ARTS AND SCIENCES.

TACTICS, MILITARY (*τακτικός*), properly signifies the art of forming the troops of an army in order of battle, and of making changes in the dispositions of the troops according as circumstances may require: that is to say, the science which guides the formations when the armies come into presence of one another; while, on the other hand, STRATEGY is that division of the science of war which considers all previous operations and combinations. These two subjects will therefore be considered together under the article WAR, SCIENCE OF.

TACTICS, NAVAL. This branch of the art of war is in some respects similar to that by which the operations of armies on land are regulated; and it is desirable that the order preserved in sailing should resemble that used in moving the battalions of an army on shore. But at sea the motive power is not always to be depended on, and many a well-arranged plan of attack becomes useless from the failure of wind, change of wind, or other causes. There are, however, accepted fundamental rules by which the navies of European nations are guided in the disposition of a fleet for attack, defence, chase, or retreat; and we first notice those applicable to sailing-ships principally.

The ancients, previously to the commencement of a naval action, drew up the ships in each fleet abreast of each other, and in that order one of the fleets moved on, or waited for the attack; for each ship being propelled by oars, and armed with a beak of iron or brass projecting before the bows, efforts were generally made to direct it so as by an oblique impulse to destroy the oars on one side of a ship of the enemy, and thus render it unmanageable, or so as with the beak to pierce a side, and thus sink the ship; and hence, in the ancient manœuvres, each commander always endeavoured to keep the prow of his ship presented to the ship which was opposed to him. But since the employment of gunpowder in naval warfare, each ship in two hostile fleets is manœuvred so as to bring one of its sides to bear against the bows or against a side of its opponent, in order that it may have the power of pouring into the latter the greatest quantity of fire; and since it is the object of both commanders to avoid being raked, a general action can take place only when the hostile fleets are drawn up in two lines parallel to each other, the keels of the ships in each being in the direction of the line. In the treatise of Père l'Hoste on naval evolutions, this mode of engaging is said to have been first employed at the battle of the Texel (1665), when James II., then duke of York, commanded the English fleet. Paul l'Hoste, who was a professor of mathematics at Toulon, and died at a comparatively early age in 1700, had personal experience in many of the battles he describes, and his remarks continue to be quoted; therefore he may be fairly considered to be the founder of the present system of naval tactics.

The order of sailing for a fleet should obviously be such that the several ships may be as near together as possible, both for the sake of mutual support and that the signals which may be made by the admiral may be distinctly seen: it depends also necessarily on the order of battle, since it is of importance that the fleet should be enabled, with the utmost facility, to pass from either of these states to the other.

Writers on naval tactics distinguish five different orders of sailing, the wind continuing to blow in one direction, and the keels of the ships remaining constantly parallel to one another; in other words, all the ships steering the same course. The first order is that in which all the ships are abreast of each other in a line perpendicular to the direction of the wind; and the second is that in which the ships are arranged so that a line joining all their main-masts is oblique to that direction; but in this order the line may have two different positions with respect to the wind, for each ship may be on the starboard (the right hand) side, or on the port (left hand) side of that which is to leeward of it. As in either of these two dispositions each ship in the line has that which is next to it on one side, opposite to one of its bows, and that which is next to it on the other side, opposite one of its quarters, this order of sailing is frequently called the *bow and quarter* line. In the first and second orders, if the ships are numerous, the line is inconveniently extended.

The third order of sailing is that in which, all the sails being *close-*

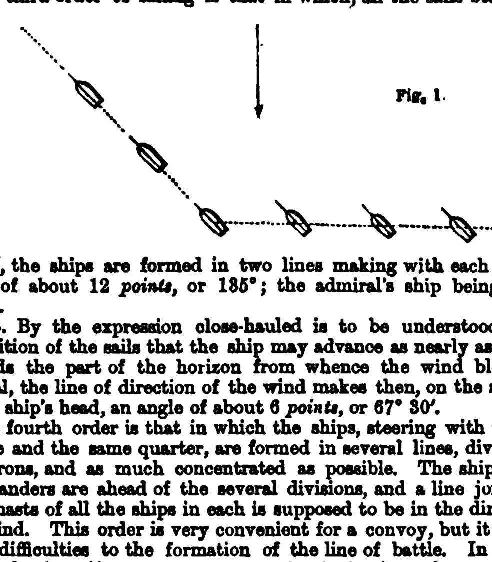

Fig. 1.

hauled, the ships are formed in two lines making with each other an angle of about 12 *points*, or 135°; the admiral's ship being in the centre.

N.B. By the expression close-hauled is to be understood such a disposition of the sails that the ship may advance as nearly as possible towards the part of the horizon from whence the wind blows. In general, the line of direction of the wind makes then, on the side next to the ship's head, an angle of about 6 *points*, or 67° 30′.

The fourth order is that in which the ships, steering with the wind on one and the same quarter, are formed in several lines, divisions, or squadrons, and as much concentrated as possible. The ships of the commanders are ahead of the several divisions, and a line joining the mainmasts of all the ships in each is supposed to be in the direction of the wind. This order is very convenient for a convoy, but it presents great difficulties to the formation of the line of battle. In the fifth order, the fleet, if not very numerous, is divided into three squadrons

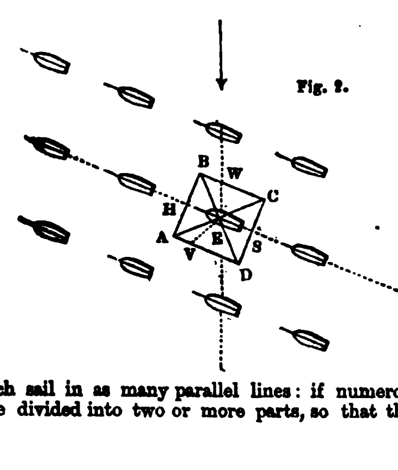

Fig. 2.

the ships of which sail in as many parallel lines: if numerous, each squadron may be divided into two or more parts, so that the whole may constitute six or nine parallel lines, the number of ships being equal in all. The ships in this order are supposed to be close-hauled, and the keel of each ship coincides with the direction of the line to which it belongs, or the ships of each line sail in each other's wake; while the corresponding ships in the different divisions may be either abreast of each other or in bow-and-quarter position. A line drawn through the mainmasts of the corresponding ships in the different divisions may be supposed to coincide with the direction of the wind. This order of sailing is that which was considered the most advantageous on account of the facility which it afforded for forming the line of battle. Generally, the fleet consisting of three divisions, the vanguard of the line constitutes the weather division, and is commanded by the vice-admiral; the centre division is commanded by the admiral himself; and the leeward or rear-division, by the rear-admiral. If the fleet consists of more than three divisions, those which are not commanded by the admirals are under the direction of commodores, or senior-captains, and each commander is in the centre of his own line; frigates, store-ships, &c. are kept to windward of the line of battle-ships.

The first and second orders of sailing are easily formed, however irregular may be the previous dispositions of the ships; for the ship which is appointed to lead in the formation may get to leeward of the whole fleet, and then hauling her wind (disposing her sails so that she may move in a line making the given inclination to the direction of the wind), she may sail in the proposed direction: the other ships then, according to their positions, follow successively in her wake, and when all are proceeding in one line, each veers [VEERING] or bears away, steering in the prescribed course, and still preserving the general line. The third order of sailing is formed after all the ships have got into one line, steering in each other's wake as above mentioned, and the line making an angle of about 10 *points*, 112° 30′, with the direction of the wind (reckoning from the latter direction towards the bows of the ship). The van ships, which are those to leeward of the admiral, who is supposed to be in the centre, successively haul their wind and steer in the proposed direction; and when the admiral's ship has hauled her wind, the sternmost or windward ships do the same, and each proceeds in a direction parallel to that of the other ships. The fourth and fifth orders of sailing are formed by the leading ships of the different divisions getting abreast of each other, or in bow-and-quarter position, at the prescribed distances; and then the ships of the respective squadrons taking their places in each other's wakes.

In the orders of sailing, the distance of one ship from another, in line, should be such that any danger of running foul of each other may be avoided: in general, that distance may be considered as equal to two or three cables' length (each = 120 fathoms). And, with respect to the distances between the several lines in the fifth order of sailing, it has been determined, the ships being close-hauled, by supposing that a line joining the headmost ship of one of the leeward divisions, and the sternmost ship of the next division to windward, should be at right angles to the direction of the wind; or that the angle which such line makes with each division should be equal to 2 *points*, or 22° 30′. In general, this interval may be considered as equal to six or nine cables' length; and it is of importance that the distances prescribed by the admiral of the fleet should be strictly preserved.

In order that the commander of any one ship may readily ascertain and preserve his relative position in a fleet when in order of sailing, the ingenious device called the *naval square*, which was invented by Père l'Hoste, may be employed. It consists in tracing upon the quarter-deck a great square A B C D (diagrams Nos. 2 and 3), having two sides, A D and B C, parallel to the ship's length; the diagonals, A C and B D, intersecting each other in E, and the line H E S being drawn vertically over the ship's keel; also the point H being towards the head of the ship. Now, if a ship were sailing in the direction S H, close-hauled on the starboard tack, as in the cut No. 2, so that B D coincides with the plane of the sail, and W E (bisecting the angle H E C) with the direction in which the wind is blowing; then, after having tacked and become close-hauled upon the port tack, since the directions of the vertical planes passing through the keel and sail make angles with the direction of the wind equal to those which they made before tacking, the line S H, that is, the line on which the ship will be sailing, will coincide with, or be parallel to, the position of E C in the diagram. In like manner, if a ship be sailing in the direction S H, close-hauled on the port tack, so that A C coincides with the plane of the sail, and V E with the direction in which the wind is blowing; then, after having tacked and become close-hauled on the starboard tack, the line S H, on which the ship will be sailing, will coincide with, or be parallel to, the position of E D in the diagram.

Hence, if a fleet be in three parallel divisions, the ships sailing abreast of each other, those in each line will be in the direction S H, and the corresponding ships in the different divisions will be in the directions A B or D C. If the fleet sails close-hauled, and, for example, on a starboard tack as in No. 2, the ships in each line will be in a direction coincident with or parallel to S H, and the corresponding ships in the several lines will be in a direction coincident with, or parallel to, W E, which is that of the wind. Again, if the fleet is in three divisions, and the ships are sailing in parallel directions not coinciding with those of the divisions; if, for example, the ships should be sailing on the port line of bearing while close-hauled on the starboard tack, as in the subjoined diagram, the ships in each line will be in the direction of

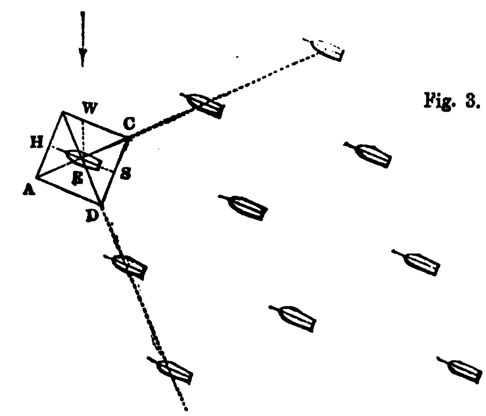

Fig. 3.

one of the diagonals of the square; and the corresponding ships in the different divisions will be in that of the other.

The order of battle consists in the ships being drawn up in each other's wake, or in one right line with which the directions of all their keels coincide: they are usually about 50 fathoms from one another, and are nearly close-hauled. The frigates, store-ships, &c., are in lines parallel to that of the line-of-battle ships, and on the side opposite the enemy. A line of ships close-hauled is particularly advantageous as an order of battle both for a fleet to windward, and also for that which is to leeward of its opponent. If a windward fleet were in any other state, the enemy might, by manœuvring, gain the weather-gage, or he might, by being able to approach as near as he pleased, compel the windward fleet to come to an action. By the "weather-gage" is meant the getting between, or the *power* of getting between, the enemy's fleet and the part of the horizon whence the wind blows. Rodney in 1782, and Nelson at Trafalgar, and other admirals have formed their plans of attack on this ground, because a fleet to leeward has difficulty with a fleet lying to windward, in forcing her to an engagement; while, on the other hand, a leeward fleet, of inferior force, has a retreat more open to it. To a fleet being to leeward of an enemy, the only hope of bringing the latter to action is in being able to outsail it, and tack across an enemy's bows; thus getting what is called the weather-gage. In a close-hauled line, also, the sails are disposed so that the ships remain nearly stationary during the action; on which account the line is steadily preserved, and any ship on becoming disabled can be easily replaced by one of those which are in the reserve line.

When the ships of a fleet are in the first or second order of sailing, and it is intended to form the line of battle, it is evident that by simply hauling the wind, or by tacking [TACKING] or veering [VEERING], as the case may require, the ships may get into each other's wake in any proposed direction of the line. If it be intended to form the line of battle from the third order, the ships in that wing which is already in a line, in the direction of their keels, must simply haul their wind and get into each other's wake in the proposed direction of the line; each ship in the other wing is then brought into a position nearly at right angles to the direction of the wind, and, as those of the first wing advance, these fall successively into their wake.

When the line of battle is to be formed from the fourth or fifth order, all the ships being supposed to be close-hauled, the formation may take place upon any one of the divisions; the ships of this division

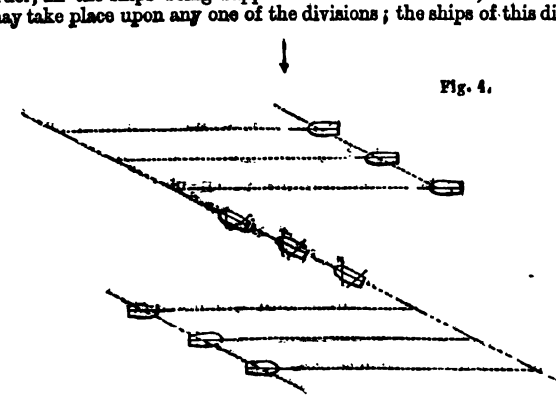

Fig. 4.

are then brought *to* (their motion stopped by bracing some sails so as to be taken aback by the wind while others are kept full), and the other ships are made to take up their proper positions in the prolongation of the line thus formed. If, for example, the fleet consists of ships sailing in three divisions close-hauled, and the line is to be formed upon the centre division, as in the subjoined diagram; then, as soon as this squadron is brought *to*, the ships in the weather division bear away and steer till they get ahead of the centre, when they haul their wind; the lee division tacks and sails on till it gets astern of the centre, and when these ships have hauled their wind the line of battle is formed. In this formation the weather division or column has been made to constitute the van, and the lee column the rear of the line; but it is sometimes thought necessary to make the columns change places, by causing that which is on the weather side of the fleet to become the centre or rear column, or by making the centre or lee column constitute the van of the line. A like interchange of the places of the van, centre, and rear divisions is also, occasionally, made when the fleet is in the order of sailing; and various other evolutions are performed by the ships of a fleet, both while sailing and in the line of battle: the principal of these consist in the several ships tacking, or veering, in succession, and in turning to windward; and there are, besides, the series of movements which are necessary in order to restore the line of battle when disordered in consequence of a shifting of the wind. But the details of these evolutions can be studied with advantage only in works which are expressly written on naval tactics.

From the order of battle it is necessary to return to some one of the orders of sailing; and with respect to the three first of these, it will be merely necessary for the ships in the line to tack, or bear away, in the assigned directions, increasing or diminishing sail, so that they may arrive in their proper positions nearly at the same time. In returning to the fifth order of sailing, there are two cases, which consist in performing the manœuvres on the same and on the opposite tack. In the first case, should it be required that the van may become the weather squadron, the van and centre tack together and stand on, while the rear proceeds in its actual course; then, when the rear comes successively abreast of the centre and van squadrons, these re-tack, and thus three parallel columns are formed. In the second case, the van being to form the weather squadron, the ships in van first tack in succession, then the ships in the centre, and lastly those in the rear. All then keep on, till the corresponding ships in the different squadrons get abreast of each other, when the order is formed. The evolutions differ, of course, from those just mentioned when the van is to form the lee, and when it is to form the centre squadron.

In the order of retreat before the wind, the ships are drawn up in two equal divisions, in lines making an angle of 135° with each other; the admiral's ship remaining to windward of the rest of the fleet, and being at the angular point.

If a fleet is much superior in force to that of the enemy, it will be of little moment whether it comes to action on the windward or the leeward side; and each of these situations when taken, either by a fleet or a single ship, has both advantages and defects. The advantages of gaining the weather-gage, as it is called, are that in such a situation a fleet may approach that of the enemy, and it may commence the engagement when it shall appear most convenient: ships may be detached to the rear in order to turn the enemy's line and put it in confusion, and a ship may board its opponent almost at will: in firing also, the windward ships are but little incommoded by the smoke. On the other hand, the disadvantages of being to windward are, the difficulty of retreat without passing through the enemy's line; disabled ships cannot quit the line without disordering the rest of the fleet, and in stormy weather the lower-deck ports can seldom be opened. When a fleet is to leeward of that of the enemy, the ships which may be dismasted can be readily drawn away, and the whole fleet may retire if unable to contend against a superior force.

If a fleet to leeward of the enemy's line should attempt to gain the windward side, it should manœuvre so as to delay the engagement for a time in the hope that a change of wind in its favour may take place, and it must then endeavour to take advantage of such change. In these circumstances the commander must however keep the enemy in sight, or at least he must obtain a knowledge of his manœuvres by means of frigates detached for the purpose. If unable to succeed in getting to windward, it should be drawn up on a line as short as possible, in which case, that of the enemy being more extended, some of the ships in it must either take no part in the engagement, or, leaving their line in order to bear down, they will lose the advantage of the wind. On the other hand, a weather fleet should be manœuvred so as always to keep that which is to leeward quite abreast of it; since then, unless the wind should shift, it will continue to hold its position.

When it is desired to bring on an action against a fleet in line on the leeward side, the general rule is that the weather fleet should get abreast of the other, then bear down upon it till within the proper distance, and form in order of battle. Should the leeward fleet bear away at a certain angle with the wind in order to avoid the engagement, the other may bear away at a still greater angle; then, according to the relation between the distance of the fleets from one another and the extent of the weather line of ships, the latter will cut the other in some particular part of its length, and thus compel it to fight in disadvantageous circumstances. Again, if being to leeward of the enemy, it be necessary to avoid an engagement, the only resource is to bear away in order of retreat. If to windward, the fleet should, if possible, in retreating, keep constantly on one tack, in order to avoid the loss of time occupied in going about; but if from want of room it be necessary to change the course, the fleet may be kept on one tack during all the time that the enemy is on the other: for thus the two fleets will be constantly diverging from one another.

It is observed by Mr. Clerk, in his 'Essay on Naval Tactics,' that when an enemy's fleet is to leeward, and in that situation is to be brought to action, both fleets being in line of battle, if the ships in the weather-line bear directly down upon the others, those in the van are liable to be disabled in their rigging; and thus, their motion being retarded, disorder must ensue in the dispositions of the ships which follow them. Precisely the same disadvantages, he adds, attend the method of coming with the whole fleet, in line of battle, obliquely upon the line of the enemy; and to these faulty modes of attack he ascribes the damages which have so frequently been sustained by British fleets at the commencement of actions. The method proposed by that writer for coming to an engagement against a fleet to leeward is similar to that of an attack in oblique order on land, and consists in detaching a squadron for the purpose of attacking some of the rear ships in the enemy's line: the squadron should engage the ships broadside to broadside while the rest of the fleet is at a distance, prepared to send support if necessary. Then, should the van and centre of the enemy's fleet continue its course in order to avoid a general action, those rear ships will be taken: if any of the van ships should tack successively in order to support the rear, some other ships of their line will be in danger of being taken by a second squadron detached from the windward fleet; and if the whole line should tack together, the disorder thence arising might cause the loss of more ships, or might bring on a general action at a disadvantage to the leeward fleet. Lastly, if this fleet should veer, and bear away, the ships would become exposed to a raking fire in their retreat.

The manœuvre of doubling an enemy's line of battle consists in sending ships round by either of its extremities for the purpose of placing some of those in that line between two fires. In order to double a fleet, the ships should advance beyond its van, or fall in its rear, when by tacking or veering according as they are to leeward or windward of the line, they may get into the required position on its opposite side. It is right to observe, however, that this manœuvre ought to be attempted under favourable circumstances only, as the doubling ships are liable to be separated so far from their own fleet as to be prevented from rejoining it; and it is, on the whole, considered more advantageous to double a fleet by its rear than by its van, since in the event of some of the enemy's ships being damaged, and unable to keep up with the rest, such ships may be taken by those which are performing the manœuvre of doubling: should any of these last be separated from their fleet, they can remain in the rear without risk, till an opportunity is offered of rejoining it. At the battle of the Nile (1798), Admiral Nelson doubled the van of the French line, and attacked it on both sides, while the other ships of that line, the whole fleet being at anchor, could afford no assistance. In order to avoid being turned, the largest ships of a fleet ought to be in the van and rear of its line when in order of battle; and the rate of sailing for each should be such that the rear ships may never be astern of the enemy. Care should also be taken that the ships are as close together as possible, that the enemy may not pass between any two of them, and thus break the order of battle.

It is well known, from the records of naval history, that the manœuvre of cutting through the line of an enemy's fleet during an engagement has been several times performed by English commanders since the middle of the 17th century. In an action with the Dutch, in the year 1652, Sir George Ayscue is said to have charged from the leeward through the fleet of the enemy; and in that between the English and Dutch fleets in 1665, the earl of Sandwich cut through the centre of the Dutch line, and caused the disorder which ended in its total defeat: again in May, 1672, Sir Joseph Jordan, of the Blue squadron, having the advantage of the wind, pierced the Dutch fleet and threw it into confusion. But the action which first gave notoriety to the manœuvre was that in which Admiral Rodney gained the important victory over the French fleet commanded by the Comte de Grasse: this action was fought in 1782. The battle in which the brilliant career of Lord Nelson terminated with a decisive victory (1805) owed the success with which it was crowned to the employment of a like mode of attack.

The honour of having been the first to demonstrate fully the principles on which the manœuvres of an attack against fleets to windward or to leeward depend, is generally ascribed to Mr. Clerk of Eldin, who published the first edition of his 'Essay on Naval Tactics' in 1782; and it has been asserted (Playfair's 'Memoir of Mr. Clerk') that Clerk had, in conversation, communicated to Sir Charles Douglas (Rodney's flag-captain) his whole system of tactics in the year preceding that in which the battle with the Comte de Grasse was fought. The accuracy of this assertion has been however disproved by Sir Howard Douglas, in his 'Memoir on Naval Evolutions;' and from an account of the circumstances under which the manœuvre of breaking the French line was performed, as they have been given by Sir Charles Dashwood (one of Admiral Rodney's aides-de-camp on the day of the action), it appears that the idea of the manœuvre was, at the moment, suggested to the admiral by Sir Charles Douglas on perceiving an opening in the French line between two of the ships near its centre. The French fleet was formed in line on a larboard tack, and tended to gain the windward side of the British line, which from the leeward side advanced obliquely towards the fifth ship from the van of the enemy. Signals were then made for the British ships to close up in their line, and the action commenced as the two fleets ranged in opposite directions alongside of each other. When the centre of the British fleet came opposite the third or fourth ship of the French line, Admiral Rodney's ship began a close action within half a musket-shot against the ships of the enemy with which it came successively abreast; and then the opening appearing as above mentioned, the opportunity was seized of passing through it: this was done so near the enemy, that the admiral's ship almost touched the French ship on each side. The ships astern of the admiral followed him closely, and these kept up a powerful raking fire against the ships in the rear division of the enemy's fleet, which, being driven to leeward as the van of the British fleet passed them, broke into two divisions, and made sail before the wind to escape. As soon as the van of the French fleet was left beyond the rear of the still advancing line of British ships, it also broke into two divisions, which retreated in different directions; and then the signal being made for the ships to close up, the British fleet followed in pursuit of that division with which the French admiral had retired. At the battle of Trafalgar (1805), the combined French and Spanish fleets were drawn up in one line, of a crescent form, the convex part being to leeward of the wings, while the fleet of Lord Nelson bore up against it in two lines, in the order of sailing; the leading ships of the lines broke through the fleet of the enemy in two places, and were followed by those of their respective divisions.

The manœuvre of breaking the line of a fleet, like that of attacking in column the line of an army, may not always succeed; and in the action, June 3, 1665, several squadrons passed through and through the Dutch fleet without gaining any advantage. If the line of the enemy is strong, the ships which would pierce it may be placed between two fires, or may be cut off from the rest of their fleet; and perhaps the manœuvre ought not to be attempted unless the line to be broken is already disordered by the action, or unless a favourable opportunity should present itself from negligence or want of skill in the enemy.

Should sufficient reasons exist for performing the manœuvre by a fleet which is to leeward of its enemy, the ships of that fleet should close up as much as possible, and by a press of sail get rapidly through the opening without attempting to engage the ships between which they pass; or each should give the fire of a broadside to one only, reserving the other broadside for the ship with which it is to engage in the new position: this position the ships should of course gain as soon as possible. On the other hand, an attempt to break the line of battle may be counteracted by causing all the fleet, as soon as some of the enemy's ships have got through, to put itself on the same tack as these; by which means some of them will be engaged between two fires, and others will be cut off from all connection with the fleet to which they belong.

When the commander of a ship intends with that ship to come to action with one of the enemy to leeward, he should bear down obliquely towards the latter till he gets nearly into its wake; and when at a proper distance, he may either run up alongside, or having shot a-head, veer and run down on the weather bow: the ship attacked should never be allowed to bring her broadside to bear except when both ships are in parallel positions.

In chasing an enemy's ship which is to windward, the chaser being presumed to sail better than the ship she pursues, it is recommended that the former should stand *on* close-hauled till abreast of the chase; she should then tack, and stand on close-hauled till again abreast; and so on. The ship chased, on the other hand, should, in order to avoid loss of time, continue constantly, if possible, on one course; but it is evident, from the supposed inferiority of her sailing, that she must at length be overtaken by her pursuer.

Such have been, and such would continue to be, the basis of systematic naval warfare with sailing fleets. As regards the Royal Navy, an extended system of manœuvres is called for, inasmuch as more precision in evolutions is attainable by steam-fleets such as will be our future defence.

To this subject both English and French writers have already given their professional attention; and the French admiral, De la Gravière, in his work called 'Guerres Maritimes,' advocates the all-predominant advantages of *speed* over an adversary. It is to Admiral Bowles, C.B., that we owe even the present position of the question of naval tactics; for in 1846 he called attention to the necessity of improved modes of manœuvring steam-vessels before an enemy, as may be seen in his 'Essay on Naval Tactics,' 1846. He was ably seconded by Capt. Dahlgren, U.S. navy, in his work on 'Shells and Shell Guns.' But it is to General Sir Howard Douglas, Bart., that this country owes that development of a system which has been very carefully illustrated by him in numerous diagrams in his 'Naval Warfare.' We refer, therefore, to that work for further details, which would be unnecessary in this Cyclopædia—a work not only valuable to every naval commander, but also to merchant captains, who may resolve to defend the costly ships and steamers committed to their charge. We merely, therefore remark in brief, as a few main features of his most recent opinions—the keeping of a fleet of steamers in well concentrated columns on lines of bearing *en échelon*; the turning an enemy's flank by an oblique movement, as practised on land by Frederick II., by Napoleon at Austerlitz, by Wellington at Waterloo, &c., &c.; and this by bringing an overwhelming force upon the point attacked; the steaming in *line abreast*, in readiness by a simple movement of each ship's head to form *échelon* of ships in line ahead, either as offensive or defensive measures. This consists of a wedge-shaped double line formed on a central ship, in the form of two sides of a right angle, the sides being right angled at such central ship, each ship making with the other an angle of four points. Sir Howard Douglas entirely repudiates the practice of fighting in parallel order.

(*Traité des Évolutions Navales*, par P. Paul Hoste, 1690. A Translation of the same by Captain Boswall, R.N., 1834; Clerk's *Essay on Naval Tactics*, 1790; *L'Art de Guerre en Mer*, par M. le Viscomte de Grénier, 1788; Steele, 1794, Admiral Sir Charles Ekins, *Naval Battles*; and Admiral Sir Howard Douglas's *Naval Warfare with Steam*, 1832 and 1858.)

TÆNIA. [MOULDING.]

TAIL, ESTATE. [ESTATE.]

TAILZIE, in the law of Scotland, is the technical term corresponding with the English word Entail, which now generally supersedes it in colloquial use, even in Scotland. The early history of Entail law in Scotland in some respects resembles that of England, but in later times they diverged from each other. In Scotland there was no early effort, such as the statute of Westminster the Second (13 Edw. I.) favouring deeds appointing a fixed series of heirs, nor does there appear to have been on the part of the judges that inclination to permit perpetuities to be defeated by fictions which was shown in England. Devices, however, of a very similar character to those of the English statute were adopted to defeat attempts by holders under entail to use their lands as if they were absolute proprietors. The first and simplest restriction laid on the destined heirs of an entail was in the form of a mere prohibition, against contracting debt which might occasion the attachment of the estate by creditors, selling the property, altering the order of succession, and the like. A provision of this character, called the "Prohibitive clause," was, however, quite insufficient to accomplish the end; because if a creditor had really attached the estate for debt, or a person had *bonâ fide* purchased it, it was no ground for wresting the title out of his hands, that the proprietor was under a prohibition against permitting such occurrences. A second provision was added, called an "Irritant clause," by which any right acquired contrary to the provisions of the entail was declared to be null. Still this did not effectually intimidate the holder under the entail from making efforts to break it, and did not give the next in succession a sufficient title to interfere. A third provision was added called the "Resolutive clause," by which the right of the person who contravenes the prohibition "resolves" or becomes forfeited. It was then provided by statute (1685, c. 22) that all entails should be effective which contained Irritant and Resolutive clauses, were duly recorded in the Register of Entails, and were followed by recorded saisins containing the Prohibitory, Irritant, and Resolutive clauses. Entails thus became a permanent feature in the institutions of the country. A sort of judicial war was for a time carried on against them, which produced a vast amount of litigation and strife, and placed the titles of property in a precarious and doubtful position. Quite recently, however, the entail law of Scotland has been assimilated to that of England; the method of creating entails has been simplified, and means of barring them provided, so that, except in matters of form, the law of Scotland with respect to entails now closely resembles that of England.

TALAPOINS is the name given by the Portuguese, and after them by other European nations, to the Buddhist priests, or rather monks, of Siam, and is supposed to be derived from the fan which they always carry, usually made of a leaf of the palmyra-tree, and hence, says Crawfurd ('Journal of Embassy to Siam'), denominated by the Sanskrit word *Talpat*. Tal is the common Indian name for the palmyra; and the older travellers give Talapa as the Siamese word for a fan. By the Burmese the Talapoins are said to be called Rahans, whence seems to come the name Raulins, given to them by the Mohammedans; as by the Chinese they are called Ho-changi; in Tibet, Lama-sen or Lamas; and in Japan, Bonzes. (Prevost, 'Histoire Générale des Voyages,' vi.; and 'Christianisme en Chine, en Tartarie, et au Thibet,' par M. Huc, 1857.) In Ceylon the name for the priests is stated by Sir J. E. Tennent, in his 'Christianity in Ceylon,' 1850, to be Samanaros, the name also given to them in Siam; apparently the same word as the Samaneans, or Buddhists of Bahar, quoted by Pliny and Strabo from Megasthenes, B.C. 300.

They are, as has been stated, a species of monks living in communities of from ten to some hundreds, and employing their time in devotion, religious study, and meditation, and in begging, or rather receiving alms, for they are not permitted actually to solicit charity. Their dresses of yellow cotton or silk (which are essential to the priesthood, and the quitting of which is an abandonment of the order) are of the same fashion as those of the Buddhist priests in Ava and Ceylon, and present a highly favourable contrast to the rags and squalidity of the general population. On the other hand, a talapoin is not only separated from society by being condemned to celibacy, and is prohibited from possessing property, but is expected to observe very strictly several of the precepts of the national religion which are very little attended to by anybody else, especially the prohibitions against the slaying of animals (although they will eat them when slain), stealing, adultery, lying, and drinking wine. Sir J. E. Tennent states that they are wretchedly poor, and in point of education rise little above the peasantry, but that they are superstitiously sincere.

TALBOTYPE. [PHOTOGRAPHY.]

TALENT (τάλαντον) was the highest denomination of Greek weights and money, and was also commonly used by Greek writers as the translation of words signifying a certain weight in other languages. It is necessary to observe that the talent is properly only a denomination of *weight*. There was no coin of that name; and when used in reference to money, it meant originally a talent-weight of gold or silver, and afterwards a certain quantity of current money, the weight of which (supposing the real and nominal value of the coin to be the same) amounted to a talent.

1. *The Hebrew Talent, or Kirkar* (כִּכָּר), contained 3000 shekels, and, according to Mr. Hussey's computation, its weight was 93 lbs. 12 ozs avoirdupois, and its value as *silver*-money 396*l.* 5*s.* 10*d.* [SHEKEL.] The Hebrews had no gold money of their own.

II. *The Greek Talent.*—The following were the principal denominations of weight and money among the Greeks :—ὀβολός, δραχμή, μνᾶ, τάλαντον, of which the ὀβολός was the smallest. Their relative proportions are shown in the annexed table :—

Obol			
6	Drachma		
600	100	Mina	
36,000	6000	60	Talent.

This system prevailed throughout Greece, but the actual values of the talent varied in different states. Most of these variations may be included under two chief standards, namely, the Attic and Æginetan.

1. *The Attic Talent.*—The value of the Attic talent before the time of Solon is a matter on which we possess little historical information, though there is no doubt that previous to Solon the Euboic talent was in use, and coins exist which are held to belong to that period. After Solon had remodelled the coinage, the Attic silver money was celebrated for its purity; and therefore from the coins of that period which still exist we may determine the value of the standard with tolerable certainty. Now the chief coin was the drachma of silver, the average weight of which, from the time of Solon to that of Alexander the Great, is found to be 66·5 grains. From this we get the following values in avoirdupois weight :—

	lb.	oz.	gr.
Obol	..	..	11·08
Drachma	..	..	66·5
Mina	..	15	83·75
Talent	56	15¼	100·32

This was the standard always used for silver money, and was therefore called "the silver standard."

Besides this there was another standard, the chief weight of which was called *the commercial mina* (ἡ μνᾶ ἡ ἐμπορική), and contained 138 drachmæ, "according to the standard weights in the silver mint" (see a decree in Böckh, 'Corp. Inscrip.', i. 123, § 4); that is, not that a commercial mina contained 138 *commercial* drachmæ, but that this was quite a different standard from that used for silver money, its unit being to that of the latter in the ratio of 138 : 100; while the *relative* proportions of the weights were the same in both systems. The following table shows the value of the Attic commercial standard :—

	lb.	oz.	gr.
Obol	..	..	15·29
Drachma	..	..	91·77
Mina	1	4¾	93·69
Talent	75	5¾	14·69

These weights were used for all commodities, except such as were expressly required by law to be sold by the silver standard.

This commercial standard is most probably, as Böckh has shown, the real ancient Attic standard, as it existed before the time of Solon. The purpose of Solon's change was to lower the value of money, in order to relieve debtors. The only direct information we have of the nature of the change is the statement of Plutarch, that "Solon made the mina of 100 drachmæ, which had formerly contained 73," which is probably a mistake made by Plutarch, through not understanding the words of Androtion, whose authority he follows. The true meaning seems undoubtedly to be, that *out of the same quantity of silver* which in the ancient standard made 73 drachmæ, Solon coined 100, or a mina; that is, that he lowered the standard in the ratio of 100 : 73. Now the ratio of the commercial to the silver standard is 138 : 100 = 100 : 72$\frac{32}{69}$. Hence the commercial standard and the old Attic only differed by a small fraction.

Still this ratio of 100 : 73 is a very singular one for Solon to have adopted. Böckh suggested that Solon meant to lower the standard by a quarter, that is, in the ratio of 100 : 75, and that the new coinage (by an accident of not uncommon occurrence in minting) was found, when actually made, to be a little too light, namely, in the ratio of 72$\frac{32}{69}$: 100, or, in round numbers, 73 : 100 to the old money, instead of 75 : 100; but a further investigation has led him to conclude that the true reason was to bring the new system into a definite proportion with the Æginetan which prevailed widely in Greece, and this proportion is as 3 : 5.

The Romans reckoned both the Attic and Euboic talents as equal to 80 Roman pounds (compare Polyb. xxi. 14, with xxii. 26, and Liv. xxxvii. 45. with xxxviii. 38).

The Attic commercial standard underwent an alteration by the edict above referred to, which made

its mina = 150 drachmæ (silver)
its 5 minæ = 6 minæ (commercial)
its talent = 65 minæ (commercial)

In this new standard the five-minæ weight was equal to 7lb. 13¾ oz. 14·96 grs., and the talent to 85 lbs. 2¼ oz. 70·7 grs.

The Athenians took the greatest care of their standards of weight. The principal set were lodged in the Acropolis, and there were other sets in the Prytaneum, at Piræus, and at Eleusis.

The highest coin used by the Athenians was the tetradrachm, or piece of four drachmæ; the mina and talent were never coined, but were paid in drachmæ, oboli, &c. The following table shows the value of all the denominations of Attic silver money, according to the computations of Mr. Hussey :—

	£	s.	d.	*farthings.*
Chalcus (of copper)				·8125
¼ Obol				1·625
½ Obol				3·25
Obol			1	2·5
Diobolon			3	1
Triobolon			4	3·5
Tetrobolon			6	2
Drachma			9	3
Didrachm		1	7	2
Tetradrachm		3	3	
Mina	4	1	3	
Talent	243	15		

2. *The Æginetan talent.*—Pollux (ix. 76, 86) says that the Æginetan talent contained 10,000 Attic drachmæ, and the Æginetan drachma 10 Attic obols, which would give the ratio of 5 : 3 for that of the Æginetan to the Attic talent. According to this statement, the Æginetan drachma weighed 110 grains English. Now the existing coins give an average of only 96 grains; and the question therefore is whether we are to follow Pollux or the coins. Mr. Hussey takes the latter course, explaining the statement of Pollux as referring to the debased drachma of later times, which was about equal to the Roman denarius. Böckh adheres to the statement of Pollux, explaining the lightness of the existing coins by the well-known tendency of the ancient mints to depart from the full value. He has supported his view by some very strong and ingenious arguments, and on the whole he appears to be right.

There were other talents used by the Greeks and Romans, most of which seem to have been derived from one of these two standards, but the accounts of ancient writers respecting them are very contradictory. Their values are discussed at length by Böckh, Hussey, and Humphrey.

The most important variations of the Æginetan standard were those used in Macedonia, Corinth, and Sicily.

The above talents were all reckoned in silver money. There was also a talent of gold, which was much smaller. It was used chiefly by the Greeks of Italy and Sicily, whence it was called the *Sicilian talent* as well as the *gold talent*. It was equal to 6 Attic drachmæ, that is, about ¾ oz. and 71 grs. It was divided by the Italian Greeks into 24 *nummi*, and afterwards into 12, each nummus containing 2¼ *litræ*. When Homer uses the word *talent*, we must always understand by it this small one of gold. In other classical writers the word generally means the Attic talent.

(Böckh, *Metrolog. Untersuch.*; Hussey, *Antient Weights and Money*; Humphrey, *Coin Collector's Manual*, 1853.)

TALES. At common law, when the number of jurymen in attendance was so small, or so much diminished by challenges that a full jury could not be had, a writ (then in Latin) issued to the sheriff, commanding him to summon *such* (tales) other fit persons, &c., for the purpose of making up the jury. The jurors so procured were called talesmen, from the Latin word used in the writ. By the statute 35 Henry VIII., c. 6, the defect of jurors might, at the request of the plaintiff or defendant in an action, be supplied from *such* other able persons of the said county then present, and these were ordinarily called, from the words in the Latin writ, "tales de circumstantibus." Subsequent statutes extended and regulated the application of this statute. The act now in force is the 6 Geo. IV., c. 50, s. 37.

TALIONIS, LEX, the law of retaliation; the notion of which is that of a punishment which shall be the same in kind and degree as the injury. This punishment was a part of the Mosaic Law: "breach for breach, eye for eye, tooth for tooth: as he hath caused a blemish in a man, so shall it be done to him again. Levit. xxiv., 20. The name "talio" occurs in the provisions of the Twelve Tables: it is not there defined what it means, but the signification of the term may be collected from other places. The word contains the same element as the word *talis*, "such," or "like."

TALISMAN, an Arabic word, supposed to be derived from the Greek *telesma* (τέλεσμα), is a figure cast in metal or cut in stone, and made with certain superstitious ceremonies, when two planets are in conjunction, or when a certain star is at its culminating point. A talisman thus prepared is supposed to exercise an influence over the bearer, preserving him from disease, rendering him invulnerable in battle, and so forth. They were probably used originally to avert disease, for we find them mentioned in the history of medicine among all ancient nations. The Egyptians made use of figures of sacred animals, such as the ibis and the scarabæus, which they wore generally suspended from their necks. The Arabs and the Turks did the same, when they were idolaters; but after their conversion to Islam, they used sentences from the Koran, taken chiefly from the surah, or chapter, entitled 'The Incantation.' These they wore inscribed on rolls of vellum or paper, enclosed in a silver box, and suspended from their neck; or else engraven upon a signet ring. Military men used similar sentences from the Koran on the hilt or blade of their swords; on their shields, helmets, and other pieces of armour; or woven into their garments. Christian nations even were not exempt from this superstition. In the middle ages, relics of saints, consecrated candles, and rods, rosaries, &c., were employed, and still are, in Spain and in some parts of Italy.

TALLAGE is derived, according to Lord Coke, from the law Latin word *tallagium*, or *tailagium*, which, as he says, "cometh of the French word *tailer*, to share or cut out a part, and metaphorically is taken when the king or any other hath a share or part of the value of a man's goods or chattels, or a share or part of the annual revenue of his lands, or puts any charge or burthen upon another; so as *tallagium* is a general word, and doth include all subsidies, taxes, tenths, fifteenths, or other burthens or charge put or set upon any man." It was generally however confined in its sense to taxes received by the king. The most important statute on the subject is entitled 'De Tallagio non concedendo,' which was passed in the 34th year of Edward III., to quiet the discontent then universal throughout the kingdom. It had arisen among the commons in consequence of the king having taken a tallage of all cities, boroughs, and towns without the assent of parliament. He was embroiled also with the nobles and landowners, from having attempted, unsuccessfully however, to compel all freeholders of land above the value of 20*l.* to contribute either men or money towards his wars in Flanders. The first chapter of the statute is the most important: "No tallage or aid may be set or levied by us or our heirs in our kingdom without the good will and assent of the archbishops, bishops, counts, barons, knights, burgesses, and other free men of the commons of our kingdom." These words, as Lord Coke says, are "plain without any scruple, absolute without any saving;" and, if there could have been perfect reliance on their operation, must have been entirely satisfactory. But the same king had just violated almost the same engagements entered into by himself only six years before. (25 Edward I., c. 5, 6, 7, 'Confirmationes Chartarum;' 2 Inst., 530.)

TALLOW (French, *suif;* German, *talg;* Italian, *sevo, sego;* Russian, *salo, toplenoe;* Spanish, *sebo*) is animal fat melted and separated from the membranous matter which is naturally mixed with it. When pure, tallow is white, and nearly tasteless; but the tallow of commerce usually has a yellow tinge. It is divided, according to its qualities, into various kinds, of which the best are used for the manufacture of candles, and the inferior for making soap, dressing leather, greasing machinery, and some other purposes.

A large proportion of the tallow used for making candles in this country is of home production. It is fitted for use by the *renderer*, who chops into pieces the fat and suet received from the butchers, and boils it in water, by which operation the greater part of the fat is melted out from the membranes, and floats to the top, whence it is removed by skimming. The remaining fat is subsequently squeezed from the membranes by a powerful press, leaving the membranous matter in the form of a cake or block, of a dark colour, which is called *graves*, or *cracklings*, and which, when macerated in warm water, softens and swells, and is used as food for poultry, dogs, and other domestic animals. The operation of *rendering* should be performed as speedily as possible after the removal of the fat from the carcass, because the fibrous and fleshy matter mixed with it tend to promote putrefaction.

Almost all our imported tallow is brought from Russia, where this article is produced in enormous quantities. About 250,000,000 lbs. of tallow are furnished annually to the rest of the world, providing the chief supply of soap and candles to England, France, Germany, Scandinavia, Italy, and the other countries of Europe; and this is all in addition to the large quantity consumed by the Russians themselves. Nearly the whole of this quantity is furnished by the Pontine steppes, in the southern part of European Russia. The large tallow-manufactories, or *salgans*, as they are called, are exclusively in the hands of the natives of Great Russia, who buy the cattle by thousands, and, after fattening them for a season, drive them to the salgans to be slaughtered. The salgans, to which the tallow-boilers usually begin to drive their oxen in small numbers towards the close of summer, generally consist of a spacious court-yard surrounded by the buildings necessary for the manufacture: embracing shambles for slaughtering the oxen, houses containing enormous boilers to boil down the flesh, places for salting the hides, and counting-houses and dwellings for the workmen. In the summer these establishments are untenanted, except by dogs and birds of prey, which hover about all the year round, attracted by the nauseous smell, which, however alluring to them, is disgusting to a visitor and distressing to the oxen. The business is generally carried on during the rainy season. The actual slaughtering is performed in so rude and unartificial a manner as to occasion much needless suffering to the beasts. After the carcasses are skinned, three or four poods of flesh are cut off from the loins and back for sale in the bazaar as meat, there being little fat in those parts of the body; but owing to the barbarous method of slaughtering, this meat is so much injured that none but the poor will buy it. The remainder of the carcass is cut up, and everything, excepting the intestines, which are given to the pigs (of which a considerable number are always kept at the salgan to fatten during the season), is thrown into the boilers, of which there are from four to six in every salgan, each large enough to contain the flesh of ten or fifteen oxen. A little water is put into the boiler, to prevent the "soup," as its contents are termed, from burning. The fat, as it collects at the top, is skimmed off with large ladles; and before it is quite cold it is poured into the casks in which it is afterwards shipped. The first fat which comes off is the best, and is quite white; while that which follows has a yellowish tinge. When there are not sufficient casks at hand, the hides of the slaughtered oxen are sewn up, and the tallow is poured into them. A further supply of fat, but of very inferior quality, is subsequently obtained by subjecting the mash of bones and flesh to huge presses. This tallow, which is rarely exported, is of a dark brown colour, and is used for greasing wheels and for other coarse purposes. An ox in good condition will yield from seven to eight poods (250 to 290 lbs.) of tallow, which is generally worth from eleven to fifteen rubles a pood. The article is always so greatly in demand, that the merchants often pay part of the price for it while the oxen are yet grazing on the steppes.

The merchants of St. Petersburg divide the tallow which they receive from the interior into white and yellow candle-tallow, and common and Siberian soap-tallow; the latter, which is considered the best tallow for soap-making, being brought by several rivers from Siberia to the lake Ladoga, and thence to the Neva by the canal of Schlusselburg. An *ambare*, or warehouse, is appropriated to the reception of the tallow on its arrival, in which it is selected and assorted (or *bracked*) according to quality, after which the casks are marked with the quality, the date of the selection, and the name of the *bracker* or selector. The white tallow is usually brought in conical casks, 2½ feet in diameter at the largest and 1¼ at the smallest end; but the yellow tallow is commonly in casks of the more usual shape. Yellow candle-tallow, when good, should be clean, dry, hard when broken, and of a fine yellow colour throughout. The white candle-tallow, when good, is white, brittle, hard, dry, and clean. The best white tallow is brought from Woronesch. Soap-tallow, however, is said to be better the more greasy and yellow it is. M'Culloch states that 120 poods of tallow, gross weight (of which the cask is usually about 10 per cent.), make a Petersburg last, and 63 poods an English ton.

Different kinds of tallow melt and retain their fluidity at very different degrees of temperature; the fat which is deposited about the kidneys being, in all animals, harder than that found in the cells of the bones, and especially than the half-oily fat found in the muscles and other soft parts; while the fat of some animals is harder than that of others—that of the sheep and deer, for example, congealing much sooner than that of the ox or horse. According, therefore, to the different kinds of fat which may enter into its composition, tallow will be found to vary considerably in fusibility; but 92° is the heat generally given as its melting-point, though Aikin states that he had seen a boiler-full of tallow perfectly fluid at 72°, and even then not sufficiently cooled to be made into candles; nor was this case, he observes, considered remarkable, "whence we may conclude that tallow, made into candles and exposed to the air, loses much of its fusibility."

The chief uses of tallow are described under CANDLE MANUFACTURE and SOAP MANUFACTURE.

During a long period of years, foreign tallow paid an import duty of 1*s.* 6*d.* per cwt., and tallow from the colonies a duty of only 1*d.* These duties were repealed in 1860, among other fiscal changes made by Mr. Gladstone.

The importation of tallow has now reached 160,000,000 lbs. annually. The exact figures for 1860, and the countries whence imported, were as follow:—

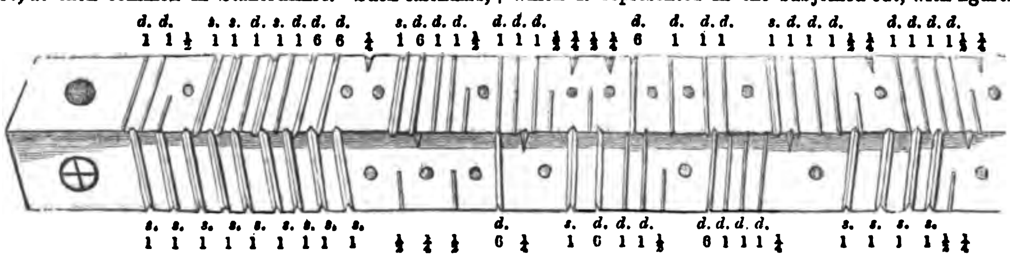
From Russia	1,082,663 cwts.	
" Australia	12,005 "	
" South America	146,957 "	
" Other countries	188,483 "	
	1,430,108 "	or, 160,172,096 lbs.

TALLY. This word appears to be derived from the French *taille*, or *tailler*, each of which expresses the idea of cutting or notching.

The use of notched sticks or tallies may be traced to a very remote period, and there is reason to believe that they were among the earliest means devised for keeping accounts. Some writers conceive that the

Greek symbolum (σύμβολον) was in some cases a species of tally, which was used between contracting parties; being broken in two, and one-half given to each. Upon tablets of wood called *axones* the Athenians inscribed the laws of Solon; and the ancient Britons used to cut their alphabet with a knife upon a stick, which, thus inscribed, was called *Coelbren y Beirdd*, "the billet of signs of the bards," or the Bardic alphabet. These sticks were commonly squared, but were sometimes three-sided; each side, in either case, containing one line of writing. Another illustration, of later date, is the clog-almanac, described by Dr. Plot, in 1686, as then common in Staffordshire. Such calendars, which had the various days marked by notches of different forms and sizes, were sometimes made small enough to carry in the pocket, and sometimes larger, for hanging up in the house. Similar calendars are said to have been formerly used in Sweden. Perhaps the most curious of these tallies is the Saxon Reive-Pole, which, down to a recent period, was used in the Isle of Portland for collecting the yearly rent paid to the crown as lord of the manor. This rent, which amounts to 14*l*. 14*s*. 3*d*., is collected by the reive, or steward, every Michaelmas; the sum which each person has to pay being scored upon a squared pole, a portion of which is represented in the subjoined cut, with figures to mark the

Fig. 1.



Saxon Reive-Pole used in the Isle of Portland.

amount indicated by each notch. "The black circle at the top denotes the parish of Southwell, and that side of the pole contains the account of the tax paid by the parishioners; each person's account being divided from that of his neighbour by the circular indentations between each. In the present instance the first pays 2½*d*., the second 4*s*. 2*d*., the next one farthing, and so on." The other side of the pole which is represented in the cut is appropriated to the parish of Wakem, of which the cross within a circle is the distinctive mark.

The tallies used in the Exchequer (one of which is represented by *fig*. 2) answered the purpose of receipts as well as simple records of

Fig. 2.

Exchequer Tally.

matters of account. They consisted of squared rods of hasel or other wood, upon one side of which was marked, by notches, the sum for which the tally was an acknowledgment; one kind of notch standing for 1000*l*., another for 100*l*., another for 20*l*., and others for 20*s*., 1*s*., &c. On two other sides of the tally, opposite to each other, the amount of the sum, the name of the payer, and the date of the transaction, were written by an officer called the writer of the tallies; and, after this was done, the stick was cleft longitudinally in such a manner that each piece retained one of the written sides, and one-half of every notch cut in the tally. One piece was then delivered to the person who had paid in the money, for which it was a receipt or acquittance, while the other was preserved in the Exchequer. Madox observes, respecting these rude and primitive records, "The use of them was very ancient; coeval, for aught I know, with the Exchequer itself in England." They were finally discontinued at the remodelling of the Exchequer in 1834; and it is worthy of recollection that the fire by which the Houses of Parliament were destroyed was supposed to have originated in the over-heating of the flues in which the discarded tallies were being burnt. Clumsy as the contrivance may appear, tallies were effectual in the prevention of forgery, since no ingenuity could produce a false tally which should perfectly correspond with the counter-tally preserved at the Exchequer; and no alteration of the sum expressed by the notches and the inscription could pass undetected when the two parts of the stick were fitted together. The officers of the Exchequer, commonly called *tellers* (talliers), as well as several other functionaries, derived their name from the word tally.

Tally Trade.—The word *tally* has come to mean a *counterpart*, although no cutting of a wooden tally is necessary. Thus, in the tally-drapers' trade carried on at the present time in various parts of the kingdom, there are 10,000 or 12,000 persons employed in the distribution of clothing or drapery which has cost them 7,000,000*l*. or 8,000,000*l*. annually, and which is re-sold by them on the tally system. They receive weekly payments from their customers; and these payments are recorded on a *tally* and a *counter-tally;* these are books, one of which is kept by the buyer and the other by the seller. Here the tally is a record of payments, as in the olden days, but maintained in a different form. There are tally-shops, also, where weekly payments are taken for goods bought; these differ from the tally-drapery trade chiefly in this—that in the latter the goods are taken round by the tally-men, who keep no shops.

TALMUD. [Hebrew Language.]

TAMARINDS, *Medical Properties of.* Of the two varieties of the only species of this genus, the fruit is much larger in the East Indian than the West Indian. The shell being removed, there remains the flat square hard seeds, imbedded in a pulp, with membranous fibres running through it. In the East Indies the pulp is dried, either in the sun, and this is used for home consumption, or with salt added, and dried in copper ovens, which kind is sent to Europe. (Crawfurd's 'Indian Archipelago.') This sort, called natural tamarinds, is much darker and drier than the West Indian, which are called prepared tamarinds.

The West Indian tamarinds reach maturity in June, July, and August, when they are collected, and the shell being removed, they are put into jars, either with layers of sugar put between them, or boiling syrup poured over them, which penetrates to the bottom. Prepared tamarinds, therefore, contain much more saccharine matter than the others. According to Vauquelin, prepared tamarinds contain per cent. citric acid 9·40, tartaric acid 1·55, malic acid 0·45, bitartrate of potash 3·25, sugar 12·5, gum 4·7, vegetable jelly (pecten) 6·25, parenchyma 34·35, water 27·55. This prepared pulp has a pleasant astringent taste, with a somewhat vinous odour.

It presents an example of one of those natural combinations of gummy, saccharine, and acid principles which are of such great utility in hot climates. It is used not only in India, but in Africa, as a cooling article of food, and the travellers across the deserts carry it with them to quench their thirst. In Nubia it is allowed to stand in the sun till a kind of fermentation takes place: it is then formed into cakes, one of which dissolved in water forms a refreshing drink. In India a kind of sherbet is made with it, and by the addition of sugar it becomes a source whence vinegar is readily obtained. In the fevers and bilious complaints, and even dysenteries of those climates, it proves highly serviceable; in small quantity it acts as an astringent, but in larger it proves laxative. Boiling water poured over tamarinds yields a drink which is very grateful in the inflammatory complaints of our own country, particularly in the bilious fevers of autumn. An agreeable whey may be made with it, by boiling two ounces of tamarind-pulp with two pints of milk. Tamarinds may advantageously be added to curries, which should always have a vegetable acid as an ingredient. Tamarinds are frequently given along with senna, but they are said to lessen its purgative property. They form an ingredient in the *confectio sennæ* and *confectio cassiæ*.

In times of scarcity in India the seeds are eaten, being first toasted and then soaked for a few hours in water, when the dark skin comes easily off; they are then boiled or dried, and taste like common field-beans.

TANACETIN. A bitter and crystallisable substance found in the flowers of the tansy (*Tanacetum vulgare*).

