from which he inferred that the former has not in reality the properties of sticking and tenacity—in short, those of a viscous substance, will be found to arise from the constant and rapid passage—the metastasis of Graham—of the colloid into the crystalloid body.

Regelation will consist of the passage, under small changes of pressure and temperature, of crystalloid into colloid ice, and its re-conversion into the former, the "cementation" and "redintegration" of the colloid intervening; and thus Faraday's own interpretation of his experiments and Professor Thomson's will be brought into harmony

* The Rev. Canon Moseley had previously defined regelation as the "property of passing from a disintegrated into a solid state."

The theories of glacier motion of Forbes, Thomson, and Tyndall (including the explanation of the plasticity of ice by the latter), and the views respecting it of Hopkins and Whewell, may prove to be equally true, or some of them unnecessary. Under the reciprocal changes of pressure and temperature going on in a glacier, it will follow that every part of it must be perpetually changing from a truly viscous or plastic, colloidal, dynamic state, maintained only for a short time, to the rigid, crystalloidal, statical condition of ordinary ice; which, under the same changes will again transiently assume the colloidal form, only to undergo the corresponding change, and so on in a succession which can terminate only with the final liquefaction of the ice, and its separation from the glacier by flowing away in the form of water. All the conditions of viscosity or plasticity, and rigidity, which the phenomena of glaciers and the known properties of ice require to be fulfilled, may thus be capable of explanation agreeably to the laws of nature. But many of Mr. Graham's results are independent of his assumption respecting ice. It is stated by him, as above, that colloidal bodies affect the vitreous structure; and he recognises the vitreous form of silica as the colloidal one. It is now evident, indeed, that what, looking primarily from organic substances, he has termed the colloidal state, is identical, allowing for inherent difference of properties, with that, which, looking primarily from inorganic bodies, has been termed the vitreous or glassy state. Every description of glass must, agreeably to Mr. Graham's inductions, be a colloidal body, and the union of two surfaces of it at all temperatures, while the solid condition is maintained, must be that cementation and redintegration which is physically identical with regelation itself; and thus Mr. Brayley's arguments for the virtual identity with regelation of the process by which two plates of plate-glass become one, which Dr. Faraday's new results appeared to invalidate, will be confirmed; while regelation, as also suggested by him, may be found to be universal, as respects all bodies which can assume the colloid form, Dr. Faraday's experiments indicating its non-extension having been confined to crystalloids. The mutability and continued metastasis of colloids are manifested in the unstable condition of arrested liquidity or potential solidity recognised by Mr. Brayley; and Mr. Graham's comparison of a colloid in that respect "to water while existing liquid at a temperature below its usual freezing point, or to a supersaturated saline solution," is a repetition of Mr. Brayley's view of the molecular constitution of glass already cited. Colloidal ice (if it shall be proved to exist), and unfrozen water below 32°, are evidently degrees of the same condition, and thus Mr. Brayley's suggested homologue of the glassy condition of water is almost equivalent to the former, and if, as seems conformable with known facts, we assume that the colloid state of water cannot begin until it is reduced to the temperature of its greatest density, that homologue will include, almost explicitly, Mr. Graham's colloidal condition of ice. Some nice questions of temperature will, however, have to be settled by experiment; and indeed the subject is now ripe for those quantitative determinations in which the existing discussions of regelation are remarkably deficient, and which must necessarily be of a minute and delicate description.

But here we must conclude on this subject; having merely indicated how wide a field for experimental research, observation in nature, the verification of hypotheses, and mathematical investigation, all relating to ice and water, has probably been opened to science by Mr. Graham's researches on liquid diffusion.

From the preceding view of the obvious characters and actual nature of ice, we proceed to describe some of its properties in relation to heat, and some also of water in its two fluid states. The dilatation of ice by heat was measured in the years 1845 and 1846, at the Imperial Observatory of Pulkowa, by Schumacher and his associates, and the particulars of their experiments were communicated by M. Struve to the Academy of St. Petersburg, in 1848, and were afterwards published in its 'Memoirs.' The measurements had reference to observed temperatures of the block of ice employed, varying from $-2°\cdot3$ R. to $-22°$ R. ($+5°\cdot175$ to $+17°\cdot5$ Fahr.)