TANGENT. In the article Contact we have given the first notion on this subject, which we now resume in a somewhat more general manner, annexing the usual details of formulæ, but without proof.

It is usual to apply the word tangent to the tangent *straight line* only, on which see Direction: generalising the definition, it will be as follows:—Of all curves of a given species, or contained under one equation, that one (B) is the tangent to a given curve (A) at a given point, which passes through that given point, and is nearest to the curve (A): meaning that no curve of the given species can pass through the given point, so as to pass between (B) and (A), immediately after leaving the point at which the two latter intersect.

To ascertain the degree of contact of two curves which meet in a point, proceed as follows. Let $y=\phi x$ and $y=\psi x$ be the equations of the curves, and a the abscissa at the point of contact; so that $\phi a=\psi a$. At the point whose abscissa is $a+h$, the difference of the ordinates of the curves is, by Taylor's theorem,

$$(\phi' a-\psi' a)\,h+(\phi'' a-\psi'' a)\frac{h^2}{2}+(\phi''' a-\psi''' a)\frac{h^3}{2.3}+\ldots$$

as to which it will be found that h can be taken so small that the series shall be convergent. Now of two series of the form $Ah^m + Bh^{m+1} + \ldots$ the value of that in which m is the greater will diminish without limit as compared with the other, when h diminishes without limit. Consequently, every curve $y=\psi x$, which has $\psi' a=\phi' a$, will approach, before the point of contact is attained, nearer to $y=\phi x$ than any other in which $\psi' a$ is not $=\phi' a$. Again, when $\phi' a=\psi' a$, those cases of $y=\psi x$ in which $\psi'' a=\phi'' a$, will approach nearer to $y=\phi x$ than any in which $\phi'' a$ is not $=\psi'' a$; and so on. Hence, to make $y=\psi x$ have the closest possible contact with $y=\phi x$ when $x=a$;—give such values to the constants in $y=\psi x$ as will satisfy as many as possible of the equations $\phi a=\psi a$, $\phi' a=\psi' a$, $\phi'' a=\psi'' a$, &c. consecutively from the beginning. This is a brief sketch, which can be filled up from any elementary work; and the following are the principal results :—

1. When the string of equations is satisfied up to $\phi^{(n)}a=\psi^{(n)}a$, the contact is said to be of the nth order.

2. In contact of the nth order, the deflection $\phi(a+h)-\psi(a+h)$ diminishes with h^{n+1}, and vanishes in a finite ràtio to it.

3. In contact of an even order, the curves intersect at the point of contact; in contact of an odd order, they do not intersect at that point.

4. When curves have a contact of the nth order, no curve, having with either a contact of an order inferior to the nth at the same point, can pass between the two.

5. A straight line, generally speaking, can have only a contact of the first order with a curve; and the equation to the tangent straight line of the curve $y=\phi x$, when $x=a$, is $y-\phi a=\phi' a(x-a)$. But if it should happen that $\phi'' a=0$, $\phi''' a=0$, &c., up to $\phi^{(n)}a=0$, then for that point the tangent has a contact of the nth order. Thus, at a point of contrary flexure the tangent has a contact of the second order, at least, with the curve.

6. A circle, generally speaking, can be made to have a contact of the second order with a curve, and the equation of the most tangent circle, or circle of CURVATURE, to the curve $y=\phi x$, at the point $x=a$, is

$$\left(x-a+\frac{\phi' a\,(1+\overline{\phi' a}^{\,2})}{\phi'' a}\right)^2+\left(y-\phi a-\frac{1+\overline{\phi' a}^{\,2}}{\phi'' a}\right)^2=\frac{\left(1+\overline{\phi' a}^{\,2}\right)^3}{\overline{\phi'' a}^{\,2}}$$

This circle cuts the curve, generally speaking: if not, as for example, at the vertices of an ellipse, it is evidence that the circle has a contact of some higher and odd order. The centre of the circle of curvature is a point on the normal, being that at which the normal touches the evolute. [INVOLUTE AND EVOLUTE.]

Not only is the term tangent most generally applied to the closest straight line only, but frequently only to that portion of the straight line which falls between the point of contact and the axis of x. Again, the normal is a straight line perpendicular to the tangent, drawn through the point of contact: but this term also is frequently applied only to that portion which falls between the point of contact and the axis of x. It is with reference to this limitation that the terms subtangent and subnormal are to be understood: the first meaning the distance from the foot of the tangent to the foot of the ordinate; the second that from the foot of the ordinate to that of the normal. The formula for the subtangent is $-\phi a \div \phi' a$; that for the subnormal $\phi a \times \phi' a$. The sign determining the mode of taking the line from the foot of the ordinate.

Let β be the angle made by the tangent with the axis of x; usually the angle made by that part of the tangent which has positive ordinates with the positive side of the axis of x. Then β, at the point whose abscissa is x, is determined by the equation

$$\tan\beta=\frac{dy}{dx};\ \text{and subtangent} = -y\frac{dx}{dy},\ \text{subnormal}=y\frac{dy}{dx}.$$

If we take the more general mode of measurement proposed in SIGN, this equation remains equally true. Now, keeping strictly to that mode, let β be the angle made by the tangent with the axis of x, θ the angle made by the radius vector r with the axis of x, and μ that made by the tangent with the radius vector. It will be found, then, that in all cases

$$\mu=\beta-\theta \quad , \quad \tan\mu=r\frac{d\theta}{dr}.$$

Unless the mode of attributing signs be carefully attended to, these last equations, though always considered as universally true, are not so in reality.

TANGUIN. A poisonous crystalline bitter substance found in the Tanghin of Madagascar (*Cerbera Tanghin*). Its composition is not known, but it appears to contain no nitrogen. [CERBERA TANGHIN, in NAT. HIST. DIV.]

TANK. The sense usually attached to this word, in England, is that of a rather large vessel, for holding water or other liquids, either placed above or below the ground; in India, the word is applied to the receptacles formed for the purpose of storing rain-water, some of which have an area of 364 (Dilwara) or 437 acres (Kalingur), with enclosure dykes of 38 feet in height.

Tanks intended to hold rain-water collected from houses, or the drainage water of farm yards in agricultural districts, are rarely made of a greater capacity than 50 or 60 cubic yards; and they are constructed of the most impermeable hydraulic masonry that can be obtained; but precautions must always be taken that the materials so employed should not be of a nature to affect the chemical properties of the waters. Brickwork set in Roman cement is, for instance, preferable for such uses to masonry of limestone, set in ordinary lime mortar; and a backing of good clay puddle is preferable to one made of concrete. Provision must be made for fixing the suction pipes of the pumps, for connecting the inlet and overflow pipes, and for means of access for examination and repair; ventilation pipes must also be provided. As it almost always happens that dead leaves, or other organic impurities, are carried into tanks of the description under consideration, it is advisable, if the water be required for domestic use, to provide some means of filtration for the water, and this object is effected in many very ingenious manners, two of which may here be mentioned. For instance, in the great chalk plateau of Upper Normandy the rain water tanks are sunk into the boulder clay, or the chalk, as the case may be, and they are made of sufficient dimensions to allow of the formation of a subsidiary lateral chamber, shut off from the body of the tank by a cross wall of a porous material, through which the water from the larger chamber filters into the subsidiary one; the suction pipe being placed in the latter, and the inlet pipes in the larger chamber. The other description of rain water tank is used in Venice, and it is formed by firstly making a large watertight enclosure, usually circular in plan, and then an inner, concentric wall is built, leaving a large annular space between them: this annular space is filled in to a certain height with filtering materials of sand, gravel, &c., through which the water passes until it reaches a series of holes made in the lower portion of the inner wall; it then accumulates in this species of well, from whence it is drawn by means of buckets. It must, however, always be observed that rain waters so stored are not of a proper quality for human consumption, and that they should be exclusively applied to washing, or to analogous household purposes.

The large vessels used for storing oils, or for the various operations of manufacturing chemistry, are made of iron, wood lined with lead, of zinc, or of other materials according to the nature of the liquids to be contained. The principles of their construction are derived from the ordinary laws of HYDROSTATICS.

As to the Indian catch-water tanks it may be observed that they are in fact RESERVOIRS, and the remarks made under that head will apply to them. Generally speaking the tanks in question are principally used for irrigation, and their dams are formed of earth-work faced towards the up stream with stone, either laid dry, or with mortar. They are provided with overflow dams, escape weirs, sluices, and all the ordinary appliances of reservoirs; and they would appear to have been constructed upon the same principles at the present century as they were in the remotest antiquity. Much information on this subject is to be found in General Baird Smith's works on 'Irrigation,' and in the 'Selections from the Records of the Bombay Government,' or in the 'Selections from Public Correspondence,' published by authority of the late East India Company.

Agricultural Tanks are sometimes large open receptacles, or ponds, formed by excavating the ground and disposing the removed earth in the form of banks to retain the water; but the tanks which will here be especially treated of are the smaller covered reservoirs used to collect and retain liquid manure.

These tanks are usually constructed of an oblong shape, of brick well cemented, with one or more divisions, and capable of containing at least ten times as many hogsheads as there are heads of cattle on the farm. They are vaulted over, having a small aperture, in which a pump is placed, sufficient to allow a man occasionally to clear out the sediment, when the liquid has been pumped up. The form preferred is that of a cube, or rather that of several cubes in succession. A tank for a farm of 200 acres of arable land should be 15 feet wide, 15 deep, and 45 long, giving 3 cubes of 15 feet, or a cavity capable of containing upwards of 10,000 cubic feet of liquid. In this tank the urine is diluted with water to prevent too rapid decomposition, and also to retain the ammonia which is formed; for which purpose gypsum and sulphate of copper are sometimes put into the tanks. In very porous soils the bottom and sides must be puddled, to keep in the liquid; and it may be advantageous to build the walls in cement altogether. The liquid from the yards and stables is carried into the tank by a main drain constructed of brick or stone, and which receives a number of smaller drains from every part of the yards and cattle-sheds. Thus the litter in the yard is always dry, and none of the richness of the manure is lost by evaporation.

Sometimes the tank is vaulted like a cellar under the cow-house and stables, which are washed out twice every day, and all the dung and water are swept into a cess-pool communicating with the tank. A very diluted, but rich liquid soon fills the first division of the tank: a sluice is then shut, and the next washings run into a second division, and when that is full, into a third. In the meantime the contents of the first tank have undergone a certain fermentation, by which the ammonia first evolved has become mild and impregnates the water. It is then in a fit state to be carried on the land in tubs or water-carts. When properly diluted, it accelerates vegetation in a surprising degree; but if put on fresh, it burns the grass or any vegetable it touches, because the ammonia is in a caustic state. If a cow drop her urine in a field in a hot summer's day, all the grass it has touched becomes yellow and is burned up: but if the same happen in rainy weather, the spot soon becomes very green, and the grass luxuriant; because, in this case, the urine is amply diluted and its caustic nature corrected. Those who live near gas-works may collect the ammoniacal gas-water in a tank, and, by the addition of sulphuric acid in very small quantities, they may produce a very fertilising liquid, which will stimulate vegetation, and be a very good manure.

The necessary concomitant of a tank, whether for water or manure, is a water-cart, that is, a large cask put upon wheels to bring water from some distance. When there are no means of bringing water in pipes, a water-cart is quite indispensable. It is simply a cask placed on the frame of a cart, with a plug-hole in the end or lower part, from which the water may be let out by a cock, or drop on a flat board or into a bucket with holes, so as to spread it about. The plug-hole is shut by a valve inside, which can be opened by means of a string, the pressure of the liquid keeping it close to the plug-hole.

Many of the artificial manures would make excellent liquids by merely mixing them up with water in a tank, and allowing a certain degree of fermentation to take place. Thus nothing is lost, and all volatile substances are taken up by the water. The soluble portions are dissolved and the earthy matters diffused, so as to be more equally spread over the land.

When a farm-yard is situated on a hill, and there are fields or pastures on a lower level, at no great distance from it, the liquid from the tank may be conducted by channels lined with clay, having small sluices to direct the streams to any particular field. It may thus be made to irrigate temporarily a considerable surface, which it will greatly enrich. It may be led into the common furrows between the lands or stitches in ploughed land, and allowed to soak in them, and then it can be spread with the earth of the furrow, by means of broad shovels, over the growing crops, and will greatly invigorate them.

Hitherto the experience in this country of liquid-manure tanks is of limited extent, but the general impression is growing, that by covered yards and box-feeding the litter may so absorb all the urine and excrement of the animals, that tanks will be unnecessary.

TANNIC ACID, TANNIN. One or other of these bodies is found, to a greater or less extent, in most vegetable substances. The name *tannin* is derived from the fact that it is the only active constituent in the various barks, &c., used in the familiar operation of making leather, or *tanning*.

Tannin is an acid body; and inasmuch as researches upon the tannin obtained from various sources have provēd that it is not in all cases identical, but that several modifications exist, the names *gallotannic acid* (from nut-galls), *caffotannic acid* (from coffee), *quinotannic acid* (from cinchona bark), *quercitannic acid* (from oak-bark), &c., have been introduced.

Tannic acid is a powerful astringent, and hence has long been used in medicine. For this purpose it is always extracted from nut-galls. The galls are reduced to coarse powder, and digested in a percolator with ether which has been previously mixed and shaken with water. In the lower part of the vessel two strata of liquid appear; the heavier is a strong solution of tannic acid, by evaporating which, the acid is obtained, as a colourless or slightly yellowish friable mass, which does not crystallise, but somewhat resembles dried gum.

The *gallotannic acid* thus obtained is readily soluble in water: the solution has an astringent but not a bitter taste: it reddens vegetable blues, and decomposes alkaline carbonates with effervescence; weak alcohol dissolves it, but ether only slightly. When the aqueous solution is exposed to the air, especially if the temperature be high, oxygen gas is absorbed, and an equal volume of carbonic acid gas evolved, while the gallotannic acid is converted into gallic and ellagic acid. Gallotannic acid precipitates gelatin from solution; the compound has been called *tannogelatin*, and when the acid is in excess a viscid elastic mass is formed, which contains about half its weight of gallotannic acid. When the liquid from which the gelatin is precipitated is heated to ebullition, the tannogelatin is re-dissolved. Gallotannic acid also precipitates albumen and starch. Boiled with dilute sulphuric or hydrochloric acids, gallotannic acid splits up into gallic acid and glucose.

When dried at 212° gallotannic acid consists of $C_{54}H_{22}O_{34}$.

Gallotannic acid combines with the alkalies to form salts, which are called *gallotannates*, and it precipitates most metallic oxides and organic bases from solution. The salts of protoxide of iron suffer no change when a solution of gallotannic acid is added to them; but by exposure to the air a deep bluish-black precipitate is formed. Gallotannate of peroxide of iron, formed by the action of the acid on a persalt of the metal, is the basis of writing-ink, and is a black pulverulent precipitate.

Gallamic or *tanningenamic acid* ($C_{14}H_7NO_8 + 3\,Aq$) is a product of the action of ammonia on gallotannic acid. It crystallises from alcohol in beautiful rectangular plates.

Tannomelanic acid is a dark ulmin-like substance formed when gallotannic acid is boiled with a concentrated solution of potash in a vessel open to the air. If the potash be dilute, a portion of the acid is oxidised to *tannoxylic acid*. The constitution of these acids has not been satisfactorily ascertained.

Sumach-tannic acid, from various species of *sumach*, is identical with gallotannic acid.

Cachoutannic acid or *mimotannic acid*. Obtained from the well-known astringent substances KINO and CATECHU by the displacement process previously described. It differs from gallotannic acid in not giving a precipitate with solution of tartar emetic, and in giving with persalts of iron a grayish-green precipitate. Moreover, it does not yield pyrogallic acid when heated. Its composition is said to be $C_{36}H_{18}O_{16}$. In other respects it resembles gallotannic acid.

Tanningenic or *catechucic acid*, called also *catechin* ($C_{40}H_{18}O_{16}$?), is another tannic acid contained in catechu. It is part of the insoluble portion which is left on digesting catechu in cold water. It may be dissolved in boiling water, and decolorised by animal charcoal: on cooling, it deposits in colourless granular crystals. It is tolerably soluble in alcohol; less so in ether. Heated to 422° Fahr., it fuses, and at a higher temperature is decomposed, yielding *pyrocatechin* or *oxyphenic acid* ($C_{12}H_6O_4$). Dilute acids dissolve it; concentrated acids decompose it; hot nitric acid converts it into oxalic acid. It does not form definite compounds with bases; gives a deep green colour to persalts of iron, but precipitates neither lime-water, baryta-water, tartar-emetic, starch, gelatin, or the alkaloids.

Rufocatechucic acid or *rubinic acid* is a red, amorphous, flocculent precipitate, slowly deposited from a solution of tanningenic acid in an alkaline carbonate. It forms red slightly soluble salts with bases.

Japonic acid is a black substance formed on exposing to the air a solution of tanningenic acid in caustic potash. It is insoluble in cold water, and gives black precipitates with most of the metals.

Caffotannic, cafeic, or *chlororginic acid* ($C_{70}H_{38}O_{34}$?), occurs in coffee berries as a double salt of potash and caffeine, and combined also with lime and magnesia. It may be precipitated by subacetate of lead from an alcoholic infusion to which water has been added to separate resinous matter. The lead precipitate suspended in water and treated with sulphuretted hydrogen, and the filtrate evaporated, yields a semi-crystalline mass of caffotannic acid. It is very soluble in water, less so in alcohol, has an astringent taste, and strongly reddens litmus-paper. By heat it gives oxyphenic acid and an odour of burnt coffee; and by distillation with peroxide of manganese and sulphuric acid, yields kinone. It does not act upon ferrous salts, but to the ferric salts a green colour is imparted. It does not precipitate tartar emetic or gelatine, but throws down quinine and cinchonine from solutions. The *caffotannates* have been but little studied. If the above formula be correct, caffotannic acid is obviously a homologue of gallotannic acid, the difference being eight equivalents of C_2H_2.

Viridic acid ($C_{28}H_{14}O_{16}$?) is a product of the oxidation of caffotannic acid in the presence of ammonia. It is precipitable by subacetate of lead, and gives deep green solutions with the alkalies.

Morintannic acid, from *yellow wood* or *fustic* (*Morus tinctoria*). This acid often forms considerable deposits in the logs of fustic, and after being purified by crystallisation from water is obtained in minute prisms. It has a sweetish and yet astringent taste; is soluble in alcohol, ether, and wood spirit, but insoluble in turpentine and the fixed oils. By distillation it yields phenic and oxyphenic acids and much charcoal. The *morintannates* have not received much attention. The solution of the acid in potash absorbs oxygen from the air, blackens, and *moroxylic* acid is probably formed.

Rufimoric acid is deposited in crystalline grains on exposing to the air a solution of morintannic acid in sulphuric acid; or on boiling the same acid with dilute hydrochloric acid. When dry it forms a deep red amorphous powder, very soluble in alcohol, less so in water, and only slightly so in ether. It is very soluble in a weak solution of ammonia, and the liquid has a dark purplish colour. In composition it differs but slightly from morintannic acid, but both bodies require farther investigation.

Moric acid, or *morin* ($C_{36}H_{14}O_{18} + 2\,Aq.$), as a lime salt, is deposited on cooling an infusion of fustic. Liberated by oxalic acid in a boiling alcoholic solution and precipitated by water, it occurs as a white crystalline powder that becomes slightly coloured on exposure to the air. It is almost insoluble in cold water, only slightly soluble in boiling water, and very soluble in alcohol or ether.

Quercitannic acid. This is the variety of tannic acid contained in oak bark. According to Stenhouse it differs considerably from that of oak galls (gallotannic acid). It cannot be made to yield gallic acid, nor does it give pyrogallic acid by dry distillation. In other respects it resembles gallotannic acid.

The tannic acid (*boheic acid*) contained in *black tea* (*Thea bohea*) appears to be identical with that of oak bark.

Cinchotannic, kino- or *quino-tannic acid*, occurs, along with kinic acid, combined with alkaloids in the cinchona barks. It resembles gallotannic acid in precipitating gelatin, starch, and albumen from their solutions; with tartar-emetic it gives a grayish-yellow precipitate, and colours persalts of iron green. Its solution absorbs oxygen from the air, especially if it be alkaline, and a deep red coloured body termed *red cinchone* is formed. By dry distillation the latter body furnishes pyrogallic acid.

Other tannic acids. Astringent principles, termed tannic acids, have been found in plants other than those above described. The following are the names and sources of these acids, but their individuality has yet to be established. *Aspertannic acid*, from the *Asperula odorata*, or

Woodruff; *Rubitannic acid*, from the leaves of the Madder plant; *Callutannic acid*, in the common Heather; *Rhodotannic acid*, in the Rhododendron leaf; *Leditannic acid*, in the wild Rosemary; and *Pinitannic acid*, in the bark of various Pines. *Gallerythronic acid* has been referred to this article on tannic acids; it is, however, a derivative of gallic acid, and is the cause of the deep blue coloration imparted to an aqueous solution of gallic acid, containing bicarbonate of lime, on exposure to the air: acids change it to red, but lime restores its blue colour.

Estimation of tannic acids. The amount of actual tanning material contained in a bark, &c., is often required to be known by the tanner. At present the only practical means of doing this, is to add a standard solution of gelatin to the decoction of a small quantity (10 to 50 grains) of the tanning substance until no further precipitate of tannate of gelatin is thrown down. The solution of gelatin is standarised by a known quantity of pure gallotannic acid; the amount of it required to precipitate the acid in the specimen under examination, is supposed to indicate the tanning value of that sample. It is a question, however, whether gelatin in solution precipitates the whole of the matters that skin does in the tan-pit; if it does, the process may be relied on, and it is certainly fair to assume that it does, inasmuch as skin is nearly all gelatinoid matter.

The following table indicates the amount of tannic acid in the chief varieties of tanning material. Not only do different substances differ much in the quantity they contain, but the same plant is much influenced by climate, soil, and age.

TANNIGENAMIC ACID. [TANNIC ACID.]

TANNIGENIC ACID. [TANNIC ACID.]

TANNIN. [TANNIC ACID.]

TANNIN, PURE, or TANNIC ACID, *Medical Properties of.* This substance in combination with extractive has been long known under the name of tannin, and recognised as the active principle in almost all astringent vegetables. [ASTRINGENTS.] As many of these are powerful in restraining excessive discharges, whether bloody or otherwise, it was conjectured that the pure principle would be yet more efficacious than when in a state of combination. Accordingly it has been administered in some passive hæmorrhages, chiefly from the uterus and the bronchial tubes. To effect any good it requires to be given for several days in small doses. It is with difficulty absorbed into the circulation, being with great reluctance taken up by the lacteals, and producing very great constipation, from its direct astringent action over the intestinal canal, with which it is brought into contact. Tannic acid has been recommended in cases of incurable organic diseases affecting the uterus, accompanied with wasting discharges. These it may for a time moderate, but the constipation induced never fails ultimately to aggravate the disease and discomfort of the patient. There is little therefore to induce practitioners to employ it to act on remote organs, as it appears to be converted into gallic acid wherever it is absorbed. To facilitate its action a solution of it in alcohol, or, better still, in ether is employed. This is a very powerful topical astringent. Tannin present in the after-math of grasses given as food for cattle seems to pass out almost unchanged, and in the quantity originally present. It is of use, along with the bitter extractive, in restraining the fermentation of the food. It is its presence in vegetables which causes the motions to become black when any preparation of iron or chalybeate water is taken.

TANNING. [LEATHER MANUFACTURE.]

TANTALUM. [COLUMBIUM.]

TANNOMELANIC ACID. [TANNIC ACID.]

TANNOXYLIC ACID. [TANNIC ACID.]

TAPESTRY (French, *Tapisserie;* Italian, *Tappezzeria*). This name is most commonly applied to the textile fabrics, usually composed of wool or silk, and sometimes enriched with gold and silver, woven or embroidered with figures, landscapes, or ornamental devices, and used as a lining or covering for the walls of apartments. It is derived from the French "tapis," which is from the Latin "tapetum," a carpet or covering for a bed or couch. The French "tapis," though generally applied to carpets, is also used to express other figured cloths used as coverings, such as the coverings of tables. Of the use of the word tapestry in this more extended sense, there is an instance in Shakspere's 'Comedy of Errors,' act iv., sc. 1.

Although the loom was employed from the earliest times by the Greeks and Romans for the production of ordinary tissues, its application to the weaving of ornamented or figured fabrics was chiefly Oriental. It is probable that many of the early tapestries were embroidered by hand or worked with the needle. This kind of work, of which the Bayeux tapestry is a celebrated example [BAYEUX TAPESTRY], was continued long after the practice of weaving tapestry in the loom had become common. The ornamented curtains of the Jewish tabernacle (Exodus, xxvi., xxxv., xxxvi.), are generally considered to have been embroidered by the needle.

Scanty as are the notices of tapestry in ancient writers, our information respecting it during the middle ages is not much fuller. Jubinal ('Recherches sur l'Usage et l'Origine des Tapisseries') observes that we find females engaged in working tapestry with the needle from the earliest epochs of the French monarchy. Gregory of Tours, writing towards the close of the 6th century, in his description of the rejoicings which followed the profession of Christianity by Clovis and his people, speaks of the streets being shaded with painted cloths or curtains (*velis depictis*), and the churches being adorned with hangings; and again, in describing the consecration of the church of St. Denis, he mentions tapestries embroidered with gold and garnished with pearls. The fabrication of tapestry hangings by the loom appears to have been introduced into France, at the earliest, about the 9th century, until which time the needle had been used exclusively in their production; and long after that period, the two processes were practised concurrently. At this time we often find embroidered cloths enumerated among the decorations of churches. From contemporary notices, it is evident that there was a celebrated manufacture of tapestry at Poitiers as early as 1025. Nor was the manufacture of tapestry confined to France at this period. The inhabitants of the north of Europe also practised it, and English embroidery was much admired and highly prized on the Continent. In the East also, where the art had been cultivated from the earliest antiquity, fine embroidery was produced in the 11th century. Much of the early Oriental tapestry was adorned with grotesque figures; and long after it became usual to depict natural figures and scenery upon tapestry, such devices were often used in ornamental borders.

In the 12th and 13th centuries the use of tapestry extended greatly. It passed from churches and monasteries, in which it had been used for curtains, palls, altar-cloths, vestments, &c., to the residences of the nobility. The use of tapestry in this way is believed by many writers on the subject to have been one of the luxuries introduced from the East in consequence of the increased intercourse occasioned by the crusades. The crusaders brought accounts of the Oriental practice of covering walls with prepared and ornamented skins, chiefly those of goats and sheep. These, which were probably at first used of their natural size and shape, were, at a later period, cut into rectangular pieces, about two feet high, and rather less in width, and united by sewing into very solid and handsome hangings, which were well adapted to resist damp. Such hangings, or leather tapestry, were manufactured much at Venice and Cordova, and were sometimes either gilt all over, or ornamented with gilt devices, in which case they bore the name of *d'or basané*. The Oriental origin of the more ordinary kind of tapestry is indicated by the name *Sarazins* or *Sarazinois*, which was frequently applied in France to the early manufacturers. In the following centuries tapestry was not only used to cover the interior walls, but was also employed on great occasions, as for instance on the public entries of princes, to decorate streets, and to impart a joyful appearance to towns and public places. It formed part of the decorations of festal halls, and was employed to ornament the galleries and other erections required at tournaments. Rich embroidery was also much employed in the decorations of the horses and men who formed the actors in those chivalric amusements; and the brilliant, though often grotesque devices of heraldry, which formed so important a part of the display upon such occasions, afforded extensive employment to the workers of tapestry and other ornamented tissues.

The art of making tapestry, for which the Flemings had been celebrated from the 12th century, made considerable progress in Flanders in the 14th century, and attained its highest perfection there in the 15th. Tapestry manufactories were early established at Brussels, Antwerp, Oudenarde, Lisle, Tournay, Bruges, and Valenciennes; but that of Arras was more celebrated than any other, and its productions were so highly prized, that the name *arras* became a common expression for the finest tapestry generally, whether made in that place or elsewhere. The hangings of Arras, as well as those of other manufactories in France, were for the most part executed in wool. Hemp and cotton were also used in them, but no silk or gold thread. The fabrication of tapestries formed of these substances was carried on chiefly at Florence and at Venice. The recollection of this difference is important in discovering where old tapestries were made. The designs included not only scenes from ancient history, from the fabulous stories of heroes, and from modern historical events; but hunts, fantastical animals, or the occupations peculiar to the different seasons of the year; while romantic and chivalric poems afforded a rich store of subjects for illustration. The 16th century, which was an age of general improvement in France, gave a new impulse to the production of tapestry. Francis I. founded the manufactures of Fontainebleau, in which threads of gold and silver were skilfully introduced into the work. It was, we are informed, with this new impulse that the practice was commenced of weaving tapestry in a single piece, instead of composing it, as before, of several smaller pieces joined together. This prince brought Primaticcio from Italy, and, among other works of art, commissioned him to make designs for several tapestries, which were woven at Fontainebleau. He also engaged Flemish workmen, whom he supplied with silk, wool, and other materials, and paid liberally for their labour. Henry II. established a manufacture of tapestry on the premises of the Hôpital de la Trinité, which attained its highest celebrity in the reign of Henry IV., and produced many fine tapestries. Henry IV. re-established, in 1597, the manufacture of tapestry at Paris, where it had been interrupted by the disorders of the preceding reigns. The establishment languished, if it did not become quite extinct, after the death of Henry IV.; but when the royal palaces, especially the Louvre and the Tuileries, were receiving their rich decorations, in the reign of Louis XIV., his minister Colbert revived it, and from that time the celebrated royal tapestry-manufactory of the Gobelins dates its origin.

The production of tapestry at the Gobelins is said to have attained the highest perfection in the time of the minister Colbert and his successor M. de Louvois. Le Brun, when chief director of the establishment, made many designs for working after; and M. de Louvois caused tapestry to be made from some of the finest designs of Raffaelle, Julio Romano, and other Italian painters. The manufacture declined greatly at the Revolution, but was revived under the government of Napoleon, and has ever since been carried on successfully, though not to the same extent as formerly. In England the art was practised from a very early date, the ladies of the Anglo-Saxon period being especially famous for their needle, and the Saxon chroniclers having frequent references to the rich hangings wrought by them. It was probably owing to the expense of such hangings, when of large size, and the very long time required for their production, that the less comfortable device of painting the walls of chambers was extensively adopted in the early Norman period.

Chaucer mentions a "tapiser," in company with a "webbe" and a "dyer," among his Canterbury pilgrims; from which circumstance it may be presumed that the business was not a very uncommon one towards the close of the 14th century. In the 15th century the use of tapestry greatly extended in England; but then, and for long after, the principal supply appears to have been from the Continent. In the 16th century a kind of hanging was introduced which holds a place intermediate between painted walls and woven or embroidered tapestry. Shakspere alludes to these hangings under the name of "painted cloths." See also the admirable description of the rich tapestry common in the Elizabethan period, by Spenser, in his 'Faërie Queene,' book iii., canto ix. The introduction of tapestry-weaving into England is usually attributed to a gentleman named Sheldon, late in the reign of Henry VIII., though it was known, if not commonly practised, much earlier. James I. endeavoured to revive the manufacture of tapestry, which had by his time considerably declined, by encouraging and assisting in the formation, about 1619, of an establishment at Mortlake, under the management of Sir Francis Crane. James I. gave 2000*l.* towards the formation of this establishment, which appears to have been originally supplied with designs from abroad, but subsequently by an artist named Francis Cleyne, or Klein, a native of Rostock, in the duchy of Mecklenburg, who was engaged for the purpose. This undertaking was a favourite hobby both with James and his successor, who regarded Cleyne so favourably that he bestowed upon him, in 1625, an annuity of 100*l.* (Rymer's 'Fœdera,' vol. xviii., p. 112), which he enjoyed until the civil war. In the same year Charles I. granted 2000*l.* a year for ten years to Sir Francis Crane, in lieu of an annual payment of 1000*l.* which he had previously covenanted to pay for that term, as the grant recites, "towards the furtherance, upholding, and maintenance of the worke of tapestries, latelie brought into this our kingdome by the said Sir Francis Crane, and now by him and his workmen practised and put in use at Mortlake, in our countie of Surrey;" and of a further sum of 6000*l.* due to the establishment for three suits of gold tapestries. ('Fœdera,' vol. xviii., p. 60.) After the death of Sir Francis Crane, his brother, Sir Richard, sold the premises to the king, and during the civil war they were seized as royal property. It was for the use of this establishment that Charles I. purchased the famous Cartoons of Raffaelle. [Cartoons.] After the Restoration, Charles II. endeavoured to revive the manufacture, and employed Verrio to make designs for it, but the attempt was unsuccessful. During its period of prosperity, this manufacture produced superb hangings, after the designs of celebrated painters, with which the palaces of Windsor Castle, Hampton Court, Whitehall, St. James's, Nonsuch, Greenwich, &c., and many of the mansions of the nobility, were adorned. An act of parliament was passed in 1663 to encourage the linen and tapestry manufactures of England, and to restrain the great importation of foreign linen and tapestry.

In the primitive method of working tapestry with the needle, the wool was usually applied to a kind of canvas, and the effect produced was coarse and defective; but some finer kinds were embroidered upon a silken fabric. The process of weaving by the loom, after the manner known as the *haute lisse*, or high warp, was practised in the tapestries of Flanders (and according to Walpole and Jubinal, in those of England also), as early as the 14th and 15th centuries; the only essential difference between these and the productions of modern times being the comparative size of the pieces woven in the loom. The weaving of tapestry, both by the haute lisse and the basse lisse, appears to be of Oriental invention: the difference between the two methods may be thus briefly described. In the haute lisse the loom or frame with the warp-threads, is placed in a perpendicular position, and the weaver works standing; while in the basse lisse the frame with the warp is laid horizontally, and the weaver works in a sitting position. In weaving with the basse lisse, now seldom, if ever, employed, the design to be copied is laid beneath the threads of the warp, which are stretched in a manner resembling that of common weaving, the pattern being supported by a number of transverse threads stretched beneath it. The weaver, sitting before the loom, and leaning over the beam, carefully separates the threads of the warp with his fingers, so that he may see his pattern between them. He then takes in his other hand a kind of shuttle, called a *flûte*, charged with silk or wool of the colour required, and passes it between the threads, after separating them in the usual way by means of treddles worked by the feet. [Weaving.] The thread of woof or shoot thus inserted is finally driven close up to the finished portion of the work by means of a reed or comb formed of box-wood or ivory, the teeth of which are inserted between the threads of the warp. In this process the face of the tapestry is downwards, so that the weaver cannot examine his work until the piece is completed and removed from the loom. The haute lisse loom, which is differently worked, consists of two upright side-pieces, with large rollers placed horizontally between them. The threads of the warp, which usually consist of twisted wool, are wound round the upper roller, and the finished web is coiled round the lower one. The design to be copied is placed perpendicularly behind the back or wrong side of the warp, and then the principal outlines of the pattern are drawn upon the front of the warp, the threads of which are sufficiently open to allow the artist to see the design between them. The cartoon is then removed so far back from the warp that the weaver may place himself between them with his back towards the former, so that he must turn round whenever he wishes to look at it. Attached to the upright side pieces of the frame are contrivances for separating the threads of the warp, so as to allow the *flûte*, or broach, which carries the woof, to pass between them. Like the weaver with the basse lisse, the operator works, as it were, blindfold; but by walking round to the front of the loom he may see the progress of his work, and may adjust any threads which have not been forced into their right position by the reed or comb, with a large needle, called an *aiguille à presser*. The process of working with the haute lisse is much slower than the other, and is, indeed, almost as slow as that of working with the needle.

It may be desirable in this place to say a few words concerning two varieties of carpet and rug-work, which, though not really tapestry, bear a certain resemblance to it, and are termed *Patent Tapestry* and *Wool Mosaic*.

The Patent Tapestry and Velvet-Pile Carpet, invented by Mr. Alexander Whytock, of Edinburgh, was intended to supersede the ordinary Brussels carpeting, and has to some extent had that effect. The peculiarity of this manufacture lies in the unlimited number of shades and colours that can be introduced; insomuch that the most elaborately-coloured designs, with flowers and scrolls, can be executed. There is also a very considerable saving of worsted, as compared with the older processes. The appearance is nearly similar to that of Brussels carpet, but the manufacture is more simple, each thread being coloured separately, at spaces, with the various shades as they follow each other in the design. The means by which this process is accomplished is simple and beautiful; but much care is required in placing and arranging the threads, and putting them on the beam. There being a heavy preparatory outlay incurred, each pattern must have a large sale to defray the cost. In the article CARPET MANUFACTURE, certain descriptive details will be met with, which will serve to show how parti-coloured warps may be introduced to produce some such effect as is here denoted; the exact apparatus and processes need not be described here.

The *Wool Mosaic*, patented and manufactured by Messrs. Crossley, of Halifax, is an exceedingly curious production, involving no weaving process whatever. It may be called a velvet tapestry effect, produced by mosaic means. Artistic designs are prepared for this, of a higher order than is usual in carpets and rugs. The design on paper is ruled over in small squares, like a Berlin pattern; the size of the squares having a definite relation to the thickness of the woollen threads to be used. This design is re-copied upon ruled paper by girls, each of whom executes a portion of about a foot square. These papers then go into the factory. Woollen threads have previously been dyed to an almost infinite variety of colours, tints, and shades; for sometimes there are as many as a hundred different varieties introduced in one rug. A woman, especially skilled in this art, selects from a classified list all the colours that will be needed, taking one thread for every single square throughout the pattern. These threads are then brought together by means of a very remarkable apparatus. Every thread is stretched out horizontally to a length of about 17 feet, and is kept tight by a pull or force of about 4 lbs. One square foot of rug-work consists of about 50,000 threads, corresponding to that number of squares in the paper pattern. The force applied to the whole thus amounts to 200,000 lbs.; and hence the iron frame-work requires to be very strong. Girls, under the supervision of the mistress, are employed to stretch these threads, guided in so doing by bars and perforated plates. Thus they continue until a dense mass of worsted has been arranged, 17 feet long, 1 foot broad, and 1 foot deep. An ordinary hearth-rug, 6 feet by 2, requires 12 of these masses to complete the pattern, or 600,000 threads in all; equal to 10,200,000 feet, or nearly 2000 miles of worsted thread. This enormous quantity is made up into about a thousand rugs, all exactly alike, in the following way. The masses are firmly bound up, and cut into portions of convenient length. They are then arranged with the 600,000 threads vertical, all according to the proper pattern. A slice is cut off from the top, to render the upper surface quite level, by means of a large circular cutter revolving horizontally with great rapidity. The surface is coated with a hot solution of india rubber and camphine, then dried, then coated again, and so on two or three times. A backing, formed of canvas, is laid on with a strong cement of caoutchouc solution; and a little rubbing or scraping makes it adhere very firmly to the worsted. The circular cutter then severs a layer $\frac{3}{16}$ of an inch in thickness, which, by further processes, becomes applicable as rug, carpet, hanging, curtain, or tapestry. The mass of threads is thus cut away about a thousand times, producing this number of repetitions of the pattern. Copies of elaborate pictures may thus be obtained. The process does not become commercially successful unless there is a large sale for each pattern.

TAPIO'CA, a farinaceous substance, prepared in South America from two species of Janipha, ***Manihot utilissima***, or the bitter, and ***Manihot Aipi***, the sweet, Cassada or Manioc plants. The chief distinction between them is that a "tough ligneous fibre or cord runs through the heart of the sweet Cassava root, of which the bitter is destitute." Though the bitter contains a highly acrid and poisonous juice, from which the sweet is exempt, yet the bitter is cultivated almost to the entire exclusion of the other, which is probably owing to the greater facility with which it can be ground or rasped into flour, owing to the absence of the ligneous centre. The poisonous principle of the bitter manioc is thought to be of the nature of hydrocyanic acid. It is easily dissipated or decomposed by heat or fermentation; hence the flour becomes perfectly wholesome in the process of baking the cassava bread. The juice, after expression, may be inspissated by long boiling, or formed into a soup, with flesh and spices, called cassarepo, said to be powerfully antiseptic. By means of molasses it can be fermented and converted into intoxicating drink.

The fecula, or flour, after the juice has been carefully expressed, having been washed, and dried in the air without heat, is termed *mouchaco* in Brazil, *moussache* in the Antilles, and *cypipa* in Cayenne. This constitutes the Brazilian arrow-root of English commerce. When this fecula is prepared by drying on hot plates, it becomes granular, and is called *tapioca*. It occurs in irregular lumps or grains, and is partially soluble in cold water. The granules, diffused through water, and examined by the microscope, are of great uniformity of size, and smaller than those of arrow-root from the Marantas. Tapioca is very nutritious and easy of digestion, being free from all stimulating qualities. It is therefore very necessary to distinguish it from an artificial tapioca made with gum and potato starch, which is in larger granules, whiter, more easily broken, and more soluble in cold water than the genuine.

TAPPING, or Paracentésis (in Surgery), is the operation usually employed for the removal of fluid from any of the serous cavities of the body in which it has collected in a dangerous quantity. It is accomplished by means of an instrument called a trocar, and a tube, or canula, in which it exactly fits. The trocar is of steel, cylindrical through the chief part of its length, and terminated by a three-sided pyramid which ends in a very sharp point. The canula being placed upon its shaft, the trocar is thrust into the cavity containing the fluid, and being then withdrawn through the canula, the latter is retained in the aperture till all the fluid is discharged. The diseases for which tapping is chiefly performed are ascites, hydrothorax, hydrocele, and, occasionally, hydrocephalus, and effusions of fluid on the pericardium.

TAR. To give a concise definition of this familiar substance is difficult inasmuch as it varies in colour, composition, and consistence, and is derived equally from the animal, vegetable, and mineral kingdoms. From the colourless oil-like NAPHTHA, on the one hand, to the hard, black, resin-like BITUMEN, or pitch, on the other, we have mixtures of the two, containing more or less of either, and to which the term tar is applied.

Tar, then, is a coloured oleo-resin. Deposits of it are frequently met with in nature, rarely however, in large quantities. The most important basins of it are found in Burmah, especially at Rangoon. Wells, about sixty feet deep, are sunk in the soil, and from their walls oozes out the tar and collects at the bottom; it has a brownish green colour, a goose-grease consistence, and is a mixture of several well-defined matters that will be referred to presently. Names, other than tar, have been given to this naturally occurring oleo-resin. Thus, we have *rock-oil* or *petroleum*, *black naphtha*, *liquid pitch*, *liquid bitumen*, *fluid asphalt*, and *mineral tar*.

But the vegetable kingdom is also a source of tar; indeed, it is the most important one, and wood and coal are the members which yield it. In commerce we meet with wood-tar in barrels holding about thirty gallons. Under the name of *Stockholm tar* it is imported from Russia, Sweden, Norway, Denmark and other northern parts of Europe; while that from the States of the New World is distinguished as *American tar*. The wood, especially that of the root, of pines, is the kind most profitably used in the production of tar; and it is subjected to a crude yet effective process of destructive distillation. A large neatly-trimmed hole of conical shape is made in a bank, hill-side or other sloping ground, and into this is lowered a similarly shaped bundle of pine-billets. The wood being kindled the whole is covered with turf. Slow partial combustion now goes on, the resin naturally existing in the wood melts, is slightly decomposed and darkened in colour by the heat, and flowing down to the bottom of the hole is there received in an iron dish having a long tubular spout which conveys it a few feet through the ground to the mouth of the barrel; the latter being placed for its reception in a cavity some two or three yards lower down the slope.

Coal-tar has already been treated of in a separate article [COAL-TAR.] In appearance and complexity of composition it much resembles mineral and wood tar.

Remembering the vegetable nature of coal, it is easy to conceive that the above-described varieties of tar have a common origin. The production of, first, wood, then coal, and finally mineral tar are possibly sequential operations in nature which are simply hastened by the restless energy of man when, in the rude Macedonian fashion he half burns wood in the forest, or submits coal to destructive distillation aided by all the appliances of refined modern ingenuity.

Animal tar has already been treated of [BONE-LIQUOR.] It is chiefly used for lubricating machinery.

Pitch.—When tar is heated in retorts it partially volatilises. The first portions of the distillate constitute *crude naphtha turpentine* and impure *pyroligneous* (acetic) *acid*, and next *oils* containing *paraffin* come over; the residue in the retort is *pitch*, a hard, black, vitreous resin.

Constituents of Tar.—By tedious processes of fractional distillation, each portion of the distillate being redistilled and its products collected in several separate quantities, and these again rectified and acted upon by powerful chemical reagents—coal-tar has been shown to consist of;—first, a number of very inflammable liquids, containing either the elements carbon and hydrogen only, as CUMOLE, EUPION, (from εὖ beautiful, and πίων fat) TOLUOLE, and XYLOLE; or oxygen also, as in KREASOTE, CAPNOMOR (from καπνὸς, smoke, and μοῖρα part), and *picamar*. The latter is an oily body, of bitter taste, and specific gravity 1·10: it forms a crystalline compound with potash. The second series contains solid bodies, namely, PARAFFIN, NAPHTHALIN CEDRIRET, (from *cedrium*, the old name for "acid tar-water," and *rete* a net, in allusion to the reticulated appearance of its crystals), PYREN, CHRYSEN, PYROXANTHIN and *pittacal*; the latter has a deep blue colour, and is insoluble in water, alcohol, or ether. The liquid called *naphtha* chiefly consists of hydro-carbon; the *oils* contain the oxidised bodies; and *pitch* is a mixture of the various solids, together with other fixed matters that are probably decomposed when distillation is effected at very high temperatures, and which yield the charcoal that under these circumstances is always left in the retorts.

Mineral tar and coal-tar have been proved to consist of the same substances as wood-tar. As might be suspected, they contain less non-volatile matter than wood-tar.

Animal tar, besides the compounds already referred to, contains METHYLAMINE, ETHYLAMINE and other bases of the same class; ANILINE and its homologues; and some nitriles of fatty acids.

TARANTISMUS is the name given to a peculiar nervous affection which was long supposed to be the consequence of the bite of the Tarantula Spider. It seems to have occurred frequently in the kingdom of Naples during the 16th century, and to have been nearly similar in its characters to the disease which was originally called St. Vitus's dance [CHOREA], and to that which has occasionally prevailed in parts of Scotland, and has been called the "leaping ague."

The patients, nearly all of whom were women, soon after being bitten (as it was supposed) used to fall into a profound stupor, from which nothing roused them but the sound of such music as pleased them, on hearing which they had an irresistible desire to dance. So long as the music continued, and was in tune and sufficiently lively, they would go on jumping and dancing till they fell exhausted; and, all the time, some used to shriek, some to laugh and sing, and some to weep. When, after a short rest, they had recovered from their fatigue, they would again begin to dance with as much vigour as before, unless the music were played slowly or confusedly, when they would stop and grow anxious and melancholy, or even, if the music were not soon made agreeable to them, would fall into a dangerous state of stupor. The disease used to last about four days, and seemed to be cured by the profuse perspirations brought on by the active exercise; but it often returned at the same time in the following year, or even for a succession of years, and on every occasion required the same treatment.

Since it has been found that the bite of the Tarantula can produce no such strange effects as these, many have suspected that the disease ascribed to it never really existed, but was feigned for the purpose of exciting pity or for the pleasure of dancing. There is good reason to believe that in most instances it was counterfeited: but there can be no doubt that such a disease had occurred and had given occasion to the practice of the fraud. Besides its similarity to diseases whose reality is generally admitted, such as the St. Vitus's dance and the leaping-ague, cases have occasionally been met with in recent times which closely resemble it, and in which there could be no just suspicion of fraud. Such a case is described by Mr. K. Wood, in the seventh volume of the 'Medico-Chirurgical Transactions;' another is recorded by Mr. Crichton, in the thirty-first volume of the 'Edinburgh Medical and Surgical Journal;' and in the 'Cyclopædia of Practical Medicine,' art. 'Chorea,' several cases of analogous affections are related. All these however occurred singly. That the Tarantismus and the St. Vitus's dance should have assumed the characters of epidemics may be ascribed to their propagating themselves, as all convulsive affections are apt to do among nervous and superstitious persons, by the propensity to imitation, the effects of which are still frequently seen in the production of hysteria, chorea, and similar diseases.

TARAXACIN. *Taxaracin.* A bitter non-azotised crystalline principle contained in the milky juice of the common dandelion. (*Leontodon Taraxacum.*)

TARE. We hardly know whether *all* the words *tare, tret, cloff, suttle, gross, net*, are still used in commerce; they all hold their places in works of arithmetic. *Tare* is said to be the allowance for the weight of the box or bag in which goods are packed; *tret*, an allowance of 4 lb. in 104 lb. for waste; *cloff*, an allowance of 2 lb. in 3 cwt., that the weight may hold good when sold by retail; the *gross* weight, that of the goods and package all together; the *suttle* weight, that which remains when tare only is allowed; the *net* weight, that which remains when all allowances are made. We shall merely state what we know of these words.

Tare (written *tara* in some of our older arithmetical works) is made from the Italian *tarare*, to abate. In that language *tara* is a technical term implying abatement of any kind, not for weight of package only. We believe *cloff* to have been the English word which originally stood for the allowance for package: in our older arithmeticians, tare and cloffe generally go together, and the latter seems to be for the package, the former for other abatements. *Cloff* or *clough* is defined in an old dictionary as that wherein any thing is put for carriage sake. Humphrey Baker (1562) speaks only of tare and cloffe; Masterson (1592), of tara, cloffe, and tret, but the first two terms are used together. We cannot find cloff used in the sense given to it by our modern books of arithmetic until about the end of the 17th century.

Tret seems to be from the Italian *tritare*, to crumble. Stevinus, in his Latin treatise on book-keeping, uses *intertrimentum* in the sense of deduction from the quantity charged for. *Gross* weight needs no explanation; the Italian form *netto* was formerly used for net weight. It being well known that these terms generally come to us from the Italian, we must suppose suttle to be from *sottile*, which is used in the sense of fine and valuable, and is applied to the finer part, as separated from the coarser. One of our old writers (Masterson, 'Arithmetike,' 1592) uses suttle weight in a manner which makes us imagine we see the origin of the *hundred* weight being a hundred *and twelve* pounds. Without any explanation, as if it were matter of notoriety, he contrasts *suttle* and *averdupois* weight, the former having 100 lbs. to the hundredweight, the latter 112 lbs. In the rougher sort of goods, at the same period, the tare was (as appears by the tables they give) very often 12 lbs. in 112 lbs.: perhaps then the hundredweight of 112 lbs. was only an allowance for the weight of the box, barrel, or other package.

TARES are a most important green crop in the improved systems of agriculture, especially on heavy soils, where they thrive best. When sown in autumn, with a small sprinkling of wheat or rye, they cover the ground in spring, and supply abundance of fodder in summer. A good crop of tares is fully equal in value to one of red clover: it comes off the ground in sufficient time to give the land a summer tillage, which is so useful in destroying weeds, and to allow turnips to be sown in the same season.

There are many species and varieties of tares; but that which is found the best adapted for agricultural purposes is the common tare (Vicia sativa), of which there are two principal varieties, very slightly differing in appearance, one of which is hardy, and will stand the severest winters: the other is more tender, and is therefore only sown in spring; but it has the advantage of vegetating more rapidly, so that spring tares sown in March will be fit to cut within a fortnight or three weeks after those which were sown in autumn. By sowing them at regular intervals from September to May, a succession of green tares in perfection, that is, in bloom, or when the pods are forming, may be cut for several months, from May to October. A prudent farmer arranges his crops so that he shall have artificial green food for his horses and cattle at least six months in the year, by having tares fit to cut between the first and second cut of clover. When there are more tares than is absolutely required for this purpose, and the weather permits, they make excellent hay; or, if the weather is not favourable, they are cut and given to sheep, which are folded on the portion already cut. It is an advantage to have portable racks for this purpose, that the fodder may not be trod under foot and wasted; or the tares may be placed between hurdles, tied two and two, which form extemporaneous racks. It is prudent to raise sufficient seed for another year; but a crop of seed-tares raised for sale is seldom profitable, as they greatly exhaust the soil: and the price varies so much in different seasons, that it becomes too much of a speculation for a farmer. The difference of spring and winter tares is probably more owing to habit than to any real botanical distinction between them. When spring tares are sown in autumn instead of winter tares, they may occasionally stand the frost, if not very severe; but, in general, they rot on the ground and never recover; whereas the real hardy winter tares, whose vegetation is slower, seem insensible to the severest frosts.

In the early part of summer green rye and tares, mixed, are sold at a great price in large towns for horses which have worked hard and been highly fed in winter. They act as a gentle laxative, and cool the blood: near London, where every produce is forced with an abundance of manure, tares are often fit to cut early in May, and the land is immediately ploughed and planted with potatoes, or sown with mangel wurzel or Swedish turnips, which come off in September or October, in time for wheat-sowing. Thus two very profitable crops are raised during the time that the land, according to the old system, would have been fallow; and at the same time it is left as clean, by careful hoeing, as the best fallow would have made it.

Tares should be sown on land which is well pulverised. If after wheat, the stubble should be ploughed in with a deep furrow after a powerful scarifier has gone over the land several times to loosen it: five or six cart-loads of good farm-yard dung should be ploughed in. The tares should be drilled or dibbled, and the surface well harrowed. The intervals should be hoed early in spring: this will accelerate the growth, and insure a complete covering of the ground. As soon as the tares show the flower, they may be cut daily till the pods are fully formed; after this, any which remain uncut should be made into hay or given to sheep; for if the seeds are allowed to swell, the ground will be much exhausted. Another piece should be ready to cut by this time, and thus there may be a succession of tares and broad clover from May to November. Tares may be sown as late as August, on a barley or rye stubble, for sheep-feed early in winter, or to be ploughed in to rot in the ground, where beans or peas are intended to be sown early in spring; this is perhaps the cheapest mode of manuring the land, the only expense being the seed; for the tillage is necessary at all events.

TARGUMS, or CHALDEE PARAPHRASES OF THE OLD TESTAMENT. During the Babylonish captivity, the language of the Jews was affected by the Chaldee dialect spoken at Babylon, to such an extent, that upon their return they could not understand the pure Hebrew of their sacred books; and therefore, when Ezra and the Levites read the law to the people, they found themselves obliged to add an explanation of it, undoubtedly in Chaldee. (Nehem. viii. 8.) [HEBREW LANGUAGE; ARAMÆAN LANGUAGE.] In course of time such explanations were committed to writing, and from their being not simple versions, but explanatory paraphrases, they were called by the Chaldee word *Targum*, which signifies "an explanation."

There are ten Targums extant:—

1. *The Targum of Onkelos*, on the Pentateuch, is the most ancient. Onkelos is supposed to have lived at Babylon. The Babylonish Talmud makes him a contemporary of Gamaliel, at the very beginning of the Christian era. No critics place him lower than the 2nd century. His language approaches nearer than that of the other Targums to the pure Chaldee of the books of Daniel and Ezra. He follows the Hebrew text so closely, that his work is less a paraphrase than a version, and he is free from the fables which prevailed among the later Jews.

2. *The Targum of Jonathan Ben Uzziel*, on the Prophets, is by many ascribed to an author contemporary with Onkelos, or even a little older, namely, Jonathan the son of Uzziel, a disciple of the elder Hillel. The mention of his name in the Talmuds proves him to have

lived earlier than the 4th and 5th centuries. But Jahn points out certain internal marks, from which he concludes that this Targum was compiled, towards the end of the 3rd century after Christ, from other paraphrases, some of which at least were considerably older. The Jews make Jonathan contemporary with the prophets Malachi, Zechariah, and Haggai, and relate marvellous stories respecting the composition of his Talmud. This Targum is more paraphrastic than that of Onkelos; its dialect is not so pure; the version is not so accurate, but it is free from the fabulous stories of the later Talmuds. It comprises the books of Joshua, Judges, Samuel, Kings, Isaiah, Jeremiah, Ezekiel, and the twelve minor prophets.

3. *The Targum of the pseudo-Jonathan*, on the Pentateuch, is so called from its having been erroneously ascribed to Jonathan Ben Uzziel. In purity of dialect, in its general style, and in its mode of exposition, it is far inferior to the Targum of Jonathan. It abounds in silly fables, and displays great ignorance of Hebrew on the part of its author. From internal evidence, such as its mention of the Turks and Lombards, it is evident that it could not have been written earlier than the 7th, or perhaps the 8th, century.

4. *The Jerusalem Targum*, on the Pentateuch, of which however it omits large portions, and sometimes explains only single words, is evidently later than that of the pseudo-Jonathan, which it generally follows closely, occasionally departing from it for the worse. Its dialect is very impure, abounding in Greek, Latin, and Persian words.

The other Targums scarcely deserve a separate notice. An account of them, and lists of the editions and Latin versions of the Targums, will be found in the works quoted at the end of this article. Taken together, the Targums form a paraphrase of the whole of the Old Testament, except the books of Daniel, Ezra, and Nehemiah, which called the less for such an exposition, as they are to a great extent written in Chaldee.

(Prideaux, *Connection*, part ii., book viii.; the *Introductions* of Horne and Jahn.)

TARIFF, a table of duties to be paid on goods imported or exported. The principle of a tariff depends upon the commercial policy of the body by which it is framed, and the details are constantly fluctuating with the change of interests and the wants of the community, or in pursuance of commercial treaties with other states. The British tariff has undergone many important alterations within the last sixty years, all tending to increased freedom of trade. Only twenty-six kinds of articles are now subject to an import duty, and none to an export duty, all being imposed merely for fiscal purposes. A tariff often aims at incompatible ends: duties are sometimes meant to be both productive of revenue and for protective objects, which are frequently inconsistent with each other. Hence they sometimes operate to the complete exclusion of foreign produce, and in so far no revenue can of course be received; and sometimes, when the duty is inordinately high, the amount of revenue becomes in consequence trifling. An attempt is in fact made to protect a great variety of particular interests at the expense of the revenue and of the commercial intercourse with other countries.

TARTAN. [WEAVING.]

TARTAR, CREAM OF. [TARTARIC ACID.]

TARTAR EMETIC. [ANTIMONY.]

TARTARIC ACID ($C_8H_4O_{10}$, 2HO). This acid occurs in nature in both the free and combined states. In the free condition it exists in the tamarind, grape, pine-apple, pepper, &c.; as a potash salt, also in the tamarind, grape, and in the mulberry; and as tartrate of lime, in the fruit of the stag's-horn sumach (*Rhus typhina*). Tartaric acid is also found in many other vegetable juices, but it is from the grape that nearly all the tartaric acid of commerce is obtained.

Bitartrate of potash is soluble in water, but not in alcohol; in a mixture of the two it is soluble to an extent dependant upon the proportion of the one to the other. When, therefore, the juice of the grape is fermented, there arrives a point at which the bitartrate of potash begins to crystallise out and deposit on the sides of the vessel in which it is contained, and this operation goes on until the whole of the sugar in the wine is converted into alcohol. In going out of solution it takes much colouring matter with it, and in this impure state is, at convenient seasons, removed and sent into commerce as *argol* or *crude tartar*. Purified by recrystallisation and treatment with animal charcoal, it constitutes purified tartar, or "*cream*" *of tartar*; and it is from this salt that tartaric acid is produced. "It is called *tartar*," says Paracelsus, "because it produces oil, water, tincture, and salt, which burn the patient as tartarus does." *Tartarus* is Latin for *hell*. The products of its destructive distillation are certainly somewhat irritating, and the properties of the "salt" (carbonate of potash) that is left are well known.

To prepare the acid, the bitartrate is dissolved in hot water, and powdered chalk added so long as effervescence continues. A precipitate of tartrate of lime is hereby formed, while neutral tartrate of potash remains in solution. The latter is then decomposed by adding the proper proportion of chloride of calcium, or by boiling with sulphate of lime. In either case the tartaric acid remaining in the potash salt is also thrown into the state of tartrate of lime. Finally, the tartrate of lime is gently heated with rather more than half its weight of strong sulphuric acid mixed with seven or eight times its weight of water. When the decomposition is complete the whole is filtered, the filtrate evaporated, if necessary, and the liquor set aside to crystallise.

Crystals of tartaric acid are colourless, inodorous, powerfully yet agreeably acid to the taste, of specific gravity 1·75, contain no water of crystallisation, and remain perfectly transparent and unaltered in the air. They are very soluble in water, alcohol, and wood spirit, but not in ether; the aqueous solution slowly decomposes if exposed. When gently warmed, they give evidence of being highly charged with electricity. Solution of tartaric acid, especially when hot, exerts a powerful twisting action on polarised rays of light. The direction of rotation is to the right, as observed in the apparatus described under SACCHARIMETRY: it is a remarkable phenomenon, and will presently be referred to as a means of distinguishing the derivatives and modifications of this acid from each other.

Tartaric acid gives a white precipitate (bitartrate of potash) when added in excess to a strong solution of a potash salt; it also throws down white tartrates from lime or baryta water and from acetate of lead, but does not decompose the chlorides of barium or calcium. Oxidising agents, such as peroxide of lead, red lead, bichromate of potash, nitric acid, &c., readily act upon tartaric acid and convert it into formic and carbonic acids. Fused with caustic potash, it splits up into acetic and oxalic acids, thus:—

$$\underbrace{2HO, C_8H_4O_{10}}_{\text{Tartaric acid.}} + \underbrace{3(KO, HO)}_{\text{Hydrate of potash.}} = \underbrace{KO, C_4H_3O_3}_{\text{Acetate of potash.}} + \underbrace{2KO, C_4O_6}_{\text{Oxalate of potash.}} + \underbrace{6HO}_{\text{Water.}}$$

By heat, tartaric acid is transformed into several modifications. Exposed to a temperature not exceeding 340° Fahr., it fuses, and is altered to an acid that has the same composition and apparently the same constitution as the original acid, but forms salts which are more soluble in water. It has a gummy appearance, is very deliquescent, does not when in excess precipitate ammonia from its salts until after some time, and then the crystals have a different form to that of ordinary bitartrate of ammonia. The solutions of its salts change into those of ordinary tartrates when boiled. The above is distinguished from the ordinary by the name *metatartaric acid*. By continued exposure to the same temperature, metatartaric acid is further modified to *isotartaric acid*, the chief peculiarity of which is that its salts correspond only to bitartrates. The formula (HO, $C_8H_5O_{11}$) probably therefore represents its true constitution. Closely associated with the above acids are the *tartralic* and *tartrelic*: they are formed on exposing tartaric acid to a still higher temperature for a shorter or longer period; they contain less water than the ordinary acid, and possibly are merely mixtures in different proportions of that substance with *anhydrous tartaric acid*, or *tartaric anhydride*. The latter body has the composition $C_8H_4O_{10}$: it always results when tartaric acid is maintained for some time at a temperature of 374° Fahr. It is insoluble in water, alcohol, or ether, and by long exposure in a moist state, or more rapidly on boiling in pure or alkaline water, is reconverted into the ordinary crystalline form of acid. Finally, on heating tartaric acid to 400° Fahr., and higher, in a distallatory apparatus, it is decomposed into carburetted hydrogen and carbonic acid gases, water, acetic acid, empyreumatic oily matters, pyruvic and pyrotartaric acids. *Pyruvic acid* (2HO, $C_{12}H_6O_{10}$) is separated from other matters in the distillate by fractional distillation and by taking advantage of the insolubility of its lead salt. Pyruvic acid is uncrystallisable, miscible in all proportions with water, alcohol, or ether, and forms difficultly crystallisable *pyruvates*; that of silver being somewhat soluble in water, and containing 2AgO, $C_{12}H_6O_{10}$. *Pyrotartaric acid* (2HO, $C_{10}H_6O_6$) in the impure state remains as a syrupy liquid when the tartaric distillate above referred to is redistilled. It may be purified by distillation and exposure of its distillate in vacuo, when it separates out in crystals. The latter may be quite decolorised by solution in water, treatment with animal charcoal, and recrystallisation. Pyrotartaric acid crystallises in oblique prisms, is very soluble in water, alcohol, or ether, is volatile without decomposition, and forms well-defined crystalline salts with bases. It forms neutral and acid *pyrotartrates*, of the general formula MO, HO, $C_{10}H_6O_6$, or 2MO, $C_{10}H_6O_6$. With persalts of iron it gives a red precipitate, and with protosalts a solution that rapidly reddens in contact with air.

Artificial Formation of Tartaric Acid.—This has been accomplished by Liebig. Its source is sugar of milk (lactose) and nitric acid is the oxidising agent. One part of lactose, two and a half of nitric acid, of sp. gr. 1·32, and an equal quantity of water, are gently heated; a mixture of carbonic acid and nitrogen oxides are disengaged and a separation of mucic acid takes place. Water is then added, the mixture filtered, half a part of nitric acid put into the liquid and the whole again boiled. More mucic acid—in all 33 per cent. of the lactose employed—then separates. After filtration a little more nitric acid is added, and the whole boiled for eighteen or twenty-four hours. On now neutralising the solution by potash, abundance of tartrate of potash is obtained, which may be purified by one or two crystallisations, and the acid isolated in the manner described at the commencement of this article.

The acid thus artificially obtained possesses all the properties of ordinary tartaric acid; it has dextro-rotative or plane polarised light, and is in fact identical with true tartaric acid. A short time since an announcement was made that tartaric acid had been artificially formed in another and totally different manner, but on optically examining it, the product proved to be racemic acid, a modified tartaric acid described farther on.

Tartrates.—Tartaric acid is bibasic, and its salts consequently are either acid ($MO, HO, C_8H_4O_{10}$) or neutral ($2MO, C_8H_4O_{10}$). The neutral salts may contain two similar or different protoxides; or a protoxide and a sesquioxide; or a protoxide and a teroxide. They are mostly formed by partially or wholly saturating the acid with the oxide or carbonate of the oxide; or, in the case of double tartrates, by saturating a bitartrate with an oxide different to that already contained in it. Heated in the air, tartrates blacken and give off an odour resembling that of burnt sugar. The chief tartrates are noticed in the following paragraph.

Tartrate of Ammonia ($2NH_4O, C_8H_4O_{10}$) is a very soluble salt; efflorescent, and losing ammonia when exposed to the air. *Bitartrate of ammonia*, ($NH_4O, HO, C_8H_4O_{10}$) is a crystalline powder tolerably soluble in hot water though but very slightly so in cold water. *Tartrate of potash* ($2KO, C_8H_4O_{10}$) crystallises with difficulty. *Bitartrate of potash* ($KO, HO, C_8H_4O_{10}$) was referred to at the commencement of this article: one part is soluble in 240 of water, at 50° Fahr. Heated to redness in a covered crucible it is decomposed, carbonate of potash and charcoal being left in a fine state of division; it constitutes the *black flux* of metallurgists. Sometimes it is deflagrated with nitre; in this the carbon is all oxidised, and *white flux* (carbonate of potash alone) is the name given to the residue. *Tartrate of soda* ($2NaO, C_8H_4O_{10} + 4$ aq.) resembles the corresponding potash salt. *Bitartrate of soda* ($NaO, HO, C_8H_4O_{10} + 2$ aq.) is far more soluble than bitartrate of potash. A solution of it—made by neutralising a given quantity by carbonate of soda, and then adding a second similar quantity of acid to the solution—forms, if it be saturated, a useful test of the presence of potash in a liquid, the bitartrate of the latter base being formed and precipitated if present in notable quantity. *Ammonio-tartrate of soda* contains ($NH_4O, NaO, C_8H_4O_{10} + 8$aq.) *Tartrate of potash and soda* ($KO, NaO, C_8H_4O_{10}$) is a laxative saline used in medicine. It is sometimes called sel de Leignette from the name of its discoverer who resided (1692) at Rochelle, hence also its name of Rochelle salt. In former times it was called *sal polychrest* (that is salt of many virtues). It is made by neutralising bitartrate of potash with carbonate of soda. *Tartrate of lime* ($2CaO, C_8H_4O_{10} + 8$aq) and bitartrate of lime ($CaO, HO, C_8H_4O_{10}$) occur native. *Tartrate of copper* ($2CuO, C_8H_4O_{10} + 6$ aq.) is a bright green crystalline powder. *Tartrate of ammonia and iron* ($NH_4O, Fe_2O_3, C_8H_4O_{10}, + 4$ to 5 aq.) and *Tartrate of potash and iron* ($KO, Fe_2O_3, C_8H_4O_{10}$) are used in medicine. They do not crystallise, but their solutions dry up when exposed on sheets of glass or other polished surfaces, and scale off in dark-red or brown laminæ. *Tartrate of potash and boron* ($KO, BO_3, C_8H_4O_{10}$ at 212° Fahr.) better known as *boro-tartrate of potash*, or *soluble cream of tartar*, is obtained on evaporating to dryness one part of boracic acid, two of bitartrate of potash, and twenty-four of water. *Tartrate of potash and antimony*, see ANTIMONY. A similar salt containing *arsenic* ($NH_4O, AsO_3, C_8H_4O_{10} + $aq) may be obtained.

Racemic Acid ($2HO, C_8H_4O_{10} + 2$ aq.) *Paratartaric Acid.*—This isomeric modification is a frequent associate of tartaric acid, but it is in the grape of the Upper Rhine that it is abundantly met with. In all its relations it exhibits a close analogy to ordinary tartaric acid. The chief points of difference are:—that it crystallises more readily from solution: it contains two equivalents of water of crystallisation; it is less soluble in alcohol; it gives a precipitate with sulphate of lime, nitrate of lime, and chloride of calcium; and, finally, the racemate of lime is soluble in hydrochloric acid, and is precipitated unchanged on adding ammonia. By taking advantage of these properties, it may readily be distinguished and separated from tartaric acid. A point of considerable interest, connected with the constitution of racemic acid, is that its solution has no effect on a ray of plane polarised light. The *racemates* are very like the tartrates: racemate of lime is, however, considerably less soluble, and the double racemate of potash and antimony crystallises in acicular tufts instead of octohedra.

Artificial Formation of Racemic Acid.—Recently Messrs. Perkin and Duppa, and almost at the same time, Dr. Kekulé, have succeeded in producing paratartaric acid. It is formed when bibromosuccinate of silver is boiled in water, bromide of silver being precipitated:—

$$C_8H_2Br_2Ag_2O_8 + 4HO = 2HO, C_8H_4O_{10} + 2AgBr.$$

More recently M. Carlet, considering that lactose, which is dextrorotative, yielded, in the hand of Liebig, ordinary tartaric acid—concluded that dulcose (a saccharine principle imported from Madagascar) should by similar treatment furnish paratartaric acid. He tried the experiment and succeeded in producing a small quantity of racemic acid.

Constitution of Tartaric and Paratartaric Acid.—By the brilliant researches of M. Pasteur in this direction, chemistry has been put in possession of four kinds of tartaric acid. First, *dextro-tartaric acid*, or that which causes right-handed rotation of a ray of plane polarised light. This is the ordinary tartaric acid met with in commerce; it is sometimes, and, as will be seen directly, not inappropriately termed *dextro-racemic acid*. Second, *lævo-tartaric acid* which produces left-handed rotation, and which is also termed *lævo-racemic*. The crystals of these two acids differ in form in a somewhat interesting manner. Neither of them is ever obtained of a perfectly symmetrical shape, but what is remarkable is that the portion not forthcoming in the one is exactly the reverse of that wanting in the other. Moreover, the salts of the two acids preserve the peculiarities of the acids themselves; their rotatory power, chemical properties and appearance differing as the acids differ: thus the image, as seen in a mirror, of the crystal which is dextro-hemihedral, as its shape is termed, has the exact form of the lævo-hemihedral crystal; while the reflected image of the latter is of course identical with the direct image of the former. The third form of tartaric acid is a combination of the first with the second, and has, of course, no rotatory power: it is, in fact, racemic or paratartaric acid.

Racemic acid was, by M. Pasteur, made to yield up its respective constituents, dextro- and lævo-tartaric acid, in the following manner. The double racemate of soda and ammonia, made by saturating a quantity of common racemic acid with carbonate of soda, adding a second equal quantity of racemic acid, and finally neutralising by ammonia, was found to crystallise in opposite hemihedral forms. On picking out, by hand, the one variety from the other and optically examining their solutions, M. Pasteur found that each powerfully twisted a polarised ray, but in opposite directions. From the two salts the acids were isolated by first precipitating with nitrate of lead, then decomposing the washed lead salts by sulphuretted hydrogen, and lastly, allowing crystals to be deposited from the evaporated filtrates. The one set of crystals were found to be dextro-rotatory, the other lævo-rotatory; on adding equal quantities together, the original non-rotatory acid was obtained.

A second process for the separation of dextro-tartaric from lævo-tartaric acid has been discovered by M. Pasteur; it is not mechanical, like that of the separation from each other of the two kinds of crystals of racemate of soda and ammonia, but chemical, and depends upon principles which are generally applicable. It consists in combining racemic acid, or any other substance suspected of having an analogous binary constitution, with an active gyratory body. The necessary dissimilarity of properties in the compounds which such a body is capable of forming with the constituents of a complete substance will at once reveal whether the suspected body is complex or not. Thus, in preparing the racemate of cinchonicine, it always happens that when the liquid has attained a certain degree of concentration the first crop of crystals formed consists almost wholly of lævo-tartrate, the dextro-tartrate remaining in solution. A similar result is obtained with quinicine, except that dextro-tartrate first crystallises out, the lævo-tartrate remaining in the mother liquor.

The fourth kind of tartaric acid, discovered by the eminent chemist alluded to, is *inactive tartaric acid*; it has no action whatever on polarised light and, moreover, is not resolvable, under the same circumstances as is racemic acid, into dextro- and lævo-tartaric acids. It is formed as follows: tartrate of cinchonine is heated for several hours to 170° Fahr.; the mass is then treated with water and chloride of calcium added, when racemic acid, formed at the expense of the tartaric acid, is precipitated in the form of racemate of lime. If now the liquid be immediately filtered, and then left at rest for twenty-four hours, an additional crop of crystals is obtained, consisting of pure inactive tartrate of lime; from the latter the inactive acid itself is easily prepared.

Nitric derivatives of Tartaric Acid.—When tartaric acid is dissolved in nitric acid, and sulphuric acid added, a crystalline mass of *nitro-tartaric acid* is produced. It is very unstable and difficult to purify. Water decomposes it into *tartronic acid* ($C_6H_4O_{10}$).

The following derivatives of tartaric acid are prepared by the usual methods:—

Methyl-tartaric acid (tartromethylic acid)	$C_2H_3O, HO, C_8H_4O_{10}$
Tartrate of methyl	$2(C_2H_3O)C_8H_4O_{10}$
Ethyl-tartaric acid (tartrovinic acid)	$C_4H_5O, HO, C_8H_4O_{10}$
Tartrate of ethyl (tartaric ether)	$2(C_4H_5O)C_8H_4O_{10}$
Amyl-tartaric acid (tartramylic acid)	$C_{10}H_{11}O, HO, C_8H_4O_{10}$
Tartroglyceric acid	$C_6H_7O_5, HO, C_8H_4O_{10}$
Tartramic acid	$C_8H_7NO_{10}$
Tartramide	$C_8H_8N_2O_8$

Tartaric acid is much used in medicine; extensively also in the preparation of effervescing drinks, and, by the calico-printer and dyer.

TARTARIC ACID, for medical purposes, should be remarkably pure, when it is without odour, but makes a powerful acid impression on the organs of taste. In small doses, properly diluted, it acts as a refrigerant, and is of much value in fevers, particularly mucous, and in biliary remittents. It excites the appetite of persons in whom the stomach is in a healthy condition; and those who, by long indulgence in stimulating food and drinks, experience loss of appetite, painful digestion, constipation, with a yellow and altered countenance, and diminished muscular vigour, find in tartaric acid a remedy of singular power. For this state of system a few crystals should be dissolved in two small tumblers, and drank in the morning fasting, an hour intervening between the tumblers. A few grains are sufficient for each tumbler, as when made too strong it excites irritation, followed by purging. Occasionally it disturbs the nervous system in a distressing way, so that patients refuse to continue its use. This plan has in many instances reclaimed individuals addicted to habitual intoxication, to which they have recourse to relieve a painful feeling of sinking and craving of the stomach, which is effectually removed by the acid draught. This is also useful after an attack of *delirium tremens*.

Tartaric acid enters the circulation, and diffuses itself through the whole body, and may be recognised in the urine, generally in combination, often with lime. Tartaric acid is much used to decompose alkaline carbonates, and form effervescing draughts, the employment of which requires caution. [ANTACIDS.]

TARTARUS (Τάρταρος) was, according to the notions of the Greeks and Romans, a part of the lower world, and was inaccessible to the light of the sun and to the winds. Homer describes it as the place in which the gods were punished; as being as far below Hades as heaven is above the earth, and as being provided with brazen gates at its entrance. ('Iliad,' viii. 13, &c., 481.) Hesiod entertains on the whole the same idea, but he adds that Tartarus is surrounded by a brazen wall and triple night; the roots of the earth and the sea hang down into it. It is the prison of the Titans. (Hesiod, 'Theog.,' 720, &c.) In later times Tartarus designated that part of the lower world in which the shades of the wicked were punished (Plato, 'De Re Publi.,' p. 616; Virgil, 'Æn.,' vi. 543), and the ideas then formed of it were more awful than in earlier times. According to Virgil, the road into the lower world was divided at a certain point into two roads, the left of which led into Tartarus, which was surrounded by a triple wall and the fiery river Phlegethon, and was closed with an adamantine gate. At its outer side Tisiphone kept watch, and at the inner side the fifty-headed hydra. Rhadamanthus was the judge in Tartarus, and at his command the Furies scourged the shades of the wicked.

TASTE, according to the definition of Sir Joshua Reynolds, "is that act of the mind by which we like or dislike, whatever be the subject." ('Discourses before the Royal Academy;' Discourse vii.)

Taste is frequently spoken of as a gift, as something independent of rules, a kind of instinct, bestowed more liberally in degree upon some men than upon others. It has been treated by some writers as the result of caprice or fashion, as having no uniform or permanent principles for the ground of its decisions. Others have resolved it into different complex elements, whose joint development is determined by certain principles of beauty or sublimity in things external.

Much obscurity has arisen in discussions on the subject of taste from the twofold sense in which the word taste has been employed, as expressive of an emotion, and of something objective in which there exists an aptitude to produce emotion. The term taste strictly applies to the emotion only; the theory of the different causes by which the emotion is produced belongs to the subject of beauty or sublimity. In what follows we shall confine ourselves to the explanation of taste in its restricted or proper sense.

When any object either of sublimity or beauty is presented to the mind, we are conscious of a train of thought being immediately awakened analogous to the character or expression of the original object. The trains of thought which are thus suggested are distinguished in the nature of the ideas or conceptions which compose them, and in the nature or law of their succession. In the case of those trains of thought which are suggested by objects either of sublimity or beauty, they are in all cases composed of ideas capable of exciting some affection or emotion. There is this distinction between the emotions of taste and all our different emotions of simple pleasure, that in the case of these last emotions no additional train of thought is necessary. The pleasurable feeling follows immediately the presence of the object or quality, and has no dependence upon anything for its perfection but the sound state of the sense by which it is received. The emotions of envy, pity, benevolence, gratitude, utility, propriety, novelty, &c., might undoubtedly be felt, although we had no such power of mind as that by which we follow out a train of ideas, and certainly are felt in a thousand cases when this faculty is unemployed. In the case of the emotion of taste, on the other hand, it seems evident that this process of mind is necessary, and that unless it is produced these emotions are unfelt. Whatever may be the nature of that simple emotion which any object is fitted to excite, whether that of gaiety, tranquillity, melancholy, &c., if it produce not a train of kindred thought in our minds, we are conscious only of that simple emotion. Whenever, on the contrary, the train of thought which has been mentioned is produced we are conscious of a higher and more pleasing emotion; and which, though it is impossible to describe in language, we yet distinguish by the name of the emotion of taste. The emotions of taste may therefore be considered as distinguished from the emotions of simple pleasure, by their being dependent upon the exercise of our imagination.

It is on this principle that Burke remarks that the excellence and force of a composition must always be imperfectly estimated from its effect on the minds of any, except we know the temper and character of those minds. ('Int. to the Sublime and Beautiful.') The rules by which taste is determined vary with the objects to which its decisions refer; but in respect of all, this general principle holds, that a composition is to be judged by its fitness to produce the end designed by it. For a further discussion of the subject, see ÆSTHETICS; BEAUTY; SUBLIMITY.

TATTOOING is the name usually given to the custom, common among many uncivilised tribes, of marking the skin by punctures or incisions, and introducing into them coloured fluids, so as to produce an indelible stain. It is mentioned in Captain Cook's account of the South Sea islanders under the name *tattowing;* and, with trifling difference in the orthography, the same name is applied by English writers to similar practices among other people. The word "tattoo" appears to be formed by a reduplication of a Polynesian verb "ta," meaning to strike, and therefore to allude to the method of performing the operation, and, if this supposition be correct, it has a curious resemblance to the English word tattoo, meaning a particular beat of the drum.

From a passage in the book of Leviticus, chap. xix., v. 28, in which the Israelites are forbidden to make any cuttings in their flesh for the dead, or to *print any marks* upon their bodies, it has been supposed that some custom resembling tattooing was practised in the time of Moses. It is also an Oriental custom, and among people whose proximity to the Hebrews affords a reason for the prohibition contained in the text referred to. "The Bedouin Arabs, and those inhabitants of towns who are in any way allied to them," observes the editor of the 'Pictorial Bible,' on the passage in Leviticus, "are scarcely less fond of such decorations than any islanders of the Pacific Ocean. This is particularly the case among the females, who, in general, have their legs and arms, their front from the neck to the waist, and even their chins, lips, and other prominent parts of the face marked with blue stains in the form of flowers, circles, bands, stars, and various fanciful figures. They have no figures of living objects, such being forbidden by their religion; neither do they associate any superstitions with them, so far as we are able to ascertain." The works of ancient writers contain many notices of the practice of tattooing, as practised by several barbarous races. As to the Britons, Cæsar merely mentions their custom of staining their bodies with vitrum, or woad; but Solinus and Isidore describe a process exactly resembling the modern mode of tattooing. Herodotus says, that among the Thracians to be tattooed or marked (ἐστίχθαι) was an emblem of rank, and the want of it indicated meanness of descent (v. 6). The extended use of clothing at a later period rendered such ornaments superfluous, and led to the decline and subsequent abandonment of the practice. It appears, however, to have been continued during the whole of the Anglo-Saxon period, and is among the English vices reprobated by William of Malmesbury after the Norman conquest. Several other ancient notices on the subject are collected by Lafitau, in his 'Mœurs des Sauvages Amériquaines.'

In modern times the custom of tattooing has been found in most of the islands of the Pacific Ocean, and among many of the aboriginal tribes of Africa and America, as well as, on a limited scale, as before stated, in the East. It is also practised by the Tunguses on the banks of the Amur, as stated by Atkinson in his 'Travels in the Regions of the Upper and Lower Amoor.' Much curious information on the various

Head of Shungie, from a carving by himself.

kinds of tattooing is collected in the volume on the 'New Zealanders,' in the 'Library of Entertaining Knowledge.' Of the character of the patterns a better idea will be conveyed by the annexed bust of Shungie, a New Zealand chief, copied from an engraving in the 'Missionary Register' for 1816, than by the most lengthened description.

The process of tattooing as practised, or rather as it was formerly practised, in other islands of the South Sea, was less painful than that followed in New Zealand; for, according to the account of Captain Cook, in some cases the punctures could hardly be said to draw blood; while in New Zealand, having taken a piece of charcoal, and rubbed it upon a stone with a little water, so as to produce a thick liquid, the operators dipped into it an instrument made of bone, with a sharp edge like a chisel, and shaped in the fashion of a garden-hoe. They then applied the instrument to the skin, and struck it twice or thrice with a piece of wood, thereby making it cut into the flesh as a knife would have done, and causing a great deal of blood to flow, which they kept wiping off with the side of the hand, in order to see whether the impression was made sufficiently clear. If not, they applied the cutting-instrument again to the same place. The instruments used, as described by Captain Cook, were edged with small teeth, somewhat resembling those of a fine comb; and, as in the case of New Zealand, the colouring tincture was introduced at the same operation as that by which the skin was punctured; the substance employed in some places being a kind of lamp-black. On the brown skins of the natives, the marks made with this substance appear black; but on the skin of a European they are of a fine blue colour. Lafitau speaks of powdered charcoal as the colouring-matter commonly used by the American Indians; and states that it was introduced by a process subsequent to that of cutting or puncturing the skin. This insertion of the colour appears to have been the most painful part of the operation of tattooing as practised among them.

TAURIN ($C_4H_7NO_6S_2$), a peculiar crystallisable substance obtained from the bile, and also produced artificially by the action of heat upon isethionate of ammonia—

$$\underbrace{C_4H_5(NH_4)O_2, S_2O_6}_{\text{Isethionate of ammonia.}} = \underbrace{C_4H_7NO_6S_2}_{\text{Taurin.}} + 2HO$$

Its properties are, that it has the form of a six-sided prism terminated by pyramids of four or six faces; the crystals are gritty between the teeth, and have a sharpish taste, which is neither sweet nor saline; they undergo no alteration by exposure to the air even at 212°, and have neither an acid nor an alkaline reaction. When heated in the naked fire, this substance becomes brown, fuses into a thick liquid, swells up, exhales a sweetish empyreumatic odour resembling that of burning indigo, and leaves a charcoal, which is readily burnt: when submitted to dry distillation, it yields much thick brown oil, and a little yellow acidulous water, which holds an ammoniacal salt in solution, and reddens a solution of perchloride of iron; one part requires 15¼ parts of water at 54° for solution; it is much more soluble in boiling water, and the excess crystallises on cooling; it is but little soluble, even in boiling alcohol of sp. gr. 0·835, and is nearly insoluble in absolute alcohol. Concentrated sulphuric acid dissolves and forms a light brown solution with taurin; nitric acid readily dissolves it, and when the acid is evaporated, it is left unaltered.

TAUROCHOLALIC ACID. [CHOLEIC ACID.]

TAUROCHOLIC ACID. [CHOLEIC ACID.]

TAURUS (the Bull), the second constellation of the ZODIAC. Its position in the heavens, surrounded by Aries, Eridanus, Orion, and Perseus, is easily obtained by the manner in which its bright star ALDEBARAN is connected with the belt of Orion. In all speculations upon the origin of the Zodiac, Taurus must be an important object of consideration, since, at the earliest date which prudent speculation can consider it advisable to begin from, Aldebaran must have been at no great distance from the vernal equinox. [ZODIAC.] The figure is only a part of a bull—the head, shoulders, and fore legs. Aldebaran and the Hyades form the forehead and eye, and the Pleiades are in the shoulder. But Aratus must have drawn the figure differently, for he puts the Pleiades in the knees.

The Hyades form a group, of which five (some of the ancients said seven) are distinctly visible to the naked eye, α, θ, γ, δ, and ϵ of the constellation: there are many more in the cluster. These stars are arranged in the form of a V, α and ϵ being the extremes, and γ at the angular point. The star α is Aldebaran. The name seems to be derived from ὕειν, to rain. The Latins called them *suculæ* (little pigs, no doubt meaning Aldebaran for the sow, and the others for her offspring), a name which Cicero and others state to have arisen from supposing the Greek word to have been from ὗες (pigs), and not from ὕειν. We think, however, it may be possible that they were right in their idea of the Greek word: the large star and the cluster of small ones might very easily suggest the notion of a sow and her litter.

The Pleiades are so close a group of stars that it is very difficult to say how many are seen by the naked eye. "They are called seven," says Higinus, "but no one can see more than six;" and six seems to be the number generally visible, though there are many more in the cluster. These stars are 17, 19, 20, 23, 25, and 26 of Flamsteed. There is accordingly a supposition that some one star, once visible, has now changed its magnitude, or disappeared altogether. The name has been derived from πλεῖν, to sail. One of the mythological stories makes these stars the daughters of *Pleione* and Atlas.

The principal stars of Taurus are as follows:—

Character.	No. in Catalogue of Flamsteed.	No. in Catalogue of British Association.	Magnitude.
o	1	1057	4
ξ	2	1068	4
η	25	1166	3
λ	35	1241	4
ν	38	1251	4
γ	54	1328	3
δ^1	61	1346	4
δ^2	64	1356	4–
ϵ	74	1376	4
α	87	1420	1
ι	102	1551	4
β	112	1681	2
ζ	123	1767	3

TAURUS PONIATOWSKI, a constellation formed by the Abbé Poczobut, a Polish astronomer (born in 1728: we do not know the year of his death; but Lalande mentions his having resumed his observations at Wilna in 1802), in honour of the reigning king of Poland, and adopted in the French (Fortin's) edition of Flamsteed's maps (or rather added to the plates). Poczobut, in 1778, proposed this constellation to the French and other academies, by whom it was received. Bode conjectures that a resemblance of certain very small stars in it to the figure of the Hyades was the reason for the first word of the name. It is situated between Aquila and Ophiuchus.

TAURYLIC ACID. [BENZOIC ALCOHOL.]

TAUTOCHRON. [TIME OF DESCENT.]

TAX, TAXATION. A tax is a portion of the produce of a country or its value, applied to public purposes by the government. Taxation is the general charging and levying of particular taxes upon the community.

In a free state it is assumed that all taxation is necessary for the public good; and it is justified by necessity alone. The amount of expenditure will, in a great measure, be determined by the magnitude of a state and by the number and importance of its political relations; yet the prudence with which its affairs are administered will affect the demands of the government upon the people nearly as much as its necessities. The expenses of a private person must be regulated by his income; but in a state, the expenditure that is needed is the measure of the public income that must be obtained to meet it. A civilised community requires not only protection from foreign enemies, and internal security, but it needs various institutions which are conducive to its welfare. It is the business of a government to provide for these objects in the best manner and at the least expense consistent with their efficiency. Every tax should be viewed as the purchase-money paid for equivalent advantages given in return. This principle assumes the necessity of moderation in levying taxes, and will scarcely be denied by any one when stated in that form; yet it is not uncommon to hear it argued that so long as taxes are *spent in the country*, the amount is not of consequence, as the money is returned through various channels to the people from whom it was derived. The principle we have just laid down exposes the fallacy of this doctrine, by reducing it to a simple question between debtor and creditor. For example, by paying a million of money every year, the people obtain the services of an army. This we will suppose to be an equivalent, and we will further assume that the food and clothing of the force are purchased, and that the entire pay of the men is spent, within the country. The whole of the money will thus be returned: but how? Not as a free gift, not as the repayment of a loan, but in the purchase of articles equal in value to the whole sum. The only benefit obtained by this return of the million is clearly nothing more than the ordinary profits of trade; for the community has already provided the money, and then out of its own capital and industry it produces what is equal to it in value, and this it *sells* to the state, receiving as payment the very sum it had itself contributed as a tax.

No branch of legislation is perhaps so important as the wise application of just principles in the matter of taxation. The wealth, happiness, and even the morals of the people are dependent upon the financial policy of their government.

Adam Smith lays down four general maxims, which are as follows:—

I. "The subjects of every state ought to contribute towards the support of the government as nearly as possible in proportion to their respective abilities; that is, in proportion to the revenue which they respectively enjoy under the protection of the state."

II. "The tax which each individual is bound to pay ought to be certain, and not arbitrary. The time of payment, the manner of payment, the quantity to be paid, ought all to be clear and plain to the contributor, and to every other person."

III. "Every tax ought to be levied at the time or in the manner most likely to be convenient for the contributor to pay it."

IV. "Every tax ought to be so contrived as both to take out and keep out of the pockets of the people as little as possible over and above what it brings into the public treasury of the state."

The justice of Adam Smith's first maxim requires no enforcement or illustration, although the object is most difficult of attainment. The second maxim is of great importance, and the necessity of adhering to it must be universally acknowledged. Uncertainty gives rise to frauds and extortion on the part of the tax-gatherer, and to ill-will and suspicion on that of the contributor, while it offers a most injurious impediment to all the operations of trade. Notwithstanding the many evils of uncertainty, it is by no means an uncommon fault in modern systems of taxation.

Under the constitutional governments of Europe, the people do not indeed suffer from violent exactions, as in the Turkish empire and in Persia; but industry and commerce are often restrained by irregular and ill-defined taxes.

To levy a tax "at the time and in the manner most likely to be convenient for the contributor to pay it" is always a wise policy on the part of the state. The time or manner of payment may often be more vexatious than the amount of the tax itself, and thus have the evil effects of high taxation, while it produces no revenue to the state. Suppose, for example, that a merchant imports goods and is required to pay a duty upon them immediately and before he has found a market for them:—he must either advance the money himself or borrow it from others, and in either case he will be obliged to charge the purchaser of the goods with the interest; or he must sell the goods at once, not on account of any commercial occasion for the sale, but in order to avoid prepayment of the tax. If he pays the tax and holds the goods, the consumer will have to repay not only the tax but the interest; and if he parts with them at a loss or inconvenience, trade is injured, and the general wealth and consequent productiveness of taxation proportionately diminished. To prevent these evils the Bonding or Warehouseing system was established in this country, which affords the most liberal convenience to the merchant and a general facility to trade. Certain warehouses are appointed under the charge of officers of the customs, in which goods may be deposited without being chargeable with duty until they are cleared for consumption, and thus the tax is paid when the article is wanted, and when it is least inconvenient to pay it. Similar accommodation is granted on their own premises to the manufacturers of articles liable to excise duties. At present the customs bonding-warehouses are confined to the ports, and a few large towns.

The evils resulting from inconvenient modes of assessing and collecting taxes have been very seriously felt in this country under the operation of the excise laws. When any manufacture is subject to excise duties, the officers of the revenue have cognisance of every part of the process, inspect and control the premises and machinery of the manufacturer, and often even prescribe the mode of conducting and the times of commencing and completing each process; while the observance of numberless minute regulations is enforced by severe penalties. The manufacturer is put to great inconvenience and expense, and his ingenuity and resources are constantly interfered with in such a manner as to impede inventions and improvements, and to diminish his profits. A London distiller stated to the Commissioners of Excise Inquiry, that assuming that the duties on spirits distilled by him should be fully secured to the revenue, "it would be well worth his while to pay 3000*l.* a-year for the privilege of exemption from excise interference." ('Digest of Reports of Commissioners of Excise Inquiry,' p. 15.)

Any injury done to trade is injurious to the state by diminishing the national wealth and the employment of labour. It has the same effect also upon the revenue as excessive taxation. The high price of the article limits the consumption and consequently the revenue arising from it. The injurious effects of the excise restrictions "must be felt in an accumulated degree by the public who are the consumers, against whom the tax operates by the addition made to the price of the commodity, not only by its direct amount, but by the necessity of compensating the manufacturer for his advance of capital in defraying it, and also by the increased cost of production." ('Ibid.,' p. 15.) In the case of a heavy tax, which also diminishes consumption, the state, at least, derives some benefit; but in the case of onerous restrictions and impediments to trade caused by the mode of collecting a tax, the state gains nothing whatever, and the manufacturer and the consumer are seriously injured, without an equivalent to any party. If the consumer must suffer, it should, at least, be for the benefit of the revenue, for then his contributions may be diminished in some other direction. During the last few years excise duties have been removed entirely from several manufactures, and in the instance of bricks and glass, especially in the latter, the improvements in the manufacture, and the remarkable diminution of price, have been of a most striking character, and produced the most beneficial effects.

The net produce of a tax is all that the state is interested in, and therefore any violation of the fourth maxim of Adam Smith is liable to the same objections as those already stated in reference to the third. Such violation increases the amount of the tax directly, as the former was shown to increase it indirectly, without any advantage to the state. Facility of collection is a great recommendation to any tax; and, on the contrary, a disproportion between the cost of collecting and the amount ultimately secured is a good ground for removing a tax, though founded in other respects upon just principles. On this account alone, as well as for the general convenience of trade, it has been a wise policy to reduce, as far as possible, the number of articles upon which customs duties are levied. The cost of collecting the duties upon the larger and more productive articles of import bears only a small proportion to the amount of the tax, while the expense of collecting the duties on the smaller and less productive articles bears a large proportion to the tax, and may in some cases exceed it.

Different Kinds of Taxes.—In selecting taxes for raising the revenue of a state, the principles already discussed should be adhered to as far as possible; but these do not point out any particular mode of taxation as preferable to others. Whatever mode of raising the necessary funds may be found to press most equally upon different members of the community, to be least liable to objections of uncertainty, or inconvenience in the mode or times of payment, or to be attended with the least expense, is fairly open to the choice of a statesman; unless objections of some other nature can be proved to outweigh these recommendations.

The two great divisions under which most taxes may be classed are *direct* and *indirect*.

Direct Taxes.—All taxes ought to be paid from the income of the community. To derive revenue from capital is to act the part of a spendthrift; and such a practice as, in private life, must be condemned. If the taxes of any country should become so disproportioned to its income, that, in order to pay them, continual demands must be made upon its capital, its resources would fail, employment of labour would decrease, and the revenue must necessarily be reduced by the general impoverishment of the tax-payers. Such a system could not long continue as regards all capital, but it may affect particular branches of capital, or all capital in certain conditions. In whatever degree it is permitted to operate, it is injurious. A tax upon legacies is a direct deduction from capital, and on that account objectionable, although it is profitable to the treasury, and very easily collected. [LEGACY; PROBATE.] The same observations apply to the probate duty, and to duties charged upon succession to the personal property of intestates.

With these exceptions, it has been the object of the British legislature to derive all taxes from income, either by direct assessment or by means of the voluntary expenditure of the people upon taxed commodities.

Direct taxes upon the land have been universally resorted to by all nations. In countries without commerce, land is the only source from which a revenue can be derived. In most of the Eastern monarchies the greater part of the revenue has usually been raised by heavy taxes upon the soil; and in Spain, at the present time, the taxes upon the soil are most oppressive and injurious.

In England, under the Saxon kings, there was a land-tax. When the invasions of the Danes became frequent, it was customary to purchase their forbearance by large sums of money; and, as the ordinary revenues of the crown were not sufficient, a tax was imposed on every hide of land in the kingdom. This tax seems to have been first imposed A.D. 991, and was called Danegeld, or Danish tax or tribute. [DANEGELD.] It was abolished about seventy years after the Norman Conquest, but a revenue still continued to be derived, under different names, from assessments upon all persons holding lands, which, however, became merged in the general subsidies introduced in the reigns of Richard II. and Henry IV. During the troubles in the reign of Charles I. and the Commonwealth, the practice of laying weekly and monthly assessments of specific sums upon the several counties was resorted to, and was found so profitable, that after the Restoration the ancient mode of granting subsidies was renewed on two occasions only. In 1692 a new valuation of estates was made, and certain payments were apportioned to each county and hundred, or other division. For upwards of a century the tax was payable under annual acts, and varied in amount from one shilling in the pound to four shillings, at which latter sum it was made perpetual by the 38 Geo. III., c. 60, subject, however, to redemption by the landowners upon certain conditions. But no new valuation of the land has been made, and the proportion chargeable to each district has continued the same as it was in the time of King William III., as regulated by the act of 1692. That assessment is said not to have been accurate even at that time, and of course improved cultivation and the application of capital have since completely changed the relative value of different portions of the soil. On account of the generally increased productiveness of land, the tax bears upon the whole a trifling proportion to the rent, yet its inequality is very great. Adam Smith imagined that this tax was borne entirely by the landlords, but this opinion has been proved to be erroneous by modern political economists, who hold that the tax increases the price of the produce of the land, and is therefore paid by the consumers. The tax is also obviously objectionable on the ground of inequality.

A tax upon the gross rent of land would fall upon the landlord, and would be in fact a tax upon his annual income, and as such would fall with undue severity upon him, unless other classes of the community should be liable to a proportionate deduction from their respective incomes for the benefit of the state. This brings us to consider the expediency of a general tax upon all incomes.

In whatever form the tax may be levied, the contribution should be paid from income, and not from capital; and, accordingly, the simplest and most equitable mode of taxation would appear to be that which, after assessing the annual income of each person arising from all sources, should take from him, directly, a certain proportion of his income as his share of the general contribution. Such a tax, equitably levied, would appear to agree in theory with all the four maxims of Adam Smith; but, practically, every tax upon income must abound in inequalities, in uncertainty, and in great personal hardships and inconvenience.

The strongest of the objections to an income-tax is, however, the inquisitorial nature of the investigation into the affairs of all men, which is necessary to secure a statement of their incomes. This objection, indeed, is treated lightly by some; but by the mass of the contributors it is considered the most inconvenient and unseasonable quality of an income-tax. Even if the exposure of a man's affairs could do him no possible injury, yet as an offence to his feelings, or even caprice, it is a hardship which is not involved in the payment of other taxes. But apart from matters of feeling, injury of a real character is also inflicted upon individuals by an exposure of their means and sources of income. Mercantile men, from the dread of competition, take pains to conceal from others, especially if in the same business, the application of their capital, the rate of profit realised, their connections, and their credit, all of which must be disclosed, perhaps to their serious injury, when there is an investigation of their profits.

For these reasons the mode of collecting the income-tax certainly cannot be approved of as being "most likely to be convenient to the contributor." Its general unpopularity when in operation is the best proof of its hardship and inconvenience. Upon the whole, a tax upon income is so difficult to adjust equitably to the means of individuals, and the mode of collection is necessarily liable to such strong objection, that, if resorted to at all, it should be reserved for extraordinary occasions of state necessity or danger, when ordinary sources of revenue cannot safely be relied on.

The English *Assessed taxes* have as few objections in principle as most modes of direct taxation. With an equitable assessment, and special exemptions in certain cases, they are capable of being made to bear a tolerably just proportion to the incomes of the individuals paying them. They share, however, in the general unpopularity of all direct taxes, and it cannot be denied that they often press unequally upon particular persons. The window-tax was indeed in many respects most objectionable, but it has happily been removed. The direct taxes upon horses, carriages, hair-powder, armorial bearings, &c., being paid voluntarily by the rich to gratify their own taste for luxury or display, are not likely to meet with many objectors. The use of such articles generally indicates the scale of income enjoyed by the contributor, and the tax is too light to discourage expenditure or to make any sensible deduction from his means.

Indirect Taxes.—In preferring one tax to another, a statesman may be influenced by political considerations as well as by strict views of financial expediency, and nothing is more likely to determine his choice than the probability of a cheerful acquiescence on the part of the people. All taxes are disliked, and the more directly and distinctly they are required to be paid, the more hateful they become. On this, as well as on other grounds, "indirect taxes," or taxes upon the consumption of various articles of merchandise, have been in favour with most governments. "Taxes upon merchandise," says Montesquieu, "are felt the least by the people, because no formal demand is made upon them. They can be so wisely contrived that the people shall scarcely know that they pay them. For this end it is of great consequence that the seller shall pay the tax. He knows well that he does not pay it for himself; and the buyer, who pays it in the end, confounds it with the price." ('Esprit des Lois,' livre xiii. chap. 7.) This effect of indirect taxes is apt to be undervalued by writers on political economy; but it is undoubtedly a great merit in any system of taxation (which is but a part of general government) that it should be popular, and not give rise to discontent. A tax that is positively injurious to the very parties who pay it without thought, is certainly not to be defended merely on the ground that no complaints are made of it; but it may be safely admitted as a principle, that of two taxes equally good in other respects, that is the best which is most acceptable to the people. The very facility, however, with which indirect taxes may be levied, makes it necessary to consider the incidents and effects of them with peculiar caution. The statesman has no warning, as in the cases of direct taxes, that evils are caused by an impost which is productive and which every one seems willing to pay. When any branch of industry is visibly declining, and its failure can be traced to no other cause than the discouraging pressure of a tax, the necessity of relief is felt at once; but if trade and manufactures are flourishing, and the country advancing in prosperity, it is difficult to detect the latent influence of taxes in restraining that progress, which but for them would have been greater; and still more difficult to imagine the new sources of wealth which might have been laid open if such taxes had not existed, or had been less heavy, or had been collected at different times or in different ways.

The government is directly interested in the increase of national wealth, and taxes upon commodities should be allowed to interfere with it as little as possible. On this account, duties upon raw materials are objectionable. They increase the price of such materials, and thus limit the power of the manufacturer to purchase them, and to employ labour in increasing their value, and in adding to the production and capital of the country. They discourage foreign commerce and the employment of shipping; for as the power of buying is restrained, so also is that of selling, and the interchange of merchandise between different countries is checked. Moreover, by increasing the price of the exported manufactures, they limit the demand for them abroad and subject them to dangerous competition.

Similar objections may be urged against taxes upon domestic manufactures, since by increasing the price they diminish consumption, and consequently discourage the manufactures, which if left to themselves would have given employment to more capital and labour, and would have added greatly to the amount of national wealth and prosperity. The object of a government should always be to collect its revenue from the results of successful employment of capital and industry, and not to press upon any intermediate stage of production.

The British legislature has of late years very wisely repealed or reduced various duties upon raw materials and upon manufactures. Of customs duties, none now remain but on articles of large consumption, such as tea, sugar, wine, tobacco, timber, &c., and all those upon raw material, and upon articles of small consumption, where the trouble and hindrance to the merchant exceeded the amount of income produced, have been repealed.

One of the chief recommendations of indirect taxes is, that, when placed upon the proper description of articles, the payment of them by the consumer is optional. If charged upon what may be strictly called the necessaries of life, their payment becomes compulsory, and falls with unequal weight upon labour. Competition generally reduces a large proportion of the working classes to a state which allows them little, if anything, beyond necessaries; consequently a duty upon these, as it will have no effect in diminishing the competition of labour and in raising wages, must reduce the comforts and stint the subsistence of labouring men.

That class of articles commonly called luxuries, of which the consumption is optional, is a fair subject of taxation. In principle there is no objection to such taxes: they do not interfere with industry or production, but are paid out of the incomes of the contributors, and paid willingly, and for the most part without undue pressure upon their means. But in laying on taxes upon particular articles of this description, care must be taken to proportion the charge to the value of the article. Excessive duties fail in the very object they have in view, by rendering the revenue less productive than moderate duties; while the causes of their failure are injurious to the wealth of the country by discouraging consumption, and to its morals by offering an inducement to smuggling.

High duties upon foreign articles imported into a country are liable to all the objections which apply to immoderate taxes upon articles of consumption, and they are chargeable with another—they diminish importation, and thereby restrict commercial intercourse and the demand for and exportation of domestic produce and manufactures.

The success of moderate duties upon articles of consumption, in encouraging the use of them, placing them within the reach of a larger number of persons, and at the same time augmenting the revenue, was never better shown than in the article of coffee. In 1824 the duty on British plantation coffee was 1*s.*, upon East India 1*s.* 6*d.*, and upon foreign coffee 2*s.* 6*d.* per lb., and the quantity cleared for consumption was 8,262,943 lbs., producing a net revenue of 420,988*l.* In 1825 those duties were reduced one-half, and the consequence was considerably more than a threefold increase in the consumption, while the revenue in 1841 had been more than doubled. The duty is now 3*d.* per lb., and the importation in 1859 was 65,358,029 lbs., of which 34,292,947 lbs. were entered for home consumption. There is no difference between foreign coffee and that of the production of British possessions.

Thus reductions of existing duties may be proved by such examples to increase the revenue; but whether the effect of them be immediate or deferred must depend upon a variety of circumstances. If the reduction puts an end to extensive smuggling, the revenue will derive immediate benefit, as both the demand and the supply of the article already exist; and the reduced tax, without affecting production or consumption, acts as a police regulation, and at once protects the revenue from fraud. But where there is little or no smuggling, and the revenue can only be increased by means of additional consumption, the effect of reduced duties may be deferred and even remote. The article may have to be produced; capital, skill, labour, and time may be required to provide it in sufficient quantities to meet the growing demands of the consumer; and even should the supply become abundant, the habits and tastes of a people cannot be changed on a sudden. The high price of an article may have placed it out of their reach, and in the meanwhile they may have become attached to a favourite substitute, or may be slow to spend their money upon a commodity which they have learned to do without. These and other causes may defer for a considerable time such an increase of consumption as would make up for the reduced rate of tax, especially when the reduction has been so great as to require an extraordinary addition to the previous amount of consumption, before the sacrifice made in the revenue can be redeemed. But where the article on which it is proposed to reduce a tax is already in universal request, and the supply immediate and abundant, and where the tax is so heavy as to restrain consumption, no present loss need be apprehended from a remission of part of the tax, and a very speedy increase of revenue may be expected. Sugar is an article of this description. It has become a necessary of life as well as a favourite luxury. There are scarcely any limits to the supply that could be raised, and the present duties add materially to the price and check consumption. As a proof of the suddenness with which the consumption of foreign sugar might be expected to increase if the excessive duty were reduced, we may refer to the effects of equalising the duties on East and West India sugars in 1836. In that year the duty on East India sugar was reduced from 32*s.* the cwt. to 24*s.* In 1835 the quantity imported had been 147,976 cwts.; and in 1837, one year only after the change, the import had increased to 302,945 cwts.; in 1838, to 474,100 cwts.; and in 1839, to 587,142 cwts. As the tax was diminished only by one-fourth, and the consumption was immediately more than doubled, the revenue at once gained considerably by the reduction of duty. The duty now varies from 18*s.* 4*d.* to 12*s.* 6*d.* per cwt., according to the quality, and the importation in 1859 was 7,426,791 cwts.; the quantity retained for home consumption was 8,847,119, on which the duty was 7,291,089*l.*, and the estimated value 12,516,757*l.*

A financial experiment will serve to show how little an increased revenue can be depended upon as the result of an augmentation of taxes upon articles of consumption. In 1840 an addition of 5 per cent. was made to all the duties of customs and excise, and a proportionate increase of revenue was anticipated, but not realised. The net produce of the customs and excise in the year ending January 5th, 1840, amounted to 37,911,506*l.* The estimated produce for the year ending January 5th, 1842, was 39,807,081*l.*, 1,895,575*l.* being expected from the additional 5 per cent. The actual increase, however, was only 206,715*l.*, or little more than ½ per cent. instead of the 5 per cent. which had been expected. This result was undoubtedly in part caused by a general stagnation of trade, and by the consequent distress which prevailed in that year; but we notice it because the principle of an indiscriminate augmentation of existing taxes, without reference to their present amount, character, and circumstances, is very unwise.

We have said that experience alone can show the precise rate of a particular tax which will not affect consumption and will at the same time discourage smuggling. It must be presumed that existing rates have been fixed in order to secure these results, and that they are justified by experience. To add to them, therefore, not because they are insufficient for their immediate object, but because a general addition to the revenue is needed, is to neglect experience and to disturb the proper relations between the amount of tax and the value of particular articles. During the last century it was a common financial course to add a general per centage of increase upon all the customs' duties whenever the revenue was found to be insufficient for immediate purposes. To this unwise policy must be attributed many of the strange anomalies which formerly existed in the British tariff. Any recurrence to so clumsy a mode of taxation should be avoided. The tax upon each article ought to be adjusted by itself upon sound principles, and then should not be changed merely to save the trouble or to avoid the unpopularity of selecting particular articles for increased taxation or of inventing new burdens.

Protective, Discriminating, and Prohibitory Duties.—The legitimate object of taxation is that of obtaining a revenue in the least injurious manner for the benefit of the community; but this object has constantly been overlooked for the sake of ends not fairly to be accomplished by taxation. Legislature should endeavour to encourage agriculture, trade, and manufactures; and it would be culpable to neglect any proper means of encouragement, which are not only beneficial to particular interests, but add to the general prosperity. Unfortunately, however, the zeal of most legislatures upon this point has been misdirected. They have seized upon taxation as the instrument of protection and encouragement; and, using it as such, have injured the great mass of their own countrymen, and ultimately have failed in promoting the very interests they had intended to serve. When the system of protection has existed, severe injuries and even injustice are inflicted whenever an attempt is made to undo the mischief which has been done. Reason and experience unite in teaching the impolicy of protective taxes; and, in our own country, this impolicy was acknowledged by the acts of 1846, which regulate the trade in grain, meal, and flour, and other articles.

The object of a protective duty is to raise artificially the price of the produce or manufactures of one country as compared with the produce or manufactures of another. A heavy tax easily effects this object, and thus prevents competition on the part of that country whose commodities are taxed, and establishes a monopoly in the supply of those commodities in favour of the parties for whose benefit the tax was imposed. The revenue, the avowed object of a tax, so far from being improved, is here actually sacrificed by the exclusion of merchandise, which at moderate duties would fill the coffers of the state. The state clearly is a loser; the foreigner, whose goods are denied a market, is a loser. Who then gains by these losses? Not the consumer; for the more abundant the supply, the better and cheaper will he find the market; but the seller, who is enabled to obtain a high price for his wares because he has a monopoly in the sale of them, is the only party who gains. The community at large suffer doubly: first, by having to buy dear instead of cheap goods, or by being denied the use of them altogether; and, secondly, by being obliged to pay other taxes which would not have been required if the very articles which would have made their purchases cheaper had been charged with a moderate impost. Even the sellers, for whom all these sacrifices are made, do not derive the benefit which might be expected. In the goods which they sell themselves, indeed, they are gainers; but in purchasing of other monopolists they lose by an artificially high price, like the rest of the community. It constantly happens too, that although the prices at which they sell are high, their profits are reduced, by the competition of others selling the same articles, to the general level of profits throughout the country. When this is the case, all parties, without exception, are losers—the state, the community, and the monopolists.