After applying the requisite corrections, it resulted from them that the coefficient of expansion of ice is for 1° R. (2°·25 Fahr.) ·00006466; which, according to the Rev. Canon Moseley, F.R.S., "is *nearly* twice as great as the coefficient of dilatation of lead, and *more* than twice as great as that of any other solid." [HEAT, col. 637.]

We do not know the modulus of elasticity of ice,* or the pressure under which it disintegrates; but Mr. Moseley has observed that "If it were as elastic as slate and did not resist crushing more than hard brick, a block of it placed with its ends between two immoveable obstacles, would crumble when its temperature was raised one degree of Fahrenheit. It is its great dilatability which gives to ice this tendency to disintegrate, when, not being free to dilate, its temperature is raised, even so slightly as this. Agassiz describes a disintegration of the transparent ice of the blue bands of glaciers when laid bare, which appears to be due to its expansion." 'Bulletin [Bibliothéque] de Genève,' vol. xliv., p. 142; ('Proc. of Roy. Soc.' vol. xi., pp. 171, 172.)

According to the experiments of Melloni on the transmission of radiant heat, ice transmits none (absorbs all) of the calorific rays issuing from copper at 212°, or at 752° Fahr., nearly approaching a red heat; and transmits only 0·5 of those from incandescent platinum, and only 6 per cent. of such rays from the Locatelli lamp. In these cases the heat is absorbed in the internal liquefaction of the ice.

The colour of liquid water varies, according to the thickness of the quantity examined, from a yellowish green of all degrees of intensity through green and blue-green to intense blue, such as that observed in great depths of the sea. Professor Tyndall has introduced into British demonstrative science, if indeed he has not devised, an experiment in which the colour of water is exhibited by passing the light from the voltaic lamp through a long tube of water closed by glass at both ends, and receiving the image on a screen. In this experiment, with no greater thickness than twenty feet, the colour of water is seen to be yellowish green. Ice, probably, has the same range of colour; being, like water, colourless in small masses; it is greenish or bluish in large masses. Pure aqueous vapour is colourless in the greatest thicknesses in which it has been examined.

Many important facts, and inductions from them, relating to the electrical properties of water in all its three states of aggregation, will be found referred to under their respective appellations in the Indexes to Faraday's 'Experimental Researches in Electricity,' and in 'Chemistry and Physics,'—indexes which are enhanced in value by having been constructed by the author of those researches himself.

The process of the solidification of water by depression of temperature is noticed under FREEZING, and FREEZING AND MELTING POINTS. The lowering of its freezing-point by pressure, as discovered by Professor J. Thomson, is stated in the article last cited, and has been referred to in the present article, and also under ICE. The theory and quantitative calculation he originally gave respecting it will be found in the 'Transactions of the Royal Society of Edinburgh,' vol. xv., and the 'Cambridge and Dublin Mathematical Journal' for November 1850. Ice, as a crystalline substance has been described under HAIL, HOAR-FROST, and SNOW. Its specific gravity is stated in the last. Mr. J. Chapman, Professor of Mineralogy in the University of Toronto, in the 'Canadian Journal of Science' for 1861, has questioned the truth of referring the crystallisations of ice to the rhombohedral system. A mode of investigating the process of formation of the stellar and other aggregations of crystals so characteristic of snow, under circumstances more convenient than those of observations which must be made at a temperature below 32° Fahr., has been pointed out by Mr. Joseph Spencer, and adopted by Mr. Glashier. It consists in observing the crystallisation of camphor, in which similar aggregates are produced; and has been described in papers read before the Greenwich Natural History Club, in the year 1856, and issued by the British Meteorological Society. The compressibility and ELASTICITY of water have both been treated of under the latter head.

The phenomena of the conversion of liquid into gaseous water or aqueous vapour, and its properties in that condition, have been stated in the articles BOILING OF LIQUIDS; EBULLITION; EVAPORATION; STEAM; VAPOUR; and VAPOUR OPALESCENT; those of its reconversion, or condensation, into liquid water and ice, under several heads above referred to, and also in the articles DEW and RAIN. The evaporation of ice has been noticed under SNOW.