Protection may be accomplished by actual prohibition of the import of particular articles, by exorbitant duties which amount to prohibition, or by such duties only as give the home producer an advantage. Duties may also discriminate between the produce of different countries, and give the preference to some, to the injury and exclusion of others. In this country all these modes of protection have been resorted to: but their impolicy has been recognised by the legislature, which, within the last few years, has advanced rapidly in the adoption of a more sound system of taxation. [TARIFF.]

Duties are called discriminating or differential when they are not levied equally upon the produce or manufactures of different countries. The object of them is to give an advantage to the country on whose commodities the tax is lightest, as compared with others. To obtain such a preference has been the object of various negotiations and commercial treaties between different states, as it opens extensive markets to the industry of the favoured nation. By the commercial policy of England the principle of discrimination may be said to have been confined to the protection of our colonies against the competition of foreign countries. As regards each other, all foreign countries enjoy equal commercial advantages in their intercourse with England. It has been contended that colonies form an integral part of the mother-country, and that the commercial intercourse between the several parts of the British empire ought to be viewed as a vast coasting-trade, but now foreign vessels are admitted to this trade in England, although foreign nations refuse to adopt the like practice. If this principle were acted upon, it would certainly present a grand fiscal union worthy of admiration. There were two great articles of consumption, sugar and timber, upon which the discriminating duties have been most mischievous in their results. These discriminating duties have been abolished. Those on sugar have been noticed. Those on timber were reduced in 1847 and 1848, and in 1860 the difference between foreign and colonial timber was abolished, and 1*s.* per load only is imposed on all.

Export Duties.—Duties levied upon goods exported to foreign countries are ultimately paid by the foreign consumer, and thus have the effect of making the subject of one state bear the burdens of another. However desirable this may appear to the state, whose treasury is enriched at the expense of foreigners, the expediency of such duties will depend upon peculiar circumstances, and great nicety is required in the regulation of them. If a country possesses within itself some produce or manufacture much in request abroad, and for the production of which it has peculiar advantages, a moderate export duty may be very desirable. In this manner Russia, which almost alone supplies tallow to the rest of Europe, derives a considerable revenue from an export duty upon that article. Upon the same principle a duty upon machinery exported from Great Britain would have been politic. British machinists far excelled all others in skill and ingenuity, and foreign manufacturers were willing to pay almost any price for their machinery. Notwithstanding the prohibition, large quantities were smuggled abroad at an enormous cost, but the difficulty and expense of evasion were so great that foreigners had latterly almost confined their purchases, in this country, to models and drawings, and made the machinery themselves, with the assistance of British artisans, whom they enticed abroad by extravagant wages. The partial relaxation of the prohibitory law in 1825, by granting licences to export certain kinds of machinery, showed the extent to which the trade might have been carried under a more liberal policy. The official value of machinery exported under licence in 1840 was 593,064*l.*, in addition to various tools allowed by law to be exported, of which no account was taken. The restriction is now removed, and the declared value in 1859 amounted to 2,562,934*l.*

Though moderate export duties upon articles of which a country has almost the exclusive supply may be advisable, heavy duties will check the demand abroad in the same manner as they affect the consumption of commodities at home. In the same manner also they are injurious to trade and unprofitable to the revenue.

All duties, whatever, should be avoided upon the export of produce or manufactures which may be also sent from other countries to the same markets. They would discourage trade and offer a premium to foreign competition.

Although the temptation is great to shift taxes from one country to another by means of export duties, this temptation is equally great in all countries; and if their several governments should be actuated by the desire to make foreigners contribute to their revenue, their opportunities for carrying out such a system would probably be equal, and thus retaliations might be made upon each other, which, after all, would neutralise their efforts to tax foreigners, and leave them in the same position as if they had been contented to tax none but their own subjects. In this power of retaliation lies the antidote to the evil of one state being forced to bear the burdens of another as well as its own. Every state would naturally resist such an imposition upon its subjects, and export duties can therefore only be safely resorted to in such peculiar cases as we have noticed, where foreigners are willing to pay an increased price for commodities which they must have, and which they cannot obtain so good or so cheap from any other place.

TAXA'TIO ECCLESIA'STICA, signifies the assessment and levy of taxes upon the property of the church and of the clergy. The pope once claimed in all countries the first year's whole profits and the tenth part of the whole annual profits of every ecclesiastical benefice. These were called "First-Fruits and Tenths" [FIRST-FRUITS; TENTHS], and were, for the most part, paid willingly by the clergy to their ecclesiastical superior. The popes founded their claim upon scriptural precepts and practice, from the time of Melchizedek. The pope had his collectors in every diocese, who sometimes by bills of exchange, but generally in specie, yearly returned the tenths and first-fruits of the clergy to Rome.

But while the clergy were thus liable to taxation by their ecclesiastical head, it was maintained by the Roman Catholic church that their property enjoyed complete immunity against all claims of temporal powers, being set apart for the service of God, the support and dignity of the Christian church, and for works of charity. Upon this point frequent contests very naturally arose, and the vast possessions of the church tempted the pope and temporal princes by various modes to exact contributions from the clergy. The means resorted to by these respective powers to raise a revenue from the clergy, and the laws and customs that prevailed upon the matter, may be conveniently stated by dividing the subject into—

1. Taxation of the church or clergy by the pope for ecclesiastical purposes.
2. By temporal princes for the service of the state.

1. The pope was by no means satisfied with the regular contributions of the clergy, but continually applied to them for extraordinary funds for special purposes. In 1199, Pope Innocent III. issued a bull commanding the prelates and clergy of the Christian church to pay the fortieth part of all their revenues to defray the expenses of a crusade. This is said to have been the first attempt to impose a tax on the clergy of all nations by the authority of the pope as head of the church. The practice became frequent; and in 1225 the pope entertained a project by which the revenues of two prebends in every cathedral, and the portion of two monks in every monastery, in all the countries in communion with the Church of Rome, were to have been granted to the pope for the better support of his dignity. When this project was laid before the parliament of England in 1226, they evaded a direct answer to the papal legate, by alleging "that this affair concerned all Christendom; and that they would conform to the resolutions of other Christian countries." (Wilkin's 'Concilia,' vol. i.)

Two years afterwards, the king of England, Henry III., in order to induce the pope to interfere in a dispute concerning the appointment of an archbishop to the see of Canterbury, recently vacant by the death of Cardinal Langton, promised him a tenth of the moveables not only of the clergy but of the laity. In this proceeding there appears to have been a twofold peculiarity. First, a temporal prince offered the pope a contribution from his clergy, which commonly originated with the pope; and, secondly, a tax was to be levied upon the laity, not for the service of the state, but for the benefit of a foreign ecclesiastic. The strangeness of the circumstances, however, did not prevent the pope from taking immediate advantage of the king's offer, and he accordingly sent a legate into England to collect the tenths. His demand met with some opposition, chiefly from the barons, but the pope and the king together were too powerful to be resisted. In the same reign the pope's legates were constantly demanding presents from the bishops, monasteries, and clergy, and convening assemblies of the church, with no other object than to extort money. Their proceedings created such disgust that the great barons sent orders to the wardens of the seaports to stop all persons bringing any bulls or mandates from Rome, and at last succeeded in driving the legate himself out of the kingdom; but the sums which the pope continued to draw from the clergy at that time appear to have been enormous, and the histories of that period are full of complaints and remonstrances against papal exactions. An act was passed by the parliament in 1307 ('Statute of Carlisle,' 35 Edward I.) to restrain, in some measure, the exactions of the see of Rome, but apparently with little good results; for seventy years afterwards we find the Commons in parliament still protesting against the extortions of the pope. In their remonstrance to the king upon that grievance, they asserted "that the taxes paid to the pope yearly, out of England, amounted to five times as much as the taxes paid to the king." (Cotton's 'Abridgment.')

Although complaints continued long after this period, no measures were effectual in limiting the demands of the court of Rome until the pope's authority was altogether suppressed in England at the Reformation in the reign of Henry VIII.

2. The immunities claimed by the church were not effectual in protecting its revenues from being laid under contribution for the service of the state. The kings of England, sometimes by the pope's authority, sometimes by forced or voluntary compliance on the part of the church, and sometimes by their own direct power, obtained large sums from the clergy.

William the Conqueror found the church very wealthy, and subjected it to much spoliation. A singular occasion for taxing the clergy arose in the reign of Henry I., A.D. 1129. An ecclesiastical council, assembled at London, denounced all married clergymen, and decreed that they should put away their wives. The council committed to the king the execution of their decrees; but he, instead of compelling the clergy to send away their wives, imposed a tax on those who chose to retain them, which is said to have been very productive.

The pope was not unwilling to assist in oppressing the clergy for the benefit of kings, when they were inclined to further his own objects, either by undertaking crusades, carrying on wars against his enemies, or making concessions to him. He would not suffer the immunities of the church to be infringed by the temporal power, but often placed at the disposal of princes the revenues of the church by his own authority. Thus, the pope, by virtue of his apostolical power, granted King Henry III., by several bulls, the goods of all clergymen who died intestate, the revenues of all vacant benefices, and of all non-residents. In 1288, Pope Nicholas IV. granted the tenths to King Edward I. for six years, towards defraying the expenses of an expedition to the Holy Land; and in order to collect them at their full value, a taxation by the king's precept was begun in that year, and finished, as to the province of Canterbury, in 1291, and as to that of York in the following year, the whole being under the direction of the bishops of Winchester and Lincoln. This taxation is a most important record, because all the taxes of the church, as well to the kings of England as to the pope, were afterwards regulated by it until the survey made by Henry VIII.; and because the statutes of colleges which were founded before the Reformation are also interpreted by this criterion, according to which their benefices, under a certain value, are exempted from the restriction in the statute 21 Henry VIII. concerning pluralities. ('Preface to Taxatio Ecclesiastica, P. Nich. IV., by the Record Commissioners.')

In 1295, Edward, notwithstanding the pope's grant, and numerous exactions from the clergy in the meantime, being still in great need of money to carry on his wars, summoned deputies from the inferior clergy for the first time to vote him supplies from their own body. In the preceding year he had, by threats and violence, exacted a tax of half the revenues of the clergy; but now he thought it prudent to obtain their consent to his demands in a more regular manner. The clergy, however, would not obey the king's writ of summons, lest they should appear to acknowledge the temporal power; and in order to overcome this objection, the king issued his writ to the archbishop, who, as their spiritual superior, summoned the clergy to meet in convocation. (Gilbert's 'History of the Exchequer.')

This was the commencement of the constitutional practice of the clergy meeting in Convocation at the same time as the Lay Parliament, and voting subsidies by its own voluntary act for the service of the state. It was not viewed without alarm by the pope and the high church dignitaries; and in order to put a stop to all such exactions of princes from the clergy, Pope Boniface VIII. issued a bull in 1296, which forbade churchmen of every degree to pay any tribute, subsidy, or gift to laymen, without authority from the see of Rome; and declared that if they should pay, or princes exact, or any one assist in levying such unauthorised taxes, all such persons respectively would incur the sentence of excommunication. (Rymer's 'Fœdera,' vol. i., part 2.)

In the same year, however, Edward I. demanded of the clergy a fifth of their moveables, which they resisted, on the ground that they could not disobey the pope; but the king was not inclined to desist; and in order to force the acquiescence of the clergy, he put them out of the pale of the laws. Orders were issued to the judges to hear no cause brought before them by the clergy, but to decide all causes in which they were sued by others. The clergy could not long resist these oppressions; and although unwilling to disobey the papal bull, they evaded it by voluntarily depositing a sum equivalent to the amount demanded of them in some church, whence it was taken by the king's officers. In this expedient the whole ecclesiastical body acquiesced, and thus yielded up their spiritual privileges, under coercion by the temporal power.

At the Reformation, the chief source of revenue to the pope, namely, first-fruits and tenths, was transferred to the king "for more augmentation and maintenance of the royal estate of his imperial crown and dignity of supreme head of the Church of England." (Stat. 26 Henry VIII., c. 3.) In order to collect this revenue, a court of first-fruits was established, and the king ordered a valuation to be made of all the episcopal sees and benefices in England. The book which contains this valuation is called the 'Liber Regis.' The first-fruits and tenths continued to form part of the royal revenue until Queen Anne, by the Act 2 & 3 of her reign, c. 11, gave up the proceeds thereof on the part of herself and her successors, and assigned them for ever to the augmentation of poor livings.

It now only remains to notice more particularly the practice of taxing the clergy in convocation, which continued in full force till the reign of Charles II. It had afforded the kings of England a lucrative revenue from the church. Their influence as heads of the church, and as having ecclesiastical preferments to bestow, was very great after the

Reformation, and enabled them very commonly to obtain larger subsidies from the convocation than those that were voted by parliament. The church, therefore, was not unwilling to be deprived of the expensive privilege of voting separate subsidies; and acquiesced in an arrangement proposed in 1664–5, by which the Commons have ever since voted taxes upon the possessions of the church and of the clergy, in the same manner as upon the laity.

TAXES. The general objects, character, and principles of taxation and of different classes of taxes, are treated of under the head of TAX, TAXATION. In this place it is proposed to give a short summary of the amount and description of taxes paid in Great Britain and Ireland, whether assessed directly upon property, or collected indirectly upon articles of consumption; including not only such taxes as are paid to the general government, but also all municipal and local assessments or contributions.

United Kingdom.

The chief sources of revenue will be seen by the following statement, made up to December 31, 1860.

	Gross Receipts.
Customs	£23,032,395
Excise	19,069,000
Stamps	8,285,258
Taxes (land and assessed)	3,126,000
Property tax	12,901,816
Post Office	3,420,000
Crown lands	289,568
Miscellaneous	1,843,457
Total revenue	£71,967,494

From which the salaries, &c. of the revenue departments, amounting to 4,509,402*l.* has to be deducted as the charge for collecting; of this, the Post Office expenses for management in 1859 was 1,851,953*l.* The remainder, 2,657,449*l.*, gives an average of less than 9*d.* in the pound as the charge of collection.

The assessed taxes are the house-tax, the tax on male servants, taxes on carriages, on horses, on dogs, armorial bearings, horse-dealers' duty, game duties, stage-coach duties, and duties on passengers conveyed for hire by carriages travelling on railways. In 1840 (3 & 4 Vict. c. 17) 10 per cent. additional was imposed on all the assessed taxes. The income-tax was imposed April 5th, 1842, for three years, and was then renewed for another three years, and has been continued at varied intervals ever since. For 1860 it was imposed at 10*d.* in the pound; for 1861–2 it is proposed to reduce it to 9*d.* in the pound.

Bachelors, except Roman Catholic clergymen, pay an additional duty of 1*l.* on male servants. [BACHELOR.] The charges for game duties are stated under GAME LAWS. The duty on passengers conveyed for hire by carriages travelling on railways is 5 per cent. on the gross amount of the fares. As to the duties on stage-coaches, see STAGE-CARRIAGE.

To these parliamentary taxes may be added the following local assessments in England and Wales:—

	£
Poor-rates (which includes county, borough and police rates, 700,000*l.*)	8,188,880
Church-rates (average of seven years)	261,716
Additional voluntary contributions	269,550
Highway-rates	1,949,817
Turnpike-tolls (England and Wales)	1,031,050
Metropolitan local management	159,886

The rates levied for local management could not be ascertained, but including poors-rates in Scotland and Ireland, in the grand jury presentments in the latter country, the whole is estimated in a return, avowedly imperfect, laid before parliament, at 15,171,646*l.* in 1860.

The tithes of Great Britain and Ireland are said to amount to 4,000,000*l.*

There was published under the direction of the Poor-Law Commissioners in 1846, a valuable work entitled 'The Local Taxes of the United Kingdom, containing a Digest of the Law with a Summary of statistical Information concerning the Several Local Taxes in England, Scotland, and Ireland.' England includes England and Wales. It is remarked in the Introduction that "these Local Taxes are of two kinds: the rates raised in defined districts; and the tolls, dues, and fees paid for particular services or on certain occasions. But those rates only will be here noticed, which are authorised by general statutes or the common law; excluding such as derive their origin from special or local Acts." The rates are divided into three classes. I. Rates of independent districts, on the basis of the poor-rate. II. Rates of independent districts, not on the basis of the poor-rate. III. Rates of aggregate districts, on the basis of the poor-rate. No. I. comprehends —1, The Poor Rate. 2, The Workhouse Building Rate. 3, The Survey and Valuation Rate. 4, The Jail Fees' Rate. 5, The Constables' Rate. 6, The Highway Rates (three). 7, The Lighting and Watching Rate. 8, The Militia Rate. No. II. comprehends—1, The Church Rates (three). 2, The Sewer Rate. 3, The General Sewers' Tax. 4, The Drainage and Inclosure Rates. 5, The Inclosure Rate. 6, The Regulated Pasture Rate. No. III. comprehends—*Counties.* 1, The County Rate. 2, The Police Rate. 3, The Shire Hall Rate. 4, The Lunatic Asylum Rate. 5, The Burial Rate.—*Hundreds.* 6, The Hundred Rate.—*Boroughs.* 7, The Borough Rate. 8, The Watch Rate. 9, The Jail Rate. 10, The Prisoners' Rates. 11, The Lunatic Asylum Rate. 12, The Museum Rate.—*Counties and Boroughs.* 13, The District Prison Rates.

The Local Taxes in Scotland are distributed by Mr. Burton under the following heads:—

I. Administration of Justice, which includes Criminal Prosecutions, Court Rooms and County Buildings, Rural Police, Town Police, Prisons. II. Internal Transit, which includes Commutation Roads, Turnpike Roads, Highland Roads and Bridges. III. Navigation. IV. Civic Economy, which includes Direct Municipal Taxes, Petty Customs, Miscellaneous Burdens. V. Relief of the Poor. VI. The Church and Education, which includes The Church of Scotland Education. VII. Miscellaneous Taxes.

Mr. Burton observes "that the money expended on the ecclesiastical establishment and on education, partakes, in some respects, of the nature of a tax." The amount of money annually levied by local taxation in Scotland is not accurately known. The sum of 956,678*l.* is the approximate amount given by Mr. Burton.

The Local Rates levied in Ireland are distributed under the following heads in the work published under the direction of the Poor-Law Commissioners.

I. Grand Jury Cess (in all the counties, including counties of cities and towns).
II. Poor-Rates (in 130 Unions, comprising every townland and denomination of land in Ireland).
III. Lighting, Cleansing, and Watching Rates (in all cities, towns, and boroughs which may adopt the provisions of the statute).
IV. Borough Rates (in certain Boroughs).
V. Pipe Water Rates (in every city and town, except Dublin, Cork, and Limerick, which gives title to a bishop or archbishop).
VI. Parish Cess (in all parishes, unions of parishes, or chapelries in Ireland).
VII. Rates for deserted children (in all parishes in Ireland, except those in the city of Cork).
VIII. Ministers' Money (in cities and towns corporate in Ireland).
IX. Board of Health Rates (in parishes in which the lord lieutenant shall direct officers of health to be appointed).

"Besides the above rates leviable under general acts of parliament, there are rates leviable under special acts in many places, as Dublin, Cork," &c.

Information about the several taxes of European States will be found in the Parliamentary Paper, No. 227, of 1842, ordered by the House of Commons to be printed, 3rd May, 1842.

TAYLOR'S THEOREM. We propose in this part of the article to give some results of the methods of algebraical development which are consequences of the celebrated theorem, the history of which is given in the article TAYLOR, BROOK, in BIOG. DIV. The simplest parts of the Differential and Integral Calculus will be presumed known. It is not usual in works on that subject to bring together in one place the most conspicuous theorems which have arisen out of that of Taylor; which makes it the more desirable that such a thing should be done in a work of reference. It is to be particularly remembered that we do not here profess to teach the subject of development, but only to recall the steps of the several processes to those who have already learnt them, and to present the theorems in a form which can be easily referred to.

As to notation, we shall frequently signify differentiation by accents: thus $\phi''x$ is the second differential coefficient of ϕx with respect to x; $(\phi x \psi x)'''$ is the third differential coefficient of the product of ϕx and ψx. And $[n]$ will signify the product $1 \times 2 \times 3 \times \ldots . \times (n-1) \times n$. Moreover, when a series is written, three terms will be written down, and the general term appended.

Taylor's theorem is as follows:—

$$\phi(x+h) = \phi x + \phi' x \, . \, h + \phi'' x \frac{h^2}{2} + \&c. \quad \left\{ \phi^{(n)} x \frac{h^n}{[n]} \right\}$$

This theorem is true whenever x has such a value that—1. No one of the set ϕx, $\phi' x$, &c. is infinite. 2. All of them do not vanish. Thus neither of the following could be allowed to be treated by it when $x = a$:—

$$\sqrt{(x^2 - a^2)} \, . \log x \quad \text{and} \quad \epsilon^{-(x-a)^{-1}}.$$

In the first function, $\phi' x$, and all which follow, are infinite when $x = a$; in the second ϕx and all its differential coefficients vanish when $x = a$. The meaning of this circumstance is as follows: the form of Taylor's theorem essentially requires that $\phi(x+h)$ should be developed in ascending integer powers of h; consequently when such form of development is impossible, this theorem may show signs of being inapplicable. Now, the first of these functions (when $x = a$) can only have $\phi(a+h)$ expanded in ascending fractional powers; and the second only in descending integer powers. Those who will only allow the use of converging series may require also that h should be so small that the resulting series is convergent: but this Cauchy has proved always happens if h be small enough.

In the Penny Cyclopædia we gave a comparison of five proofs of Taylor's Theorem. This was twenty years ago: since which time the character of elementary works has changed. The Penny Cyclopædia being still perfectly accessible, we think it will be best to confine ourselves, in the present work, to a statement of the best form of the best proof. This we hold to be a variation and amendment, by Mr. Homersham Cox, of Cauchy's proof, which may be seen in De Morgan's Differential Calculus. Mr. Cox's proof was first published in the Cambridge Mathematical Journal, vol. vi., p. 80.

From $\phi(a+v)$ subtract any number of Taylor's terms, and one more with an undefined constant, and write this down with as many differential coefficients as Taylor's terms: as in

$$\text{P}\quad \phi(a+v)-\phi a-\phi' a\, v-\phi'' a\,\frac{v^2}{2}-\phi''' a\,\frac{v^3}{2\,.\,3}-\text{C}\,\frac{v^4}{2\,.\,3\,.\,4}$$

$$\text{Q}\quad \phi'(a+v)-\phi' a-\phi'' a\, v-\phi''' a\,\frac{v^2}{2}-\text{C}\,\frac{v^3}{2\,.\,3}$$

$$\text{R}\quad \phi''(a+v)-\phi'' a-\phi''' a\, v-\text{C}\,\frac{v^2}{2}$$

$$\text{S}\quad \phi'''(a+v)-\phi''' a-\text{C}v$$

$$\text{T}\quad \phi^{\text{iv}}(a+v)-\text{C}.$$

All these vanish with v, except the last: choose for C that value which makes the first vanish when $v=h$. Let ϕx be such that $\phi^{\text{iv}}x$ (and consequently ϕx, $\phi' x$, $\phi'' x$, $\phi''' x$) does not become infinite from $x=a$ to $x=a+h$. Now remember that a function which vanishes in two places, and does not become infinite in the interval, must change from increasing to diminishing, or from diminishing to increasing, in that interval: so that its differential coefficient must change sign, and, if not infinite, must vanish. Now P satisfies these conditions, vanishing at $v=0$ and at $v=h$: hence Q must vanish before $v=h$, and as it vanishes at $v=0$, and does not become infinite in the interval, Q also satisfies the conditions: hence R vanishes before $v=h$: and by like reasoning S, and T. Now if some value of v between 0 and h makes T vanish, let it be $v=\theta h$, θ being a positive fraction between 0 and 1. Hence $\text{C}=\phi^{\text{iv}}(a+\theta h)$: and since C was so taken that P vanishes when $v=h$, we have

$$\phi(a+h)=\phi a+\phi' a\,.\,h+\phi'' a\,\frac{h^2}{2}+\phi''' a\,\frac{h^3}{2\,.\,3}+\phi^{\text{iv}}(a+\theta h)\,\frac{h^4}{2\,.\,3\,.\,4}.$$

This, if the reasoning be carried to n terms of Taylor's series, is Taylor's theorem with Lagrange's theorem on the *remainder* of the series appended. If no differential coefficient of ϕx up to $\phi^{(n)}x$ should become infinite from $x=a$ to $x=a+h$, then

$$\phi(a+h)=\phi a+\phi' a\,.\,h+\ldots\ldots+\phi^{(n-1)}\,a\,\frac{h^{n-1}}{2\,.\,3\ldots n-1}+\phi^{(n)}\,(a+\theta h)\,\frac{h^n}{2\,.\,3\ldots n}.$$

If the remainder term diminish without limit as n increases without limit, Taylor's series gives a true development.

Some views of Lambert on the reduction of the roots of equations (Acta Helvetica, 1758) into series were generalised by Lagrange (Mém. Acad. Sci., 1768) into a celebrated theorem of development bearing his name; and this again was generalised in form by Laplace (Méc. Cél.). The problem is as follows: given

$$y=\text{F}(z+x\phi y)\ldots.(\text{A})$$

required the expansion of ψy, when possible, in powers of x. Since ψy is, by the preceding equation, a function of x and z, if z be constant, and we differentiate with respect to x, and then make $x=0$, or $y=\text{F}z$, we may use Stirling's theorem. But this differentiation would be laborious and indirect; it was made more direct (by Laplace) in the following manner:—A constant may have any value given to it, or may be made to vanish, either before or after differentiation with respect to a variable: if then we can express differentiations with respect to x in terms of differentiations with respect to z only (in which x is constant), it will be in our power to make x vanish *before* the differentiations, which will reduce the indirect or implicit to direct differentiation. This substitution of z-differentiations in place of those of x is done as follows:—Differentiate (A) both with respect to x and z separately, and we have

$$\frac{dy}{dx}=\text{F}'\,(z+x\phi y)\,\left\{\phi y+x\phi' y\,\frac{dy}{dx}\right\}\qquad\text{whence}$$

$$\frac{dy}{dz}=\text{F}'\,(z+x\phi y)\,\left\{1+x\phi' y\,\frac{dy}{dz}\right\}\quad \frac{dy}{dx}=\phi y\,\frac{dy}{dz}$$

Let u be a function of y only, that is, not of x or z except as those variables are contained in y: then

$$\frac{du}{dy}\,\frac{dy}{dx}=\phi y\,\frac{du}{dy}\,\frac{dy}{dz}\ \text{ or }\ \frac{du}{dx}=\phi y\,\frac{du}{dz}$$

From this equation only it may be shown (by INDUCTION) that

$$\frac{d^n u}{dx^n}=\frac{d^{n-1}}{dz^{n-1}}\left((\phi y^n)\,\frac{du}{dz}\right)$$

as follows. Assume the preceding to be true for one value of n, and since $(\phi y)^n\times du:dy$ is a function of y only, let it be $dv:dy$, v being another function of y.

$$\frac{d^n u}{dx^n}=\frac{d^{n-1}}{dz^{n-1}}\left(\frac{dv}{dy}\,\frac{dy}{dz}\right)=\frac{d^n v}{dz^n}$$

$$\frac{d^{n+1}u}{dx^{n+1}}=\frac{d^n}{dz^n}\,\left\{\frac{dv}{dx},\ \text{or}\ \phi y\,\frac{dv}{dz},\ \text{or}\ \phi y\,\frac{dv}{dy}\,\frac{dy}{dz},\ \text{or}\right.$$

$$\left.\phi y\,(\phi y)^n\,\frac{du}{dy}\,\frac{dy}{dz},\ \text{or}\ (\phi y)^{n+1}\,\frac{du}{dz}\right\}$$

whence the theorem remains true after writing $n+1$ for n. But it is true when $n=1$; therefore it is true for all values of n. If then we make $x=0$, or $y=\text{F}z$, which may be done before the differentiations on the second side of the equation, we have (u being ψy)

$$\left\{\frac{d^n\psi y}{dx^n}\,(x=0)\right\}=\frac{d^{n-1}}{dz^{n-1}}\left\{(\phi\text{F}z)^n\,\frac{d\psi\text{F}z}{dz}\right\}$$

Apply this to Maclaurin's Theorem, and we have *Laplace's Theorem*, namely,

$$y=\text{F}\,(z+x\phi y)\ \text{gives}\ \psi y=$$

$$\psi\text{F}z+\left(\phi\text{F}z\,\frac{d\psi\text{F}z}{dz}\right)x+\frac{d}{dz}\left((\phi\text{F}z)^2\,\frac{d\psi\text{F}z}{dz}\right)\frac{x^2}{2}+,\ \&\text{c}.$$

$$\text{the general term, }\frac{d^{n-1}}{dz^{n-1}}\left\{(\phi\text{F}z)^n\,\frac{d\psi\text{F}z}{dz}\right\}\frac{x^n}{[n]}$$

Lagrange's theorem, from which Laplace generalised, is the case in which $\text{F}x=x$; namely,

$$y=z+x\phi y\ \text{gives}\ \psi y=\phi z+(\phi z\psi' z)x+\frac{d}{dz}\left((\phi z)^2\,\psi' z\right)\frac{x^2}{2}+,\ \&\text{c}.$$

$$\text{the general term}\ \frac{d^{n-1}}{dz^{n-1}}\left\{(\phi z)^n\,\psi' z\right\}\frac{x^n}{[n]}$$

$$y=z+\phi z\,.\,x+\frac{d(\phi z)^2}{dz}\,\frac{x^2}{2}+\frac{d^2(\phi z)^3}{dz^2}\,\frac{x^3}{2\,.\,3}+,\ \&\text{c}.$$

Lagrange's Theorem leads to *Burmann's Theorem* (presented to the institute in 1796). The second is in fact the same as the first, though very different in form, and arrived at independently. It is required, when possible, to expand ψx in powers of ϕx. This might be done indirectly, by expanding $\psi\phi^{-1}x$ in powers of x, and substituting ϕx for x in the result. The form in which Burmann obtained Lagrange's theorem avoids the indirect process. Let ϕx vanish when $x=a$, and let $\phi x=(x-a):\chi x$, or $x=a+\phi x\,.\,\chi x$. We can now employ Lagrange's theorem to expand ψx in powers of ϕx, and we have

$$\psi x=\psi a+\chi a\psi' a\,.\,\phi x+\frac{d}{da}\left((\chi a)^2\,\psi' a\right)\frac{(\phi x)^2}{2}+,\ \&\text{c}.$$

Now the general term of this has for its coefficient the value of

$$\frac{d^{n-1}}{dx^{n-1}}\left((\chi x)^n\,.\,\psi' x\right)\ \text{or}\ \frac{d^{n-1}}{dx^{n-1}}\left\{\left(\frac{x-a}{\phi x}\right)^n\psi' x\right\}$$

when $x=a$: consequently ψx, expanded in powers of ϕx, is found by making $x=a$ in the coefficients of the powers of ϕx in the following series:—

$$\phi a+\left\{\frac{x-a}{\phi x}\,.\,\psi' x\right\}\phi x+\left\{\frac{d}{dx}\left(\left(\frac{x-a}{\phi x}\right)^2\psi' x\right)\right\}\frac{(\phi x)^2}{2}+,\ \&\text{c}.$$

When, in a function of any number of variables x_1, x_2, &c., the variables are severally to receive increments h_1, h_2, &c., the law of the development is best seen by the calculus of operations. [OPERATION.] To change x into $x+h$ is to perform the operation $\varepsilon^{h\text{D}}$, D being the symbol of differentiation with respect to x: the condensed form of the development now before us is

$$\varepsilon^{h_1\text{D}_1+h_2\text{D}_2+\ldots.}\ \phi(x_1,\,x_2,\,\ldots..)$$

where D_1, D_2, &c. refer to x_1, x_2, &c. The general term of the development is

$$\frac{(h_1\text{D}_1+h_2\text{D}_2+\ldots..)^n}{[n]}\,\phi(x_1,x_2,\ \&\text{c}.)$$

which must itself be developed. It is not worth while to pursue this case further: we shall only observe that when it is desired to stop, the remnant may be obtained by writing in the last term $x_1+\theta h_1$ for x_1, $x_2+\theta h_2$ for x_2, &c., where θ, the same in all, is either 0 or 1 or between them.

The value of x which makes $\phi x=0$ is represented by

$$a-\frac{\phi}{\phi'}-\frac{\phi''\phi^2}{2\phi'^3}-\frac{(3\phi''^2-\phi'\phi''')\phi^3}{2\,.\,3\phi'^5}-\frac{(15\phi''^3-10\phi'\phi''\phi'''+\phi'^2\phi^{\text{iv}})\phi^4}{2\,.\,3\,.\,4\,\phi'^7}$$

$$-\frac{\{105\phi''^2(\phi''^2-\phi'\phi''')+10\phi'^2\phi'''^2+15\phi'^2\phi''\phi^{\text{iv}}-\phi'^3\phi^{\text{v}}\}\phi^5}{2\,.\,3\,.\,4\,.\,5\phi'^9}-\&\text{c}.:$$

where a is any assumed value (the nearer the root the better) and ϕ, ϕ', &c. represent ϕa, $\phi' a$, &c. This series is obtained by common reversion from $\phi\,(a+h)=0$. For the forms which Paoli gave to this series, and also to Burmann's, see Lacroix, vol. i., pp. 306-308. The preceding series has been used, as far as three terms, in the article **Approximation**.

All that precedes is found in elementary treatises, with the exception of a few terms of the last series: we now come to matter which has been hitherto only the property of the well-read mathematician, but which well deserves to be made as common as Taylor's Theorem. We refer to Arbogast's *method of derivations*. [Arbogast, in Biog. Div.] Few, even among mathematicians, are aware of the power of this process, which may perhaps arise from their taking Lacroix's account of it, instead of consulting the work of Arbogast himself: the former has only exhibited it to show that it may be reduced to processes of the differential calculus; and even the latter has so loaded his method with heavy applications, that he has concealed much of its beauty and simplicity.

The foundation of Arbogast's methods is a contrivance for expediting the expansion of $\phi(a+bx+cx^2+\ldots.)$ into a series of the form $\mathrm{A}+\mathrm{B}x+\mathrm{C}x^2+\ldots.$ The process by which B is formed from A, C from B, &c. is uniform, and is called derivation; and A being ϕa, B may be called $\mathrm{D}\phi a$, C may be called $\mathrm{DD}\phi a$, or $\mathrm{D}^2\phi a$, and so on. Hence b ought to be called $\mathrm{D}a$, C ought to be D^2a, and so on. This notation is not precisely that of Arbogast, but will do for our purpose. For more detail,* see the Differential Calculus ('Library of Useful Knowledge'), pp. 328-334.

If, for a moment, we write the expansion thus—

$$\phi(a_0+a_1x+a_2x^2+\ \&c.)=\mathrm{A}_0+\mathrm{A}_1x+\mathrm{A}_2x^2+\ \&c.$$

and if we differentiate both sides with respect to a_m, x and all the other coefficients remaining constant, we have

$$\phi'(a_0+a_1x+\&c.)\,.\,x^m=\frac{d\mathrm{A}_0}{da_m}+\frac{d\mathrm{A}_1}{da_m}x+,\&c.$$

which shows that a_m cannot enter any coefficient preceding A_m, or

$$\phi'(a_0+a_1x+\&c.)=\frac{d\mathrm{A}_m}{da_m}+\frac{d\mathrm{A}_{m+1}}{da_m}x+,\&c.$$

The first side of this is the same series, whatever letter a_m was made to vary; the second side is therefore always the same series; whence we collect that $d\mathrm{A}_{m+n}:da_m$ does not alter with the value of m, being always the coefficient of x^n in the development of $\phi'(a_0+a_1x+,\&c.)$. It is enough to satisfy this condition for each letter and its preceding one; that is to say, each coefficient differentiated with respect to any one letter, is to yield the same result as the directly preceding coefficient differentiated with respect to the directly preceding letter. The following rules are found sufficient. To pass from any one derivative of ϕa to the next, arrange the letters a, b, c, &c., or a_0, a_1, a_2, &c., whichever may be used, in order, in every term: differentiate with respect to the last letter in each term, and multiply by the letter which comes next to it. And when the last but one immediately precedes the last in the alphabet or other consecutive system, do the same with the last but one, and divide by the exponent of the last letter, as it becomes after the increase which it receives from the process of the preceding letter; but in no case use any letters but the last or the last but one. For instance, beginning with ϕa, in which is only one letter, we have $\phi'a\,.\,b$, or

$$\mathrm{D}\phi a=\phi'a\,.\,b;$$

in which are two letters, a and b, consecutive. Operate upon b, and we have $\phi'a\,.\,c$; operate on $\phi'a$, and we have again $\phi''a\,.\,b$, which, with the b which was in before, is $\phi''a\,.\,b^2$, which we divide by the new exponent of b, or by 2, whence

$$\mathrm{D}^2\phi a=\phi'a\,.\,c+\frac{\phi''a}{2}b^2.$$

In forming $\mathrm{D}^3\phi a$, we use only c in $\phi'a\,.\,c$, because a does not immediately precede c; and we get (the succession being a, b, c, e, f, g, h, k, &c.)

$$\mathrm{D}^3\phi a=\phi'a\,.\,e+\frac{\phi''a}{2}\,.\,2bc+\frac{\phi'''a}{2\,.\,3}b^3;$$

and so on. As soon however as the law is established, it is best to form a table of the successive derivatives of the powers of b by this same law: we then have

$$\mathrm{D}^n\phi a=\phi'a\mathrm{D}^{n-1}b+\frac{\phi''a}{2}\mathrm{D}^{n-2}b^2+\frac{\phi'''a}{2\,.\,3}\mathrm{D}^{n-3}b^3+\ \&c.$$

$$\text{as far as }\frac{\phi^n a}{[n]}b^n;$$

in which $\phi'a$, $\phi''a$, &c. are to be taken from the function by common differentiation, and the derivatives of the powers of b from the table. This being done, we have

$$\phi(a+bx+cx^2+ex^3+fx^4+gx^5+,\&c.)=$$
$$\phi a+\mathrm{D}\phi a\,.\,x+\mathrm{D}^2\phi a\,.\,x^2+\mathrm{D}^3\phi a\,.\,x^3+,\&c.$$

and the process is shortened to its utmost extent; all that is not differentiation being merely reference to a table and writing the result.

We shall give materials for proceeding as far as the term $\mathrm{D}^{12}\phi a\,.\,x^{12}$, not that so much will often be necessary, but because it is desirable to show with how little trouble questions of enormous labour in the ordinary way, such, for instance, as that solved in **Reversion of Series**, may be looked at without dismay. We have to form every derivative of every power of b, $\mathrm{D}^m b^n$, in which $m+n$ does not exceed 12.

$\mathrm{D}b^{11}=11b^{10}c$

To verify these results, observe that if we consider each letter as of

* There is a great deal on the subject in the 'Mathematical Treatises' (posthumous) of the Rev. John West, published at Edinburgh in 1838. Mr. West has substituted a notation, for that of Arbogast, in which he will probably have few followers. The student who is not repelled by this, and cannot procure Arbogast's work, will find West's treatises abounding in derivations.

the first dimension, every term of $D^n b^r$ is of the rth dimension; but if we consider each letter as of the dimension following:—

b	c	e	f	g	h	k	l	m	n	p	q
1	2	3	4	5	6	7	8	9	10	11	12:

then every term of $D^n b^r$ is of the $(n+r)$th dimension. To find out if all the proper terms be there, and with the proper exponents, write down the number of ways in which $n+r$ can be made out of r numbers. Thus, to verify this point for $D^7 b^3$, write down the ways in which 10 can be made out of three numbers, namely:—

$$8+1+1,\ 7+2+1,\ 6+3+1,\ 6+2+2,\ 5+4+1,\ 5+3+2,\ 4+4+2,\ 4+3+3;$$

take the letter answering to each number, in the above list, and multiply the letters of each set together, which gives

$$b^2l,\ bck,\ beh,\ c^2h,\ bfg,\ ceg,\ cf^2,\ e^2f,$$

which are, coefficients excepted, the terms of $D^7 b^3$ in the table. To verify the coefficients separately, observe that the coefficient of that term of $D^n b^r$ which contains the sth power, tth power, &c., is

$$\frac{1.2.3\ldots\ldots(r-1)r}{1.2.3\ldots s\times 1.2.3\ldots t\times\ldots\ldots}.$$

Thus, in $D^4 b^8$, the term containing b^5c^2e ought to be multiplied by

$$\frac{1.2.3.4.5.6.7.8}{1.2.3.4.5\times 1.2\times 1},$$ or 168, as is the case.

But the best general mode of verification is derived from the theorem

$$D^n b^{r-1} = \frac{1}{r}\frac{dD^n b^r}{db}, \text{ or } D^{n+1} b^{r-1} = \frac{1}{r} D\left(\frac{dD^n b^r}{db}\right);$$

that is, having a certain derivative of a certain power, the next higher derivative of the next lower power may be found by differentiating with respect to b, dividing by the exponent of the original power, and then performing the derivation. Thus:—

$$D^3 b^9 = 9b^8f + 72b^7ce + 84b^6c^3,$$

differentiate with respect to b, and divide by 9, which gives

$$8b^7f + 56b^6ce + 56b^5c^3.$$

Now derive, which gives

$$8b^7g + 56b^6cf + 28b^6e^2 + 168b^5c^2e + 70b^4c^4,$$

the same as is found in the table for $D^{3+1}b^{9-1}$. Here we verify the earlier result of the table from the later: to verify the later from the earlier, use the following:—

$$D^n b^r = D^{n-1}c\,.\,r\,b^{r-1} + D^{n-2}c^2\,.\,r\frac{r-1}{2}\,b^{r-2}+, \text{\&c.}$$

$$\text{up to } c^n\ \frac{r(r-1)\ldots\ldots(r-n+1)}{1.2\ldots\ldots n}\,b^{r-n},$$

in which the derivatives of powers of c must be formed from the corresponding tabular ones of b, by changing each letter into the next following. There are thus abundant means of verification. We will mention yet one method more. Only the last letter and the last but one (and that only when the two letters are consecutive) are used in the derivations. If we use any letter, no new term is produced, but only a repetition of those which other terms give. For instance, in $D^6 b^5$ is the term $60b^2cef$; and in passing to $D^7 b^5$, we derive from f because it is the last letter; and from e because, being the last but one, it immediately precedes f in the series. We do not here use b and c at all; but if we did use them, we should only repeat terms which will come into $D^7 b^5$ from other sources. Thus:—$60b^2cef$ gives, from f, $60b^2ceg$, which is set down in $D^7 b^5$; from e, $60b^2cff \div 2$, or $30b^2cf^2$, which is also set down; from c, if c had been used, we should have had $60b^2eef \div 2$, or $30b^2e^2f$, which, on looking, we find set down, as arising from the last letter of $10b^2e^3$. From b, in $60b^2cef$, had it been used, we should have got $120bccef \div 2$, or $60bc^2ef$, which is also found, and arises from the last letter of $30bc^2e^2$. If then we ever find that derivation from one of the unused letters gives anything but what arises from some of the letters which are used, it is a sign that some error has been committed.

By help of the preceding method, expansions which analysts usually avoid as much as possible, at almost any expense of circumoperation, are carried on with the greatest facility even further than is necessary. The development of $\phi(a+bx+cx^2+\text{\&c.})$, already given, is one instance; the process in REVERSION OF SERIES is another. This last is done by expanding x in powers of $ax+bx^2+$, &c., by Burmann's Theorem, and making the expansion of the negative powers of $(a+bx+cx^2+$, &c.), which will be wanted, by the method of derivations. We shall state some further applications:—

$$(b+cx+ex^2+\text{\&c.})^m = b^m + Db^m\,.\,x + D^2b^m\,.\,x^2+, \text{\&c.}$$

When m is integer, these derivatives are in the table. When $b+cx+$, &c., is a finite series, the whole result is brought out with great ease, compared with the trouble of the common algebraical operation: in this case, the value of every letter after the last in the finite series is 0, or the last letter of that series is not to be employed in derivation. Let the reader try for himself $(b+cx+ex^2+fx^3)^5$ by this mode and then in the common way, going only so far in the latter as to feel sure that the former is of no trouble compared with it. Let m, $m\frac{m-1}{2}$, &c., be denoted by m, m_2, &c.

$$(a+bx+cx^2+\text{\&c.})^m = a^m + mba^{m-1}x$$
$$+(mac+m_2b^2)\,a^{m-2}x^2$$
$$+(ma^2e+m_2aDb^2+m_3b^3)\,a^{m-3}x^3$$
$$+(ma^3f+m_2a^2D^2b^2+m_3aDb^3+m_4b^4)\,a^{m-4}x^4+, \text{\&c.};$$

the law of which is evident, the only thing left being the substitution of the values in the tables instead of the derivatives of b. This form is convenient for fractional or negative powers. The following case is worth exhibiting separately:—

$$\frac{1}{a+bx+,\text{\&c.}} = \frac{1}{a} - \frac{b}{a^2}x + \frac{b^2-ac}{a^3}x^2$$
$$-\frac{b^3-aDb^2+a^2e}{a^4}x^3 + \frac{b^4-aDb^3+a^2D^2b^2-a^3f}{a^5}x^4-, \text{\&c.}$$

We have avoided the formality of writing Db for c, D^2b for e, &c.

$$\frac{A+Bx+Cx^2+,\text{\&c.}}{a+bx+cx^2+,\text{\&c.}} = \frac{A}{a} - \frac{Ab-Ba}{a^2}x$$
$$+\frac{A(b^2-ac)-Bab+Ca^2}{a^3}x^2$$
$$-\frac{A(b^3-aDb^2+a^2e)-Ba(b^2-ac)+Ca^2b-Ea^3}{a^4}x^3+, \text{\&c.}$$

The law is here evident enough; the next numerator would be

$$A(b^4-aDb^3+a^2D^2b^2-a^3f)-Ba(b^3-aDb^2+a^2e)+Ca^2(b^2-ac)-Ea^3b+Fa^4.$$

The derivatives of the general term b^n may be readily formed, but the particular cases are more useful; see the derivatives of a^m in the general form above given. We shall not overload this subject with further examples: enough have been given to show those who require developments of some extent how much labour they might save.

We shall conclude this article by recommending that the process of derivation should be introduced, without demonstration, of course, into elementary books of algebra, as one of the best exercises of simple algebraical operation. We are firmly of opinion that the arithmetician and the analyst should be trained early in the performance of operations in which numerous details, each very simple in itself, follow one another in rapid succession with much sameness and some diversity. For this reason we should recommend, in arithmetic, Horner's process [INVOLUTION AND EVOLUTION]; and in algebra, Arbogast's derivation. We proceed accordingly to divest this method of the phraseology of the differential calculus, and to put it before the elementary student in algebra.

The name of the process is *derivation*; its primary object the raising of any power of an expression of the form $b+cx+ex^2+fx^3+$, &c., immediately—that is to say, by writing down the result at once, without any but simple mental processes in passing from term to term. The rules are as follows:—

1. Begin with that power of b which is to be raised.

2. To pass from the coefficient of one power of x to that of the next, multiply each letter by its exponent; then diminish that exponent by a unit; then introduce the next letter. And if this last process increase an exponent, owing to the letter newly introduced having been in the term before, divide by the increased exponent. *But remember never to operate on any letter except the last in the term, or the last but one;* upon the last always, upon the last but one when it immediately precedes the last in the original series b, c, e, f, &c.

3. If $b+cx+$, &c., be not an infinite series, but a finite number of terms, operate as if the succeeding letters were severally equal to 0: for instance, if g be the last letter, drop every term in which h should appear, as fast as it arises.

For example, the fifth power of $b+cx+ex^2+fx^3$. Begin with b^5, derive from it $5b^4c$, the two first terms are $b^5+5b^4c\,.\,x$.

To form the coefficient of x^2, take $5b^4c$, and observe that b and c follow each other in the series, so that in the next derivation there are two processes. First, use c or c^1, the last letter, which by the rule gives $1c^0e$ or e: so that derivation applied to the first power of a letter gives merely a change of that letter into the next: hence $5b^4c$ gives $5b^4e$. But b^4, which must also be used, gives $4b^3c$, and $5b^4c$ gives $5(4b^3c)c$; so that c becomes c^2, and we must therefore divide by the increased exponent 2, giving $10b^3c^2$. Hence the next term is

$$(5b^4e+10b^3c^2)x^2.$$

In the next derivation $5b^4e$ gives only $5b^4f$, for b not immediately preceding e in the series b, c, e, &c., is not used. But $10b^3c^2$ gives

$$10b^3(2ce)+\frac{10(3b^2c)c^2}{3}, \text{ or } 20b^3ce+10b^2c^3.$$

Next term $(5b^4f+20b^3ce+10b^2c^3)x^3$.

In the next derivation $5b^4f$ must be neglected entirely, because f is the last letter, and b is not the one immediately preceding. Also $20b^3ce$ gives $20b^3cf$ and $20b^3ee \div 2$, or $10b^3e^2$; while $10b^2c^3$ gives $30b^2c^2e$

and $2 \times 10bc \,.\, c^3 \div 4$, or $5bc^4$. The whole value of $(b + cx + ex^2 + fx^3)^5$ is as follows, and a little practice would enable any one to write it down at once, without any intermediate operations :—

$$\begin{aligned} &b^5 + 5b^4cx + (5b^4e + 10b^3c^2)x^2 + (5b^4f + 20b^3ce + 10b^2c^3)x^3 \\ &+ (20b^3cf + 10b^3e^2 + 30b^2c^2e + 5bc^4)x^4 \\ &+ (20b^3ef + 30b^2c^2f + 30b^2ce^2 + 20bc^3e + c^5)x^5 \\ &+ (10b^3f^2 + 60b^2cef + 10b^2e^3 + 20bc^3f + 30bc^2e^2 + 5c^4e)x^6 \\ &+ (30b^2cf^2 + 30b^2e^2f + 60bc^2ef + 20bce^3 + 5c^4f + 10c^3e^2)x^7 \\ &+ (30b^2ef^2 + 30bc^2f^2 + 60bce^2f + 5be^4 + 20c^3ef + 10c^2e^3)x^8 \\ &+ (10b^2f^3 + 60bcef^2 + 20be^3f + 10c^3f^2 + 30c^2e^2f + 5ce^4)x^9 \\ &+ (20bcf^3 + 30be^2f^2 + 30c^2ef^2 + 20ce^3f + e^5)x^{10} \\ &+ (20bef^3 + 10c^2f^3 + 30ce^2f^2 + 5e^4f)x^{11} \\ &+ (5bf^4 + 20cef^3 + 10e^3f^2)x^{12} + (5cf^4 + 10e^2f^3)x^{13} + 5ef^4x^{14} + f^5x^{15} \end{aligned}$$

This process, so simple as compared with the actual performance of the four multiplications, has hitherto lain hid in works on the higher parts of the differential calculus: it is time it should take its place in every system of algebra which contains the binomial theorem, of which it is the legitimate extension.

TEA AND THE TEA TRADE. Though now so extensively employed, the introduction of tea into Europe is of comparatively recent origin. Macpherson, in his 'History of European Commerce with India,' states that "tea (sah) is mentioned as the usual beverage of the Chinese by Soliman, an Arabian merchant, who wrote an account of his travels in the East about the year A.D. 850;" but that he had been unable to find any other mention of it prior to the times of the Jesuit missionaries, who entered China and Japan a little before the middle of the 16th century. Anderson, in his 'History of Commerce,' quotes Botero as giving the earliest account in 1590, when he says that the Chinese, "have also an herb, out of which they press a delicate juice, which serves them as drink instead of wine." Texeira, a native of Portugal, about the year 1600, saw the dried leaves of tea at Malacca; and Olearius found them used in 1633 by the Persians, who obtained them from China by means of the Usbeck Tartars. Tea, coffee, and chocolate are all mentioned in an act of parliament of 1660, whereby a duty of 8*d.* is charged on every gallon of chocolate, sherbet, and tea made for sale. But the use of it in England at that time must have been new; for Pepys in his 'Diary,' writes, September 25, 1661, "I sent for a cup of tea (a Chinese drink), of which I had never drank before." The Dutch East India Company probably first introduced it into Europe, and from Amsterdam it was brought to London. But tea must have continued to be brought in small quantities only; for in the year 1664 the East India Company purchased, for the purpose of presenting to the king, 2 lbs. and 2 ozs. of tea; and in the year 1678 they imported 4713 lbs. of tea, which was then for the first time thought worth their attention as a branch of their trade. ('Macpherson,' p. 131.)

The botanical characters of the chief species of the tea-plant are described in the NAT. HIST. DIV., under the name of the genus THEA, to which they belong.

Tea Cultivation.—Tea is cultivated in China over a great extent of territory. Dr. Wallich mentions it as being cultivated in Cochin China, in 17° N. lat. We know that it is cultivated in the southern provinces of Yunnan and of Canton. Farther north the principal cultivation of teas for the foreign trade is between 27° and 31° N. lat.: but tea is said to be produced in several places to the north of 31°; even in 36°, and also in the Japanese Islands, which extend from 30° to 41° N. lat. It is generally said to be cultivated in hilly situations. Grozier states that the songlo-tcha (our green tea) takes its name from the mountain Song-lo, situated in the province of Kiangnan, in 30° N. lat.; while the bou-y tcha (bohea) takes its name from a mountain called Bou-y, situated in the province of Fo-kien. Mr. Cunningham (at the time when Chusan had a British factory) collected specimens on the tops of mountains, where the tea-plant flourished along with pines. The deputation sent into Asam to examine the sites of the tea, saw it growing in the valley of Asam, and were thus led to think that it must grow in similar situations in China; but even in Asam it is also found on hills; and there is no doubt that it is found in both situations in China, and in many which must be moist, though it is probable that the finest varieties of tea are cultivated in the drier soils, and in situations exposed to light and air. Some soils in which the tea-plant is cultivated in China yielded, on analysis, in 200 parts—of silex, 135; alumina, 36; carbonate of magnesia, 6; carbonate of lime, 4; oxide of iron, 13; roots and fibres of plants, 2; water of absorption, 4. Dr. Abel thought that the débris of granitic rocks would yield a fitting soil, and that the Cape of Good Hope would afford a suitable climate.

The culture of the tea-plant in China seems simple enough. The plants are raised from seeds, sown in the places where they are to remain. Several are dropped into holes 4 or 5 inches deep and 3 or 4 feet apart, shortly after they ripen; or in November and December, as they do not preserve well, from their oiliness. The plants rise up in a cluster when the rain comes on, and require little further care, except that of removing weeds, till they are three years old, when they yield their first crop of leaves. They are seldom transplanted; but sometimes four to six plants are put close together, so as to form a fine bush. After growing seven or ten years they are cut down, in order that the numerous young shoots which then spring out may afford a more abundant supply of leaves. In some districts the bushes grow unrestrained, in others they are regularly pruned, to keep them low. The gathering of the leaves is performed with great care: they are usually gathered singly, first in March or April (according to the district), when the young leaves are scarcely expanded; the second about two months later, or May and June; and the third in August, or about six weeks after the second; but the times necessarily differ in different districts, as well as the number of crops which are obtained, some growers avoiding the third, for fear of injuring the bushes. When the leaves are gathered they are dried in houses that contain small furnaces, on each of which there is a flat iron pan; upon this, when heated, the leaves, partially dried by exposure to the sun, are thrown; the leaves require frequent shifting and turning. When all are properly dried, they are quickly removed either by the hand or with a shovel, and either thrown upon a mat or into baskets kept ready to receive them. They are then removed to a table where they are rolled and cooled, and the process is repeated; after which they are sifted and sorted into several varieties.

It is difficult to determine whether the green and black teas are produced by one or two distinct species of plants; as the statements of apparently equally well qualified judges are not only contradictory, but directly the reverse of each other. The difficulty is owing partly to the Chinese in the neighbourhood of Canton being able to prepare a tea which can be coloured and made up to imitate various qualities of green tea; and large quantities are thus yearly made up. The Chinese tea-makers in Asam and those in Java alike state that the black and green teas may be prepared from the same plant. But as there are plants of the genus *Thea*, of which the leaves resemble some the black and some the green teas of commerce, and as these differ very considerably from each other in their powers of resisting cold, and as there are green tea and black tea districts (the former to the north of the latter), it seems probable that different plants are preferred for preparing the finer qualities of these different teas.

Tea having become so extensive an article of commerce, and a source of considerable revenue, various attempts have been made to introduce it into other countries. The climates are very different in which the several experiments have been made; such as in Rio Janeiro and the warm part of Brazil, and latterly in the hilly parts of Java and Brazil, in Penang, Asam, and the Himalayas. Dr. Abel recommended the Cape of Good Hope. It is requisite to have not only a suitable soil and climate, but also cheap and abundant labour. Many have been of opinion that tea could be cultivated in the Himalayas, but the first published opinions seem to be those of Dr. Royle ('Illustr. Himalayan Botany,' p. 5 and 107, and 'Productive Resources of India,' p. 259), where, from a consideration of a similarity in latitude, climate, and vegetation, as far as any information could be procured on those subjects, he was of opinion that tea could be successfully cultivated in the Himalayan mountains; "for the different elevations allow of every variety of climate being selected, and the geographical distribution of this plant is sufficiently extended, and the natural sites sufficiently varied, to warrant its being beneficially cultivated." He recommended experiments being made in that tract of the Himalayas which extends from Almorah nearly to the Sutlej, at various elevations from the valleys up to 7000 feet, and thought that about 5000 feet of elevation would afford a suitable climate. Dr. Falconer formed similar opinions at the same time in a report to government. The correctness of these opinions has been clearly proved by the success of the tea plantations established in the Kumaon and Gurhwal districts of these mountains, which were formed when the tea nurseries were established in Asam, and the seeds and plants sent up which had been obtained from China.