The absorptive power for heat of aqueous vapour has recently been examined by Professor Tyndall, in his researches on the absorption and radiation of heat by gases and vapours, ('Phil. Trans.' 1861); in which he found that hydrogen, the two gases which are the essential constituents of the atmosphere, and atmospheric air itself, absorb respectively about 0·3 per cent. of the calorific rays emanating from a copper surface coated with lamp-black, heated by boiling water. "On a fair November day," he adds, "the aqueous vapour in the atmosphere produced fifteen times the absorption of the true air of the atmosphere. It is on rays emanating from a source of comparatively low temperature that this great absorptive energy is exerted; hence the aqueous vapour of the atmosphere must act powerfully in intercepting terrestrial radiation; its changes in quantity would produce corresponding change of climate. Subsequent researches must decide whether this *vera causa* is competent to account for the climatal changes which geologic researches reveal." 'Proc. of Royal Soc.' vol. xi., pp. 101, 102.

Under EVAPORATION, HYGROMETRY, and VAPOUR, an account has been given of Dr. Dalton's researches and views respecting the production and tension of aqueous vapour and its relations to the atmosphere, which for many years have been almost universally accepted and relied upon. Meteorologists, accordingly, have been accustomed to separate the pressure of the aqueous vapour from the whole barometric pressure of the atmosphere, and thence to infer the pressure of the permanently elastic portion, or as it has been called, the *gaseous pressure*, or the *pressure of the dry air*. Colonel Sykes, in a paper read before the Royal Society some years since, and Lieut.-Col. Strachey

* The expression "modulus of elasticity," we believe, has not been explained in any preceding article. It is thus defined by Dr. Thomas Young, Sec. R. L., by whom it was introduced. "The modulus of the elasticity of any substance is a column of the same substance, capable of producing a pressure on its base which is to the weight, causing a certain degree of compression, as the length of the substance is to the diminution of its length." This definition is given in Dr. Young's 'Mathematical Elements of Natural Philosophy,' appended to his celebrated 'Lectures,' Lond., 1807, vol. ii., p. 46. It occurs in Section ix, treating 'Of the equilibrium and strength of elastic substances.' These elements are not inserted in Professor Kelland's edition of that work; but the section is reprinted in the late Dr. Peacock's collection of the 'Miscellaneous Works' of Dr. Young, vol. ii., p. 129. The application of the expression is explained and illustrated in Lectures xiii. and xxxi.

in a recent communication 'On the Distribution of Aqueous Vapour in the Upper Parts of the Atmosphere,' have questioned both the truth of Dalton's hypothesis and the correctness of the application. A mathematical argument, showing the incompatibility of the hypothesis of a separate vapour atmosphere with the facts, will be found in a paper by the late astronomer Bessel, translated in Taylor's 'Scientific Memoirs,' vol. ii. A more generally appreciable form has been given to this by Lieut.-Col. Strachey, who also has compared the results calculated from Dalton's hypothesis with the facts of the distribution of vapour in the atmosphere, as observed by Dr. Joseph D. Hooker, the late Mr. Welsh, Colonel Sykes, and himself. From the entire investigation he concludes that "The subtraction of the observed tension of vapour from the total barometrical pressure, in the hope of obtaining the simple gaseous pressure, must consequently be denounced as an absurdity; and the barometrical pressure, thus corrected, as it is called, has no true meaning whatever." ('Proc. of Royal Soc.' vol. xi., pp. 182-189.)

On the other hand, the application of Dove's method for obtaining the gaseous pressure, deduced from Dalton's hypothesis, in Major-General Sabine's paper on the 'Meteorology of Bombay,' published in the 'Report of the British Association' for 1844, appears to have been successful in bringing out true results, which also verify the law assumed. It would appear that there is something important on the subject yet to be explained; probably in respect of the relation of the observed phenomena which Dalton expressed by the hypothesis of gaseous substances being vacua to each other, to their aggregate pressure when mingled, and the manner in which that is made up of their separate pressures, if such they have.

WATER (*Medical Uses of*). Several of the uses of water having been already stated, either under the article BATHING, or that of FOOD in ARTS AND SCIENCES, or WATER, in NAT. HIST. DIV., it is intended to treat here of some of the applications of water.

Snow-Water has been accused of causing goitre; but this charge seems unfounded; and the occurrence of that complaint is due to the calcareous salts which the snow-water in its descent from the mountains dissolves in large quantities.