The Asam tea-plant first attracted public attention in 1834, in consequence of replies to the circulars which had been addressed to several gentlemen. Captains Jenkins and Charlton, in May of that year, wrote that a kind of tea-plant was undoubtedly indigenous in Asam. Since then it has appeared that several gentlemen were well aware of the fact, and also that Mr. David Scott had, in June, 1825, sent leaves and seeds of a plant discovered originally by Major Bruce, which he said the Burmese and Chinese concurred in stating to be wild tea. A scientific deputation, composed of Dr. Wallich and Messrs. Griffith and MacCleland, was sent for the proper investigation of Upper Asam. Tea plantations were subsequently established, and Mr. Bruce was appointed their superintendent. Mr. MacCleland states that the tea tracts are found in Asam, first on the level plain and secondly on mounds or hillocks, and that the former situations have a porous structure which enables them to maintain a dry surface under exposure to excessive moisture. Asam teas were first sold in 1839; and from the excitement and competition created by the novelty of the sale, such extravagant prices were paid as from 16*s.* to 34*s.* a pound; but they in due time found their true level.

Recent explorations have rendered it probable that the tea-plant is growing wild in the forests and jungles of Upper Asam, the Sylhet Hills, the Himalaya, and the great range of mountains extending thence through China to the Yang-tse-Kiang. If so, its extended artificial culture may reasonably be expected. Mr. Leonard Wray, in an elaborate paper on the Cultivation of Tea, read before the Society of Arts in January, 1861, gives an account of the recent proceedings on that subject in India. The Asam Tea Company, after many commercial discouragements, have brought their affairs into a healthy condition. They now own 4000 acres of land, which yielded 1,000,000 lbs. of tea in the year 1860. This tea, selling in England (wholesale, and minus the duty) at an average of about 2*s.* per lb., is strong, coarse, harsh, and astringent, and is considered to be well fitted for mixing with China tea, which is mostly of weaker quality. There is another company, and there are many private individuals, also cultivating tea in Asam. Still more important are the operations which the India government has for several years been conducting in the North-West provinces, under the able management of Dr. W. Jameson. Begun on a small scale in 1835, they have now become very extensive. In 1859 the government tea plantations in Kumaon, Gurhwal, Deyra Dhoon, and the Kangra Valley comprised 2250 acres and seven factories. The Bohea variety is that chiefly cultivated. The government established these tea plantations with a view to the making of experiments, and the encouragement of companies and private speculators; and a liberal transmission of seeds and young plants is granted to beginners. Land fit for the tea-culture is also granted by the government on very liberal terms; and of such land there is believed to be not less than a million acres in the North-West provinces alone. The experience of 1859 showed that a handsome profit is derivable from the culture; and numerous persons are embarking in the enterprise. Many of these persons are military officers lately in the East India Company's service, who find the healthy climate of the hill districts suitable at once to themselves and their families, and to the tea-culture.

Tea-curing and Use.—Whether obtained from one species only of the genus *Thea*, or from several, all the tea of China is in commerce brought under two distinct terms, *green* tea and *black* tea. These are also distinguished as *hyson* and *bohea*. The European name *tea* is borrowed from the common language of the province Fu-kian (Fokien of D'Anville), where this article is called Tiä in their patois: at Canton it is called Tscha or Tschai. Black tea is called He-tscha, green tea Lo-tscha. The sub-varieties owe their names to other circumstances, the number of which is endless. Thus there occur in the catalogues of the Chinese merchants at least one hundred and fifty names, many of which are synonymes of other sorts, or names invented to impose on foreigners and obtain a high price. The distinguished Oriental scholar, Klaproth, gives a list of about forty genuine varieties, with an explanation of the terms applied to them. Thus Pak-ho, corrupted into Pekoe, merely means "white down," being the first sprouts, or yet hairy leaf-buds of young plants, three years old, after their first flowering. With us it is applied only to a black tea; but it is equally applicable to a green tea, which is never brought to Europe, as it is so delicate and slightly fired as to spoil by the least damp.

Though it is stated that black tea may be cured as green tea, and green tea as black, the green being cured without fermentation to which black tea is always subjected, certain it is that the preparation of the respective kinds is carried on in different parts of the empire, and a different practice pursued with the leaves from the first stage. In the green teas the leaves only are taken, being nipped off above the foot-stalk or petiole, while of the black teas the foot-stalk is always collected. "Thus black tea contains much of the woody fibre, while the green is exclusively the fleshy part of the leaf itself; which is one good reason why it should be dearer." (Davis's 'China,' ii., p. 351.) Besides this, the constant removal of the young leaf-buds, by which the plant is prevented from being-clothed with full grown leaves, which alone can elaborate the sap and contribute to the further growth of the shrub, causes it to perish earlier, and compels a more frequent renewal of the plantations. Indeed some cultivators restrict the gathering of the leaves to two harvests, instead of three, to save their plants. Those of the third gathering are large and coarse, and often so rigid that they cannot be rolled. This yields a tea so inferior in quality that it is consumed only by the poorest of the natives, or, when very bad, is, as are some of the finer kinds when spoiled, used for dyeing.

Such are the pains taken to ensure the excellence of the finest sorts of green tea, that for two or three weeks before the harvest commences the collectors, who are trained to this business from a very early age, are prohibited from eating fish or other kinds of food reckoned unclean, lest by their breath they should contaminate the leaves. They are also made to take a bath two or three times a day, and not allowed to gather the leaves with the naked fingers, but always with gloves. The finest tea may, if the proper time for gathering it be neglected, be changed into an inferior tea in one night. It is necessary to roast the leaves the same evening that they are collected, for if kept till the following day they ferment, become black, and lose much of their virtue. Previous to putting them into the iron pans or furnaces, which are heated by charcoal, they are dipped for about half a minute into boiling water. About half or three-quarters of a pound of leaves are put into the pan at once, and diligently stirred, to prevent them from being burnt. They are then removed with a shovel and thrown on mats or into baskets; and while yet hot the soft leaves are rolled between the palms of the hands, during which operation a quantity of yellowish green juice exudes from them. This process of roasting and rolling is often repeated even to the sixth or seventh time. This method is called the *dry way*: but by the *wet way* the leaves are first exposed to the vapour of boiling water, after which they are rolled and dried on the iron pans like the others. Leaves prepared in the wet way have a bright green colour; those by the dry, a dark green verging to brown. From the green tea, when prepared in the dry way, less of the above-mentioned juice exudes, a circumstance to which the greater strength of green tea is in some degree owing. The larger leaves are generally selected to be prepared in the wet way. By the process of roasting the leaves lose two-thirds of their weight; so that three pounds of fresh leaves dry into one pound of tea fit for preservation. It is by the process of roasting that the flavour is first developed, the leaves when fresh being as insipid as the bean of coffee before heat is applied. Siebold is of opinion that the agreeable violet-like flavour of tea is inherent in the leaves themselves; but most writers ascribe the different flavours of the choicer kinds of tea to the admixture of the flowers, leaves, or oils of a variety of different plants. The chief of these are the *Olea fragrans, Chloranthus inconspicuus, Gardenia florida, Aglaia odorata, Mogorium (Jasminum) Sambac, Vitex spicata, Camellia Sasanqua*, and *C. oleifera, Illicium anisatum, Magnolia Yulan*, and the *Rosa Indica odoratissima*, as well as the root of the *Iris florentina*, and *Curcuma longa* or turmeric, and the oil of *Bixa Orellana*. The Chinese annually dry many millions of pounds of the leaves of different plants, to mingle with the genuine, such as those of ash, plum, &c.; so that all the spurious leaves found in parcels of bad tea must not be supposed to be introduced into them by the dealers in this country. While the tea trade was entirely in the hands of the East India Company, few of these adulterated teas were shipped for this country, as experienced and competent inspectors with large salaries were kept at Canton, to prevent the exportation of such in the Company's ships; but since the trade has been opened, all kinds find a ready outlet; and, as the demand often exceeds the supply, a manufactured article is furnished to the rival crews.

The object of the drying and rolling is both to diminish the bulk and to enable the leaves to preserve their flavour. No tea is thought fit for use till it is a twelvemonth old; and the rich and luxurious Chinese keep the fine tea in jars, made of the finest porcelain, some of which are thought to communicate an additional aroma to the tea, and all of which have very narrow mouths (as may be observed in those brought to Europe, and sold at a high price), to retain the peculiar odour. If the tea contracts damp, it is taken out and roasted again.

To make the infusion, the Chinese pour boiling water on a small portion of the leaves; they do not allow it to stand or macerate, as is done in England, but instantly pour it off again, by which they obtain only the more volatile and stimulating portion of its principles. The poorer Chinese indeed boil the very inferior and coarse leaves, which alone are within their reach, and drink the decoction repeatedly during the day. This is done not only to extract such virtues as the tea possesses, but to qualify the water, seeing that little good drinking water is met with in China. Travellers find a supply of tea a very valuable accompaniment on long journeys, as it improves the most brackish waters. The exciting effects of fresh tea are such that it is rarely used till it has been kept twelve months, as already stated; and where indulged in, it produces great mental excitement. This property is diminished by repeated roastings, but as green tea is less exposed to heat than black, it retains more of this power. Besides, the green tea for exportation undergoes some process, which changes its colour, giving it a bluish-green hue. The Chinese themselves do not consume those kinds of green tea which are prepared for exportation. It is altogether a mistake to suppose that the colour of green tea is owing to its being dried on copper pans, as none such are used, and the most searching chemical analysis is unable to detect a trace of copper unless as a constituent of the vegetable.

The subject of the adulteration of tea has occupied a large amount of attention within the last few years. Irrespective of any adulteration, however, the value of tea varies enormously, according to its delicacy and aroma. Mr. Wray, when at Malacca, had a small quantity of "Mandarin tea" given to him by some Chinese merchants; it is a kind never sold to foreigners, but commands 50*s.* per lb. in China itself. The vast bulk of tea used by the Chinese is of poor quality; and much of the poorest is mixed to adulterate the better kinds for the English market. Mr. Wray estimates that the Chinese consume 2,000,000,000 lbs. of tea annually, more than ten times as much as they sell to all other countries. When the English tea trade with China was wholly conducted by the East India Company, it is believed that the sophistication mostly took place after the tea reached the hands of other dealers; but now the Chinese adulterate it themselves. Mr. Wray states that seven-eighths of all the tea shipped from China in 1859 was adulterated; this was publicly announced at a meeting of merchants, held in Canton in April, 1859, to consider the subject. The adulterants were found to be: spent tea-leaves from some of the provinces, unsound leaf from others, and three or four sorts of plants. When brought to this country, the tea sold at a (nominally) low price in the poorer neighbourhoods, undergoes a still further process of adulteration. This is proved, not only by the analyses of Drs. Hassell and Letheby, and others, but also by the Excise seizures which so frequently occur. All admit that imitations of good tea can be produced by very easy means; and this facility offers a perilous temptation to dishonest persons.

Tea Trade.—The period when tea was first introduced into this country has already been noticed. The first importation by the English East India Company took place in 1669, from the Company's factory at Bantam. The directors ordered their servants to "send home by their ships one hundred pounds weight of the best *tey* they could get." In 1678, 4713 lbs. were imported; but in the six following years the entire imports amounted to no more than 410 lbs. The continuous official accounts of the trade do not commence before 1725; but, according to Milburn ('Oriental Commerce'), the consumption in 1711 was 141,995 lbs.; 120,695 lbs. in 1715; and 237,904 lbs. in 1720. Then, taking periods twenty years apart, we find that the quantities entered for home consumption were, in round numbers, 1,000,000 lbs. in 1740; 4,000,000 lbs. in 1760; 5,000,000 lbs. in 1780; 20,000,000 lbs. in 1800; 22,000,000 lbs. in 1820; 32,000,000 lbs. in 1840; and 77,000,000 lbs. in 1860.

For above a century and a half the sole object of the East India Company's trade with China was to provide tea for the consumption of the United Kingdom. The Company enjoyed this trade to the exclusion of all other parties, and were bound from time to time to send orders for tea, and to provide ships to import the same, and always to have a year's consumption in their warehouses. The teas were disposed of in London, where only they could be imported, at quarterly sales; and the Company was bound to sell them to the highest bidder, provided an advance of one penny per lb. was made on the price at which each lot was put up. This price was determined by adding together the prime cost at Canton and the bare charges of freight, insurance, interest on capital, and certain charges on importation; but by the mode of calculating these items, and the heavier expenses which always attend every department of a trade monopoly, the upset prices were greatly enhanced. The prices realised at the Company's sales were however in still greater proportion beyond the upset prices; a result easily produced by a body who monopolised the sole supply; as it was only necessary that the quantity offered for sale should not be augmented in proportion to the growing demand of a rapidly increasing population. The 18 Geo. II., c. 26, passed immediately after a large reduction of the duty had taken place, provided for such a contingency as this, by enacting that if the East India Company failed to import a quantity sufficient to render the prices as low as in other parts of Europe, it should be lawful to grant licences to other persons to import tea. This would have constituted a very efficient check if it had been acted upon; but eventually the mode of levying the duty gave the government almost the same interest in a restricted supply as the East India Company. The duties were collected *ad valorem* on the amount realised at the Company's sales; and thus the very circumstance which enhanced the price raised the total amount of duty. The duty, at that time, was nominally 90 and 100 per cent. *ad valorem*, but being charged on a monopoly price, the difference on the cheaper teas consumed by the working and middle classes amounted to above 300 per cent. on the cost price of the same teas at Hamburg; and in 1830 the difference between the prices realised at the Company's sales and the Hamburg prices amounted to a sum of 1,889,975*l.* The sales in the last year of the East India Company's monopoly are shown in the following table:—

An Account of the Quantity and Prices of several sorts of tea sold in England from May 1st, 1833, to May 1st, 1834:—

	lbs.	*s.*	*d.*
Bohea	6,170,963	1	10
Congou	18,653,835	2	1
Campoi	1,603	2	4
Souchong	354,515	2	9
Pekoe	514,811	2	10
Twankay	4,339,672	2	1
Hyson Skin	141,610	2	2
Hyson	987,052	3	6
Total	31,164,061		

The Company's sales were in March, June, September, and December, the latter being the largest. About 2,000,000 lbs. were offered belonging to the officers of the Company, who were allowed to import a certain quantity of tea on their own account. In 1839 there were only 122,312 lbs. offered for sale by the East India Company; and the change effected by the 3 & 4 Wm. IV., c. 93, which, on the 22nd of April, 1834, opened the trade to China, is now complete. The importation of tea is no longer confined to the port of London. In the four years ending 1834, the average annual number of ships entered inwards from China at the ports of the United Kingdom was 23; in the four following years the average was 66; other commodities besides tea have since been extensively imported, and a corresponding increase in the quantity and variety of the exports to China has taken place. The exports of tea from the United Kingdom, which formerly did not exceed 250,000 lbs. annually, amounted to 4,347,432 lbs. in 1841, and have gradually much increased. The quantity retained for home consumption has also considerably increased, although accompanied by an extraordinary increase in the use of coffee.

The tea duty has long constituted an important item in the English revenue. It has varied greatly in amount at different times. In 1725 there was a Customs' duty of 13*l.* 18*s.* 7½*d.* per 100*l.* of value, and an Excise duty of 4*s.* per lb. Sometimes, during the next period of a hundred years, the Customs' duty was raised, sometimes lowered, and on a few occasions repealed altogether; and precisely the same may be said of the Excise duty. In 1834 the Excise duty was finally repealed, and at the same time the Customs' duty was rated at 1*s.* 6*d.* to 3*s.* per lb., according to price and quality. In 1836 it was reduced to 2*s.* 1*d.* per lb. for all qualities: and in 1840 an additional 5 per cent. was imposed. During the existence of the Excise duty, it was very vexatious to the retailers. Each of the hundred thousand tea-dealers in the United Kingdom were visited once a month by the officers of excise, who took an account of their stock; and no quantity exceeding six pounds could be sent from their premises without a permit, of which above 800,000 were required in a year. In short, this system of supervision was very troublesome, costly, and answered no useful purpose. The number of tea-dealers in 1839 was 82,794 in England; 13,611 in Scotland; 12,774 in Ireland: total, 109,179. Tea is now sold by the importing merchants by public auction and private sales.

The revenue which the tea duty yielded from 1805 to 1841 was singularly uniform, never rising above 4,700,000*l.* and never falling below 3,100,000*l.* Within the last twenty years, the rate of duty and the amount received have varied much. In 1851 the duty was fixed at 2*s.*, plus 5 per cent. In Mr. Gladstone's tariff of 1853, the duty was intended to undergo successive diminutions, bringing it to 1*s.* 10*d.* in 1854, 1*s.* 3*d.* in 1855, and 1*s.* in 1856 and later years,—plus 5 per cent. A warlike expenditure so far interfered with this plan, as to prevent the lowering going beyond 1*s.* 5*d.* plus 5 per cent. In 1857 the average price of all kinds of tea in bond was exactly equal to the duty, each being about 1*s.* 6*d.* The actual prices in bond ranged from 5*d.* to 4*s.* 6*d.* per lb. Mr. M'Culloch supposes that all the Chinese tea brought to England costs on an average about 1*s.* per lb. when on board ship in Chinese ports, all charges included; and that this is raised to the retail consumer to 3*s.* 4*d.* by the following steps—freight, insurance, and interest 1¾*d.*, duty 1*s.* 6*d.*, wholesale and retail profits 8*d.* The average price in bond, between 1850 and 1860, varied from 1*s.* 2¼*d.* to 1*s.* 6½*d.*; and the duty realised varied from 4,800,000*l.* to upwards of 6,000,000*l.* The actual trade in 1860 is represented in the following figures:—

	lbs.
Imported	88,946,532
Re-exported	12,087,104
Retained for home consumption	76,859,428

This consumption is about 2¼ lb. per annum for each individual of the whole population.

On a recent occasion (May, 1861) the House of Commons consented to a renewal of the present tea duty (1*s.* 5*d.*, plus 5 per cent.) for the financial year 1861-62; supporting Mr. Gladstone in an abolition of the paper duty instead of a reduction in that on tea.

The usual net weight of a chest of tea is 138 lbs. for Bohea, 49 lbs. for Pekoe and Hyson, and 64 lbs. for Congou. So greatly does the proportion of Congou excel that of the other kinds, that 64 lbs. is considered a fair average of all the chests; this will afford an approximate rule for converting chests into lbs., in the commercial lists of imports and deliveries. The Chinese weights and moneys are of course very different from the English; but it may be convenient to know that 30 *taels* per *picul* of tea is about equal to 1*s.* 3*d.* per lb. More than nine-tenths of all the tea brought to the United Kingdom in 1859 entered the port of London; and the preponderance is still increasing. The great increase in the use of tea has not checked that of coffee. The following table shows the average annual consumption of tea, coffee, and cocoa, in the last four decennial periods:

		Tea.	Coffee.	Cocoa.
		lbs.	lbs.	lbs.
Average	1820–29	25,000,000	12,000,000	500,000
	1830–39	34,000,000	24,000,000	1,000,000
	1840–49	41,000,000	33,000,000	2,500,000
	1850–59	63,000,000	35,000,000	3,500,000

Bringing in a more modern article of consumption, chicory, the figures for 1859 were—tea 76 million lbs., coffee, 34 million lbs., chicory, 30 million lbs., and cocoa 3 million lbs. The proportion of black to green tea consumed in the United Kingdom is about 6 or 7 to 1; in the United States the use of green tea is greater than that of black.

TEA, *Medical Properties of.* The botany of tea is given under THEA, in the NATURAL HISTORY DIVISION of this work; its chemical properties are noticed under CAFFEINE; for an account of its culture see TEA AND THE TEA TRADE.

Before attempting to estimate the action of tea on the human system, it is necessary to call to mind that some of the effects are due to the plants mixed with the real tea, several of which, such as the *Chloranthus inconspicuus*, are stimulants of the highest order; and in other instances deleterious chemical compounds are used by the Chinese to convert damaged black teas into saleable green teas. (Davis, 'Chinese,' ii. 466.) For the effects of these, tea is not justly chargeable. A correct estimate of the action of tea is not easily formed; yet the most dispassionate inquirers regard it as a narcotic, the stimulating period of which is the most conspicuous and of longest duration. Tea has been preposterously praised by some writers, and unjustly accused by others as being productive of numerous diseases: above all it has been charged with causing an increase of nervous diseases. It would perhaps be more just to attribute the increase of such complaints to the more complicated state of our social relations, arising from an augmented population, and an advance in luxury, with the more frequent infringement of the natural laws, particularly turning night into day, and not seldom day into night, as is the practice of the votaries of fashion. That tea should not suit all constitutions or all ages is not remarkable. It is less suited for young children than for adults; indeed for very young children it is extremely improper, producing, like all narcotics, a morbid state of the brain and nervous system. It is also unsuited for those of an irritable nature, and likewise for those of a leucophlegmatic constitution. Such persons can ill bear much liquid of any kind, particularly in the evening, and prosper best on a very dry diet, to which growing children of this constitution should be strictly confined. [DILUENTS.] It may not be true that the use of tea, as alleged by Dr. Lettsom, has been the main cause of the increase of scrofulous diseases, still as diseases of this class are the only diseases which are proved by the reports of the registrar-general to be stationary, or perhaps more frequent than others, whatever impairs the nervous power and ultimately the digestive function in strumous children should be avoided. His advice is sound where he says, "It ought by no means to be the common diet of boarding-schools; if it be allowed sometimes as a treat, they should be at the same time informed that the constant use of it would be injurious to their health, strength, and constitution." Those to whom it is most suited are the plethoric and sanguine. Upon the same principle it is a proper article of diet and perhaps the best common drink at the beginning of fevers and inflammatory complaints. In a peculiar state of brain, termed by Mr. Newnham ('Observations on Medical and Dietetical Properties of Green Tea') *sthenic excitement*, a state clearly bordering on inflammation, especially if produced by alcoholic stimulants, or by intense and long-continued application of mind to any particular object of literary research, green tea acts as a salutary remedy. On the contrary, in states of diminished excitement, morbid vigilance and nervous disturbance follow its use. It is not an uncommon practice with ardent students, when pushing their studies far into the night, to resist the claims of nature for repose, and keep themselves awake by the frequent use of tea. That it answers the purpose at the time cannot be denied, but the object is often attained at a fearful price, the destruction of health and vigour both of mind and body being the penalty. But more effect is produced by small doses, frequently repeated, than by large ones. See the paper on the 'Uses of Tea in the healthy System,' read before the Society of Arts, 15th February, 1861, p. 188. Dr. Smith's remarks are based upon a most extensive series of experiments—the results of which are most important. Less injury results in these cases from the use of coffee. There is this difference between the morbid states of the nervous system produced by coffee and those resulting from tea: that the former generally subside or disappear entirely on relinquishing its use; those from the latter are more permanent, and often incapable of being eradicated. Nevertheless many persons have immediately found their health improved by entirely relinquishing the use of tea, or even omitting it only at breakfast, for which meal it is certainly less proper than for the evening beverage. Those for whom tea is unsuited will generally find weak cocoa the most proper substitute.

Persons of a gouty and rheumatic nature, above all, those prone to calculous diseases of the lithic acid diathesis, find weak tea the least objectionable article of common drink. They should take it without sugar, and with very little milk. (Prout, 'On the Stomach,' p. 217.) Where the water is hard, the addition of a little carbonate of soda not only improves the tea, but renders it a more proper beverage for such persons. This addition of an alkali seems to increase the action of tea upon the skin, and to augment its cooling properties. Cream appears to lessen the action on the skin, as does also lemon-juice. (Smith, *ut supra*, p. 189.) Tea should not be used till about four hours after any solid meal.

The medical uses of tea are not many. In fevers it is not only an excellent diluent at the commencement, but a tincture of tea made by macerating tea in proof-spirit, and adding a teaspoonful of this to a small cup of water, and given at short intervals during the night, after the acute symptoms have subsided, is often of great service. For this purpose, in hospitals and workhouses, the leaves which have been used for the ordinary infusion may be macerated in alcohol, and a spirit of sufficient strength for this purpose obtained at a cheap rate.

In some forms of diseased heart tea proves a useful sedative. It is nearly as valuable an antidote to poisoning by opium as coffee is. Some cases of poisoning by arsenic and tartarised antimony have been prevented proving fatal by the immediate administration of tea in the form of a very strong infusion. Here its power as an antidote depends upon its tannin decomposing the poisonous substances. [ASTRINGENTS.] But in poisoning by opium it is useful only in combating the secondary symptoms, and should not be administered till the stomach-pump or other means have removed the opium from the stomach. Some cases of severe nervous headache are relieved by a cup of strong green tea, taken without milk or sugar. But this should be sparingly resorted to; it is a wiser plan to avoid the causes of such headaches. Tea has been looked upon as the great means by which intoxication was to be banished, but it is certain that to relieve the tremblings and other unpleasant effects of the abuse of tea, a little brandy or other alcoholic stimulant is occasionally added to the cup of tea, and so a habit is acquired which can never afterwards be relinquished.

Tea has frequently been denounced as a useless article of diet to the poor, as it is assumed to be devoid of nutriment, and the milk and sugar which are added are supposed to be the only beneficial ingredients. Dr. Lettsom has given a calculation, partly his own, and partly taken from 'Essays on Husbandry,' to show how much is, in his view, unnecessarily expended by them in this way. But the observations of Liebig are thought to offer a satisfactory explanation of the cause of the great partiality of the poor not only for tea, but for tea of an expensive and therefore superior kind:—

"To see how the action of caffeine, asparagine, theobromine, &c., may be explained, we must call to mind that the chief constituent of the bile contains only 3·8 per cent. of nitrogen, of which only the half, or 1·9 per cent., belongs to the taurine. Bile contains in its natural state water and solid matter, in the proportion of 90 parts by weight of the former to 10 of the latter. If we suppose these 10 parts by weight of solid matter to be choleic acid, with 3·87 per cent. of nitrogen, then 100 parts of fresh bile will contain 0·171 parts of nitrogen in the shape of taurine. Now this quantity is contained in 0·6 parts of caffeine; or $2\frac{4}{10}$ths grains of caffeine can give to an ounce of bile the nitrogen it contains in the form of taurine. If an infusion of tea contain no more than the $\frac{1}{10}$th of a grain of caffeine, still, if it contribute in point of fact to the formation of bile, the action, even of such a quantity, cannot be looked upon as a nullity. Neither can it be denied, that in the case of an excess of non-azotised food and a deficiency of motion, which is required to cause the change of matter of the tissues, and thus to yield the nitrogenised product which enters into the composition of the bile; that in such a condition the health may be benefited by the use of compounds which are capable of supplying the place of the nitrogenised substance produced in the healthy state of the body, and essential to the production of an important element of respiration. In a chemical sense—and it is this alone which the preceding remarks are intended to show—caffeine, or theine, asparagine, and theobromine, are, in virtue of their composition, better adapted to this purpose than all other nitrogenised vegetable principles. The action of these substances, in ordinary circumstances, is not obvious, but it unquestionably exists. Tea and coffee were originally met with among nations whose diet is chiefly vegetable." (Liebig's 'Animal Chemistry,' p. 178.) These facts show in what way tea proves to the poor a substitute for animal food, and why females and literary persons who take little exercise manifest such partiality for it. They also explain why the attempts, and they have been numerous, to find among other plants a substitute for tea have invariably failed of success.

TEA, PARAGUAY, or MATÉ. [TEA, PARAGUAY, in NAT. HIST. DIV.]

TEAK, ECONOMICAL USES OF. The teak tree is found in Burmah, in India, and in various islands in the Indian seas. It grows to an immense size, and is remarkable for its very large leaves, which are from 12 to 24 inches long, and from 8 to 16 inches broad. The wood is light, brownish coloured, and easily worked, as well as very strong and durable. It is soon seasoned, and from containing a resinous oil, resists the action of water, as well as that of insects. The density of the wood varies from 0·594 to 0·876, according to its quality and the mode in which it is seasoned; the average is about 0·711. One specimen has been described having a specific gravity of 1·056; but the accuracy of this statement is doubtful. From extensive experience, teak has been found to be the most valuable timber for ship-building. Teak is the principal article of export, both in quantity and value, from Moulmein; near which port are vast forests of the best teak in the world. Splendid baulks of timber are shipped there, 50 feet in length, and as much as 24 inches square. The price of first class teak at that port, squared into baulks, is usually about 60*s.* per ton of 50 cubic feet. At the Great Exhibition of 1851, a very interesting collection was displayed, consisting of more than seventy species of teak, obtained from various localities and arranged according to their density. They were collected by Mr. Seppings of Calcutta, and were contributed by the Naval Department of the East India Company.

TEAM. Nothing is of greater importance in the management of a farm than the cattle which perform the necessary work in ploughing and other operations on the soil, in drawing manure to the land and carrying the produce to market. It is evident that the smaller the expense of the team which does the requisite work in proper time, the greater the profit of the farmer, and every saving in this part of the expense of cultivation is so much added to the clear gain. Wherever the land is only partially cultivated, and a portion of it remains in coarse pasture, which costs little or nothing to the occupier, or where extensive open commons afford cheap food for oxen, these last are naturally employed in farm labour. If four oxen do only the work of two horses, they are maintained at a much smaller expense, and, after working for two or three years, their value is improved for the purpose of fatting for the butcher. The necessary gear is much less expensive, especially where the old yoke is still in use, whether across the neck or the horns. In fact, for a poor man who has only a few acres of land, and who is situated near a waste or common, oxen are the most economical team. Many, who in general have more theoretical than practical knowledge of husbandry, have maintained the general superiority of an ox team over that composed of horses, and have given calculations which appear clearly to establish their point. But on the other side, it may be observed, that wherever arable land is the chief object of the farmer's attention, and the tillage of the soil is brought to any degree of perfection, there oxen are never seen at work, but have been invariably superseded by active horses. Oxen as draught animals are almost invariably part of a sluggish agriculture; and though less costly themselves, yet teaching slow and dilatory movement to everything about them, their use for tillage operations is everywhere diminishing.

As to the cost of horses per annum, the following may suffice. In the old mode of feeding, with as much hay as they would eat, and two bushels of oats for each horse per week, during at least nine months in the year, and giving them tares or artificial grasses between spring sowing and harvest, when there was less to be done, the expense of a horse was much greater than most farmers could now afford; and more land was devoted to the keep of the team than was necessary. The following is the calculation of the cost of the keep of a horse in this way:—

	£	s.
32 weeks, at 2 bushels of oats per week, at 3s. 6d. per bushel	11	4
20 weeks, at 1 bushel of oats per week, at 3s. 6d. per bushel .	3	10
Tares, &c., 20 weeks, at 6s. (1 cwt. daily, at 6d.) . . .	3	10
Hay, 32 weeks, about 1½ cwt. weekly, at 4s. per cwt. . .	9	2
Shoeing	0	15
Farrier	0	5
Total	£28	6

The hay and oats are at high prices, but at all events a horse cannot be kept in this way under 10s. per week. They are then, however, in excellent condition, and able to work ten hours per day in summer and eight in winter.

The use of bruised corn and carrots, and mangold-wurzel and chaff of hay and straw, secures a considerable economy; and taking smith, farrier, harness, and depreciation of value (3l. per annum) into account, the cost per horse should not be more than 30l. a year. In fact, on 21 farms, the details of which have been given by Mr. Morton in the Agricultural Society's 'Journal,' 282 horses working 8851 arable and 2549 pasture acres, cost 7513l. 8s. per annum, or about 26l. 12s. apiece. In this, the wages of team-men had to be added, nearly 13,000l., in order to find the cost of horse-labour per annum.

It is of great importance to a person about to hire a farm to know exactly what number of horses will be required for its proper cultivation, and this depends upon many circumstances, which must all be taken into consideration, and which will make a very material difference, often as much as half the rent of the land. He is to consider the situation of the farm-buildings, especially the stalls and cattle-yards, where the manure is to be made, with respect to their distance from the fields; the state of the roads and the access to the fields; the distance of a good market-town, and whether the fields lie in a ring-fence or are scattered. A farm of good light loam will require one horse for every thirty-five acres for its cultivation. The larger the farm, or rather the fields, the fewer horses are required in proportion to its size, because much time is lost in turning the plough where the furrow is short; and ploughing is always the principal work of the team. If more than two horses are required to plough the ground, the soil must be very compact and heavy, and if this is not compensated by greater fertility, the expense of the horses will much reduce the profit of the farmer. The work in the field when the days are long should be divided so as to give the horses at least two hours' rest, during which they should be fed with corn. When the fields are near the stables the horses may be brought home, but a portable manger is easily carried into the field, such as is used at the inns on the roads where carriers stop to bait. In winter it may be as well to finish the day's work with only an interval of half an hour. The time in summer should be from 5 in the morning till 10, and from 2 till 7 if the weather is very warm, resting four hours; or from 6 till 11 and from 1 till 6, resting two hours. In winter the time is from 7 till 3, resting half an hour or an hour between 11 and 12. With good feeding and grooming this is by no means too hard work when the work requires to be carried on briskly. The heavier and lighter kind of work should be so arranged that when horses have worked hard for a day or two, they may have one or two days of lighter work. In most parts of England the pace of the horses and their daily work are much less than in Scotland; two horses should plough an acre a day or more, on an average, but few farmers can get much more accomplished than three-quarters of an acre, if they plough a good depth or break up clover or grass lays. In the light sands of Norfolk and Lincolnshire they go over much ground; but there the furrows are wide and shallow, and the horses might easily trot with the plough if the ploughman could keep up with them.

TEAZLE (*Dipsacus Fullonum*) is a plant which grows wild in the hedges, but an improved variety is carefully cultivated in those districts of England where cloth is manufactured. It is used for the purpose of forming a species of brush with which the finer hairs of the woollen fabric are drawn to the surface, where they produce what is usually called the *nap* of the cloth. Several attempts have been made to substitute artificial teazles, formed of hooks of very fine and elastic steel wire; and at one time there was so much appearance of success, as to cause the cultivation of teazles to be neglected: but it was soon found that the wires tore the fine fibres of the wool, especially where there were knots in the thread, whereas the hooks of the teazles gave way, and either bent or broke off before the fibre of the wool was injured.

Teazles grow strongest and best in a stiff loam. They require the soil to be in good heart, and are supposed to exhaust it much; but no great portion of manure is required to obtain a good crop. The growing of teazles is a peculiar trade. The teazle-grower hires a piece of ground suited to his purpose from the farmer for two years, and pays a considerable rent. If the ground is broken up from grass, it is ploughed as deep as the staple of the soil permits, and as early as possible, if before winter so much the better: the ground is laid in narrow stitches, on which the seed is sown in April, in rows from 12 to 18 inches apart: moisture is necessary to make the seed germinate. As soon as the plants appear, they are thinned out, and the intervals carefully hoed and weeded. During the summer, the ground is several times dug, or *spaded*, as it is called, to a considerable depth, with very narrow and long spades; this greatly invigorates the plants. In November, plants may be transplanted from where they stand too thick to the places where they have failed, and also to other land cultivated for the crop. They should stand about a foot apart in the rows. During the ensuing spring, the cultivation is repeated. They soon begin to push up their stems, and are fit to be cut in July, just when the blossom has fallen. As they do not come to proper maturity at the same time, several successive gatherings are made. They are cut with a sharp knife about nine inches below the head, and tied in small bundles or handfuls: thick gloves are very necessary in this operation. They must be carried under cover before night, as the rains or heavy dews would injure them. When the sun shines, they are exposed to dry in the same manner as is done with onion seed, and they are never packed close until they are perfectly dry. When drying they are usually hung on poles; so that the air may circulate between the bundles. The bundles are afterwards opened, and the teazles sorted into kings, middlings and scrubs, according to their size; 9000 kings or 20,000 middlings make a pack.

Teazles are a very precarious crop; sometimes they produce a very great profit, and at other times a serious loss. Care and cultivation lessen the chances of failure greatly: but the price also fluctuates so much that it is an uncertain speculation, resembling in this respect the cultivation of hops. Hence it is undertaken by men who are prepared for the event, and who make the profits of one year repay the loss of another. A good crop of teazles is about 10 or 12 packs on an acre: this is sometimes exceeded, but more often it fails by one-half, and a total failure is not uncommon. The price may average 5l. or 6l. a pack, so that a good crop is worth more than the land it grew on; the expenses, however, are large. Although teazles are said to exhaust the ground much, yet from the continual stirring of the soil they render it very fit to grow other crops, provided a proper quantity of manure is used: thus very good crops of wheat have been obtained after a crop of teazles.

TEETH, DISEASES OF THE. The teeth, like other organs of the body, are subject to a variety of diseased conditions. For practical purposes they may be divided into—1. Disorders attending dentition or the cutting of the teeth; 2. Diseases of the teeth themselves; 3. Diseases of the gums and alveolar processes.

Diseases of Dentition.—The eruption of the temporary or milk-teeth is a natural process after birth [DENTITION, DISEASES OF; and TEETH, NAT. HIST. DIV.]. The order in which the milk-teeth appear after birth is subject to considerable variations. Although dentition is a natural process, it is frequently attended with morbid conditions. Prior to the appearance of a tooth the gum above it increases in breadth, becomes swollen, and is hot to the touch. There is an increased flow of saliva, which comes out of the mouth; the child thrusts whatever may be placed in its hands into its mouth. It is more fretful than usual, has sudden fits of crying, and starts in its sleep. The cheeks are flushed, the bowels are irregular, and its food is often thrown off its stomach. It not unfrequently happens that a dry cough is present, and sometimes even severe derangement of the nervous system.

In the *treatment* of these symptoms little more is needed than to regulate the state of the bowels, and to prevent the child overloading its stomach with milk. It should not be put to the breast after every time it is sick, but cows' milk, with a little water and sugar, may be substituted for its mother's milk. When convulsions occur and evidently arise from the irritation of the gums, a free incision of the gum over the pressing tooth will often give great and immediate relief. Whenever in fact the irritation has proceeded so far as to produce obvious inflammatory symptoms, recourse may be had to lancing the gums. In this operation care should always be taken to divide the gum down to the surface of the pressing tooth.

Sometimes instead of inflammation of the jaws there is an excessive hardness or induration of the gums. In this case there is great irritability and restlessness, with other symptoms of derangement of the system, which can only be removed by dividing the indurated gums freely down to the pressing tooth.

During the presence of the milk-teeth, they and the gums are subject to the same diseases as the permanent teeth in after life. They are however subject to one form of disease which is peculiar to children, and which is called *ancrum oris*. It is in fact an ulceration attended with a death of parts similar to what is called phagædena in other organs of the body. The ulceration commences in this case at the free edge of the gums and extends to the alveoli and other parts of the mouth. The surface of the cheek lying in contact with the ulcerated gums becomes involved in the same disease, so that the surfaces of the two ulcers are in contact. The teeth loosen and in some cases become black from necrosis. The surface of the ulcer is of a pale yellow or straw colour, with here and there a red point raised above the surface, and which bleeds on being touched. This disease spreads in some cases till the cheek is perforated, but it more frequently happens before this takes place that the patient either sinks from exhaustion or hæmorrhage from the ulceration of some large vessel.

The treatment in these cases must be both constitutional and local. The bowels should be kept open, and tonic medicines (iron and quinine), with a liberal diet, must be given. Locally, the nitrate of silver should be applied, and the mouth should be washed out with a lotion containing chlorate of potash. This latter salt has also been strongly recommended as an internal remedy.

The milk-teeth disappear as they came, at various ages. They are succeeded by what are called the permanent teeth. The number of these is thirty-two. Twelve of them, however, belong to the first set, as they are never superseded. So that the true view of the case appears to be, that the first set of teeth consists of thirty-two, of which twenty disappear under the name of milk-teeth, and are followed by twenty others, which are called, with the other twelve, permanent teeth.

Diseases of the Permanent Teeth.—The diseases to which the permanent teeth are subject have been arranged as follows by Mr. Tomes:—

Irregularity in the time of the eruption of the permanent teeth.	
Irregularity in the position of the permanent teeth.	
Mechanical injuries of the teeth	Fracture. Dilaceration. Dislocation.
Mechanical injuries of the alveoli	Fracture.
Diseases of the dental tissues	Caries. Necrosis. Exostosis. Abscess. Loss from the surface. Absorption. Pain.
Diseases of the pulp	Irritation. Inflammation. Ulceration. Granulation.
Diseases of the alveolar periosteum	Inflammation. Hæmorrhage.
Diseases of the alveoli	Inflammation. Necrosis. Exostosis. Absorption.
Diseases of the gums	Inflammation. Ulceration. Recedence. Tumours. Epulis. Polypus. Vascular tumours. Blue gum.
Tartar.	

It will be unnecessary here to refer in detail to these disorders of the teeth and gums, as many of them are common to these tissues with other parts of the body, and require the same general treatment. We shall therefore refer more particularly to those disordered conditions of the teeth and gums which produce the complaints known under the name of toothache and faceache, and the other more frequent disorders of these organs.

Dental Caries.—One of the most frequent causes of pain in the teeth is that destructive process known by the name of caries. Various views have been taken of the nature of this process; but Mr. Tomes defines it as "the death and subsequent progressive decomposition of a part or the whole of a tooth." The changes which indicate the occurrence of this condition are, first, a discoloration of the dental tissue, which is succeeded by softening and disintegration. The enamel first suffers, and then the dentine. The disease spreads in the direction of the dentinal tubes down to the pulp, forming a conical cavity with an oblique direction. It is not, however, infrequent to find the hole in the enamel less than that in the dentine, as the process of decay goes on much more rapidly in the latter than in the former.

This process of decay may or may not be attended with pain from the time of its first setting in. Eventually, however, the caries extends to the pulp cavity where the nerves are situated, and pain is the result. Even this is sometimes prevented by a kind of reparative process going on in the dentine, which forms the walls of the cavity, and which prevents the nerves from being affected.

If the caries extends, the pulp may become inflamed, and also the dental periosteum, which may be followed by alveolar abscess. Before inflammation of the pulp is established, the pain from the tooth becomes intolerable by *irritation* in the pulp. This state comes on gradually: first a little pain is felt when hot or cold or sweet or acid things are put into the mouth. This goes on increasing till inflammation is established in the pulp of the diseased tooth. This frequently leads to irritation in the pulp of the sound teeth, so that pain may be felt in several teeth by the unsoundness of one.

It is when the pulp becomes inflamed that the violent throbbing pain known as toothache comes on. In this state a destruction of the pulp may take place and the pain cease, and the tooth retaining its vitality from its external periosteum alone may still be useful. This is, however, a very rare occurrence.

In the treatment of caries of the tooth, and its attendant irritation and inflammation of the pulp, it should be recollected that all external remedies are palliatives. A natural cure, which is very unlikely, may go on whilst a little relief is obtained by such applications as opium, ether, creasote, alum, chloroform, tannic acid, nitrate of silver. The multitude of remedies for toothache show how utterly intractable a disease it is, and how little amenable to anything like external treatment. Nor will internal remedies affect the tooth, or in any manner arrest the caries which produces the pain.

If caries is observed in the early stages, before the pulp cavity is affected, then the diseased part may be scooped out, and the cavity plugged up in various ways. This, however, must be done early, in order to ensure success. It not unfrequently happens that where irritation of the pulp cavity has been set up plugging will relieve. Where irritation is set up in neighbouring teeth from inflamed pulp, then the removal of the offending tooth is immediately atteuded with relief to the others.

In the case of inflammation of the pulp, where the pain is severe, the tooth should be removed. The hazard of ulterior consequences to the alveolar process and the jaw should always prompt to the removal of the inflamed tooth.

The consequences of decay of the teeth are not at all confined to the simple pain called toothache. The inflammation may extend from the tooth to the gums, and from the gums to the surrounding structures, so that inflammation of the submaxillary glands takes place, and a swelling of the whole face occurs. Such inflammation may be acute or chronic. When it is acute it may subside in a few days after the application of the ordinary remedies for an acute inflammatory condition of the soft tissues. It may, however, be chronic, and attended with ulceration of the mucous membrane, which may extend to the throat. In these cases local remedies may relieve. The application of tannic acid, alum, or chlorate of potash will be of service, but the great remedy of all is the removal of the cause—the extraction of the decayed tooth or teeth.

Again, the nervous system may be the seat of the engendered disease. The whole of the nerves of the face singly or together may be the seat of reflected pain from the inflamed pulp of a single tooth. These pains, often taken for idiopathic neuralgia, cannot be effectually relieved till the cause of their excitement is removed. The reflected irritation of the nerves may not only affect nerves, but even the brain itself and the organs of the senses. All obscure pains of the head and affections of the senses should be examined in relation to the condition of the teeth, as a source of irritation not indicated necessarily by pain in the tooth may be frequently found in its disorganised and decayed condition.

The other forms of disease of the teeth are less common and special than those we have spoken of above. Sometimes excessive pain is suffered from *inflammation of the dental periosteum*. When there is no decay of the tooth, and the pain is clearly referable to this cause, much good may be done by the application of one or two leeches to the gum opposite the end of the root of the affected tooth. Antiphlogistic remedies should also be generally applied. Where morbid growths are the result of such inflammation, the extraction of the tooth will be of service; but even then the inflammation may continue in the socket. Sometimes the inflammation is of a rheumatic character, and demands a treatment adapted to this state of the system.

Diseases of the Alveoli and Gums.—From the periosteum we pass on to the alveoli and gums. The diseases of the alveoli which are most frequent are absorption and hæmorrhage.

Absorption of the alveoli frequently takes place as the result of constitutional tendency, and a disposition to this malady is handed down from father to son. Under these circumstances it is not an unusual thing to observe a man under fifty with scarcely any teeth in his head. This process takes place slowly, and almost imperceptibly, till the teeth drop out one after another. Absorption of the alveoli may also be induced by inflammation of the gums, which may be kept up by decayed teeth. The salivation attendant upon the administration of mercury is also accompanied with an absorption of the alveolar processes and a falling out of the teeth.

In the treatment of these cases the great thing is to remove the cause. Where decayed teeth, inflammation of the gums from tartar, or irregular teeth, are present, these must be removed. Nothing seems to arrest the hereditary absorption of the alveoli. It is like the loss of hair, or other defect, an accompaniment of old age, and in certain cases these symptoms come on prematurely. The great resource and comfort of the sufferer in these cases is the introduction of artificial teeth. The manufacture of these organs has been carried to such perfection that little or no inconvenience is felt from their presence in the mouth, whilst they perform the functions of mastication and give the necessary modulation to the voice as though they were the original teeth. They have even this advantage over natural teeth, that they never ache.

Hæmorrhage from the periosteum of the alveoli is not unfrequently a source of alarm, and cases are recorded in which death has occurred from this cause. It usually comes on after the extraction of a tooth. Under ordinary cirumstances the socket becomes filled with a coagulum of blood, which arrests all further bleeding; but in these cases the blood continues to be poured out from the wounded vessels, and resists all attempts at arrest. The best method of treating these cases is to plug the socket with a piece of lint dipped in some strong styptic. One of the most efficient styptics for these cases is the matico, which should be powdered and applied on the outside of a plug of moistened lint.

Inflammation of the Gums.—This may be either acute or chronic, and may come on independent of caries of the tooth or other disease. Acute inflammation is most frequently seen as the result of taking mercury. [MERCURY, *Medical Properties of.*] Chronic inflammation attended with ulceration of the gums is very frequent. It may arise from diseased conditions of the teeth, or from a disordered state of the system. In inflammation without ulceration stimulant applications are very beneficial, whilst the ulcers may be touched with nitric acid, or painted with a strong solution of chlorate of potash.

Blue Gum.—When lead is introduced into the system in small quantities for a length of time, its presence in the system is indicated by a blue or purplish line running along the edges of the gums just where they meet the teeth. This curious fact, which was first pointed out by Dr. Burton, has since been confirmed in a large number of cases. The blue line is, however, only seen in cases where tartar has accumulated on the teeth. It is not seen in cases either where there are no teeth in the gums. Wherever present it indicates the action of lead on the system, and should lead to the investigation of the circumstances under which the patient has received this substance into the system. Mr. Tomes has mentioned two cases in which the same kind of discoloration has taken place from the action of mercury on the system. It is not, however, impossible that the preparations of mercury taken in these cases contained lead.

Tartar.—The saliva which is poured into the mouth contains certain earthy matters in solution, which are precipitated on the roots of the teeth at the point where they are covered by the gums. This precipitate, which is a true salivary calculus, is called "tartar." When chemically examined it has been found to contain in 100 parts—

Earthy phosphates	79·0
Salivary mucus	12·5
Ptyalin	1·0
Animal matter	7·5
	100·0

It assumes a variety of colours on the teeth, according to the nature of the food habitually taken. The accumulation of this substance on the teeth tends to produce inflammation of the gums and to cause their absorption as well as that of the alveolar processes.

When tartar has accumulated to a considerable extent it should be scaled off the teeth by means of instruments fitted for the purpose. One of the great objects of the daily brushing of the teeth is the prevention of the accumulation of this tartar. One of the best dentifrices for habitual use is the camphorated tooth-powder, which consists of camphor carefully powdered and mixed with chalk. All agents that would dissolve the tartar would dissolve the teeth, and must therefore be carefully avoided.

TEETH OF WHEELS. [WHEELS.]

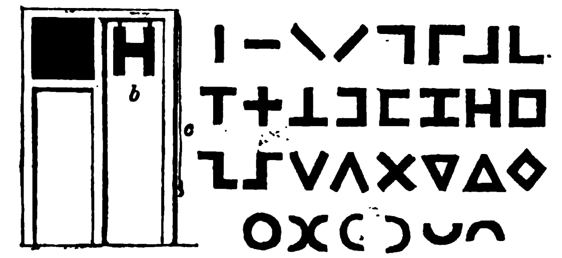
TEKORETIN (C_8H_4?). A native crystalline resin found in the peat of Denmark.

TELEGRAPH (from τῆλε, "distant," and γράφω, "write"), a machine or process for communicating intelligence to a distance, usually by means of preconcerted signals, to which some conventional meaning is attached. The name *semaphore* (from σῆμα, "a sign," and φέρω, "bear"), was also applied to some of the machines used for effecting telegraphic communication; which, in an extended sense, may be considered to embrace every means of conveying intelligence by gestures and visible signals, as flags, lanterns, rockets, blue-lights, beacon-fires, &c., or by audible signals, as the firing of guns, the blowing of trumpets, the beating of drums or gongs, &c., as well as by the machines specially provided for the purpose.

Although telegraphic communication, as a means of conveying *any* required intelligence, is an invention of recent date, the use of signals for the speedy transmission of such brief messages as might be previously arranged between persons, is a practice derived from the most remote antiquity. The use of beacon-fires, for example, as a means of giving speedy warning of the approach of an enemy, is alluded to by the prophet Jeremiah, who wrote about six centuries before the Christian era, and who warns the Benjamites to "set up a sign of fire in Beth-haccerem; for evil," he adds, "appeareth out of the north, and great destruction." (Jeremiah, vi. 1.) The fine description given by Æschylus, in his 'Agamemnon,' of the application of a line of fire-signals to communicate the intelligence of the fall of Troy, is often referred to as an early instance of this kind of telegraphic despatch. This simple means of spreading an alarm, or communicating intelligence, is described by Scott in the 'Lay of the Last Minstrel;' and in a note he refers to an Act of the Scottish parliament in 1455, c. 48, which directs that one bale or faggot shall be warning of the approach of the English in any manner; two bales, that they are *coming indeed;* and four bales blazing beside each other, that the enemy are in great force. Such signals, though best adapted to give information by night, were also available in the daytime, when they appeared as columns of dense smoke. Torches held in the hand and moved in any particular manner, or alternately displayed and hidden behind a screen, were also used in ancient times as signals. Polybius describes two somewhat complicated methods of telegraphing by means of torches; and Bishop Wilkins, in his curious work entitled 'Mercury; or the Secret and Swift Messenger,' after describing this telegraph of Polybius, mentions another which requires only three lights or torches to indicate the twenty-four necessary letters of the alphabet, which are, according to this plan, which he gives on the authority of Joachimus Fortius, to be divided into three classes of eight letters each. The first class is represented by one torch, the second by two, and the third by three; and the number of the letter by the number of times which the torches are elevated or discovered. Similar to this, is the night-telegraph contrived by the Rev. James Bremner, of the Shetland Islands, and rewarded by the Society of Arts in 1816. ('Soc. Trans.,' xxxiv.) A single light constitutes the whole apparatus, and the whole operation consists in its alternate exhibition and concealment. This plan had been found suitable for distances of twenty miles and upwards, and had been successfully put in operation between the lighthouse on Copeland Island and Port Patrick on the opposite side of the Irish Channel. Bishop Wilkins also describes a method which depends upon the relative positions of two lights attached to long poles, and which, he says, "for its quickness and speed is much to be preferred before any of the rest." This plan came very near to the principle upon which some of the subsequent telegraphic systems depended. In suggesting the use of extended lines of telegraphic communication, he further hints at the application of the telescope (or, as he styles it, 'Galileus his perspective'), to the deciphering of distant signals.

Other writers, such as Kircher, Schottus, and Kessler, have published plans for telegraphic signals. Kessler proposed to cut out such characters as it was desired to show in the ends of a cask, which was to be elevated with a light enclosed in it. The Marquess of Worcester also, in his 'Century of Inventions,' 1663, announces, "How at a window, as far as the eye can discover black from white, a man may hold discourse with his correspondent, without noise made or notice taken," &c.; and again, "A way to do it by night as well as by day, though as dark as pitch is black." But the earliest well-defined plan of telegraphic communication appears to be that described in a paper addressed to the Royal Society in 1684, by Dr. Robert Hooke, and published in 1726 in Derham's collection of his 'Philosophical Experiments and Observations,' pp. 142-150, "showing a way how to communicate one's mind at great distances." Hooke's scheme will be understood by referring to *fig.* 1, which represents an elevated

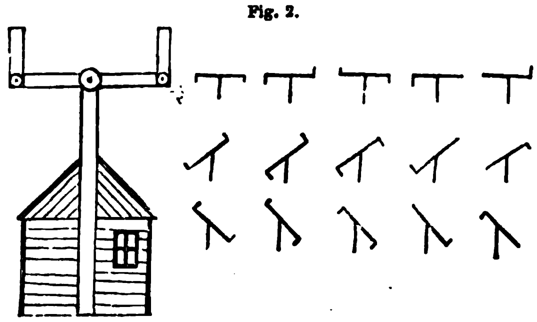
Fig. 1.



frame-work supporting a panel or screen, *a*, behind which were to be suspended a number of symbols or devices, formed of deal plank, of the various shapes represented by the small black figures. The first twenty-four of these, which consist entirely of straight lines, were to stand for alphabetic characters; and the six devices consisting of curved lines were to be used as arbitrary signals. Whenever it was desired to display any of these characters, they were to be drawn from behind the screen by a rope *c*, passing over pulleys in the frame-work, and so rendered visible in the open space at *b*. These telegraphs were to be erected upon elevated stations, and telescopes were to be used by the observers. The order of connection between the signs employed and the letters of the alphabet might, it is explained, be infinitely varied, for the sake of secrecy; and none of the parties employed, excepting those at the terminal stations, need have any knowledge of the message communicated. Hooke further proposed a scheme for night communication by means of lights disposed in a certain order

About twenty years after the date of Hooke's paper, Amontons brought forward a similar plan in France. Some other individuals subsequently devised similar schemes, but nothing was effected in the practical application of telegraphic communication until the wars of the French revolution. Macdonald states that, "Following the principles laid down by Dr. Hooke, in 1684, Dupuis, in France, invented the French telegraph, which Don Gualtier, a monk of the order of Citeaux, in 1781, modified, and proposed to Condorcet, Milli, and Dr. Franklin, who recommended it to the French government." The telegraph brought into use in 1793 or 1794, by M. Chappe, was, as will be seen by *fig.* 2, a very superior machine to that of Dr. Hooke.

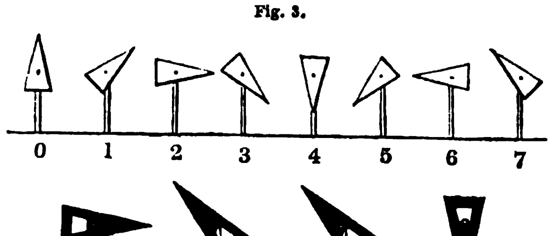
Fig. 2.