Such is the great purity of some springs, that they have been reckoned *mineral* waters, and resorted to as such. The chief of these is Malvern, the specific gravity of which is only 1·0002, and which contains a smaller proportion of foreign ingredients than any other water. The water now supplied to the City of Glasgow, from Loch Katrine, is nearly equally pure, a point of great importance to the health of the inhabitants, and to the numerous manufactories of that city. Water artificially purified by Dr. Clark's process, is supplied to Woolwich. Some of the springs of Matlock are likewise very pure. Those of them which are *thermal* have their powers increased by the higher temperature; but their beneficial effects, like those of Malvern, and Holywell in Flintshire, are mainly owing to their extreme purity; which shows how conducive to health pure water is, compared with that which is impure or contaminated. Many springs have their waters largely impregnated with carbonic acid gas. These are sparkling and pleasant to the taste, and when fresh-drawn produce some slight exhilaration.

Water charged with much free carbonic acid should never be conveyed through leaden pipes, but through those of zinc or block-tin.

Well-water is generally obtained from a greater depth than spring-water. It is also generally hard, or is apt to become so if kept in a reservoir lined with bricks, unless they be coated with an insoluble cement. The water from old wells is more pure than from recent ones, the soluble particles having been all gradually washed away. The pump and well waters in and about London, and chalky districts in general, are mostly hard. (Prout, 'On Stomach and Renal Diseases,' p. 210, 4th edit.) Not so that of the artesian wells, which is of unusual softness. This renders water from these wells proper as a beverage for persons with a tendency to certain forms of calculous complaints, to whom hard waters are most hurtful. The causes of hardness in water and of the injurious influence of it on the health of many persons, is scarcely sufficiently understood. Filtration only removes mechanical impurities, and even long boiling only precipitates certain of them, while in some instances it renders the water harder. For the analysis of water and an estimate of its mechanical impurities, see WATER (*Chemistry*); and for the means of determining its hardness, see SOAP-TEST.

Distilled Water.—For many chemical, pharmaceutical, and even dietetical purposes, water must be of greater purity than it is generally found. For this end it is directed to be distilled, in which process never more than two-thirds of the water put into the still should be allowed to pass over.

Toast-Water.—This is water boiled and poured on toasted bread, which in some degree lessens the vapid taste. An agreeable and beneficial degree of sapidity may be communicated to water which has been long boiled, by adding, previous to drinking it, a little of the common soda-water, which is merely carbonic acid gas diffused through the water under strong pressure.

Mineral Waters are generally characterised by possessing some principle different from what is found in common water, or some of the ordinary principles in unusual proportion, yet among these are reckoned certain springs which have no claim to repute beyond what is due to their extreme purity, such as Malvern and Holywell; or to having a higher temperature throughout the year, than the mean of the latitude where they are situated. These last are classed among the *thermal* springs, which are properly divided into two sections, the *mineralised hot* springs and the *unmineralised*, among which are some only tepid, such as Matlock, where some springs are 66°, the lowest of the class in Britain, and others cold, presenting this peculiarity, that the tepid springs arise from fifteen to thirty yards above the level of the river Derwent, whilst those which arise either above or below this range are cold.

For practical purposes mineral-waters may be classed under four heads, each susceptible of secondary heads, according as they are hot or cold, or have other peculiarities, namely; saline, alkaline, chalybeate, and sulphureous. It will not be possible to mention more than a few of the most important of each.

Saline aperient springs: of these some are hot, others cold. The chief are Carlsbad, Marienbad, Egra, Kissingen, Wiesbaden, Baden-Baden, Seidlitz, and Saidschutz, with Pullna, in Germany; Cheltenham, Leamington, and Harrowgate in England; Dunblane, Pitcaithly, and others in Scotland.

Alkaline waters, owing their properties to different saline principles, are found at Carlsbad, Marienbad, Kissingen, Pullna, Saidschutz, Ems, Töplitz, and Wiesbaden, in Germany; Vichy and Mont d'Or, in France; Harrowgate, Scarborough, and other Yorkshire springs, Cheltenham, Leamington, Bath, and elsewhere, in England.

Chalybeate waters: with these acidulous waters are often reckoned, as the iron is often associated with much free carbonic acid gas. Some of the chief are Spa, Pyrmont, Schwalbach, Marienbad, Aix-la-Chapelle, and Seltzer in Germany; Tonbridge, Harrowgate, and Brighton, in England; and Peterhead, in Scotland.

Sulphureous waters: Aix-la-Chapelle, Barèges, and other Pyrenean springs, are hot; Harrowgate, Askern, and others in Yorkshire, cold; Moffat and Strathpeffer, in Scotland, are also cold.