Chappe's telegraph, which, from its position when at rest, is sometimes called the T telegraph, consisted of an upright pole or post, at the top of which was pivoted, by its centre, a transverse beam, which, by means of ropes worked in the chamber below, that served also for an observatory, might be made to assume any required angle with the post. Each end of this moveable beam carried a short arm, that was capable of assuming any required angle with it; and these arms also were worked by ropes, which were conducted through the axis of the beam, in order that the necessary degree of tension might not be disturbed by the action of the machine. By this contrivance, without the use of any angles of less than 45° (which might be indistinct when viewed from a great distance, or under the influence of a refractive atmosphere), as many as 256 different signs might be made. A much smaller number was however sufficient, as M. Chappe communicated his intelligence letter by letter, and simplified the movements by using an alphabet of only sixteen letters. The small figures in the cut show some of the different positions assumed by the beam and arms; and, as the connection between these and the letters they were made to represent, was quite arbitrary, their signification might be changed as often as was necessary for the purposes of secrecy; it being only necessary that the key should be known to the parties sending and receiving the message, although it might be transmitted through a great number of intermediate stations. Such telegraphs were first erected on a line commencing at the Louvre, in Paris, and proceeding by Montmartre and other elevated points to Lisle, in order to communicate between the Committee of Public Welfare and the combined armies in the Low Countries. Telescopes were used at each station, and the signals displayed at one station were immediately repeated at the next; four seconds being found sufficient for effecting the required motions, and sixteen seconds the time allowed for observing and noting down each signal, during which the machine remained stationary. Barrère, in announcing the invention of the telegraph to the Convention, on the 17th of August, 1794, stated that the news of the recapture of Lisle had, by means of this machine, reached Paris in an hour after the troops of the Republic had entered the place. ('Annual Register,' 1794.)

The advantages of such extraordinary celerity of communication were so obvious, that in England and other countries many plans were immediately brought forward, some of which differed materially from that which had been successfully put in practice in France. Among these was that contrived by Mr. R. L. Edgeworth, whose numerical telegraph (or a telegraph expressing numbers, which numbers refer to letters, words, or sentences, in a dictionary), will be understood by

Fig. 3.

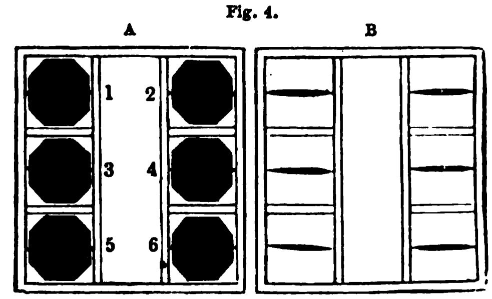


means of *fig.* 3, in which an index or pointer, in the form of an isosceles triangle, was so mounted upon a post, or on a portable triangular stand, that it might be turned into any of the eight positions shown in the upper part of the cut; these positions indicating, respectively, 0 and the numerals 1 to 7. Four such pointers, mounted side by side, as in the lower part of the figure, afford power for expressing any number from 1 to 7777, excepting 8, 9, 18, 19, 28, 29, and all others in which the numerals 8 and 9 are required: the first pointer representing thousands, the second hundreds, the third tens, and the fourth units. Thus, the four black pointers in the figure being, respectively, in the positions indicating 2, 7, 7, and 4, express, collectively, the number 2774. Further particulars of this method will be found in Edgeworth's 'Essay on the Art of Conveying Secret and Swift Intelligence,' published in the sixth volume of the 'Transactions of the Royal Irish Academy.' He also published a pamphlet entitled 'A Letter to the Right Honourable the Earl of Charlemont on the Tellograph, and on the Defence of Ireland,' which was reprinted at London in 1797.

The Rev. J. Gamble, chaplain to the Duke of York, proposed a shutter telegraph, consisting of a frame-work containing five boards, or shutters, arranged vertically one above the other, and pivoted in such a way that any or all of them might be closed, so as to present their broad surfaces to the eye, or opened, so as to show merely a thin edge, which would be invisible at a distance. The various signals produced by closing one or more of these shutters may be applied either to a numerical or an alphabetical system. A similar plan submitted to the Admiralty in 1795, by Lord George Murray, was adopted in the first government line of telegraphs established in England, in 1796, between London and Dover. The 'Annual Register' for that year (p. 4 of the 'Chronicle') mentions the erection of the telegraph over the Admiralty on the 28th of January, and states that information had been conveyed from Dover to London in seven minutes. The action of this kind of telegraph, which was continued in use by the Admiralty until the year 1816, is illustrated by *fig.* 4, in which A

Fig. 4.

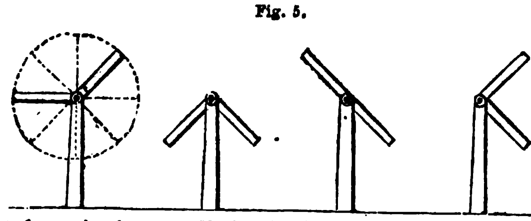
A B



represents a square frame-work with six octagonal shutters, 1, 2, 3, 4, 5, and 6, arranged in two vertical columns, or sets, and turned into a vertical position, so as to display their broad surfaces completely, and B represents the same apparatus with the boards or shutters placed horizontally, or turned one-quarter round upon their respective axes, so as to present nothing but their edges to the eye. The central space between the two columns of shutters serves to render them more distinct to a distant observer, and affords room for the ropes and pulleys by which the telegraph is worked, and which are managed by persons in the observatory below. A modification of this kind of telegraph, intended for night as well as for day service, was submitted to the Society of Arts, in 1805, by Mr. Joseph Davis. About the same time that shutter-telegraphs were being introduced in England, the Chevalier A.ˢ N. Edelcrantz, of Stockholm, was devising similar machinery for use in Sweden. (See Nicholson's 'Journal,' 1803; Society of Arts 'Transactions' for 1808.) Other modifications of the shutter telegraph were put forward from time to time, but experience established the superiority of telegraphs or semaphores with moveable arms; and these were greatly simplified, so as to avoid the objection raised to the old French telegraph. Among the schemes proposed soon after the first practical application of telegraphs, was one which consisted in dividing a large circle into twenty-four parts, for the letters of the alphabet, and employing a traversing radius, or index, to point them out; wires being fixed before the object-glass of the telescope to enable the distant observer to determine the position of the radius. This plan could only be applied to short distances, because refraction might render it difficult to distinguish between positions so little varying from each other. The same radiating principle was, however, adopted in some machines of a more practical character; among which was a telegraph contrived by the Rev. J. Gamble, consisting of five beams or arms pivoted at the top of a post, upon one axis, and capable of producing many different combinations without using angles of less than 45°. On a similar principle were constructed the French coast telegraphs adopted in 1803, to which the name of *semaphore* was first applied, and from which it has been given to other telegraphic machines, the action of which is dependent upon the motion of arms around pivots placed at or near their extremities. These French semaphores, or, as they were sometimes called, *signal-posts*, consisted of upright posts with two or three moveable arms, turning upon separate pivots, one above the other. Before they were much known in this country, Captain Pasley had been led to observe the inferiority of the common land-telegraph to that used at sea, which consisted of coloured flags.

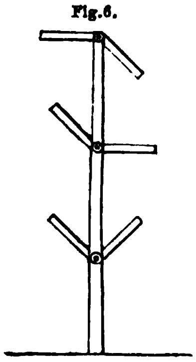
and by which three numbers, or rather three numerals combined to form one number, might be readily expressed. To remedy this defect, he, in 1807 (before he had seen the French semaphore), devised what he termed a "polygrammatic telegraph," a description of which was published in Tilloch's 'Philosophical Magazine,' vol. xxix. This machine, *fig. 5*, consisted of four posts, at the top of each of which was

Fig. 5.



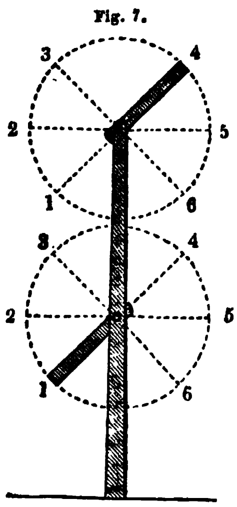
pivoted a pair of arms. Each pair of arms was capable, by assuming the various positions indicated by the dotted lines added to the first pair, of forming more than a sufficient variety of distinct signals to express any of the numerals or the 0; and consequently the whole machine could represent any number composed of not more than four figures, besides having several signals to spare. In 1809 Captain Pasley saw the French semaphore, which he described in the following year, together with a modification of his own polygrammatic telegraph, founded upon it, in the thirty-fifth volume of the periodical just mentioned. This simplified polygrammatic telegraph, represented in *fig. 6*, has three pairs of arms, representing hundreds, tens, and units, pivoted to different parts of the same vertical post. This contrivance is adopted by Lieutenant-Colonel Macdonald, with very trifling variation, in his 'Treatise explanatory of a new System of Naval, Military, and Political Telegraphic Communication,' published in 1817. By the addition of a ball and a vane at the top of the mast, it becomes a machine of the same power as Macdonald's thirteen-shutter telegraph; as each pair of arms is capable of assuming fifteen distinct positions. Another semaphore on the same principle was submitted to the Society of Arts in 1821, by Lieutenant N. H. Nicolas, and described, together with a method of applying a shifting key to telegraphic communications, for the purpose of insuring their secrecy, in the thirty-ninth volume of the Society's 'Transactions.' The telegraphs upon the commercial line of communication established between London and the Downs were constructed upon another modification of the polygrammatic principle; four pairs of arms being employed, but mounted upon two posts instead of one, as in Nicolas's semaphore, or four, as in the original design of Captain Pasley.

Fig. 6.



In 1816 it was determined to change the Admiralty telegraphs into semaphores constructed on the principle of those used in France, with the improvements suggested by Sir Home Popham, who had previously done much for the improvement of naval signals. The action of Popham's semaphore is explained by *fig. 7*, in which dotted lines are added to show the various positions in which the arms may be placed, and numerals to show the numbers indicated by those positions. Only two arms are employed; but as they are mounted upon separate pivots, each of them can assume six different positions, and the two together are capable of affording forty-eight signals; which number, though less than that given by the six-shutter telegraph, is sufficient to express the letters of the alphabet and the Arabic numerals, and to leave thirteen signals unappropriated, for abbreviations and arbitrary signs. This kind of semaphore (which is minutely described in the 'Society of Arts Transactions,' vol. xxxiv.) was used at the government stations until superseded by the electric telegraph.

Fig. 7.

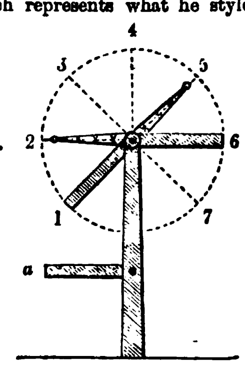


The vertical post of this telegraph was a hollow hexagonal mast, which, turning on a pivot at its foot, and in a collar where it passed through the roof of the observatory, could be moved so as to display its signals in any direction. The moveable arms were provided with balance-weights in the form of masses of metal attached to their shorter ends, very near to the pivots upon which they turned, by which means they could be moved in any direction with the exertion of a very small force; and they were made, when out of use, to fall into grooves or recesses in the post, so as to become invisible. The movements were effected by means of two winch-handles near the base of the mast, within the cabin, one for each arm. The winch-handles turned two small bevel-wheels, which communicated motion by means of two horizontal bevel-wheels to long upright shafts or rods, which passed up the inside of the hollow post of the telegraph. At the upper ends of these rods, which were held steady by suitable bearings, were endless screws, working into toothed wheels fixed upon the axes of the arms, and thereby communicating motion to them. In order that the person who worked the machine might know precisely when the arms were brought to the required positions, similar endless screws were added near the lower ends of the vertical rods, to give motion by toothed wheels to indexes, which gave a miniature representation of the motion of the arms. Excepting these indexes and the winch-handles, the whole apparatus was inclosed in the vertical shaft of the telegraph, on the outside of which small blocks were added, to enable a man, with the assistance of a rope from the top of the post, to ascend the machine for the purpose of cleaning and oiling it.

About the same time, Sir Home Popham proposed a modification of the semaphore for marine purposes, which, he conceived, would be found very advantageous for the merchant-service, by superseding the necessity for a costly set of signal-flags, the expense and wear and tear of which formed a serious objection to a system of general telegraphic communication at sea, excepting in the ships of the East India Company. His proposed sea-telegraph would not, it is stated, cost more than fifty shillings at first, and its wear and tear would not amount to five shillings a year. As the height of an apparatus resembling the land-semaphore would be objectionable for marine purposes, Popham proposed to use two posts, 12 feet 2 inches high and 6 inches thick, each having a single arm, 6 feet 4 inches long and 10 inches broad, pivoted to the top, but not falling into a slot in the post, as in the last-described machine. In a small slot at the top of each post is a grooved pulley or sheave, fixed upon the same axis as the arm; and at a convenient height from the bottom of each post another precisely similar pulley is mounted in like way, its axis passing through the post, and carrying a small wheel with four handles at right angles with each other, by which the machine is worked; the motion of the lower pulley being communicated to the upper one, and consequently to the arm, by an endless rope, which has two or three turns round each of the sheaves, and passes up by the sides of the post. When the telegraph is in use, the posts may be attached to the sides of a vessel by stepping their lower ends into blocks fixed for the purpose, and lashing them to the bulwarks; or they may be mounted upon trucks, so as to be readily moved from one part of the ship to another. The description of this machine in Sir Home Popham's communication to the Society of Arts mentions but four positions for each arm, and states that when placed in the four positions diagonally to the post, one arm denotes 1, 2, 3, and 4, and the other 5, 6, 7, and 8. This arrangement gives twenty-four distinct signals, and avoids the possibility of mistaking the horizontal for an inclined position of either arm, of which there might, owing to the motion of the ship, be some risk.

Major-General Pasley, in a pamphlet published in 1823, entitled 'Description of the Universal Telegraph for Day and Night Signals,' abandons the polygrammatic principle, and adopts the simple form shown in *fig. 8*, which represents what he styles the "universal telegraph," as adapted for day-service.

Fig. 8.



It consists of an upright post with two arms, both attached to one pivot at its upper extremity. Each arm is capable of assuming the seven positions indicated in the cut, besides what is called the *stop*, which is made when turned down and obscured by the post. Twenty-eight distinct signals may therefore be made by the apparatus, as shown in the subjoined table; these being more than sufficient for the letters of the alphabet, though not numerous enough to allow of a full alphabet and the numeral characters.

Table of the separate or distinct Signals given by Pasley's Universal Telegraph.

1	6	15	25	36	56
2	7	16	26	37	57
3	12	17	27	45	67
4	13	23	34	46	
5	14	24	35	47	

It had been found, in using Sir Home Popham's ship-semaphores that uncertainty was occasioned by the signals being sometimes seen in reverse, in which case one number or sign would be confounded with another; Pasley provided against this occurrence with his universal telegraph by the addition of the auxiliary arm, or indicator, marked *a*, *fig.* 8, which, in whatever direction the machine may be viewed, distinguishes the side at which the numeral signs commence. It serves also to prevent the position marked 4 from being confounded with the stop, which it might be if there were nothing to indicate that the telegraph is at work, and to enable the eye to measure its height. The counterbalance weights of the arms are not fixed close to the pivot, but extend to some distance from it, in the form of a slender framework of iron, with a ball at the outer extremity, their light appearance rendering them almost invisible at a distance. Pasley states that telegraphs should in general be painted black, and, if possible, so placed that they may be seen without any background. If, however, a background be unavoidable, the telegragh should be of such a colour as to contrast with it. In some cases, where the appearance of the background varies much at different periods of the day, it has been found useful to paint the arms white and black, in large chequers, each occupying half of the width and half of the length of the arm.

The contrivances which have been suggested for effecting telegraphic communication are so very numerous, that anything like an enumeration of them is impossible in this place. Several depend upon the application of arms of various forms to a semaphoric telegraph, while another class of telegraphic contrivances depend upon the exhibition of devices or symbols, in a manner somewhat resembling the original contrivance of Dr. Hooke. In Mr. Spencer's 'anthropo-telegraph,' a man holds a couple of discs in his hands, and makes signals by placing them in different positions with respect to each other. But the reader, interested in this sort of detail, which is now purely historical, may gratify his curiosity by referring to the 'Transactions of the Society of Arts.' Macdonald's 'Treatise on Telegraph Communication' (1817), also contains a multitude of similar details.

Marine telegraphic communication is an object of great importance, since there are many circumstances which render personal communication between vessels at sea impracticable, and that sometimes in cases of the greatest emergency. But, although naval signals have been, of necessity, long used, and flags of various forms and colours have been extensively employed for the purpose of making them, it was not till within a comparatively recent period that they were reduced to anything like an efficient telegraphic system. Sir John Barrow states ('Ency. Brit.,' art. 'Navy') that "The idea of *numbering* the flags, and of assigning a certain number of corresponding sentences to certain combinations of these numbers, was reduced to something approaching a regular system in the fleet of Lord Howe;" and that in the year 1798 a new signal-book was issued by the Admiralty, the references to which were made by a numerical arrangement of flags. This book contained about four hundred sentences, expressive of the most usual operations of the fleet; but it was so imperfect that, if any order had to be transmitted which was not to be found in the dictionary, it became necessary to make the signal for "a boat from each ship;" an order which could not always be complied with. This inconvenience was remedied by the plan, suggested by Sir Home Popham, of making the flag-signals represent the letters of the alphabet, as well as words and sentences, in connection with numbers. He also printed, at Calcutta, a new code of naval signals, which was subsequently reprinted in England, greatly extended, and adopted for use in the navy. Among the numerous improvements introduced by him is a new method of cutting the signal flags, so that, as he explained to the Society of Arts in 1816, "the selvages of the buntin are brought on the outer edges of the flags, and the gorings in the centre; by which means the outer edge is susceptible of the least air of wind, and when the flag blows out, the gorings assist in keeping it out; whereas the old flags had a hem on the outside, which rendered them difficult to be moved without a fresh breeze, especially in damp and rainy weather, as the hem then became very heavy." "Besides," he adds, "it is impossible, from the nature of the buntin, to sew a straight seam, for the instant it is cut it will become in some degree curved." ('Transactions,' vol. xxxiv.)

The principle of the numerical system as applied to flag-telegraphs in the navy is briefly explained by Macdonald. Nine different variegated flags are employed to express the numerals 1 to 9, another for 0, and another called a *substitute*, to repeat any flag under which it is hoisted, in the case of the same numeral occurring twice in the number to be expressed. A pendant is also used in some cases as a substitute for the uppermost figure; and thus, by the use of eleven different flags and a pendant, any number from 1 to 999 may be expressed without displaying more than three flags, or two flags and a pendant, at once.

The Codes best known in England are those of the Admiralty, 1808, and again in 1816 and 1826, and the modifications which form the present Admiralty Code; Lynn's Code, 1818; Squire's, 1820; Raper's, 1828; Phillippe's, 1836; Rohde's, 1836; Walker's, 1841; Eardley Wilmot's, 1851; Roger's (American), 1854; Reynold's (French) 1855; Marryatt's (last edit.), 1856; Board of Trade (2nd edit.), 1859. In all these the general principle is the same as above explained. A certain number of flags and pendants of different patterns have to each its own name, some being expressed by numerals, others by letters, while a third set are used for specific purposes: one called the Interrogatory, asks a question; another signifies an affirmation, another a negation, and so on. In the Admiralty, this system is carried to a considerable extent, and requires about fifty flags or pendants; while there is a general system-book, by which orders are given for evolutions in the fleet, and much routine information. There is also a second telegraphic book, including common words in English, a list of ships in the Royal Navy, with the names of the flags by which each is distinguished, and other useful information. There is also a system of night signals, the same as the general signal book, but instead of flags, lamps, with or without blue lights or guns, convey the signals. There is also a system of fog-signals made by the firing of guns, the variations being marked by the intervals between the reports. In addition to all this, each commander is furnished with private and secret signals, which are only used to ascertain whether a ship of war is a foreigner or not; for if a foreigner the proper return signal will not be known.

A general code adapted to merchant vessels was invented by Captain Marryatt, and continued in use up to the year 1857, when the Board of Trade published their 'Commercial Code of Signals for all Nations,' which soon came into general use. It includes only 18 flags or pendants, which were named after the consonants, and were so arranged as to show the distinguishing flag of every British merchant ship, a list of such ships as are registered being published every year by the Board of Trade, with an official number to each. Each ship always retains its name and number, although it may change its port. The signals provided for were 20,000, and 4 flags the greatest number for any signal. The system was modified by a committee appointed by the Board of Trade in 1855, and as now in operation provides by means of 18 flags and 3 pendants for upwards of 70,000 signals: the flags and pendants are given under FLAG. The signals are arranged in classes for easy reference. We may lastly refer to a system of boat-signals arranged by Captain Wilmot.

Sir John Barrow, in the article before alluded to, observes that a telegraph employed for public purposes should be possessed of *power*, *certainty*, *simplicity*, *celerity*, and *secrecy*. It should have sufficient power to express, by distinct positions or combinations of moveable parts, any possible order or information, either by letters, words, or sentences. Its certainty will depend upon all its parts being clearly defined, wholly within the field of the telescope, and so distinct that there shall be no risk of mistaking one signal for another; whence the importance of simplicity becomes obvious. In order to decide the question as to distinctness, the shutter-telegraph at Nunhead, near New Cross, was left standing for some time on the same hill as the semaphore; and the result of the trial for a whole winter was, "that the semaphore was frequently distinctly visible when the boarded telegraph was so much enveloped in mist and fog that the particular boards shut or thrown open could not be distinguished;" and that the number of days in the course of the winter upon which the semaphore was visible exceeded those upon which the shutters could be seen by fully one-third.

Any means of telegraphic communication which depends upon the deciphering of signals exhibited at a distant station is necessarily dependent upon contingencies of weather; but many plans have been contrived for effecting the object in such a manner as to be independent both of light and of the state of the atmosphere. For communication between the different parts of a house this object may be effected by a mechanical connection, by chains or wires, between two dials with revolving indexes or pointers, in such a way that when one pointer is directed to a particular letter or word inscribed upon the dial to which it is attached, the other may exhibit a similar movement. The attention of the servant is engaged previously by ringing a bell; and when the required signal has been made, a spring returns both indexes to their original position. Speaking-pipes, or tubes to convey the voice from one place to another, are also available for short distances, but their range is too limited for application on an extended scale. One of the early schemes of this character depends upon the principle of water finding its level; but, independently of the difficulty which might arise from the friction of water in a very long pipe of small diameter, such as would be required to connect the vertical tubes in which the observations would be made, such a plan involves the necessity of having all the communicating stations at or near the same level. Other hydraulic telegraphs depend upon the comparative incompressibility of water or other liquids; it being proposed to lay down small pipes of any required length, and to indicate different signals by pressing more or less upon the surface of the fluid contained in them, which would transmit the motion to the opposite end of the pipe, where it might be pointed out upon a dial, or in any other convenient manner. Mr. Vallance described such a method of telegraphic communication in a pamphlet, published in 1825, of which Hebert gives some account ('Engineer's and Mechanic's Encyclopædia'); and some similar schemes have been more recently propounded. Air confined in small pipes has also been tried to a limited extent as a pneumatic telegraph; but in this, as well as in the hydraulic system, the risk of leakage is a serious disadvantage.

TELEGRAPH, ELECTRIC. The attempts to render one or other of the phenomena of electricity subservient to the purposes of telegraphy, have been numerous. From the earliest date which we can assign to the existence of an electric telegraph, its essential parts have been the same. These are, 1st, the source of electrical power; 2nd, the conducting material by which this power is enabled to travel to the required locality; and 3rd, the apparatus by which at the distant end of the line, the existence of this power, its amount, or the direction of its action, is made known to the observer. In the earlier stages of the invention, the investigations of its promoters were confined to the last of these three essentials; and so long as the illustration of the idea was confined to the lecture-table, this part claimed pre-eminence. But, with the proposed application of the principle to purposes of general utility, there arose the necessity for an equal degree of attention to the two former requisites.

The experiments of Dr. Watson in England, in 1747, and of Franklin, in 1748, on the banks of the Schuylkill river, may have suggested the conveyance of information by means of electricity. The earliest authenticated instance of any attempt to reduce this idea to practice, appears to have been that of M. Lesage at Geneva, in 1774, and of Lomond in France, in 1787. They employed as an indicator a pair of pith balls, suspended from one end of an insulated wire, at the other end of which was the operator, provided with an electrical machine. On charging the wire with electricity, the pith balls would exercise mutual repulsion, and diverge from one another; but on removing the electrical charge from the wire by the contact of some conductor, the balls would collapse. It is evident that certain numbers of successive divergences might be made to denote particular preconcerted signals. Subsequently to this, the phenomenon of the spark, as seen on the passage of electricity through an uninterrupted conductor, was used for the transmission of signals. Were the various letters of the alphabet formed in this manner, upon a table, and connected each one with a distinct and insulated wire, any particular letter might be rendered visible in a darkened room, by passing an electrical charge through the appropriate wire. This in fact constituted the telegraph of Reusser, or Reiser, invented in 1794. Betancourt and Dr. Salva in Spain, in 1798, appear to have made experiments on the transmission of the charge through wires of great length.

A somewhat similar form of apparatus, involving the same principle, was constructed by arranging the several wires in succession, with a single break in each. The various wires bore the names of the different letters or figures, and any required signal was indicated by passing the charge through the proper wire, when the spark visible at the interruption of the circuit would denote the letter to the observer at the farther end.

This was the point to which the invention had advanced, at the commencement of the present century. The discovery by Volta, in 1800, of the pile which bears his name, forms the commencement of a new era in electric telegraphs, although there was no immediate application of the phenomena of the galvanic current to the purpose. Indeed several important discoveries had to be made before an electric telegraph of any value was possible.

In 1807, Sömmering at Munich proposed to construct an electric telegraph on the principle of the decomposition of water by the Voltaic current, as discovered in 1800 by Nicholson and Carlisle. The form of his apparatus was the following:—In a glass trough containing water, thirty-five gold pegs or pins were arranged vertically, this number of pegs corresponding to the letters of the alphabet, together with the nine digits. Each of these pins was connected with a wire, which extended to the place whence the signal was to be transmitted. At this point they terminated in brass strips, arranged in a frame side by side, but, like the wires and pins, insulated from each other. Each brass strip bore the name of the letter or figure which belonged to the pin to which it was connected. The operator, when wishing to send any communication, connected the two poles of the battery with the brass strips bearing the names of the two first letters required. Decomposition of the water in the trough at the distant end was instantly indicated by the evolution of bubbles of gas from the two gold pins, which thus became the two electrodes or poles of the battery. The letters forming any communication were to be in this manner denoted in pairs, the inventor ingeniously availing himself of the different quantities of the two gases evolved to point out the relative position of the letters in each pair, the hydrogen being employed to indicate the first letter. Schweigger proposed to add to this system a plan for calling the attention of the correspondent at the distant station by the discharge, by the current, of a pistol charged with the mixed gases.

In 1816, Mr. Ronalds, of Hammersmith, invented an electric telegraph, in which the use of frictional electricity was recurred to. This telegraph, which was shown to several scientific men at the date above given, was fully described by the inventor in a work published by him in 1823. Mr. Ronalds employed the divergence and collapse of a pair of pith-balls as the telegraphic indication, in which respect the principle was the same as that adopted by Mr. Lomond; but to this simple apparatus, a distinct contrivance was appended, in order to render the communication more rapid and easy. A single wire, perfectly insulated by being suspended from silken strings, or buried in glass tubes, surrounded by pitch, and protected by wooden troughs, was extended between the two stations. From the end of this wire was suspended in front of the dial of a clock a pair of pith-balls, so that while the wire was charged the balls would remain divergent, but would instantly collapse, when the wire by contact with the earth, or with the hand of the operator, was discharged. A person at one end having therefore an electrical machine by which he could maintain the wire in an electrified state, and the pith-balls at the farther extremity consequently in a state of divergence,—had it of course in his power to give an instantaneous indication to an observer at that farther extremity by touching the wire with his hand, which, discharging the electricity, would allow the balls to collapse for an instant. But instead of merely employing the successive movements of the pith-balls to denote the various signals, Mr. Ronalds added another apparatus for this purpose. Two clocks, very accurately adjusted to the same rate of going, carried, instead of the ordinary seconds hand, light discs, on which the various letters of the alphabet, the figures, and other required signals were engraved. These discs turned with a regular step by step movement, behind a screen of metal, in which was made a small opening, sufficient to allow of one letter at a time being seen. As the discs turned round, each letter in succession would be visible through this space; and it is evident that if the clocks were started with the same signal visible, the movement of the discs would bring similar signals into view at the same time. One of these instruments was situated at each end of the communicating wire. The operator who was about to transmit any communication, watched the dial of his clock until the letter he required was visible, and at that instant discharged the wire. The momentary collapse of the balls at the distant end would then warn the observer to note the letter visible on his instrument, which would form a part of the intelligence to be received. The successive letters or signals constituting any message were denoted in this manner as the clock dials continued to turn round. In order to avoid the necessity for constant attention on the part of the observer, an arrangement was adopted by which a pistol could be fired by the spark at the farther end, to summon the attendant to his instrument. Various signals were also concerted beforehand, by the use of which the time necessary for the transmission of any intelligence was lessened. These experiments of Mr. Ronalds' were made with the intervention of several miles of wire, carried backward and forward across his grounds.

In 1819, Professor Oersted of Copenhagen made his great discovery of the action of the galvanic current upon a magnetic needle. He observed that when a current is passed along a wire, placed parallel and near to a magnetic needle, free to turn on its centre, the needle is deflected to one side or the other, according to the direction in which the current is transmitted. He further noticed that the position of the wire, whether above or below the needle, had an equal influence with the direction of the current in determining the side to which the deflection took place. [Electro-Dynamics.] The power of a single wire in causing this deviation of a needle is but small, but this was remedied by the invention of the *multiplier*, or Galvanometer, by Professor Schweigger, in which the needle, being surrounded with many successive coils of insulated wire, is acted upon by the joint force of all. Under a somewhat different form, this discovery now forms the basis of the needle electric telegraph.

Very shortly after this important discovery had been made, Arago and Ampère in France, and Seebeck in Berlin, succeeded in rendering iron magnetic, by the passage of a galvanic current through a wire coiled around the iron, and Sturgeon in England produced the first electro-magnet. [Electro-Magnetism.] It was found that, provided the iron to be magnetised were perfectly soft and pure, the magnetic property remained only during the actual transmission of the electricity, and was lost immediately on the interruption of the electric circuit. If the iron which was exposed to the influence of the galvanic current were combined with sulphur, carbon, or phosphorus, the magnetic power became to a greater or less extent permanent in it.

The invention of the voltaic battery, of the deflection of the needle, and of the magnetisation of soft iron, formed the three great steps in the history of the electric telegraph.

M. Ampère suggested the employment of the discovery of Oersted as early as 1830, and this suggestion was acted upon by Professor Ritchie, in a model telegraph exhibited by him at the Royal Institution. Ampère's plan however was far from possessing the simplicity so essential in an instrument designed for practical use. Not less than thirty pairs of conducting wires were necessary, according to his scheme, for maintaining a telegraphic communication.

Baron Schilling also, in Prussia, in 1832 and 1833, following the idea originated by Ampère, proposed a similar form of telegraph, in which there were as many of these galvanometers, each with its appropriate circuit, as there were letters or signs to be used in the various communications. In fact there were 36 needles and 72 wires. In 1833, Gauss and Weber proposed to employ the separate movements of a suspended bar as signals: but its indications must have been feeble, as they had to be observed through a telescope placed at some distance from the oscillating bar. In 1837, M. Alexander exhibited a model of a proposed form of telegraph, containing 25 needles, to be acted upon as in Ampère's arrangement. In this instrument a distinct needle was employed for the indication of each letter, these needles bearing at one end light screens of paper, which concealed from view a letter or figure, until by the deflection of the needle the screen was removed, and the letter brought into sight. M. Alexander, however, effected one great improvement, in substituting a single return wire, to which one end of all the coils was joined for the several distinct return wires existing in the previous invention of M. Schilling. At a later period this gentle.

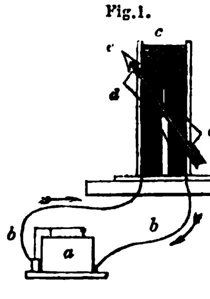
man undertook a series of experiments, with a view to the establishment of a communication by means of a single wire; but some mechanical difficulties appear to have arrested his progress. In both of these telegraphs all that was requisite, in addition to the indicating apparatus and conducting wires, was a contrivance by which the connection of the voltaic batteries could be made with any pair of wires in the former, and with any single wire and the return-conductor in the latter of the two inventions. In M. Alexander's instrument, a set of keys resembling those of a pianoforte, and corresponding to the number of needles, was arranged on a frame or table. One pole of the battery being connected to the return or common wire, the other pole was joined to a plate of metal, or to a trough of mercury, extending beneath all the keys. On depressing any key, the wire belonging to it, which was continued to the end over the battery connection, was brought into contact with this bar or trough. The current would then flow along the conducting wire, around the multiplier-coil in the distant instrument, and return by the common wire to the voltaic battery. The keys bore the same letters as the needles to which they were connected, so that the operator communicated any letter by pressing down the corresponding key.

In these two instruments no use was made of the power which exists of determining the deflection of the needle to either side, by merely reversing the connections of the battery.

We have thus traced the history of the telegraph up to the point at which it first assumed the practical form in Cooke and Wheatstone's inventions; but what had been accomplished remained either unknown or was known only to a few leading men of science, until the unexpected development of the electric telegraph in the hands of those gentlemen led each one who was in possession of any title to the merit of having believed in, and experimented upon, its possibility, to produce his title, or to have it eagerly put forward by his friends and fellow-countrymen.

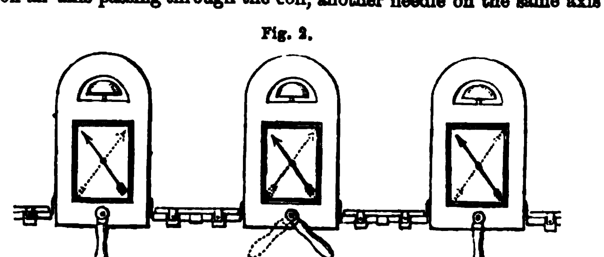
In June, 1837, the experiments of Messrs. Cooke and Wheatstone, which had been progressing for more than a twelvemonth, appeared so far successful as to induce them to apply for a patent for their inventions. The principal points of novelty in this patent were the use of a much smaller number of needles to denote all the required signals, the employment of the temporary magnetism excited by the current in soft iron, to ring an alarum; and the reciprocal arrangement by which the invention was rendered practically applicable to a long line of communication. In explaining the invention, Mr. Cooke ('Telegraphic Railways') says:—"If a magnetic needle were placed parallel and near to any part of a conducting wire, which we will suppose to be laid down between London and Blackwall, the transmission of an electric current from a voltaic battery would cause the needle to change its position, so as to stand during the continuance of the current at right angles to the wire, being turned in one direction or the other according to the course of the current. If this deflexion of the needle were limited by two fixed stops placed respectively at the two sides of one of its poles, the motion of that pole to one stop might evidently constitute one signal, and its motion to the other stop another signal." Such an apparatus is shown in *fig.* 1, the dial upon which the signals

Fig. 1.



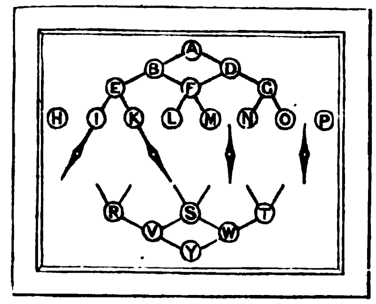
are represented being removed. In this cut *a* may be supposed to represent the battery, and *b b* the conducting wire, which is formed behind the dial into a coil *c*: *d d* is the front or index needle, mounted upon an axis passing through the coil, another needle on the same axis

Fig. 2.



being within the coil. The front needle carries upon its extremity, which comes through the dial, an index or pointer *c*. The arrows indicate the direction of the current required to deflect the magnet to the position indicated in the figure; and a current in the opposite direction would produce a deflexion towards the opposite side. While no current passes through the wire, the magnet and pointer remain vertical. The next cut (*fig.* 2) represents three such instruments complete, and connected together by wires enclosed in tubes, which may be of any required length. One of these may be supposed to be at the Minories, the next at an intermediate station, and the third at Blackwall; and as each is provided with a battery, and a handle (beneath the dial) by which the conducting wire may be connected with it at pleasure, the attendant at every station at which such an instrument is placed can instantaneously communicate the signal to "stop" or to "go on" to all the other stations; attention being previously engaged by ringing a bell, placed above the dial. *Fig.* 3

Fig. 3.

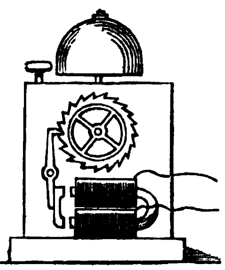


represents a dial, in which, by the combination of four such magnets and pointers, all the letters of the alphabet may be expressed by pointing one or two needles towards them; and of course a larger or smaller number of signals might be made on the same principle if necessary. A telegraph with two pointers, showing eight signals, is considered by Mr. Cooke to be sufficient for all ordinary purposes. The wires, where several are used, are covered with some insulating material (such as a mixture of cotton and caoutchouc), and combined into a rope and enclosed in an iron tube, which may be either buried beneath the surface of the earth or supported above it.

The instrument which was brought into use on the Great Western Railway shortly after the date of the patent, contained five needles, arranged with their axes in a horizontal line. The needles when at rest hung vertically, by reason of a slight preponderance given to their lower ends. Each coil was connected with one of the long conducting wires at one end, and was united at the other with a rod of metal, which joined together the similar ends of all the coils. The current was transmitted from the opposite end of the wires (where a set of five pairs of finger-keys, for making the connections with the battery, was placed) through two of the wires at once. That is to say, one of the wires, of which one key was pressed down, served to convey the current from one pole of the battery to the distant instrument, while the key of a second wire being brought into contact with the other pole, the current returned by the rod of metal connecting the coils and the second wire to the battery again. Two needles were in this manner deflected at once, and it will be obvious that the current would pass in opposite directions around their coils, and consequently that the deflections must be in contrary directions. The needles would therefore converge, either above or below their line of centres, as one or other of the pair of keys belonging to each wire was depressed. Fixed stops were so placed on each side of the needles as to limit their motion, and when resting against them, the needles were parallel to two converging lines, at the point of intersection of which a letter was placed. (*Fig.* 3.) This was the signal indicated by the movement of the needles. In a similar manner, as lines were drawn diverging from the centre of each axis, mutually crossing one another, a number of points of intersection were formed, at each of which was a letter or signal. Any of these letters could be indicated by the simultaneous movement of two needles, so that a communication could be carried on with certainty and tolerable rapidity. At the same time a plan was recognised, by which the number of wires requisite for maintaining a communication might be reduced, by using one of them at times as a return wire only, there being no needle in connection with this one. One needle could by the use of this wire be deflected by itself either to the right or left, and thus of course each would furnish two signals, in addition to those formed by its simultaneous deflection with any other. The instruments at the two stations were always rendered reciprocating; that is, at each end of the line were placed an instrument, a set of finger-keys, and a voltaic battery, so that either station could transmit or receive a signal. By an ingenious arrangement, the keys, on being released after depression, were made to resume by themselves the position necessary to enable that which had been the signalling station to become the recipient. By this means messages and answers, or words and their acknowledgments, could follow one another without the necessity for any intervening adjustment of the instruments.

The bell or alarum which was to be rung, when the attention of the clerk at the distant terminus was required, was either direct or indirect in its action. In the first case the attraction exercised by a horse-shoe piece of soft iron, rendered temporarily magnetic by the galvanic current, was made to draw an armature, likewise of soft iron, towards it, and by this action impel a small hammer against a bell. In the second form of alarum, *fig.* 4, the movement of the armature merely released

Fig. 4.



a detent or catch from a train of clock-work driven by a spring or weight. This clock-work, by the intervention of a scape-wheel and pallets, rang the bell as in a common alarum.

In April, 1838, Mr. Cooke obtained a patent for some further improvements in this apparatus. Of these the most prominent was the mode of introduction of the intermediate apparatus. Before the date of these patents, the two stations at the extremities of a line of telegraph had alone been put in communication with each other; but means were now devised by which any number of intermediate instruments might be introduced between the two terminals, and any intelligence rendered simultaneously visible in all or in any of them, as required. Furthermore any one of these instruments could be put in communication with the rest, either generally or in part only; and the same mechanical adjustment which limited the connection of any intermediate instrument to one part of the line, placed its bell in the circuit of the other part. Thus if, while intelligence was being transmitted in one direction from an intermediate station, some message of importance were required to be sent from the terminus, or any other station on the excluded side, the ringing of the bell at the communicating station would warn the attendant to restore his instrument to its intermediate position, and thus leave the line clear throughout.

In the same patent were included some improvements on the mode of protecting and insulating the wires, which were to be laid beneath the earth, in tubes or troughs of wood, iron, earthenware, or other material; and also in the expedients for detecting the exact position of any accident or derangement, without the necessity of uncovering the whole length. Two needles were also shown to be sufficient for carrying on a complete communication with ease and rapidity.

In the course of the ensuing year (1839) Messrs. Cooke and Wheatstone's telegraph was brought into actual operation upon the Great Western Railway, where its capabilities were tested. The results of this trial demonstrated that the undertaking was thus far successful, and that the question of the practicability of the electric telegraph, so long at issue among scientific men, was set at rest.

We must here go back a little, to notice Dr. Steinheil's telegraph, which was erected between Munich and Bogenhausen in 1837. In this instrument, two needles or magnetic bars were placed within an elongated coil of fine wire. These bars were suspended on axes passing transversely across the coil, and in their quiescent position lay parallel to one another and to the sides of the coil. They had their poles placed the same way, so that when a current was transmitted along the wire, they had a tendency to move in the same direction, remaining still parallel to each other. Against the outer end of each needle or bar a stop was placed, which checked its motion on one side, but left it free to turn to the other. The opposite poles of the two bars were therefore prevented from moving out from the coil, under the influence of the deflecting current; and the effect of this arrangement was, that the two bars could not move simultaneously, but only alternately. Both were acted upon alike, but when the inner end of one was free to move outward, the other bar remained pressed against its stop, and was fixed; and on reversing the current, the effects upon the two needles were also reversed; that which was before stationary, now moved forward, while the other was fixed. In order to bring back the needles to their ordinary position, a permanent magnet was fixed near to each at the back of the coil, by the attraction of which the needles were again rendered parallel after the cessation of the deflecting power of the current. The inner ends of these bars carried each a light brass arm, terminating in a cup furnished with a small perforated beak or spout. These cups were filled with printing-ink, which oozed through the beak, and formed a minute bead or drop at its point, which, from its viscid consistence, did not drop off. These beaks were arranged so as to be in the same horizontal line, and at a distance from each other a little less than the width of a strip of paper, which was placed before them. If then a galvanic current were passed through the coil, so that the right-hand needle tended to pass, with the end bearing the cup, out from the coil towards the paper (the cup on the other needle receding as far as the stop would allow, and then remaining fixed), the little beak would just touch the paper, and leave a minute dot of ink on its surface. By reversing the current the other needle would approach and leave a point of ink on the opposite edge of the strip of paper. By the varied number and arrangement of these dots, on one or both edges of the paper, the various letters of any communication were denoted. The paper used in this apparatus, being obtained in a long strip or ribbon, and coiled upon a roller, was made to pass slowly lengthwise before the printing points by a simple application of a weight and cord, which as the printing was effected gradually wound the ribbon upon a second drum or reel. This instrument was also adapted to give audible signals, by the substitution of small knobs for the ink-cups, and of two bells of different tones for the ribbon of paper. One bell being so placed as to be sounded by the first needle, and the other by the second, the pre-concerted combinations of their sounds might indicate various letters to a listener.

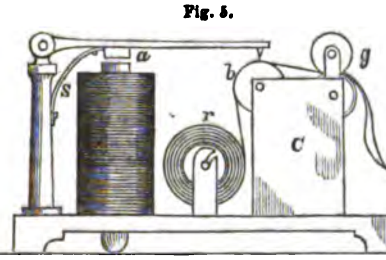
In the construction of his telegraph, Dr. Steinheil made a capital discovery. He found that the conducting power of the earth might be made to occupy the place of the return wire. All that is necessary is, that the wire which connects the two ends of the metallic conductor with the earth, shall be carried to a sufficient depth below the surface so as to be always in contact with moist earth or with water: and that it shall be at this point attached to a plate or other piece of metal, of about two or three feet superficial. For the ordinary Voltaic battery, Dr. Steinheil substituted the magneto-electric machine; in which, according to Faraday's great discovery, the electric current was derived by induction from a permanent magnet.

The electric telegraph invented by Prof. Morse, of America, has led to a large amount of controversy, a claim having been put in for him as the first actual inventor of a practical electric telegraph in 1832, while on board the packet-boat Sully. The Abbé Moigno states that a Mr. Jackson wrote to the Académie Française, affirming that he had, in 1832, communicated this plan to Mr. Morse, while returning together from Europe to America, on board the Sully. Even admitting, however, the claims of either party, it would only show that they did not think sufficiently well of their scheme to enter upon it until nearly three months after the first English patent for an electric telegraph had been sealed, and the practicability of such an apparatus demonstrated in England. The first really official letter on the subject from Professor Morse, is dated September 27, 1837. Cooke and Wheatstone's first patent for an electric telegraph was sealed three months before this, namely, on June 12, 1837. The difference between this telegraph and the preceding suggestions and contrivances was very great. The experiments of these gentlemen had been proceeding for a long time previously, so that when in June, 1837, their patent was obtained, it was not for an arrangement of doubtful practicability, or of a form to be perfected only after repeated trial. On the contrary it was, within a few months after the date of the patent, put up and brought into actual and daily use. Some of its details have since been simplified, and the modes in which the electric current is made to give the required indications have been greatly varied; but the great features and principles of their first invention remain unchanged, and not only so, but they form an essential part of nearly if not quite all the later telegraphs of other inventors.

The telegraph exhibited by Morse in September, 1837, was essentially a registering instrument, the various signals being traced on a strip of paper. The plan appears to have been the following:—an electro-magnet was so placed as to be within attracting distance of an armature fixed to the shorter arm of a lever, of which the longer end carried a pencil projecting sideways from it, and pressed lightly against a sheet of paper. This paper, by a contrivance analogous to that of Dr. Steinheil, was made to travel slowly beneath the pencil. So long as no attractive power was exerted by the electro-magnet, the pencil would continue to trace a straight line as the paper moved onwards; but on momentarily making the circuit with the battery, the armature was drawn to the electro-magnet, and the pencil, carried by the arm of the lever upwards, made an angular mark, like the letter V reversed, on the paper. These angles might either be joined in groups, by rapidly succeeding completions of the circuit, or they might be separated by longer or shorter spaces of straight line. The nine digits were represented by corresponding numbers of angles, and these were combined so as to form all possible numbers. A short space intervening between two or more successive groups, denoted that they must be taken together to form a total of two or more places of digits; while a longer space showed the actual completion of one number and the commencement of the next. All the necessary words were represented by various numbers, as arbitrary signs, a previously arranged dictionary being used for their interpretation. This plan had also been proposed by Mr. Ronalds, to simplify the working of his telegraph.

In the telegraph erected by Professor Morse, in 1844, between Baltimore and Washington, a different mode of recording the signals was adopted. The use of the pencil was found objectionable, from its so frequently requiring fresh pointing, and from the risk of breakage. The same arrangements were retained in regard to the paper, but it was made in its course to pass over a roller having a groove around it. The long arm of the lever carried a blunt steel point, standing over the groove in the roller. When therefore the arm of the lever was depressed, by the attraction of the magnet upon the armature, the steel point pressed the paper into the groove, and produced an indentation. If the attraction were momentary, a depressed point was produced; but if the action were continued for a longer time, a lengthened depression was the result, as the paper was drawn on. The combinations of these two kinds of marks denoted the various letters and figures. Thus, dot and dash . — is taken to signify *a*; — . . . to signify *b*; — . — . for *c*; — . . *d*; . for *e*; and so on. This is called the dot and dash code. *Fig.* 5 shows the arrangement of what is

Fig. 5.

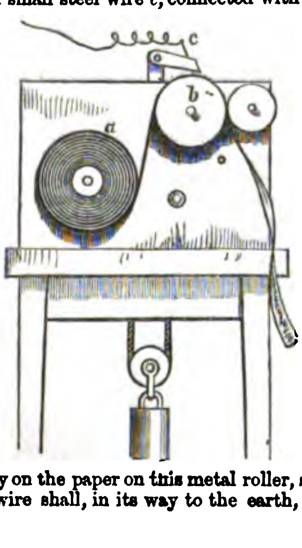


called the *symbol-printing* telegraph: *a* is the armature attached to the lever which carries the steel point. The ribbon of paper is drawn slowly off from its roller *r*, by a train of clockwork in the box c, which drives two gripping rollers *g*. In its passage the paper goes over a brass roller *b*, containing the groove. If while the paper is thus being drawn over the roller *b*, the clerk at the communicating station were by means of a common telegraph key or handle to transmit the current for an instant, the armature would be momentarily drawn down, and the steel point would mark the paper with a depressed dot. The spring *s* would raise the arm the moment the magnet had ceased to act. But if, instead of transmitting only a momentary current the communicating clerk were to continue the transmission for a short time, the arm would be pulled down during that time, and the point would indent a line in the paper.

In July, 1838, Mr. Edward Davy obtained a patent for improvements in apparatus for making telegraphic signals by means of electric currents. The principal feature in this patent is a *chemically marking* telegraph, in which a local circuit (completed by galvanometer needles acted on by the line circuit, and forming the basis of what is called the *relay system*) marks chemically prepared paper, which is moved forward by clockwork released by an electric magnet. Two line wires are used to convey the electric current and one return wire, with a battery and two galvanometers (deflecting opposite ways) to each wire; the battery to the return wire giving a preponderance to currents through that wire, twelve different signals can thus be produced. The action is as follows: on one or more of six keys being pressed down, either two or three of the galvanometers act; and as the three wires admit of the current proceeding in either direction through them, it can complete either two or three out of the six circuits of the local battery; thus marking longitudinally properly prepared paper at two or three out of six places. The clock-work escapement for moving the paper a sufficient distance between the signals, consists of two levers, one of which carries the armature, and works on a horizontal axis carried by the other lever. When the armature is attracted, it releases a pin from a notched fly vane, and enables it to move half a revolution; and when the current ceases, the pin is again removed, and replaced by lateral motion given to the second lever by a wheel pressing against a projection on it. Calico "impregnated with hydriodate of potash and muriate of lime," is preferably used to receive the marks or signals.

We may here state in more precise terms the principle of the *chemical printing* telegraph. A train of clockwork is used to keep a ribbon of paper constantly unwinding from a drum, and passing over a metal roller *b*, *fig.* 6. A small steel wire *c*, connected with the wire from the

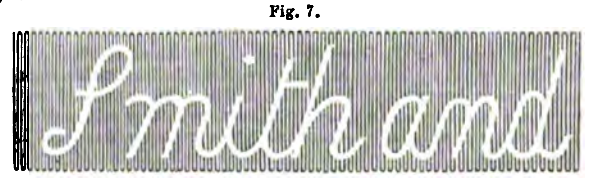
Fig. 6.



line, presses lightly on the paper on this metal roller, so that any current sent through the wire shall, in its way to the earth, pass through the steel wire *c*, through the paper strip, to the roller *b*. This paper being chemically prepared with a colourless solution, is coloured when decomposed by the passage of an electric current through it. In this way, by regulating the duration of the current, the paper can be stained in dots and lines, as in the symbol-printing arrangement.

An ingenious modification of the chemical printing telegraph was made in the *writing telegraph*. It is evident that if, instead of employing a long ribbon of paper, enough of it were taken to pass once round the roller *b*, and if this roller not only rotated on its axis, but was also by means of a screw made to advance slowly from side to side as it rotated, the steel wire would trace on the paper a spiral line. If also, instead of communicating by a key, there were at the other end another roller, exactly like *b*, and which by means of clockwork could be turned at precisely the same speed as *b*, and with the same rate of shift endwise, then a tracer, resting on this second roller would, if the current were kept continually passing, trace precisely the same spiral as the wire on the first roller *b*. But supposing the current only to be maintained by the pressure of this tracer against the metal roller, and if the surface of the roller were partly covered with a non-conducting material, such as shell-lac or resin, the tracer in passing over this as the roller turned round, would cease to make its stained mark, but it would begin to mark again as soon as the tracer had come upon the metal. In using this machine the words of the message are written on a slip of tin-foil in a non-conducting varnish. As soon as this is dry, the tin-foil is wrapped round the tracer roller, and the tracer being made to bear upon it, the two rollers, one at the communicating and the other at the receiving station, are started at the same moment. Then, while the tracer rests on the tin-foil, the wire on the roller *b* will continue to make its stained spiral line on the prepared paper; but whenever in its passage the tracer rests on a piece of the varnished writing, the current will be broken, and the spirals traced by the steel wire will be interrupted; which interruptions will evidently coincide with the writing which has passed under the tracer; so that on taking the paper off the roller, there will be a fac-simile of the original writing in clear spaces left free from the parallel lines traced close together over every other part of the paper. This fac-simile will appear like *fig.* 7.

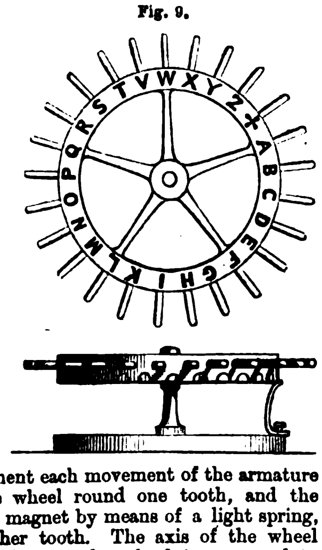
Fig. 7.



In January, 1840, and in July, 1841, Professor Wheatstone obtained two important patents, the first of which was in connection with Mr. Cooke. The *electro-magnetic* telegraph may be regarded as a variation of the alarum; but instead of the detent, there are two light spring pieces, shown in *fig.* 8, one with a hook-shaped end, and the other an obtuse wedge or pushing piece (known as a *clawker and driver*), and instead of the catch-wheel of the alarum, there is a light escape-

Fig. 8.

Fig. 9.



ment wheel. Under this arrangement each movement of the armature towards the magnet will pull the wheel round one tooth, and the motion of the armature from the magnet by means of a light spring, will push the wheel round another tooth. The axis of the wheel carries a light index hand, which points as the wheel turns round to the various letters arranged near the edge of a disc. The currents which work this telegraph are sent by means of a *communicator*, *fig.* 9, consisting of a brass disc turning freely on its centre, and marked with letters, as in the disc, *fig.* 8. Opposite each alternate letter, the brass is cut away, and a small notch of ivory inserted, so that on turning round the disc a metal spring, which bears against its edge, rests alternately on the conducting brass and the non-conducting ivory, whereby the current is alternately transmitted and interrupted. A radiating arm proceeds from each letter for the convenience of turning the disc. If the disc stand so that its stop-mark + be opposite to a fixed mark, the spring is resting on an ivory piece, and if at the same moment the index of the distant telegraph in connection with it be also pointing to the +, then on moving the communicator one step forward, so that the letter A comes to the fixed mark, the current will be transmitted along the wire, the electro-magnet, *fig.* 8, will draw down its armature so as to pull the wheel one tooth forward, and make its index also point to the letter A. On again moving the communicator so that the index points to B, the current is interrupted, the armature of the distant telegraph falls back, pushing the wheel round another tooth, and bringing its index also to B. In this way the index may be moved step by step to different letters so as to spell out a word or message, which word or message will be repeated on the disc of the distant telegraph. A slight pause is made after each letter of the message, to insure certainty; numerous modifications have been made in this machine, for increasing the rapidity of its action. An addition of printing mechanism to this instrument forms the *type-printing* telegraph. In this the escapement axis, instead of carrying a fixed disc, has light radiating arms of steel, at the ends of which are printing-types *a*, *figs.* 10, 11. In front of the types is a small roller or

Fig. 10.

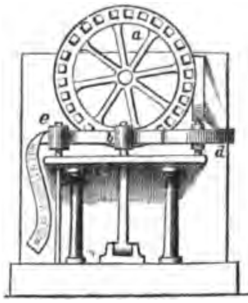


Fig. 11.

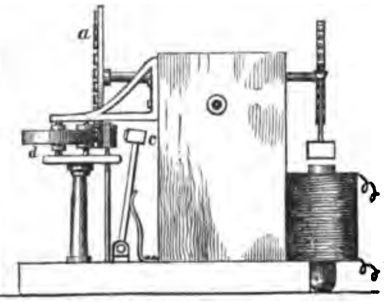

plate *b*, for receiving the blow of a printing-hammer *c*, which stands behind the type disc. The paper which receives the impression is placed between the roller and the type disc, which paper is coiled on the roller *d*, and is drawn off by passing between two other rollers *e*, which hold the paper tightly and turn a little way round after each blow of the hammer.

The action is as follows:—The type-disc is turned round by alternately transmitting and interrupting the current until the proper letter is brought into the proper position to be struck, when, the hammer being released, it presses the type on the paper. The drawing-rollers immediately jerk the papers forward through a space equal to that of one letter, when the type-disc is again moved onward to the next letter required, which is struck in like manner, and so with all the rest of the letters in the message. The hammer usually strikes by the force of a spring, which is released by the train which acts upon the drawing-rollers. The mechanism is so contrived that the hammer cannot strike while the type-disc is in motion, but falls as soon as a pause is made, that is, when the right letter is brought into position. The types are inked by means of a small roller smeared with printing-ink, which, as the type-disc revolves, presses lightly against their surfaces. Or a ribbon of carbonic ink transfer-paper may be drawn round between the type-disc and the white paper ribbon. Numerous variations have been made in the type-printing telegraph, the best known of which is by Mr. Bain. In this machine the types were arranged on the edge of the disc or wheel, radiating from its centre; and the printing of any one upon the cylinder was effected by the movement forward of the entire type-wheel and its axis, by a crank and connecting gear in the printing train, instead of one punch or type only being struck down by the printing-hammer, in impressing a signal. It was also proposed to use two clocks at the two communicating stations, to rotate the type-wheels with a uniform motion. These clocks, having been adjusted to exactly the same rate, and being started from the same signal, would bring continually, at each station, similar type opposite to the paper-cylinders at the same moment. The action of this part of the apparatus is exactly analogous to that of Mr. Ronalds', already described. A hand or index revolving on a dial in front of the machine, at the same rate as the type-wheel, indicates to the operator the signals which are successively in a position ready for printing in his own instrument, and therefore, if the clocks go accurately together, in a similar position in his correspondent's instrument. At the same time this hand, by coming in contact in its revolution with a pin, placed by the operator opposite to any signal that he wishes to print, completes the electric circuit at this moment, and by so doing stops the type-wheel, and releases the printing-train at each station. A similar figure having thus been impressed on the cylinder at the two ends of the line, the operator removes the pin, and replaces it opposite the next signal he requires to send. The moment the pin is removed, and the circuit therefore broken, the hands and type-wheels at each station resume their evolutions which are again checked by the contact of the hand and pin as before. It should be stated that the idea of the two clocks, as well as that of the printing-telegraph, was borrowed from Wheatstone.

Bain's *single-index* telegraph, which was the instrument proposed by him for practical use, consisted of two hollow cylindrical coils of wire, placed horizontally a short distance apart, with their axes in the same line. Between them a small bar-magnet was fixed across a delicate spring, which in front passed through the dial-plate of the instrument, and was turned up to form an index. The two coils were connected, so that an electric current entering from the line wire would pass through both. When this was the case, the bar-magnet would be attracted towards one coil, while at the same time it would be repelled by the other. These actions tended to carry the magnet to the same side, as far as the spring to which it was attached and a fixed stop would allow of its moving. The reversal of the current inverted the effects of the coils, and the magnet would then pass to the other side. The combinations of these two movements represented the various letters and signals, they being denoted to the observer by the index on the dial of the instrument. The movement of the index to the left denoting the letter I, and to the right the letter V, this instrument obtained the name of 'I and V Telegraph.'

In 1842, Mr. Bain patented his proposed plan for working an electric telegraph by means of an *earth battery.* At one end of the line he buried in moist earth a large plate of zinc, and at the other end a plate of copper, iron, or other substance such as coke or charcoal, which might act the part of a negative plate to the zinc. Then, on connecting these distant plates with a wire insulated from the earth, a current of electricity would constantly pass from the one plate to the other. Indeed, the distant plates connected with the wire, as above described, may be regarded merely as a battery of one pair of plates, separated by a very wide interval of exciting material, represented by the earth. It was at first supposed by Mr. Bain that this current would be applicable to all telegraphic purposes, but subsequent experiments showed that it was available only for a few miles of distance; its intensity not being sufficient to enable it to travel through any great length of wire. In some cases, where a constant current of low intensity is required, this earth battery might be of use.

In 1843, Mr. Cooke introduced the mode of extending the wires between distant places, so that their insulation from one another, and from the earth, might be maintained without the expense and difficulty hitherto incurred; before this period the wires having been covered with cotton, and insulated by coating them with shell-lac, resin, or pitch, had been laid down in pipes of wood or iron. It was now proposed to insulate the wires by suspending them in the air upon posts or standards of wood or iron, the wires not coming in actual contact with any part of the standard, but passing through rings of porcelain or earthenware. [Glass was afterwards found to be the best insulator.] The standards were usually fixed at from forty to sixty yards asunder, and at each quarter of a mile a stouter post was placed, to bear the winding or straining apparatus. This was a simple winding-reel, connected with a ratchet-wheel and click to prevent its recoil, after the wire had been strained up by its means. The intermediate posts within each quarter of a mile only supported the wire, without reference to its tension, which depended solely on the winding posts. Instead of the copper wires hitherto employed, iron wires of a larger size were now used. By the adoption of this method of extending the conducting wires, the cost of construction of an electric telegraph was reduced nearly one-half, and at the same time the risk of imperfect insulation was diminished. So long as the wires were buried in tubes beneath the ground, it was always deemed prudent to add a return wire, extending from one end of the line to the other; as it was found very difficult to render the insulation sufficiently good to enable the earth itself to be used as half of the circuit. The tendency of the electric fluid to escape from the wires in the tubes to the earth, was much greater than to another wire lying in the same tube, so that the latter plan was always adopted. But when the suspended conductors came into operation, the insulation was rendered so complete, that the earth was subsequently in all cases used to return the current, by which means an economy of one wire throughout the whole line was effected. In addition to this, another advantage was gained by the suspension of the wires, in the facility with which accidental errors or injuries were discovered and rectified. While the tubes were in use, it was necessary to supply, at about each quarter of a mile along the line, a proving or testing post, within which the wires were brought up to a box, so as to afford the means of examining any of them as to their insulation and conducting power. For this purpose, Mr. Cooke had invented an instrument called the *detector*, by which the perfect state of each wire could be tested, and the position of any error or fault discovered with considerable accuracy. Still, with all these appliances, the detection and repair of any derangement of the wires demanded considerable skill, and led to no small expense. But when the wires were in sight throughout, any contact or fracture was at once visible, and was easily and quickly repaired.

We must here pause in the attempt to trace the history of this great invention through the medium of its patents. The reader who is desirous of pursuing the subject in this way, is referred to one of the valuable volumes printed by order of the Commissioners of Patents, entitled 'Abridgments of Specifications relating to Electricity and Magnetism, their Generation and Applications' (1859). This volume contains an introduction of xciii. pages, and an abstract of patents extending to 728 pages, exclusive of a copious index. A single specimen of this index will show the extent of patent influence that has been exerted down to the year 1857. For example: under 'Telegraphs' (Electric), we have for acoustic telegraphs, 14 patents; copying telegraphs, 8; dial telegraphs, 68; embossing, 1; gold leaf, 2; magneto-electric, 23; marking, 33; needle, 39; pointer, 32; portable, 7; printing, 44; and recording telegraphs, 5 patents; while the component parts of electric telegraphs are the subjects of separate patents under distinct heads, such as alarums, telegraphic, 76 patents; insulators, 42 patents; galvanic batteries, nearly three columns of names.

It is not, however, too much to say, that amidst this formidable list of patentees in our own country, without referring to claimants in Europe and America, there are but a very few names—perhaps only one name—that posterity will care to remember in connection with the practical working of the electric telegraph. Although the principal facts necessary to the construction of an electric telegraph had been known, as we have seen, ever since 1821, yet it was not until the general establishment of railways that telegraphic wires could be safely carried to any great distance. Moreover, the importance of the invention was by no means understood. The government was satisfied with the working of the semaphore; railway directors looked upon the electric telegraph as a new-fangled invention, and the public was not yet alive to its innumerable advantages. One fact, however, must be insisted on, namely, that to this country belongs the honour of this great invention; that in the year 1837 a needle telegraph had been invented, so complete, and at the same time so simple in its operation, that it could be worked by any one who knew how to read; that in June of that year the patent for this telegraph had been sealed, and, a month later, the wires were laid down between the Euston Square and Camden Town Stations of the North-Western Railway, a distance of a mile and a quarter, and that on the 25th of July messages were actually sent between these two stations, Professor Wheatstone being in the Euston Square Station, and Mr. Cooke in that at Camden Town, the witnesses being the engineers, Messrs. Fox and Stephenson. Now, it is quite true that M. Arago claimed, before the French Academy of Sciences, for M. Steinheil the precedence in this matter, inasmuch as he had his telegraph in operation on the 19th of July, 1837; but it must be remembered that Wheatstone's patent was taken out in the June of that year, and was based on numerous previous successful experiments; whereas Steinheil published no description of his instrument until August, 1838, and it is admitted that in the interval he had altered and amended his instrument, and soon afterwards abandoned it for a modification of one by Morse. The claim of the last-named gentleman we have already disposed of. In September, 1837, he exhibited an imperfect instrument, although he afterwards succeeded in producing one of first-rate excellence, which is still largely used in the United States of North America.

But to return to Cooke and Wheatstone's telegraph: it received notice to quit the London and Birmingham line, but Mr. Brunel gave the patentees permission in 1839 to lay it down on the Great Western Railway. This was first done as far as West Drayton (13 miles), and it was afterwards extended to Slough (18 miles), the wires in both these preliminary trials being inclosed in iron tubes laid on the ground. On proposing to extend this line to Bristol, much opposition was offered by the directors, and the telegraph again had notice to quit. But on the proposal of Mr. Cooke to retain the line of wires at his own expense, he was permitted to do so, on condition of transmitting the railway signals free of charge, and of extending the line to Slough. In return for this favour, he was allowed to transmit messages for the public, which was accordingly done, one shilling being charged for a message; but the public did not avail themselves much of the new instrument, and its value was scarcely appreciated until the 3rd of January, 1845, when it was used to convey a message to the London police, directing them to arrest Tawell on a charge of murder, the message flashing past the criminal while he was travelling express to escape the consequences of his crime. By the end of 1845 upwards of 500 miles of telegraph were in operation in this country. In 1846 the Electric Telegraph Company commenced their operations with a considerable capital, a large portion of which was expended in the purchase of Wheatstone and Cooke's patents, and the system which they had introduced became rapidly extended. In due time other telegraph companies were competing with the original company, the system spread over Europe, and soon no railway was deemed complete without its telegraphic wires. In the United States of America the telegraphic system is far more complete and extensive than in the Old World; but the telegraph wires are for the most part independent of the railways, and hence, it is said, arises the larger number of railway accidents in that country. But the telegraphic system could not be regarded as complete while nations separated from each other by seas and oceans remained unconnected by the electric wire. So long back as 1840, Mr. Wheatstone stated to a parliamentary committee his conviction of the practicability of uniting Dover to Calais by means of a telegraphic wire, and two years later he had made arrangements for a line across Portsmouth Harbour, although circumstances over which he had no control prevented its being carried out. About this time the introduction of gutta percha offered itself as an excellent insulating material for the wire, and its first application was made in 1847, by Lieut. Siemens, of the Prussian artillery, for a line across the Rhine at Cologne. The first submarine wire was laid down in August, 1850, by the "Submarine Telegraph Company," between Dover and Cape Grisnez, near Calais. It was a copper wire inclosed in gutta percha. About 27 miles of it were conveyed on board the Goliath steam-tug, and wound round a large iron drum to facilitate the paying out. The end of the wire attached to the land was conveyed to the South-Eastern Railway Terminus, and the vessel started from Dover, paying out the wire, and attaching pieces of lead to it at intervals to assist it in sinking. Electric communication was kept up hourly. At length the vessel came to an anchor off Cape Grisnez, and the end of the wire was sent ashore in a boat. Several messages were passed between the two shores during the day; but on attempting to resume the correspondence next morning, no answer could be obtained. It was ascertained that the wire had snapped asunder; but the experiment proved the possibility of connecting England with the Continent by means of a submarine electric cable. In the following year a stronger cable was laid successfully, and has continued to work down to the present time, notwithstanding occasional injuries from the anchors of ships and boats. In 1851 and 1853 lines were laid between England and Ireland and England and Belgium. In 1853 a line was laid from Orfordness to Schevening in Holland; in fact four separate cables were laid, each containing one conducting wire, so that the injury to one line might not interfere with the working of the others. In the same year a line was laid across the Solent, from Hurst Castle to Yarmouth, in the Isle of Wight. The first line of considerable length, however, was that laid in 1855 between Balaklava and Varna, during the Crimean war. This line was 310 miles in length, and consisted of a copper wire covered with gutta percha, except at the shore ends, which were protected by iron wire. This line was laid by Messrs. Newall, and it remained in good order for some months, until the end of the war, when it was broken. This temporary success of the Black Sea Telegraph led to the formation of the Atlantic Telegraph Company. The attempt made by this company to lay a line to America in 1857 failed from the breaking of the cable after about 335 miles had been payed out. Another attempt in 1858 was apparently successful, and messages were exchanged during three weeks between Valencia, in Ireland, and Newfoundland; but the signals became variable and feeble, and at length ceased altogether. And thus was lost 3000 miles of cable, and 375,000*l*. sterling, for the value of the cable can scarcely exceed the expense of lifting it, and therefore its recovery will not probably be attempted. It is now proposed to alter the route for this line, and to carry a cable by way of Greenland to America. In 1854 the Mediterranean Telegraph Company laid down wires between Spezzia and Corsica, and between Bonifacio and Sardinia, and from thence in 1855 to Algeria. This last cable seems to have failed. In 1857 the British government agreed to assist the company in the construction of a line from Cagliari to Malta, and thence to Corfu. This line has been unfortunate. Another line from Portland to the Channel Islands has met with several accidents, and the experience with it, as well as with the Red Sea and India telegraph cable, show the wisdom of the Report made by the Board of Trade, that our knowledge in 1859 was not such as to justify the submerging of another deep sea cable, without further experiments being made; and they recommended the appointment of a committee to investigate the subject. A committee was accordingly appointed, and from the connection with it of such men as Professor Wheatstone, Mr. E. L. Clarke, and Mr. Varley, we should hope for a great increase of our knowledge on the subject. While we are writing, a case is under investigation which shows the necessity for this inquiry. A cable manufactured for the government for the purpose of connecting Falmouth with Gibraltar, had its destination changed in the spring of 1860 to a projected line from Rangoon to Singapore. In order to preserve the cable, it was placed in water-tanks, but when transferred on board the ship which was to convey it to India, it was coiled dry, and the moisture imbibed by the hemp, being gradually squeezed out, caused the iron covering to rust; and as this process of rusting generates heat enough to soften the gutta percha, the safety of the cable became endangered, so that it had to be again taken out of the ship and deposited in tanks.

The practical working of a telegraph involves such a multiplicity of details, that we cannot attempt in an article of this kind to convey much minute information. Still, however, there are certain prominent features which a reader moderately acquainted with electrical science will readily understand. An electric telegraph, whether for land or sea, consists of three essential parts: 1st, the *transmitting apparatus*, for generating electric action at one end, known as the *sender*; 2ndly, an electrode or insulated path along which the electricity may travel, and familiarly known as the *line* or the *wire*, or, in the submarine telegraph, the *cable*; 3rdly, the apparatus used at the other end of the line to render evident the signals forwarded by the transmitting apparatus: this is called the *receiving apparatus* or *instrument*, or simply the *instrument*.

And first as to the transmitting apparatus. This is usually a voltaic battery, consisting of alternate pairs of copper and amalgamated zinc plates, arranged in troughs of some compact wood made tight with marine glue, subdivided into compartments by means of slate, or the troughs are of glazed gutta percha. Each compartment contains the copper of one pair and the zinc of the next. [GALVANIC BATTERY.]

After the plates have been introduced, the compartments are filled with sand, which is moistened with dilute sulphuric acid (1 strong acid to 15 water). This arrangement diminishes the risk of leakage, and lessens the amount of evaporation. The acid has to be renewed once in ten or fourteen days, according to the amount of work performed by the telegraph. In the Electric Telegraph Company's central office at Lothbury the batteries are contained in two long narrow chambers in the basement of the building. There are upwards of sixty Daniell's batteries at work: they take rank as sixes, twelves, and twenty-fours, according to the number of their elements or plates, the twenty-fours working the longer lines, and the smaller batteries the shorter circuits. A twenty-four, when in full work, requires only a gill of dilute sulphuric acid per month, and its zinc plates last three months. Other batteries require 1 lb. of sulphate of copper per month, with a little sulphate of zinc or salt and water. The entire amount of electric power employed by this company throughout the country is said, on the authority of an article in the 'Quarterly Review' (1854), to be produced by 8000 twelve-plate batteries, or 96,000 cells, which are lined with 1,500,000 square inches of copper, and about the same of zinc. To work these batteries, 6 tons of acid and 55 tons of sand are required every year. When a distant station-clerk finds by the weak action of his needles that the battery is not up to its work, he sends word that it requires "refreshment," and it is accordingly served with its gill of sulphuric acid.

Another form of battery which continues in action for a considerable time consists of plates of amalgamated zinc and gas coke excited by solid sulphate of mercury moistened with water; they are arranged in compartments as in the sand battery.

Some lines are worked by means of the magneto-electric machine. [MAGNETO-ELECTRICITY.] The Atlantic cable during a portion of its brief existence was worked by a secondary current. An electric cable sunk in water is apt to become charged with electricity after the manner of a Leyden jar, and so to resist the passage of the current along its central conducting wire. The idea was, that by using a secondary current it would by its pulsations displace the charge, and allow the current to be transmitted. Mr. Whitehouse fed his double induction coils by means of what he calls a "perpetual maintenance battery." This battery consists of large plates of platinized silver, and amalgamated zinc, mounted in cells of gutta percha. There are several plates, both of silver and zinc, in each cell; but all the zinc plates rest upon a longitudinal bar of metal at the bottom of the cell, and all the silver plates hang upon a similar bar at the top of the cell, so that thus there is virtually but a single stretch of silver, and a single stretch of zinc in operation. This arrangement is made because it enables any portion of either silver or zinc to be removed for repair or renewal without stopping for a moment the operation of the battery. As any one lamina becomes imperfect, it can be taken out from its groove, and replaced. Each cell contains two thousand square inches of acting surface, and is charged with the usual mixture of acid and water, and there are ten such cells in the battery. This combination is so powerful that when the broad strips of copper plate which form the polar extensions are brought into contact or separated, brilliant flashes are produced, accompanied by a loud crackling sound. The points of large pliers are made red-hot in five seconds when placed between them, and iron screws burn with vivid scintillation. These brilliant effects are, however, produced at the expense of the apparatus; the metallic surfaces from which they are emitted rapidly burning away during their continuance. In order to alleviate this injurious effect, contact is made and broken, during the transmission of electrical signals, by means of a key presenting a very large surface of metal. A horizontal bar, flattened at the top, turns backwards and forwards pivot-ways, and tilts its edges against twenty flat brass springs resembling in form the keys of a piano-forte, ten being on each side. A constant slight leak of the current is also continuously maintained through a coil of platinum wire placed in water. By this contrivance the injurious force of the spark is pretty well absorbed and destroyed. The cost of maintaining this magnificent battery at work is said not to exceed a shilling per hour.

But for the reason above stated the voltaic current is by no means a fleet messenger compared with other agents which are at the command of the electrician. Consequently it is not the electric stream generated in this powerful battery which was designed to be actually sent across the Atlantic on the performance of telegraph service. This primary power is only used to call up and stimulate the energy of a more speedy traveller. The voltaic current, generated in the battery, is transmitted to induction coils, arranged in pairs, each coil being arranged as in Ruhmkorff's apparatus, a figure of which is given under MAGNETO-ELECTRICITY, col. 428. It is the secondary current induced by this apparatus which it was proposed should perform the work of rushing across the Atlantic. This independent secondary current was therefore the *transmission current*, and the coil in which it was produced was properly the *transmission coil*. The coils were used in pairs, because each one inductively increases the power of its neighbour, and in return has its own energy inductively increased as well. The great heating power of the battery-current is rendered harmless by the size and extent of the primary coil through which it is passed. If at any time, by accident, the current should find a short course for itself in consequence of the silk covering of the wire being injured, the accident is immediately indicated by the rapid rise of the temperature of the coil. The transmission-current necessarily gets considerably weakened when it has passed through a distance of 1800 or 1900 miles. Consequently this weakened current was not to be immediately employed to print or record the signals transmitted. The weakened transmission-current was merely caused to open and close the outlet of a fresh battery destined to do the printing or recording labour. The strand of the Atlantic cable was continued into a coil of fine wire, wound about a bar of soft iron. When the transmission-current flowed through the coil, the bar became a temporary magnet, which had the direction of its polarity determined by the nature of the current (positive or negative) sent through the coil. The pole which is north when the transmission-current is positive, becomes south when the transmission-current is negative. Near to the temporary magnet a permanent magnet was so placed that it could traverse backwards and forwards upon a pivot as it was actuated by the temporary magnet. The north pole of the permanent magnet was attracted by the south pole of the temporary one, and *vice versâ*; so that as the polarity of the temporary magnet was reversed, the permanent magnet was made to traverse. When it traversed one way, it opened the outlet of the local battery by effecting a contact, and caused it to print; when it traversed the other way it shut off the current of the local battery, so that it ceased to print.

It was the peculiar advantage of this relay-instrument (as it is called) that the temporary magnet had no other work to do than to turn the permanent magnet upon its almost frictionless pivot. It had no spring to overcome, such as is more commonly employed in this class of instruments. The arrangement was so sensitive that the apparatus could be put in action by a fragment of zinc and a sixpence pressed against the tongue. These relays might indeed be ordinarily heard clicking backwards and forwards, and working automatically when the large induction-coils were in operation within a few feet of them, actually doing a little business on their own account, although not in communication with any current, and transmitting the same signals and messages as those which were being forwarded through the agency of the induction-coils. As the poles of the induction-coil magnets were reversed, the poles of the relay-magnets were actuated different ways. Mr. Whitehouse made the instruments even more delicate by applying a second permanent magnet, so that it could be made by a screw-adjustment to increase or diminish the attraction acting on the working magnet, either way. When the printing battery was brought into operation by the relay, it delivered its message by the agency of one of Professor Morse's printing instruments already described.

Professor W. Thomson, in commenting on the above arrangement ('Encyc. Brit.,' art. 'Electric Telegraph'), prefers the voltaic battery to any other source of electricity "for all great telegraphic work;" and he expresses his conviction—somewhat boldly, we think,—that "if no induction coils and no battery power, either positive or exceeding 20 cells of Daniell's negative, had ever been applied to the cable since the landing of its ends, imperfect as it then was, it would be now in full work day and night, with no prospect or probability of failure."

Secondly, as to the *line*.—In most parts of England the wires, as from the commencement of the system in this country, are supported on poles at a height of several feet from the ground; but in a few cases, such as along the mail-coach road from London to Dover, a subterranean arrangement has been adopted: the wires being encased in a wooden trough, and deposited a foot or two beneath the surface of the ground. This arrangement is also adopted in the streets of London, and of other large towns. It has also been adopted by the English and Irish Magnetic Company, on a great extent of their lines; and it is that adopted in Prussia. The wires from the central station in London are insulated by being wrapped with cotton thread, and coated with a mixture of tar, resin, and grease, or gutta percha is used in preference. Nine such wires are packed in a half-inch leaden pipe, and four or five such pipes are packed in an iron pipe about 3 inches in diameter, which pipes are laid under the foot-pavements, and are thus conducted to the terminal stations of various railways. Testing-posts are placed at intervals along the streets, by which any failure can be detected and the locality of the defective wire ascertained at least within the distance of two posts. The London District Telegraph Company do not bury their wires, but are now engaged in weaving a metallic web over the tops of our houses.

The exposed conducting wires which run along the side of a railway are of galvanised iron, about the sixth of an inch in diameter. The higher price of copper prevents it from being employed, although this metal is a much better conductor of electricity than iron. When a great length of wire is to be stretched between two distant points, without immediate support, steel wire is sometimes used. The galvanised iron wire, in the neighbourhood of large manufacturing towns, is liable to be attacked by the sulphur acids of the smoke, and the zinc being converted into a soluble sulphate is washed off by the rain, and the iron wire becomes quickly corroded. We have already spoken of the earthenware or glass insulators attached to the posts, for supporting the wire. An insulator should not only be a non-conductor, but it should throw off the rain quickly and completely, otherwise the moisture will form a conductor to the earth; indeed, the dripping of wet from one line to another below it, will sometimes turn away the current from its work. Wet and foggy weather always has the effect of diminishing the current and requiring greater battery power; unless, indeed, the plan should be adopted of *switching* the line, that is, instead of sending a message along a direct line, where the wires are enveloped in rain or damp fog, or are otherwise "sick" as it is called, the line is switched on to another and more circuitous route, where the wires are in good working order. Spiders' threads covered with dew sometimes divert the current, as does also atmospheric electricity. Indeed, a thunder-storm was formerly a source of danger to the telegraph clerks. Professor Loomis says that the telegraphic wires are very sensitive to an approaching storm, and often become highly charged, even when the storm is so distant that the thunder cannot be heard nor the lightning seen. Under such circumstances, if one stand in the room of a telegraphic station, and place one hand upon a telegraphic wire, and rest the other on the wire which communicates with the earth, a sharp shock is felt in the arms, and sometimes across the breast. This shock is very painful; although when the two wires are brought within striking distance of each other, only a faint spark is to be seen. But when the thunder-cloud is near, such experiments are dangerous. In such case, a thunder-cloud passing over the wires may charge them to such an extent that the electricity may fuse the thin wire of the electro-magnet, and render the magnet itself unserviceable. On some occasions an explosion takes place in the telegraph-room sufficient to fuse thick wires, and to expose the clerks to considerable danger. A weak charge of atmospheric electricity has the same effect on the wires as the current of a voltaic battery; it makes a point in the telegraphic register. If, however, a storm pass over the wires, these points become numerous; and as they show themselves between the points of a telegraphic message, they make the writing indistinct, and often illegible, so that on such occasions the clerks usually suspend their labours. Various contrivances have been made for drawing off electricity from the wires, without disturbing the current, advantage being taken of the tension of the former, which gives it a striking distance not possessed by the latter. In addition to atmospheric electricity the line is liable to be disturbed by what are called "earth currents." If both ends of a long wire be connected with the earth, currents will pass through the line apparently in consequence of variations in the electrical condition of the earth in different places. Mr. Varley has observed that these currents are continually flowing about the earth in one direction or another throughout the day, and reach a maximum about 2·40 P.M. During magnetic storms or the aurora borealis, currents are sufficiently strong to interrupt the working of the lines: they flow sometimes in one direction, sometimes in another, and often change their direction in a few seconds.

But if in land lines the insulation of the wires is attended with difficulty, the insulation is very much more difficult and uncertain in carrying a cable through great lengths of ocean. In transmitting a current along an insulated land line connected with the earth at one end, and with a battery communicating with the earth at the other, the strength of the current diminishes in an inverse ratio to the length of the wire. When, however, the conducting wire is wrapped up in an insulating material and immersed in water, we have the three parts of a Leyden jar, namely, the wire takes the place of the inner metallic coating, the gutta percha that of the insulating glass, and the iron wire covering or the water that of the outer coating, so that not only does the strength of the current diminish inversely as the length, but the arrangement must be discharged before a message can be sent, and the rate of signalling must depend ultimately on the rapidity with which the charge and discharge can be effected.

But there are mechanical difficulties arising from the materials employed. The copper conducting wire is deficient in strength, and a moderate strain put upon it may produce a permanent elongation: while the materials which envelope it, being more elastic, return to their original bulk when the strain is removed, the elongated copper does not do so, but will thus cut its way through the gutta percha cover. The copper wire is usually made into a strand for the sake of strength, and it has even been proposed to cover the copper with fine steel wires before putting on the gutta percha, so that the chief strength of the cable might be in its core. Copper wire is preferred on account of its superior conducting power for electricity, which is seven times greater than that of iron. But this superiority is greatly dependent on the purity of the copper. No substance added to copper increases its conducting power; but the presence of other metals may reduce its conducting power below that of iron. The conducting power of copper also varies with the temperature.

Gutta percha is also subject to various changes which interfere with its insulating power; although usually considered as a good insulator it is by no means perfect, especially when it is exposed to a tolerably high temperature. At 32° there is a very small leakage of electricity through it; at 52° the leakage is three times as great; at 72° it is nearly six times; and at 92° ten times as great as at 32°. While laying the Red Sea cable, the temperature in the hold of the ship was 92°, and the insulation was so bad that the engineers could not speak through the cable; but when in the water at the depth of 300 fathoms and the temperature 73°, the insulation became much better. Gutta percha also varies greatly in its quality: it may contain foreign matter, or be porous, or air bubbles may become entangled with it during the laying on, all of which may tend to destroy its insulating power. There may be bad joints or small punctures, or a strong battery power may produce a chemical action injurious to its stability. Its durability is also seriously affected by exposure to light and air, so that in shallow water india rubber may be a preferable coating. Gutta percha is also liable to injury from friction or from pressure, and both it and the hempen packing are liable to the attacks of marine animals, a species of Teredo devouring the hemp, and another Teredo penetrating the gutta percha.

Hence it will be seen that the great problem of ocean telegraphy cannot by any means be regarded as solved. The best form of cable remains to be invented: it should be light and flexible for deep waters, and sufficiently strong in shallow ones to resist the rude grip of an anchor. Some cables weigh 3 or 4 tons per mile; others 8 or 9 or even more, while light cables weight about 1¼ or 2 tons per mile. The method of stowing them on board a ship, and the machinery for paying them out require to be reconsidered; but, above all, the many costly blunders which have been perpetrated with various cables ought not to be again possible, such as the heating of the Rangoon cable, and the error in reckoning in paying out the Cagliari and Algeria cable, so that there was not enough cable to reach the land: the ship held on during five days to the cable and then broke off in the midst of a storm. It is not our business here to do more than allude to the failures of telegraphic cables consequent on the plan adopted by our government of granting premiums to telegraphic companies.

This part of our subject will not be complete without a few details as to the mode of preparing the Atlantic cable. A strand of seven wires of pure copper of the No. 22 gauge, was first prepared, it being the sixteenth of an inch in diameter when twisted. The strand of seven wires was adopted in preference to a single wire of the same practical capacity, because the probability of a destruction of continuity was in this way greatly diminished. In case of any accident occurring it was very unlikely that all the seven wires would be broken in exactly the same place, and so long as only one of them remained sound, the electrical transmission could be carried on. The strand itself was subject to a strain which stretched it twenty per cent., without any appreciable injury to its conducting power being discovered. To show that no amount of attenuation which could be produced by accident, could interfere to any important extent with its utility as a telegraphic conductor, one mile of wire eleven times smaller than the strand, was introduced into a gap made in a 600-miles length of the cable, and the effect produced on the transmitting power of the cable by the interpolation was tested. It proved that the transmitting capacity of the cable was only diminished by one thirty-seventh part.

As the copper strand was prepared, it was rolled upon drums, and then taken from the drums to have three separate coatings of gutta percha applied, until the aggregate diameter was thus brought up to about three-eighths of an inch. The gutta percha used for these coatings was prepared with great care. It was first rasped into shreds, and washed, and next pressed through several layers of fine wire gauze, and kneaded for hours in the interior of iron cylinders by steam machinery. It was then squeezed by powerful screws, through dies, as the strand of copper was gradually drawn along between them, and so made to adapt itself as a compact sheath to the strand. Three several and successive coatings were given to the strand in order that any imperfection left in the first might be compensated and remedied by the next coat applied. The completed core was subjected to a pressure of five tons upon the square inch, by the use of hydraulic power, without the insulating material being at all injured by the force applied.

During the process of the manufacture of this core it was submitted to constant examination to prove both that the continuity of the copper strand continued unimpaired, and also that the insulating power of the gutta percha sheath was as complete as it was required to be. The continuity was proved by passing a voltaic current of *low intensity* from a battery of a single pair of plates, through the strand, and then causing it to record a signal after issuing from the wire. A battery of low intensity was employed for this purpose, because it made the test so much the more severe. A strong battery might have thrown the current through a slight imperfection, which a weak battery might not be able to overcome. The due perfection of the insulation was tried by turning up into the air the end of the length of core about to be examined, and by then connecting one pole of a voltaic battery of five hundred pairs of plates with the nearer end of the length of wire, and the other pole with the earth, a magnetic galvanometer being suspended within a coil continuous with the strand. So long as the insulation of the strand was fairly perfect, the copper wires became charged with the electricity of which but very little could escape, and so no current was produced through the strand, and no deflection of any consequence appeared in the magnetic needle. When the insulating sheath, on the other hand, was imperfect, the electrical charge *leaked* through the imperfections to the earth, and so got back to the opposite pole of the battery. In this way a current was set up in the wire to supply the leakage, and the magnetic needle was deflected from its position of equilibrium, the deflection being in proportion to the amount of the current. A strong battery of five hundred pairs of plates was employed in detecting imperfect insulation, in preference to a weak one, because a strong current would force a passage through an imperfection which might be too slight to allow a weak current to make its way. During the progress of the work, a plan was devised which enabled the testing for both continuity of the strand and insulation of the sheath to be carried on simultaneously. A voltaic current can pass through a charged Leyden jar without either the current or the charge being in any practical way interfered with. Therefore the entire length of cable under examination was joined up into a loop or endless ring, and a voltaic battery of five hundred pairs of plates had one of its poles connected with the conducting strand of this ring, and the other pole placed in communication with the earth. A small *insulated* battery of low tension was also introduced into the circuit of the ring, so that its current flowed round continually, from pole to pole, through the strand. An insulated bell was also so placed in the circuit, that any break of continuity dropped a needle, before held magnetically fast, and caused the bell to sound. Another bell instrument was so arranged that it was rung whenever the current from the five hundred-cell battery began to run, in consequence of electrical leakage, with undesirable speed. The feeble battery in the circuit rung its bell whenever the circuit was broken. The strong battery out of the circuit rung its bell whenever an outflowing current was set up through the strand, in consequence of the insulating sheath being unable to retain the charge.

During the prosecution of these experiments the discovery was made, that the insulating power of gutta percha is very materially affected by temperature. A high temperature seems greatly to impair its insulating capacity, and the recurrence of a low temperature speedily restores it to its original excellence. An opportunity was taken, when a single flake or tier of the completed cable was lying at the bottom of the receptacle in the yard of the manufactory at Greenwich, to watch the changes which the natural variation of temperature during forty-eight hours produced in its conducting capability. When the thermometer stood at 42°, the deflection of the galvanometer needle was barely 3°; but when the thermometer rose to 59°, the deflection of the magnetic needle became 64°. Even passing sunshine and cloud made the telltale needle traverse out and in with surprising rapidity. There was reason to conclude, from the soundings taken by Lieutenant Dayman of the Cyclops, that the bottom of the Atlantic would supply the low temperature essential to the good performance of the insulating material.

The separate lengths of manufactured core were joined into longer extents in the following manner. The gutta percha was scraped from the ends for a short distance, and these were placed in contact. A piece of copper wire was then attached by firm brazing to one side of the joint, and *wound* round the strand until it reached as far on the other side, being there brazed again. A second binding was then effected outside the first in precisely the same way, and several layers of gutta percha placed over the whole by the aid of hot irons. In case of the core on each side of the joint being at any time so dragged that the ends of the strand were broken asunder, this outer investment of wire would unroll spirally without being detached from the strand. Thus the electric continuity of the strand would be preserved even when the strand itself was severed.

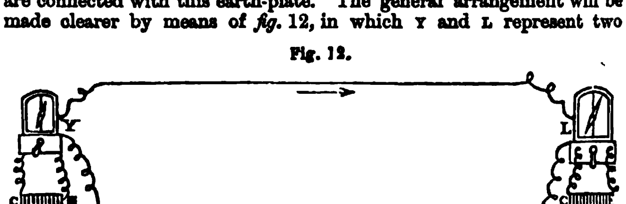
Every two miles of the completed core were wound upon channelled drums with deep flanges, iron shod at the rim, so that they could be rolled about and made to perform their own locomotion. When the contents of these drums were used in supplying the cable with more core, one of the ends was attached to the outgoing core of the compressed cable, and so the contents were unrolled from the drum as the external metallic wires were spun round the core. During the unrolling, a serving of hemp, saturated with a mixture of pitch and tar, was compactly wound round the core to act as a bed for the external metallic sheath. Then eighteen strands, each of seven wires of charcoal iron, were twisted firmly round the core. The strands and the cable were made by precisely analogous machinery. A large horizontal table, containing seven bobbins on the circumference in the case of the strand machine, and eighteen in the case of the closing or finishing machine, was whirled round by steam-power with great rapidity. A central wire, or the core, was drawn up through a hole in the middle of the table, and so invested with a twisted whorl of wires or strands, given off from the bobbins as the table revolved. The strands were used in completing the cable, instead of solid wires, because by this means greater flexibility and strength, for the material used, were obtained. The external investment of iron was solely designed to protect the coated core from mechanical violence during the act of submergence, and to confer upon it a convenient amount of weight for effecting its sinking in the sea.

Each strand-machine, during the manufacture of the cable, was worked day and night, and in twenty-four hours spun ninety-eight miles of wire into fourteen miles of strand. The several strand-machines at work simultaneously every twenty-four hours transformed 2058 miles of wire into 294 miles of strand. As much as thirty miles of cable have been made within twenty-four hours. At one time all the wire-drawers in England proved to be unable to supply the exacting demands of the machinery, and the works had to pause for a short space. The entire length of wire, iron and copper, spun into this wonderful structure, amounted to 332,500 miles; a length sufficient to engirdle the earth thirteen times! The completed cable weighed from nineteen hundredweight to one ton per mile, and proved to be able to bear with impunity a direct strain of five tons. In the salt-water the weight of the cable would, however, not exceed fourteen hundredweight per mile; and as the greatest depth of the Atlantic in which it would have to be laid is only a little more than two miles, and a certain portion of the weight would necessarily be borne by friction against the particles of the water as the rope sank, it was anticipated that the cable would never, under any circumstances, be required to meet a strain of more than one ton and a half.

The failure of the Atlantic cable was due, in some respects, to the haste with which it was manufactured. The company had obtained, in 1854, the exclusive right, for fifty years, of landing cables on the shores of Newfoundland and Labrador, and in 1856 the British as well as the American government made a grant of 14,000*l.* a year, conditional on success, the company pledging themselves to make the first attempt to lay the cable in 1857. It is now admitted that the construction of the cable was hastily commenced, before the experiments necessary to ascertain the proper form and other conditions had been completed. "The manufacture was, however, not fairly commenced till February, 1857, and 2500 miles were completed in June, 1857. Half was made at Messrs. Newall's works at Birkenhead, and half at Messrs. Glass and Elliot's works at Greenwich. The manufacture was very much hurried. The portion made by Messrs. Glass and Elliot, not being under cover, suffered from exposure to heat. The testing of each coat of gutta percha in water was recommended by Mr. Whitehouse, but this could not be performed on account of the speed at which the cable was required to be made. In the manufacture of the last 400 miles a system of testing the copper wire for its conducting power was introduced, by which an improvement of from 20 to 25 per cent. in the conductivity of the cable was obtained. Messrs. Newall's half of the cable was put on board the United States' ship Niagara, and Messrs. Glass and Elliot's half wasput on board the Agamemnon; but so backward were the preparations, that the machinery for laying the cable was being put together as the ships went round to Valentia. The break machinery was novel and cumbrous." ('Edinburgh Review,' 1861.)

The object for which all these complicated arrangements are made is for the purpose of indicating at the distant station certain electric signals by visible motions or by sounds, or by marks on a ribbon of paper. In all these cases there must be a contrivance for connecting the voltaic battery or other electro-motor with the line, in such a way as to be able to send along it a positive or a negative current at will, so as to be able to produce variety in the signals at the distant station, and having performed its work there, the current returns back to the battery by way of the earth. In this way, as already explained, the circuit is completed without the necessity of a return wire. Although a line of earth, as a conductor of electricity, is many thousand times inferior in power to a line of metal of the same diameter, yet as the conducting power of bodies increases in proportion to the area of the section of the conductor, and the area of the conducting portion of the earth between the two stations may be indefinitely extended, we thus have a return line offering less resistance than the wire which conveys the current. All that is necessary, therefore, instead of the return wire, is to bury a large copper plate in the earth, and to connect with it a wire from the telegraphic apparatus at the end of the line. Instead of this copper plate, or *earth* as it is called, the gas-pipes and water-pipes of towns are used as earths. In the Electric Telegraph Company's Central Station at Lothbury, an earth was formed by digging a hole in the foundations until moist ground was arrived at, and into this a cylinder of copper, 40 lbs. in weight, was sunk, and this was covered up with crystals of sulphate of copper. All the earth-wires of the establishment are connected with this earth-plate. The general arrangement will be made clearer by means of *fig.* 12, in which Y and L represent two

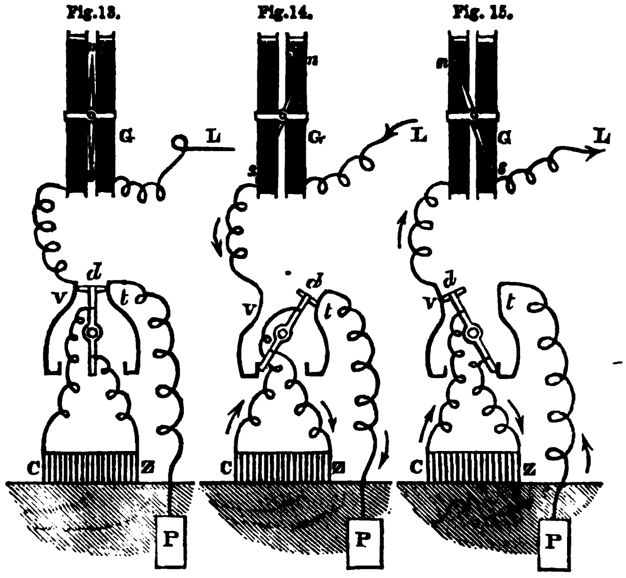
Fig. 12.



telegraphic instruments, one stationed in York, another in London, connected by an insulated air-line. P Q are two earth-plates, connected by means of wires to each instrument. A message, we will suppose, is being transmitted from London to York. If C Z represent the battery at the London Station, the current will pass from C, to a wire connected with the earth-plate Q, thence through 200 miles of earth; when at the York earth-plate, P, the current will be taken up again, and, by means of the wire, will act upon the instrument Y, from which it will pass to the line, return back to London, pass through the coil of the instrument, deflecting the needle, and so back to the end Z of the battery, where the current will be completed.

Now, in order that the clerk may have it in his power to send the current in either direction, so as to deflect the distant needle either to the right or to the left at pleasure, some such arrangement as the following is necessary. There are many arrangements, more or less simple, having the same object in view, but we give this one for the sake of illustrating the principle:—*Fig.* 13 represents the galvanometer coil, with its needle, *n s*, at rest, or in a position to *receive* a message. Now, suppose the current from the distant battery to enter the coil G by the wire L. It will pass through the coil and come out by the left-hand wire connected with a metallic spring, V. It will then pass along the brass cross-piece *d* to the metallic spring *t*, and complete the circuit by means of the wire attached to the earth-plate P, and the earth, by which it returns to the distant station. The battery C Z, at the receiving station, remains inactive, its extreme wires being attached to insulated pieces of brass at either end of the vertical piece connected with *d*. Hence no current can pass, since the wire from C

Fig. 13. Fig. 14. Fig. 15.



is insulated. If, however, a signal has to be transmitted from this instrument to the distant station, the clerk works the handle in front of the instrument, and presses *d* against the spring *t*, *fig.* 14, whereby the lower extremity of the brass piece is brought into contact with the other spring, V, and the current now passes in the direction of the arrows, that is, from C to V, through the wire attached to P, into the earth through the distant station, where the instrument is arranged for receiving the signal, as in *fig.* 13, where it produces a deflection of the needle; the current then returns by L to the galvanometer coil G, deflects the needle, and returns by the wire attached to the spring *t*, and so by the metallic piece *d*, through the wire attached to Z, and thus completes the circuit. By reversing the motion of the handle, the direction of the current, and the motion of the needles in the coil, will be reversed, both in the near and in the distant instrument, as in *fig.* 15. When the clerk has finished making his signals, the springs V and *t* restore the cross-piece *d* to the position shown in *fig.* 13, so that the instrument adjusts itself for receiving signals from the distant station, the battery C Z is thrown out of action, and the conducting communication with the line is restored by means of the cross-piece *d*. In this way the same motion of the needle is produced at the same instant at both stations, so that the sender and the receiver of the message each perceives the signals.

There is in general but one needle in connection with each galvanometer coil. The astatic arrangement formerly adopted is not now in use; the outside needle, by which the clerk knows how the signals are proceeding, being formed of ivory, or some inert substance, attached to the same axis which carries the magnetic needle within the coil. The needles are limited in their motions by means of small ivory studs fixed in the dial, and they are thus prevented from swinging too far over, while their motions are made precise and clear. It was formerly the practice to give a preparatory notice of a message to the distant station by ringing the electric alarum, but this was found to be so intolerable to the persons in waiting that it has been abandoned, and the clicking sound of the needle against the ivory studs is sufficient to draw the attention of the clerk to the arrival or passing of a message. When a message is sent from London to York, for example, all the needles of the intermediate stations are similarly deflected; but each clerk knows, by a special signal, when he is required to be spoken with. There are, however, contrivances called "commutators," by which a message is made to pass any one or more stations without entering them. In this way intermediate stations may communicate with each other; otherwise, they would have to remain idle while two exterior stations were communicating with each other. Of course, the larger the number of stations which can communicate with each other simultaneously, the larger must be the number of the wires.

When the instrument consists of two needles and two coils the alphabet may be made out somewhat in the following manner. Calling the left-hand needle No. 1, and the right-hand No. 2, and indicating one movement of either needle to the left by *l*, and one movement to the right by *r*, the combinations of movements which stand for the various letters of the alphabet are the following:—

	No. 1 Needle.	No. 2 Needle.		No. 1 Needle.	No. 2 Needle.
a	ll		o		rr
b	lll		p		rrr
c	rl		q	r	l
d	lr		r	r	r
e	r		s	rr	rr
f	rr		t	rrr	rrr
g	rrr		u	lr	lr
h		l	v	rl	rl
i		ll	w	l	l
k		lll	x	ll	ll
l		rl	y	lll	lll
m		lr	z	l	r
n		r			

Of course it is possible to form an alphabet with one needle and one wire only; the communication is not so rápid as with two wires and two needles, but the construction of the line is more economical, and the system is adapted for use between places of second-rate importance. Various alphabets and modes of signalling have been contrived with a view to celerity, and some of these are ingenious. We select one by the Rev. H. Highton, as described by Mr. E. Highton: a small slip of gold leaf inserted in a glass tube is made to perform part of the electric circuit of the line wire, and near it is a permanent magnet. When a current of electricity is passed along the line wire, the gold leaf is instantly deflected to the right or to the left according to the direction of the current. Now supposing the deflection of the gold leaf to the left signified the figure 1, and the deflection to the right the figure 3, we have the alphabet made up in the following manner: twice to the right, or 33, signifies A; twice to the left, once to the right, and once to the left, or 1131 = B; 311 = C; 133 = D; a single signal to the left, or 1 = E; thus acting on the correct principle of representing the letters of most frequent occurrence by the most rapidly executed signals; F 313, G 1133, H 113, I 31, J 3133, K 1331, L 331, M 1113, N 13, O 11, P 1111, Q 1313, R 333, S 111, T 3, U 131, V 1311, W 1333, X 3113, Y 3111, Z 3131. A motion to the left signifies "Do understand," and one to the right "Not understand." "Repeat" is expressed by 3331, and "Wait" by 3333.

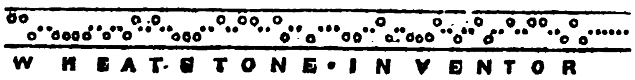
Steinheil suggested the plan of receiving telegraphic signals by means of two bells, one muffled and the other free, to be struck by the needle or needles when deflected by two currents. This plan has been adopted by Sir Charles Bright on the relay system, with a local battery to supply the mechanical power required to strike the bells. This is used at the principal stations of the British and Irish Magnetic Telegraph Company. The transmitting instrument is a key invented by Highton, consisting of a couple of springs, one marked + and the other —, connected one with the earth and the other with the line. When these springs are at rest, or pressing upwards, the line and the earth are in connection with one another, and with the positive pole of the battery, the negative pole being insulated. When the earth-spring marked +, is pressed down by the finger, the earth connection is thrown on the negative pole, and the positive pole is left on the telegraph line, which thus receives a positive current. When the line-spring marked — is pressed down, the positive pole of the battery is left in connection with the earth, and the line is thrown into connection with the negative pole of the battery, and will thus receive a negative current. Now it is perfectly easy to make the two bells take the place of the gold strip, and calling the left-hand bell 1, and the right-hand bell 3, Highton's nomenclature becomes applicable. The receiving-clerk is seated between the two bells, and his ear being alone engaged in receiving the signals, he can write down the letters which they represent as easily as when one clerk is employed to watch the needle, and dictate the message to another who writes it down. Whether this system may not induce an increased amount of nervousness in the clerks employed, we are not able to say, but it is stated that the use of the ordinary needle telegraph is apt to produce nervous irritability in the clerks who are long employed upon it.

A considerable advance has recently been made in telegraphs in consequence of Professor Wheatstone's copious list of improvements in the whole of the telegraphic system, embodied in two patents dated 2nd of June, 1858, and numbered respectively 1239, 1241. We give these numbers in order that persons interested in the subject may the more readily procure the printed copies of the specifications, which are accompanied the one by six and the other by ten sheets of illustrative engravings. The basis of this invention is the Letter Telegraph of 1839, now called the *Universal Telegraph;* and it is so simple in its action that no training is required to use it; for the message may either be spelt out on a dial by bringing common letters opposite a fixed point, the necessary electrical currents being developed by an ordinary voltaic battery, or, still better, by induction from a permanent magnet. This telegraph is being rapidly adopted in London, where it forms the London District Telegraph; and also throughout the country by merchants and manufacturers, as a means of communication at their offices and establishments at a distance; also from one portion of a large warehouse to another, between the several heads of departments and the manager's room, through mills and public works, or wherever the constant transmission and receipt of intelligence is of importance. This system has been in use at the London Docks during the last few years, and also serves to communicate between the Houses of Parliament and her Majesty's printers in Shoe Lane. All we can pretend to do in this place is to give a brief outline of the more important features of this invention. It is described as Wheatstone's *Automatic Printing* Telegraph, and is capable of printing 500 letters per minute. The order and succession of the electric currents are determined by perforated bands of paper, somewhat after the manner of the cards in a Jacquard loom. The different letters are represented by groups of points, *fig.* 16, and these, when arranged for a message, are separated

Fig. 16.

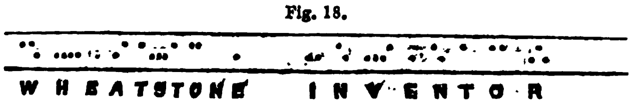
by smaller points, *fig.* 17, so as to prevent any mistake from the coalescence of adjacent letters, and the characters are printed without adding to the weight or causing any resistance in the moving parts of the electro-magnets. The invention consists of a new combination of

Fig. 17.



mechanism, for the purpose of transmitting messages previously prepared through a telegraphic circuit, and causing them to be printed at a distant station. Long strips of paper are perforated by a machine, provided with apertures so grouped as to represent the letters of the alphabet and other signs (*fig.* 17): a strip thus prepared is placed in an instrument associated with a source of electric power, which on being set in motion moves it along, and causes it to act on two pins, in such a manner that when one of them is elevated the current is transmitted to the telegraphic circuit in one direction, and when the other is elevated it is transmitted in the reverse direction: the elevations and depressions of these pins are governed by the apertures and intervening intervals. These currents following each other indifferently in these two opposite directions act upon a writing instrument at a distant station in such a manner as to produce corresponding marks on a slip of paper (*fig.* 18) moved by appropriate mechanism.

Fig. 18.



Each part of this telegraphic system is stated by the inventor to have its independent originality and to be capable of association with other forms of apparatus already known. The first of these inventions is an instrument called a *Perforator* for piercing the slips of paper in the order required to form the message. The slip passes through a guiding groove, at the bottom of which is an opening large enough to admit of the to-and-fro motion of the upper end of the frame containing three punches on a level. Each of these punches, however, may be separately elevated by the pressure of a finger-key, and at the moment of its elevation two different movements are successively produced. 1st, a clip is raised, which holds the paper firmly in its position; 2nd, the frame containing the three punches advances, by which the punch which is raised carries the ribbon of paper forward the proper distance; during the reaction of the key consequent on the removal of the pressure, the clip first fastens the paper and then the frame falls back to its normal position. The two external keys and punches are employed to make the holes, which grouped together represent letters and other characters, and the middle punch makes the holes which mark the intervals between the letters. A simple addition to the perforator enables a printed message which has been received to be retransmitted to a more distant station, without any translation or knowledge of the meaning of the message. The printed band passes between two rollers, one of which is moveable by a finger-screw, so as to cause the characters to pass successively before the eyes of the operator. The keys of the perforator are acted upon with the right-hand and the finger-screw with the left; as the characters successively appear the keys are pressed down in the order of the points of which the letters consist, an operation which scarcely requires any skill to perform, and which needs no change in the alphabet usually employed, the points at one side representing the short dashes, and those at the other side the long dashes, the order usually observed remaining the same.

The second apparatus is the *Transmitter*, which receives the strips of paper as prepared by the perforator and transmits the currents produced by the electro-motor in the order and direction corresponding to the holes perforated in the slip. This it effects by mechanism somewhat similar to that of the perforator. An eccentric produces and regulates three distinct movements. 1st, the to-and-fro movement of a small frame which contains a groove to receive the strip of paper, and carry it forward; 2nd, the rising and falling of a spring-clip, which holds the paper firmly during the receding motion, but allows it to move freely during the advancing motion; 3rdly, the simultaneous elevation of three wires placed parallel to each other, resting at one of their ends over the axis of the eccentric, and their free ends entering corresponding holes in the grooved frame. These three wires are not fixed to the axis of the eccentric, but each of them rests against it by the upward pressure of a spring, so that when a light pressure is exerted on the free ends of either of them it is capable of being separately depressed. When the slip of paper is not inserted, and the eccentric is in action, a pin attached to each of the external wires touches, during the advancing and receding motions of the frame, a different spring, and an arrangement is adopted by means of insulation and contacts properly applied, by which, while one of the wires is elevated and the other remains depressed, the current passes from the voltaic battery to the telegraphic circuit in one direction, and passes in the other direction when the wire before elevated is depressed, and *vice versâ*; but while both wires are elevated or depressed the passing of the current is interrupted. When the prepared slip of paper is inserted in the groove and moved forward, whenever the end of one of the wires enters an aperture in its corresponding row, the current passes in one direction, and when the end of the other wire enters an aperture in the other row it passes in the other direction. By this means the currents are made to succeed each other automatically in their proper order and direction, to give the requisite variety of signals. The middle wire only acts as a guide during the operation of the current. The wheel which drives the eccentric may be moved by the hand or by any motive power. Were the movements of the transmitter effected by machinery, then any number might be attended to by one or two assistants. Instead of a voltaic battery, a magneto-electric, or an electro-magnetic machine may be used as the source of electric power, in which case the transmitter and the magneto-electric, or electro-magnetic machine form a single apparatus, moved by the same power, and so adapted to each other that the currents are produced at the moments when the pins of the transmitter enter the apertures of the perforated paper. The transmitter requires only a single telegraphic wire.

The third apparatus is the *Recording* or *Printing apparatus*, which prints or impresses legible marks on a strip of paper corresponding in their arrangement with the apertures in the perforated paper. The pens or styles are elevated and depressed by their connection with the moving parts of electro-magnets. The pens are entirely independent of each other in their action, and are so arranged that when the current passes through the coils of the electro-magnet in one direction, one of the pens is depressed, and when it passes in the contrary direction the other pen is depressed; when the currents cease, light springs restore the pens to their usual elevated positions. The method of supplying the pens with ink depends on the principle that a liquid will not flow from a capillary opening unless it be electrified. Accordingly a shallow reservoir is made in a piece of metal, gilt within, and at the bottom of this reservoir are two capillary holes; the ends of the pens are placed immediately above these small holes, which they enter when the electro-magnets act upon them, carrying with them a sufficient charge of ink to make a legible mark on the strip of paper which passes beneath them. The motion of the strip is produced and regulated by apparatus similar to that employed in other register or printing telegraphs. Among the auxiliary improvements is a *Translator*, for converting the points or marks into the ordinary alphabetic characters. In this instrument there are nine finger-stops in two parallel rows of four each and the remaining one is placed separately. There is also a wheel on the circumference of which are placed at equal distances thirty types, representing the letters of the alphabet and other characters. Other mechanism is so disposed and connected thereto, that when the keys of the upper row are depressed the wheel is made to advance one, two, four, or eight steps or letters, and when the keys of the lower row are depressed the wheel advances two, four, eight, or sixteen steps respectively. By this arrangement, when the stops are touched successively in the order in which the points are printed on the paper, touching the first stop for one point, the first and second for two points, &c., and selecting the stops of the upper or lower row, according as the point is in the upper or lower row of the printed ribbon, the type wheel will be brought into the proper position for placing the letter corresponding to the succession of points over a ribbon of paper. The ninth stop, when it is pressed down, acts so as to impress the type on the paper, to cause the advance of the paper, in order to bring a fresh place beneath the type wheel, and subsequently to restore the type wheel to its initial position.

Professor Wheatstone remarks, that for the profitable working of a telegraphic line, the operator should manipulate as rapidly as is consistent with the correct transmission of the message; but this requires skill, even when the language of the despatch is known, but in a language unknown to the operator, or in cipher, he must proceed with caution and slowness. Under the new system the prepared messages can be transmitted with equal rapidity in whatever language or cipher they may be, and the perforated bands may be prepared at leisure, and even be subjected to the revision of a corrector.

Although this system is being extensively introduced in the metropolis and elsewhere, it does not interfere with the working of other companies, such as the Electric and International Telegraph Company, as it is now called, which transmits messages not only to all parts of the United Kingdom and Ireland and the Continent, but also by street lines between various parts of the metropolis, its central station in Lothbury gathering up the messages from its branch offices, and transmitting them to distant stations. Arrangements are made for sending messages at small cost between any of the metropolitan stations, of which at the time we are writing there are about 33. In addition to these stations there are wires between the Octagon Hall in the Houses of Parliament, and the St. James's Street Commercial Station, so that during the sitting of Parliament an abstract of the business of the two houses is made every half hour as it proceeds, and is posted up at the various club-houses, and also at the Italian Opera House. Members can thus know whether their presence is required in the House or not. The Opera House wire communicates with the Strand office, so that messages may be sent thence to all parts of the kingdom. The government wires proceed from Somerset House to the Admiralty, and thence to Portsmouth and Plymouth by the South-Western and Great Western railways.

The Portsmouth and Plymouth Dockyards also communicate by means of subterranean lines with the naval establishments at Deptford, Woolwich, Chatham, Sheerness, and with the Cinque Ports of Deal and Dover. These wires are worked independently of the Telegraph Company, and the messages are sent in cipher, the meaning of which is not known to the clerks who transmit the signals. There are also wires running from Buckingham Palace, and the chief Police Office in Scotland Yard, to the station at Charing Cross, and thence on to Lothbury, whilst the Post-Office, Lloyd's, the Stock Exchange, and the Corn Exchange, communicate directly with the Central Office.

At the present time almost every important town in Great Britain is furnished with means of telegraphic communication to other towns. As fast as any new railways, whether trunk or branch lines, are opened, so surely is the telegraph laid down; insomuch that the length of telegraph is nearly coincident with the length of rail. The exceptions to this rule are so few as scarcely to disturb the simplicity of the rule itself. From numerous places in the metropolis, messages are every day being quickly flashed to Aberdeen in one direction, to Liverpool in another, to Dover in a third, to Southampton in a fourth, to Plymouth, to Milford Haven, to Holyhead—indeed, to almost all our outports, and to nearly every inland town of any commercial pretensions. A system is everywhere acted on, that the principal railway stations shall at the same time be telegraph stations, some of the wires being for public use, and the others for railway use. The charges have been and are being gradually lowered, to the great advantage of all parties; and the messages now sent are of countless variety—the price of funds, the state of the markets, orders to purchase, the arrival of ships, what ships have just hove in sight, what ships have foundered, the receipt of important news, the Queen's speech, the result of elections, the divisions in a debate, the running of a race, the progress of the Court while travelling, the state of the weather, the direction in which a great storm is travelling, the verdict of an important trial, the sending for a doctor, the detection of a thief or murderer, inquiries after health, announcements of illness or of death, inquiries after lost luggage—these are only some of the open or confidential communications intrusted to the wires. Nor must we forget the various submarine cables, which although all have had occasional mishaps, yet taken collectively afford a remarkably complete series of channels through which messages may be exchanged between Great Britain and all the neighbouring countries; and now the English public hear with as little surprise of messages or *telegrams* (to use a new word, concerning which Greek scholars for a time carried on a fierce battle) brought under water as if brought on dry land.

On the continent of Europe we find telegraphic wires ramifying in all directions. Nations were never more struck with the wonders of the electric telegraph than on the occasion of the death of the Czar Nicholas in 1855. On the 2nd of March the Earl of Clarendon announced in the House of Lords that the Czar had died at St. Petersburg at one o'clock on that same day. Two distinct messages had been received, one *viâ* Berlin and the Hague, the other *viâ* Berlin and Ostend, both communicating a message telegraphed to Berlin from St. Petersburg, and all in four hours after the actual death. Not only have the dreary wastes of Russia been brought within the civilising influence of the electric wire, but lines in all directions have been laid, with or without regard to railways. Nearly all the chief cities in Europe are now linked together. Circuitous as is the route from London to Trieste, going through Belgium, Prussia, several minor German States, Saxony, Bohemia, Austria, and Istria, the connection is nevertheless complete; and telegrams are twice a-month transmitted to us relating to Indian affairs, brought to Trieste from Alexandria. Italy, in railways and in telegraphs, is in arrear of Austria; and Spain is lower on the list than Italy. Turkey, to the great astonishment of many of the Osmanlis, has been made a sharer in the fast-going, high-pressure operations of the age: she possesses an electric telegraph, extending from the Austrian frontier to Constantinople; and messages can now be flashed from London to the seat of the Ottoman empire. We have already glanced at other submarine lines, and must now conclude.

In sending messages in the United Kingdom by telegraph, either cipher may be used, or the ordinary signals known at the Telegraphic Office; but such is the jealousy of despotism, that on the continent of Europe cipher is never permitted, except by the governments for their own use.

An interesting use of the sub-way telegraph may be here noticed. In proportion as the use of Greenwich time has become familiar on all the English railways, so has it become important to ascertain this time with precision, in such a way as to enable all the station-clocks to be regulated thereby. This is one purpose of the time-ball in the Strand. The Electric Telegraph Company, the South-Eastern Railway Company, and the Astronomer Royal, have acted in conjunction in the establishment of this plan. A subterranean wire has been carried from the Observatory, through Greenwich Park, and across Blackheath to the Lewisham station of the North Kent Railway; thence to the London Bridge station; and thence to the Telegraph office in the Strand. At the top of this office has been erected a hollow shaft, up the interior of which the electric wire is carried, and a large light ball, capable of moving eight or ten feet vertically, slides easily up and down near the top of the shaft. At ten minutes before one o'clock each day the ball is raised nearly to the top of its shaft or spindle; and at five minutes before one it is raised quite to the top. At one o'clock precisely, exact to a single second, the great or master-clock at Greenwich Observatory puts in action a small piece of mechanism which sends an electric shock through the wire to the Strand; the wire at this end is connected with another piece of mechanism, which releases the ball and allows it to fall suddenly. The ball falls upon a kind of piston in an air-cylinder, so as to break the force of the concussion. As this ball is 130 feet above the level of the Thames; as it is six feet in diameter, exhibits bright colours, and falls through a considerable space, its descent can be seen for a great distance on all sides; and all who choose to regulate their clocks and watches by this standard can do so. An electric clock with four dials, illuminated at night, has been put up on a pillar in front of the office; it indicates Greenwich time at all hours. The various railway stations receive their time from the Strand office, which is the medium of communication from the Greenwich Observatory. There can be little doubt that these arrangements will contribute powerfully to the adoption of Greenwich time in church clocks and other public clocks. So useful is this considered to be, that a plan has been under consideration for erecting an electric time-ball on the summit of the South Foreland; the descent of such a time-ball at one o'clock each day, could be witnessed by the captains of ships many miles out in the Channel, who could regulate their chronometers by this means, as the time-ball would show Greenwich time. It was also proposed that the electric current should fire off a gun at the same time and place, so that the sound might be heard if the descent of the ball could not be seen. This proposal has actually been adopted at Edinburgh and elsewhere.

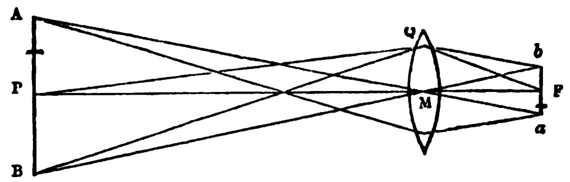
TELERYTHRIN. [LICHENS, COLOURING MATTERS OF.]

TELESCOPE (from the Greek *teléscopos*, *τηλεσκόπος*, "far-seeing"), an optical instrument consisting of a tube which contains a system of glass lenses having all their centres in one common axis, or a tube containing a metallic speculum in combination with such lenses: by either kind of instrument distant objects are caused to appear magnified, and more distinct than when viewed by the naked eye. Those which are constructed with glass lenses only are called *dioptric*, or *refracting*, and the others *catoptric*, or *reflecting* telescopes. In the former kind the rays in the pencils of light which come from every part of the object viewed are, by the first lens on which they are incident, made to converge so as to form an image at the focus of the lens. In some cases the rays in each pencil are intercepted by a second lens, and, by its refractive power, are made to enter the eye in parallel directions: in other cases, the rays, after having crossed each other at the place where the image is formed, fall in a divergent state upon a second lens, and by it are refracted so as to emerge from it in parallel directions. Frequently, however, the parallelism of the rays is effected by two or more lenses in addition to that, called the *object-glass*, by which the image was formed. In reflecting telescopes an image is formed by the reflection of the rays in the pencils of light coming from the object, after having impinged upon the concave surface of the speculum: in some cases this image is viewed through one glass lens or more, but frequently the rays, before or after forming the image, are reflected from a second mirror, and are subsequently transmitted to the eye through lenses.

By these instruments objects even in the remotest depths of space are rendered accessible to human vision; and terrestrial objects faintly visible in the distance are brought, as it were, close to the eye. In the hands of astronomers they were the means, almost immediately on being invented, of making more discoveries in the heavens than had been made during 5000 years previously; they form a valuable addition to the instruments employed by the mariner and the surveyor, and they will ever constitute the most agreeable companion of the traveller, by enabling him to distinguish, in every direction from him, objects which it might be difficult or impossible for him to approach.

In exhibiting the principles on which a telescope is constructed, it will be proper to commence with an explanation of the means by which the image of an object is formed at the focus of a lens or of a reflecting mirror. With respect to a lens, if it be of the kind called *convex* [Lens], the rays in the pencils of light which proceed from every part of an object, as A P B, *fig.* 1, in passing through the lens, supposing

Fig. 1.

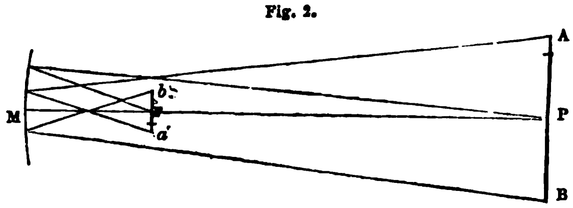


the latter to have a proper degree of curvature, are made to converge by the refracting power of the glass at points, as *a*, F, and *b*, and the assemblage of such points constitutes an *image* of the object: if a screen were placed at F perpendicularly to the axis P F, the object would be represented on it, in an inverted position.

If the lens were of a concave form, the rays in the several pencils, after passing through it, would be made to diverge from one another, and consequently no image could be formed: yet if the directions of the rays, after refraction, were produced backwards, they would unite between the lens and the object, in points corresponding to those which constitute the image formed by the convex lens.

If the rays in the pencils of light proceeding from different points, A, P, B, *fig.* 2, in an object are reflected from the surface of a concave

Fig. 2.



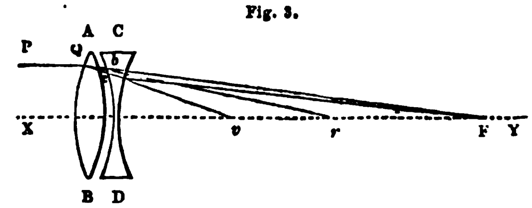
mirror, supposing the latter to have a certain degree of curvature, those rays will unite in as many points, *a*, F, and *b*, and form an image of the object. If a screen were placed at F the object would be represented on it, in an inverted position. The rays in each pencil reflected from the surface of a *convex* mirror are made to diverge from each other; and in that case no image is formed.

Now, if the object A B be so remote that, in each pencil, the rays incident upon a lens may be considered as parallel to one another, the point F is called the *principal focus;* and in the article Lens, there will be found a collection of formulæ for the reciprocals of the focal lengths of lenses of all the different kinds; it being understood that the diameter of the lens is small, which is generally the case with telescopes, and that the light is homogeneous. But, since all light is not of one kind, and a lens acts like a prism in causing in each pencil the rays of the differently coloured light to diverge from one another, it follows that each of the coloured lights will form its *own image* at its proper focus; and the image formed by light of one kind being seen by the eye along with the images formed by light of the other kinds, the representation of an object when formed by a single lens appears to be indistinct and surrounded by a coloured fringe. [Achromatic; Light; Dispersion.] It may be observed that the principal focus of any lens, with respect to each colour, may be obtained from the formulæ in Lens, by substituting in them the value of μ (the index of refraction) for the given kind of light.

Thus, in an optical instrument, in addition to the distortion of the image arising from the sphericity of the lens, there is an indistinctness caused by the dispersion of the different colour-making rays; and, in a good telescope, it is requisite that both of these imperfections should as far as possible be removed. The *chromatic aberration*, as the dispersion of the colour is called, constitutes by far the greater evil of the two, for Newton has shown that it exceeds the former nearly in the ratio of 5449 to 1; but fortunately it is that which, to an extent sufficient for practical purposes, admits of being easily corrected.

Since different kinds of glass have different degrees of dispersive power, it is evident that the chromatic aberration may be diminished, if not wholly removed, by causing the light to pass through two lenses of different kinds of glass, and of such forms that they may refract the rays in each pencil in opposite directions. The object-glass of a telescope when so formed is said so be *achromatic*, and the manner in which the effect is produced may be understood from the following description. Let P Q be the direction of a pencil of compound light incident on the first surface of the convex lens A B, *fig.* 3, in a direction parallel to the common axis, X Y, of the two lenses. By the refractive power of this lens (*crown* glass) the red rays in the pencil would, if no object were interposed, proceed in the direction Q *b*, meeting X Y in *r*, and the violet ray in the pencil would proceed in the direction Q *c*, meeting the axis in *v*. But the refractive power of the concave lens C D (*flint* glass) acts, from its form, in a direction contrary to that of the convex lens, causing the rays either to diverge from the axis X Y, or to meet it in points beyond *v* and *r*, towards Y: suppose the curvature of this lens to be such that the red rays in the pencil P Q would, after refraction in both lenses, meet the axis in F (the ray Q *b* F taking

Fig. 3.



the direction *b* F); then the dispersive power of this kind of glass exceeding that of the other kind, the violet rays in the refracted pencil will tend farther away from the axis than the red rays do, and thus will tend towards the latter; the ray Q *c v*, for example, taking the direction *c* F. It is conceivable, therefore, that the curvatures of the surfaces of the lenses may be such that, in each incident pencil, the red and violet rays (the extreme rays of the spectrum) shall, after refraction, unite at the place of the image; and thus the fringe due to these two colours may be destroyed.

If the two kinds of glass dispersed the different colour-making rays in the same proportions, their contrary refractions would cause all the colours to be united on the image formed at F: no two kinds of glass have, however, been as yet discovered which possess this property; and therefore the red and violet images only are united: fortunately, in uniting the extreme rays of the spectrum, the others are brought so near together, that for ordinary purposes the image is as free from colour as can be desired.

From the description just given it will be evident that the place F, of an image in which the dispersion of the red and violet rays is corrected, may be determined on obtaining, from the common theorems of optics, algebraic expressions for the focal lengths of the compound lens for each of those kinds of light, and making the expressions equal to one another. Thus, supposing R and S to be the radii of the curve surfaces of a double convex lens of crown glass, and μ the index of refraction for light of one kind (red, for example); supposing again that the rays in the pencils of incident light are parallel to one another and pass through the lens very near the axis; then, by a fundamental theorem in optics we have, F being the distance from the focus to the lens, which is moreover without thickness,

$$F = \frac{R \, . \, S}{R + S} \cdot \frac{1}{\mu - 1}:$$

but since, in the present case, the lens may be supposed to be isosceles ($R = S$), we have $F = \dfrac{R}{2(\mu - 1)}$.

In like manner the focal length F', of a double concave lens of flint glass, R' being the radius of each surface, and μ' the index of refraction for red rays, is equal to $-\dfrac{R'}{2(\mu' - 1)}$, the rays being incident near the axis.

Hence, by a fundamental theorem in optics,

$$\frac{R'}{\mu' - 1} - \frac{R}{\mu - 1} : \frac{R'}{\mu' - 1} :: \frac{R}{2(\mu - 1)} : \frac{RR'}{2\{R'(\mu - 1) - R(\mu' - 1)\}}$$

and this last term is the focal length of the compound lens for red rays. Its reciprocal is equal to $\dfrac{2(\mu - 1)}{R} - \dfrac{2(\mu' - 1)}{R'}$, which, in the algebraic sense, is the sum of the reciprocals of the focal lengths of the separate lenses.

On writing $\mu + \delta\mu$, and $\mu' + \delta\mu'$, in place of μ and μ' in the last expression, we have for the reciprocal of the focal length of the compound lens for violet rays,

$$\frac{2(\mu + \delta\mu - 1)}{R} - \frac{2(\mu' + \delta\mu' - 1)}{R'}.$$

In an achromatic telescope the focal lengths of the compound lens for red and violet rays are to be equal to one another; and it is evident that this condition will be fulfilled when $\dfrac{\delta\mu}{R} - \dfrac{\delta\mu'}{R} = 0$. From this equation we have $R : R' :: \delta\mu : \delta\mu'$; then, dividing the antecedents by $\mu - 1$ and the consequents by $\mu' - 1$, we have [Dispersion] the ratio of the focal lengths of the two lenses equal to that of the dispersive powers of the two kinds of glass; and hence, the focal length of the compound lens being assumed at pleasure, those of the separate lenses, consequently the radii of their surfaces, may be obtained.

In order to diminish the spherical aberration, the object-glasses of achromatic telescopes frequently consist of three lenses, of which the first and third are of the kind called double convex, and are formed of crown glass, while the second is double concave, and made of flint glass. In this case, since the index of refraction is the same for the third lens as for the first, if the radius of each surface of the third lens be R'', the reciprocal of the principal focal lengths of the separate lenses for red rays will be

$$\frac{2(\mu-1)}{R},\quad -\frac{2(\mu'-1)}{R'},\ \text{and}\ \frac{2(\mu-1)}{R''};$$

these being added together, their sum will be the reciprocal of the focal length of the compound lens for one kind of light. On substituting in the above terms, $\mu+\delta\mu$ for μ, and $\mu'+\delta\mu'$ for μ', in order to obtain the reciprocals of the focal length for violet rays, we shall have, when the chromatic aberration is corrected,

$$\frac{\delta\mu}{R} - \frac{\delta\mu'}{R'} + \frac{\delta\mu}{R''} = 0,\ \text{or}\ R'\left(\frac{1}{R}+\frac{1}{R''}\right) = \frac{\delta\mu'}{\delta\mu}.$$

But $\frac{\delta\mu'}{\delta\mu}$ is known from tables of the refractive indices for different kinds of glass: therefore if any convenient relation between the radii of two of the lenses be assumed, the values of all the radii, and consequently the focal lengths of the several lenses, may be found.

The investigation of formulæ for the correction of the spherical aberration is a process of some labour, and is scarcely a fit subject except for a mathematical work: it is treated with great perspicuity in Robison's 'Mechanical Philosophy,' vol. iii., from which the subjoined theorem is borrowed, the notation only being changed for that which has been adopted above; and also in the articles LENS and SPECULUM. If a compound object-glass consists of one double convex lens of crown glass and a double concave lens of flint glass, and a ray of light be incident upon the anterior surface of the former in a direction parallel to the axis, at a distance from thence, which is expressed by e; the distance from the lens, of the point at which the ray after refraction will meet the axis, is $f-f^2(q+q')$, where f is the focus for parallel rays infinitely near the axis, and may be found as above, and $f^2(q+q')$ is the aberration. Here, neglecting the thickness of the lenses and the interval between them,

$$q=\frac{\mu-1}{\mu}\left\{\frac{\mu^3}{n^3}-\frac{2\mu^2+\mu}{Rn^2}+\frac{\mu+2}{R^2n}\right\}\frac{e^2}{2},\ \text{and}\ n=\frac{RS}{R+S};$$

(R and S being the radii of the two surfaces of the convex lens), and

$$q'=\frac{\mu'-1}{\mu'}\left\{\frac{\mu'^3}{n'^3}-\frac{2\mu'^2+\mu'}{R'n'^2}+\frac{\mu'+2}{R'^2n'^2}+\frac{3\mu'^2+\mu'}{F.n'^2}-\frac{4(\mu'+1)}{F.R'n'}\right\}\frac{e^2}{2}:$$

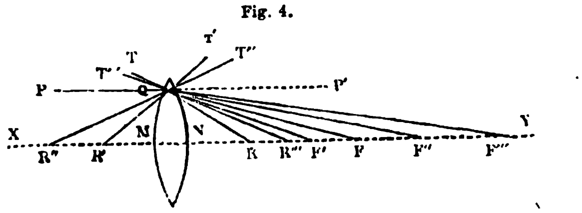
where F is the principal focus of the convex lens, and $n'=-\frac{R'S'}{R'+S'}$; (R' and S' being the radii of the surfaces of the concave lens.)

It is evident that, in order to correct the spherical aberration, the values of the radii of the surfaces must be determined from the equation $q+q'=0$. This equation is however indeterminate, because it contains several unknown quantities; but it may be made subject to certain conditions by which there will remain only one: for example, the different radii of the lenses may be made to have any given relation to one another, so that the values of all, in terms of any one, may be substituted for them. In the values of q and q' the terms represented by n and n' are respectively equal to half the radii of equivalent isosceles lenses; and it has been shown, in the investigation concerning the chromatic aberration, that these are to one another as $\delta\mu$ to $\delta\mu'$; consequently $n'=n\frac{\delta\mu'}{\delta\mu}$, and therefore n' is known in terms of n. If again it be supposed that $R'=S$, or that the nearest surfaces of the convex and concave lenses have equal curvatures, the value of R may be found from the equation $q+q'=0$, in terms of n, by a quadratic equation.

Sir John Herschel, in a paper on the aberration of compound lenses and object-glasses ('Phil. Trans.,' 1821), has also investigated formulæ for the values of the chromatic and spherical aberrations; and M. Littrow, of Vienna, setting out with Euler's formula for spherical aberration ('Dioptrica,' tom. iii., 1769), and introducing in it the values of the focal lengths of two lenses so that the former aberration may be corrected, has obtained two equations from which the radii of the four surfaces may be determined by such conditions as may be thought convenient. ('Memoirs of the Astron. Soc.,' vol. iii., part 2). In solving the problem relating to the determination of the four radii, Professor Littrow uses a method which possesses some facilities for computation, and on that account it has been adopted in the following process.

The radii of the surfaces of the first lens may be determined on the supposition that the whole refraction of light in passing through the

Fig. 4.



lens is a minimum; that is, that the incident and emergent rays make equal angles with the surfaces, or with those radii. Thus let a ray PQ,

fig. 4, be incident on the first surface in a direction parallel to the axis XY of the lens, and infinitely near it; and RQT being the radius (=R) produced, of that surface let the angle PQT of incidence be represented by a; then $\mu:1::a:\frac{a}{\mu}$ (=RQF, the angle of refraction at that surface). But if $R'QT'$ be the radius (=S) produced, of the second surface; then, in the triangle $R'QR$, neglecting the thickness of the lens and substituting arcs for their sines, $S:R::a:\frac{R}{S}a$; and $\frac{R}{S}a+a-\frac{a}{\mu}$ (=$T'QF$) is the angle of incidence on the second surface: and, by optics, 1 is to μ as this last angle is to $\frac{a\mu R}{S}+a(\mu-1)$, the angle of refraction (=$T'QF'$) at the second surface. But by hypothesis, this angle is to be equal to a; therefore $\frac{R}{S}=\frac{2-\mu}{\mu}$. Again, by optics $\frac{RS}{R+S}\cdot\frac{1}{\mu-1}$ is equal to the focal length of the lens; and supposing this to be equal to unity, we obtain $\frac{R}{S}=\frac{R-\mu+1}{\mu-1}$: equating this last term with $\frac{2-\mu}{\mu}$ above, we get $R=\frac{2(\mu-1)}{\mu}$ whence $S=\frac{2(\mu-1)}{2-\mu}$. Therefore the two radii are found on the supposition that the focal distance of the lens is unity.

Now PQT being the angle of incidence as above, and QF the direction of the ray after one refraction, we have by optics, $\sin RQF=\frac{\sin PQT}{\mu}$; and by trigonome in the triangle RQF,

$$RF=R\,\frac{\sin RQF}{\sin P'QF},\ \text{and}\ MF=R\left(\frac{\sin RQF}{\sin P'QF}+1\right);$$

also, representing the thickness MN of the lens by t,

$$R'F=R\left(\frac{\sin RQF}{\sin P'QF}+1\right)+S-t.$$

Then, by trigonometry, in the triangle $R'QF$,

$$\text{we get}\ \frac{SF+S-t}{S}\sin P'QF=\sin T'QF;$$

consequently by optics, $\frac{SF+S-t}{S}\mu\sin P'QF=\sin T'QF'$ or the sine of the angle of refraction at the second surface.

Now $T'QF'-T'QF+P'QF=QF'M$, or the angle which the second refracted ray makes with the axis of the lens: but by trigonometry, in the triangle $R'QF'$, we have

$$R'F'=S\,\frac{\sin T'QF}{\sin P'QF};\ \text{whence}\ NF'=S\left(\frac{\sin T'QF}{\sin P'QF}-1\right).$$

Suppose next a double concave lens, the centres of whose surfaces are at R'' and R''', and whose radii are R' and S', to be applied to the convex lens on the side N: then, neglecting the thickness of the concave lens and the distance between the two, and supposing QF'', QF''' to be the directions of the ray of light after the third and fourth refractions respectively, we have in the triangle $R''QF'$, by trigonometry,

$$\frac{R'+S'F'}{R'}\sin P'QF'=\sin T''QF',$$

or the sine of incidence on the first surface of the second lens; and by optics,

$$\frac{R'+S'F'}{R'\mu'}\sin P'QF'=\sin T''QF''.$$

But $P'QF'-(T''QF'-T''QF'')=P'QF''$; and in the triangle $R''QF''$, by trigonometry, we have

$$R''F''=R'\,\frac{\sin T''QF''}{\sin P'QF''};$$

wherefore $NF''=R'\left(\frac{\sin T''QF''}{\sin P'QF''}-1\right)$; and considering NR''' to be equal to S', $R'''F''$ will be equal to $NF''-S'$.

Again, in the triangle $R'''QF''$, we have by trigonometry,

$$\sin R'''QF''=\frac{NF''-S'}{S'}\sin QF''N$$

for the sine of incidence on the fourth surface; therefore, by optics,

$$\frac{NF''-S'}{S'}\mu'\sin QF''N=\sin R'''QF''',$$

the sine of refraction at the fourth surface; then

$$QF''N-(T'''QF''-T'''QF''')=P'QF''',\ \text{or}\ =QF'''N;$$

and by trigonometry, in the triangle $QF'''R'''$, we have

$$R'''F''' = S' \frac{\sin R'''QF'''}{\sin QF'''N}, \text{ and } NF''' = S' \left(\frac{\sin R'''QF'''}{\sin QF'''N} + 1\right),$$

the focal distance of the compound lens.

These values being reduced to what they become when the incident ray PQ is infinitely near the axis of the lenses; that is, when the angles are substituted for their sines, there may be obtained

$$\frac{R}{MF} = \frac{\mu - 1}{\mu}, \quad \frac{S}{NF'} = \frac{\mu S}{MF - t} + \mu - 1,$$

$$\frac{R'}{NF''} = \frac{R'}{NF'\mu'} + \frac{\mu' - 1}{\mu'} \text{ and } \frac{S'}{NF'''} = \frac{S'\mu'}{NF''} + \mu' - 1.$$

By means of these equations, eliminating the quantities MF, NF', and NF'', and neglecting powers of t above the first, there may be obtained a value of $\frac{1}{NF'''}$: then differentiating this value with respect to to μ, μ', and NF''', and making the resulting value of the differential of NF''' equal to zero (which is a condition necessary in order that the chromatic dispersion may be corrected for rays near the axis), there may be obtained a value of $\frac{1}{R'} + \frac{1}{S'}$. Again on substituting $\frac{2(\mu-1)}{\mu}$ for R, and $\frac{2(\mu-1)}{2-\mu}$ for S, as above found, there will result

$$\frac{1}{NF'''} = 1 - \frac{\mu' - 1}{\mu - 1}\left\{1 + \tfrac{1}{2}(\mu + 1)t\right\}\frac{d\mu}{d\mu'} + \tfrac{1}{2}\mu t, \text{ and}$$

$$\frac{1}{R'} + \frac{1}{S'} = -\frac{1}{\mu - 1}\left\{1 + \tfrac{1}{2}(\mu + 1)t\right\}\frac{d\mu}{d\mu'}.$$

Now the value of NF''' may be directly computed from the formulæ first investigated; afterwards assuming different values of R', and substituting them in the last equation. let the corresponding values of S' be found. With these values of S' find corresponding values of $S'\left(\frac{\sin R'''QF'''}{\sin QF'''N} + 1\right)$; that is, of NF''', and proceeding according to the usual methods of trial and error, there will at length be found a value of N F''' agreeing with that which was computed by the direct process: the four radii will then, consequently, be determined.

Investigations relating to the dispersion of light, and rules for computing the radii of curvature for achromatic object-glasses, will also be found in an essay by Mr. P. Barlow of Woolwich, printed in the 'Philosophical Transactions' for 1827.

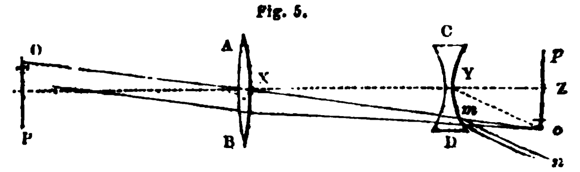
Though on thus uniting the red and violet light by lenses of crown and flint glass the chromatic dispersion is in a great measure corrected, yet when the image is examined, it is found to be surrounded by a green-coloured fringe. The difficulty of procuring flint glass of sufficient purity is also a serious impediment to the perfection of achromatic lenses for telescopes. The steps that have from time to time been taken to remedy this evil are noticed in the following article on the history of the telescope, [TELESCOPE, HISTORY OF,] but we may here mention that in the 'Transactions' of the Royal Society of Edinburgh, 1791, there is given an account of some experiments made by Dr. Blair, from which he was led to the discovery of the fluid medium, which, being applied between lenses of crown glass, renders the compound lens completely achromatic. By adding liquid muriatic acid to chloride of antimony, or sal ammoniac to chloride of mercury, he succeeded in obtaining a spectrum in which the coloured rays in each pencil followed the same law of dispersion as takes place in crown glass. Therefore, confining a small quantity of either of these liquids between the convex surfaces of two plano-convex lenses, or between those of a plano and a convex meniscus lens, of crown glass, Dr. Blair obtained an object-glass in which the chromatic aberration was entirely destroyed; and he is said to have thus constructed one of 9 inches focal length, and as much as 3 inches in diameter or aperture. Object-glasses so made were for some years on sale in London; but either from the crystallisation of the fluids, or the negligence of the artists in compounding them, the telescopes became imperfect, and gradually fell into disuse.

Dr. (Sir David) Brewster, in his 'Treatise on New Philosophical Instruments,' recommends the employment of sulphuric acid and oil of cassia for the composition of fluid lenses, by which the secondary spectrum may be destroyed; the acid being, of all known substances, that which exerts the greatest, and the oil that which exerts the least, action on the green-coloured rays. The correction of the chromatic dispersion by means of fluids was also attempted by Mr. Barlow, as noticed in the following article. But probably from imperfections in the forms of the glasses, the images of objects were found to be not well defined; and the construction, in consequence, has not been adopted.

The image formed by the great speculum of a reflecting telescope is free from the inconveniences attending the chromatic aberration of light; for the angles of incidence being equal to those of reflection, in any pencil coming from a point in an object, all the rays will converge to one point at the place where the image is formed. If the surface of the speculum were that which is formed by the revolution of a parabola about its axis, then all the rays in any pencil proceeding from a very remote object, as one of the celestial bodies, and being incident on the speculum in a direction parallel to the axis, would, by the nature of the parabola, converge accurately in the focus of the curve; and on this account, an effort is always made to give to the reflecting surface of the speculum a paraboloidal figure. The advantage does not, however, hold good with the pencils which fall on the mirror in directions oblique to the axis; and therefore that figure is of less importance, when the telescope is to be used for viewing terrestrial objects, than when it is to be employed for astronomical purposes; for then, on account of the great distance of the objects, the several pencils of light fall on the mirror with a very small obliquity to its axis.

The telescope invented by Galileo consisted of one convex lens, A B, *fig. 5*, and of a concave lens, C D; the distance between them being equal to the difference between the focal lengths of the two lenses. In this instrument, if the object O P were so remote that the rays in each

Fig. 5.



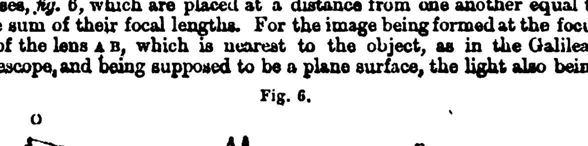
pencil of light might be considered as parallel to one another, there would be formed at its principal focus an inverted image (o p) of that object by the union of the rays in each pencil in one point; then the concave lens being placed between A B and that image, in such a situation that its principal focus may coincide with the place of that image, the rays in each pencil will, by the refracting power of the lens, be made to emerge parallel to one another; and in this case, by the optical properties of the eye, distinct vision is obtained.

The line O X o is the axis of the pencil of light from O; and, as this passes through the centre X of the lens A B without refraction, the angle Z X o is equal to half the angle under which O P would be observed by an eye at X when no telescope is interposed, while (m n parallel to Y o being the direction of a ray in that axis after refraction in C D) Z Y o is half the angle under which O P is seen in the telescope: the ratio between these angles is therefore the measure of the magnifying power of the telescope; and since the angles are to one another as Y Z is to X Z, nearly, it follows that $\frac{XZ}{YZ}$ nearly expresses the magnifying power.

This is the construction of what is called an *opera glass*; and the Galilean telescope is now used chiefly for viewing objects within a theatre, or an apartment, since if considerable magnifying power were given to it the extent of the field of view would be very small.

A simple telescope may also be constructed by means of two convex lenses, *fig.* 6, which are placed at a distance from one another equal to the sum of their focal lengths. For the image being formed at the focus Z, of the lens A B, which is nearest to the object, as in the Galilean telescope, and being supposed to be a plane surface, the light also being

Fig. 6.



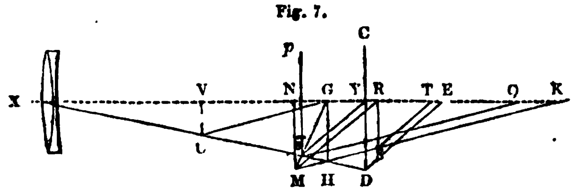
supposed to be homogeneous, the rays of each pencil, after crossing at the focus and proceeding from thence in a divergent state, on being allowed to fall upon the surface of the second lens, C D, may be refracted in the latter so as to pass out from thence in parallel directions; and consequently distinct vision of the object may be obtained by an eye situated so as to receive the pencils.

If X o be the direction of the axis of a pencil of light coming from O, one extremity of the object O P, which is supposed to be so remote that all the rays in each pencil may be considered as parallel to one another; then the angle Z X o is half the angle under which the object O P would be seen by an eye at X without a telescope, while the rays of that pencil entering the eye at E in the direction D E, which is parallel to o Y, the angle Z Y o is half the angle under which the same object is seen when viewed through the telescope. Now these angles are to one another nearly as Z Y to Z X; therefore $\frac{ZX}{ZY}$ will express nearly the magnifying power of the instrument. As the pencils of light from O and P cross the axis of the eye at E before they are united on the retina, the image of the object O P is formed in the eye in a position contrary to that which is formed when the object is viewed without the telescope; therefore, on looking through the latter, the object O P appears to be inverted.

But the image formed at o p, instead of being a plane, is nearly on a portion of a spherical surface whose centre is at X; and, on the other hand, in order that the rays in each pencil may after refraction in C D be parallel to one another, they ought to diverge from a point nearly in the surface of a sphere whose centre is at Y, the two spherical surfaces being in contact at Z: consequently when the distance between the lenses is such that the crossing of the rays in a pencil parallel to the axis takes place exactly at E, the crossing e in one of the oblique pencils will be at a certain distance from the point e', at which it ought to be to permit the rays in it to go out of C D parallel to one another; the rays of the pencils which proceed from the margin of the object will not then emerge parallel to one another, and consequently that margin will not be distinctly seen. Moreover, from the unequal refrangibility of the different kinds of light, the rays in each pencil will be decomposed in passing through the lens C D, so that though the chromatic aberration were perfectly corrected in the image at $p\,o$, it would exist in the image which is formed in the eye by the rays emerging from C D.

The spherical aberration can only be diminished by diminishing the inclination at which the rays in the marginal pencils fall upon the surface of the lens after having crossed at the focus of the object-glass; that is, by using a lens of less convexity or of greater focal length; adding a second eye-glass in order finally to render the rays in each pencil parallel to one another. Thus, if it be required to preserve the

Fig. 7.

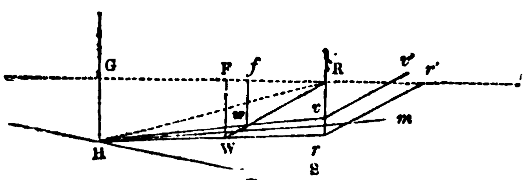


same magnifying power and field of view as might be obtained with any single eye-glass; let, as before, X, *fig.* 7, be the place of the object-glass, $o\,p$ the image formed by it, and let C D be the place of the single eye-glass: then draw a line o Q so as to bisect the angle D o Y, which may be considered as the whole refraction produced by the lens C D: let G, on the right or left of $o\,p$, be the assumed place of what is called the *field-glass*, and draw G H perpendicular to X Y, the axis of the telescope, meeting X D in H; also through H draw M H K parallel to o Q, cutting G o, or G o produced, in M: again draw M N perpendicular to the axis of the telescope, and M R parallel to o Y; also draw R S perpendicular to the axis. Lastly, draw G U parallel to o Q to meet X o in U, and U V perpendicular to the axis. Then, from the principles of optics, if a lens be placed at G, having its focal length equal to G V, and another at R, whose focal length is R N; the ray X o H will by refraction in the first lens take the direction H S, and by refraction in the second lens it will take the direction S T parallel to o Y or D E: thus the present visual angle S T R will be equal to D E Y, which was obtained with the single eye-glass.

This is called the *Huyghenian eye-piece*, and it is that which is generally used for astronomical telescopes: the object seen through it is inverted, as in the last-mentioned telescope.

If the places G and R of the two eye-glasses are given (G H being very near op; its focal length being also known), and it be required to find the focal length of R S so that the red and violet rays in each pencil may emerge from it parallel to one another, that length might be determined in the following manner. In a pencil of rays crossing each other at H, *fig.* 8, let Hm be the direction of a mean ray, and Hr, Hv those

Fig. 8.



of a red and a violet ray; these last will make with one another an angle equal to about $\frac{1}{28}$ of the angle D Hm, which may be supposed to be known. Now, by optical principles, if these rays are to emerge from R S in directions parallel to one another, the focal lengths of the lens for red and violet rays, namely, R F and Rf must be to one another as 28 to 27, and the foci F and f must be in places determined by perpendiculars drawn to the axis from points W and w, in which the line R W supposed to be drawn parallel to rr' or vv', meets Hr and Hv; that is, by finding the position of a line to be drawn from R to cut the given lines Hr, Hv, so that R W may be to Rw as 28 to 27. For this purpose, having drawn the straight line H R, the angles R H W, R Hw will be known; let them be represented by a and b; also let the angle H R W be represented by θ: then by trigonometry we shall have, after a few reductions, 27 cotan. a − 28 cotan. b = cotan. θ.

In order to afford a view of objects in the same position as they appear to have when seen by the naked eye, a telescope may be formed with three lenses besides the object-glass. In the construction of this instrument, if attention is paid only to the rays which suffer a mean refraction, the first eye-glass, or that which is nearest to the object-end of the telescope, may be placed between the image formed by the object lens and the eye, with the foci of the two lenses in coincidence; by this means the rays in each pencil will emerge from the first eye-glass in directions parallel to one another, those of the pencils which are oblique to the axis of the telescope crossing each other at some point in the latter axis. A second eye-glass is then placed at any convenient distance from the former, beyond the place where the oblique pencils cross each other; and by this lens a second image is formed in a position contrary to that which is formed by the object lens. Lastly, the third lens being placed between this image and the eye at a distance from the former equal to its focal length, the rays in the several pencils will emerge parallel to one another, and an erect image of the object will thus be formed in the eye.

The ratio between the angles under which an object would be seen by the naked eye, and that by which it is seen in the telescope, is compounded of the ratios of the focal lengths of the several lenses; thus, if F be the focal length of the object-lens, f', f'', f''' those of the eye-lenses, reckoned in order towards the eye, the expression $\frac{F\,.\,f''}{f'\,.\,f'''}$ will denote the magnifying power.

But both the spherical aberration and the chromatic dispersion in such a telescope are very considerable; and before the invention of the achromatic object-glass, Mr. Dollond endeavoured to diminish the former by an eye-tube consisting of five lenses disposed so as to divide the bendings of the pencils nearly equally between them. Such telescopes are not now used; and Mr. Dollond succeeded at length in constructing telescopes with four eye-glasses, from which both distortion and colour are removed as much perhaps as a removal is possible.

This is accomplished by placing the first eye-glass beyond the image formed by the object-glass, and at a distance from it less than the focal length of that eye-glass: by this disposition the rays of mean refrangibility in each pencil which diverges from the image are not, after refraction, parallel to one another, but go on with diminished divergency. A little way beyond the place where the axes of the oblique pencils cross the axis of the telescope there is placed the second eye-glass, which is of such focal length that the mean refrangible rays in each pencil, after passing through it, meet in a point, and thus a second image of the object is formed near the eye: the use of these two lenses, therefore, is to cause the second image to be formed by a gradual convergence of the rays in each pencil. But the several pencils of rays are intercepted by the third eye-glass (commonly called the field-glass), and the second image is thereby formed rather nearer to the first than it would be without such field-lens: from this image the rays in each pencil diverge, and by the refractive power of the fourth eye-glass they are made to enter the eye in parallel directions: thus distinct vision of the external object is obtained. The field-glass might have been placed between the eye and the second image, as in the Huyghenian eye-piece before described; but the aberration arising from the spherical form of the glasses is a little less by the construction just mentioned.

Now, in each pencil, the red and violet rays which had been united at the image formed by the object-glass, and which there crossed each other, go on from thence diverging from each other till, on the opposite side of the axis of the telescope, they fall upon the surface of the second eye-glass: after passing through this lens, the violet ray, which is always more refracted than the red ray, gradually converges towards the latter, and at length meets it in some place short of that at which the rays of mean refraction unite to form the second image. The practice is to fix the third or field-glass exactly or nearly at the place where the red and violet rays so unite in all the pencils; for the different coloured rays crossing each other in that place, they are finally, by the refractive power of the fourth eye-glass, made to enter the eye in parallel directions, and thus afford a view of the object nearly or wholly free from colour.

In forming the eye-glasses of telescopes it may be observed that they should be such as will allow the incident and emergent pencils of rays to be nearly equally inclined to their surfaces: on this account the first and fourth eye-glasses are of the plano-convex form; the flat side of that which is nearest to the object-glass being towards the latter, and that of the other towards the eye.

Besides the power of magnifying objects, that of affording distinct vision with given quantities of light is often an essential requisite in a telescope, particularly to naval men, who have occasion during the obscurity of the night to keep in view a ship of which they may be in chase. This subject was investigated by the late Sir William Herschel, and an account of his researches on what he calls the "space-penetrating power of telescopes" was printed in the 'Philosophical Transactions' for 1800.

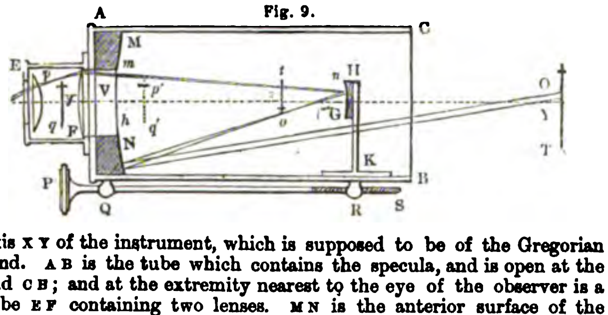
Herschel states that he was aware of this property of telescopes as early as the year 1777, when he had constructed a Newtonian telescope with a speculum whose focal length was 20 feet: for, on directing the instrument to a church-steeple at a considerable distance, he could distinguish the hour by the clock, though with the naked eye he could not see the steeple itself. In order to obtain a formula for the space-penetrating power, he observes that the quantity of light received by the natural eye varies directly with the aperture of the *pupil*, or with the square of its radius, and inversely with the square of the distance of the object: also that the quantity of light transmitted by a telescope, supposing none to be lost in the reflections from the mirrors, or in refraction through the lenses, will vary directly with the square of the radius of the aperture and inversely with the square of the distance of the object. But, from experiments on the measure of light, it appears that the whole quantity incident upon a plate of glass is to the quantity transmitted through it as 1 is to ·9381, or to the quantity lost as 1 is to ·0619; and from this, the whole quantity of incident light being unity, an estimate may be made of the quantity of light transmitted through all the lenses of a telescope: with respect to the quantity lost in reflection from mirrors Sir W. Herschel found that out of 100,000 incident rays, only 45,242 reached the eye after two reflections.

Let the quantity of incident light be to that which arrives at the eye as 1 to m; then r being the radius of the pupil, and R that of the aperture of a telescope, $\frac{R^2 m}{r^2}$ will express the ratio between the quantity of light transmitted to the naked eye, and through a dioptric telescope: therefore the space-penetrating power varying with the square root of the quantity of light, $\frac{R}{r}\sqrt{m}$ expresses the penetrating power. With respect to reflecting telescopes, if R′ be the radius of the small speculum, the penetrating power will be expressed by $\frac{1}{r}\sqrt{\{m(R^2-R'^2)\}}$. It is necessary to observe that, in these expressions, it is supposed that the pencil of light transmitted by the telescope is not greater than the pupil of the eye.

It has been said above that, in reflecting telescopes, a speculum at one extremity of the tube serves the purpose of the object-glass in refracting telescopes by forming an image at its focus; and the manner in which, in the former instruments, the image is transmitted to the eye remains now to be explained.

The following diagram represents a longitudinal section through the

Fig. 9.



axis X Y of the instrument, which is supposed to be of the Gregorian kind. A B is the tube which contains the specula, and is open at the end C B; and at the extremity nearest to the eye of the observer is a tube E F containing two lenses. M N is the anterior surface of the great speculum, which has a circular perforation, mh, at its centre: G is a small speculum, concave like the former, its surface being either spherical or parabolical. It is connected with the side of the tube A B by the arm H K, and is capable of being moved in the direction of the axis X Y by means of the rod P S: the latter passes through a knob Q, which is fixed to the side of the tube, and works in the knob R, which passes through an oblong perforation in the side of the tube, and is attached to the part K of the arm H K. This movement is given to the small mirror in order that its focus may be made to coincide with the place of the image formed by the great speculum; that image being at different distances from the latter according to the distance of the object from the observer.

Let O be the upper part of an object, and let O N be the direction of the rays in a pencil of light diverging from O; the rays of this pencil will, after being reflected at N, converge to o, which will be the lower part of the image ot. From o the rays in the pencil diverge, and having fallen upon the small mirror at n, they are reflected from thence towards the eye-piece E F: having passed through the orifice mh, they fall on the lens at F, by which they are made to unite at p, where an image, pq, of the object is formed. From p the rays in the same pencil again diverge, and, falling on the lens at E, they are made to emerge in parallel directions, so that the eye is enabled to obtain distinct vision of the object in the same position as if the latter were viewed by the naked eye. The rays, after being reflected at n, might with a due concavity of the smaller mirror have united, as at p', in front of the great mirror, and the second image might have been formed at $p'q'$: in this case the rays in each pencil, after crossing one another, would have fallen in a divergent state on the lens at F, and then, by the refractive powers of both lenses, they would have entered the eye in parallel directions as before. The positions of the lenses at E and F, and the curvatures of their surfaces, are determined according to the method of Huyghens; and the construction differs in no respect from that which has been described in speaking of the eye-pieces of dioptric telescopes.

The magnifying power of a reflecting telescope of this kind is expressed by the formula $\frac{Vz \cdot Gy}{Xy \cdot Gz}$; in which V$z$ is the focal length of the great speculum, Gy is the distance of the small speculum from the image pq, Xy is the focal length of the second eye-glass, and Gz is the focal length of the small speculum for parallel rays.

In the Cassegrainian telescope the small mirror G is made convex, and it is placed so as to intercept the rays from the great speculum M N before the image ot is formed; the rays of each pencil consequently fall in a convergent state on the small mirror, and, after reflection from thence, unite to form the image either at $p'q'$ or after refraction in the first eye-glass F. It is obvious that these telescopes, with equal magnifying power, will be shorter than the Gregorian telescopes by more than twice the focal length of the small speculum; and it may be added that, in some degree, the spherical aberration is corrected by the contrary curvatures of the two mirrors.

The Newtonian reflecting telescopes have one concave speculum at the bottom of the tube; and, in each pencil of light, the rays reflected from it fall in a convergent state upon a small plane mirror placed so as to make an angle of 45° with the axis X Y of the telescope: after the second reflection the rays unite and form an image which is viewed through a Huyghenian eye-piece fixed in the side of the tube A B, opposite the plane mirror; that is near the open end of the tube.

The great telescope constructed by Herschel differs from the Newtonian telescope only in having no small mirror. The surface of the great speculum, which is 4 feet in diameter, has a small obliquity to the axis X Y, so that the image formed by reflection from it falls near the lower side of the tube at its open end: at this place there is a sliding apparatus which carries a tube containing the eye-glasses. The observer in viewing, is situated at the open end of the tube, with his back to the object, and he looks directly towards the centre of the speculum, the magnitude of which is such that the rays intercepted by his head, in coming from the object, do not in any sensible degree diminish the brightness of the image.

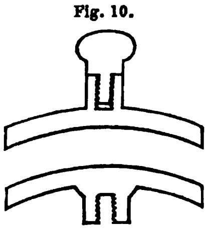
Formerly the great speculum of a reflecting telescope was pressed into its cell by means of springs attached to the interior side of the brass plate at A; but the vibrations of the springs were found to cause tremulous motions in the image at the focus of the mirror; and this effect was so great as to render reflecting telescopes inferior to those of the dioptric kind. The Rev. Mr. Edwards, who detected the cause of the tremors, at once removed it by taking away the springs ('Naut. Alm.,' 1787); and the same gentleman further improved the distinctness of the image by enlarging the aperture to which the eye is applied. It has been observed also that when the great speculum is nearly in a vertical position, and consequently rests on its lower extremity, its weight bends it, and thus causes a change in the figure of its polished surface: on this account it is recommended that the speculum should be made to rest on two small wedges, placed one on each side, at about 45° from the lowest point.

Since specula have been enlarged in their proportions the difficulties in the way of attaining distinct vision have increased. Sir W. Herschel's 48-inch reflector weighed 25 cwt., but the 6-feet speculum of Lord Rosse weighs no less than 4 tons. This, as Sir John Herschel remarks, requires the use of very powerful and costly machinery in the construction of such specula and also in their management when constructed. Speculum metal, though highly elastic and rigid is, as above noticed, liable to bend, and thus lose its figure. Herschel notices the case of a speculum of 18 inches aperture, 20 feet focus, and 2 inches in thickness which was found to be totally spoilt, by being supported on three points at its circumference, and when reclined against a flat and strong wooden back, with a single thin packthread interposed down the middle, all trace of figure was destroyed, and the surface was divided into two lobes, each producing an imperfect image of a star, connected with an irregular burr of light. Lord Rosse found that a strong pressure of the hand at the back of his 6-feet speculum, which is nearly 6 inches in thickness, produced sufficient flexure to distort the image of a star; and in one of Foucault's silver-glass mirrors the excess of central pressure of a somewhat over-inflated air cushion destroyed distinct vision. The speculum, therefore, requires to be uniformly supported over every part of the back. Where the weight does not exceed 200 or 300 lbs. a bed of several layers of even textured woollen blanket is sufficient, provided, as Herschel remarks "the whole be supported on a back so strong as not to yield under the pressure in any part more than a small aliquot of the total compression of the cushion." For small mirrors or for light glass ones an air-cushion is a good contrivance. For a very heavy one, such as Lord Rosse's six-feet speculum, an ingenious plan was adopted on the idea of the common "splinter bar," by which the pull of two, four, or eight horses drawing at once is equalised so as to distribute the work equally among them. The back of the mirror, supposed to be of uniform thickness, is divided into three sectors of 120°. Let the centre of gravity of each of these sectors be sustained by a projecting knob, at one of the angular points of a slab of iron in the form of an equilateral triangle, which is itself sustained by a point under its centre of gravity. In this way each sector being separately supported would produce no strain on the others, and the whole weight would be equally distributed among the three points of support. But to prevent the flexure of each sector it may be divided into three portions of equal weight, and the centre of gravity of each portion being found, it in turn is supported on a pin or knob on one angle of a smaller or secondary iron slab, which in its turn is supported on its centre of gravity by resting on one of the points of the primary triangle. In the case of a six-feet speculum each of these secondary areas may be subdivided into three equal tertiary areas similarly supported on tertiary triangular slabs each supported at its centre of gravity on one angle of a secondary one. In this way the mirror may be conceived as being subdivided into twenty-seven equal areas, each separately supported at its centre of gravity, and thus not liable to bend by its own weight. In practice, however, certain levers are introduced, the action of which does not interfere with the principle of the contrivance. This clever arrangement, however, was defeated by the adhesion or stickage, as it is called, of the metal to its cushion, and this stickage amounted to two tons when the speculum was resting on the bottom of the tube. Hence it has been found necessary to suspend the speculum from above, by means of bands of steel or some other support.

A reflecting telescope is liable to irregular action from currents of unequally heated air in the tube, which cause remarkable distortions and movements in the images of objects. Sir John Herschel ('Results of Cape Observations') describes a method of substituting for the tube an open frame-work of iron which gets rid of the objection from counter currents of air.

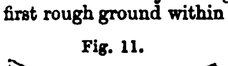
Under SPECULUM some details are given respecting the composition, the grinding, and the polishing of specula. As similar information respecting glass lenses is not given under the article LENS, the deficiency may to some extent be supplied in this place; the reader desirous of more ample information is referred to the third volume of Holtzapffel's 'Mechanical Manipulation,' 1850. The spherical surfaces of lenses are formed by grinding the glass in counterpart metal tools (*fig.* 10), prepared to the proper curvatures with the assistance of grinding and polishing powders. The tools are in pairs, concave and convex, and these are first made to correct each other's errors, which they do on the principle which applies also to the lenses themselves "of the natural tendency of two surfaces which grind each other by equable rubbing over every part to work each other into a spherical concavity and convexity exactly fitting." (Herschel.) Hence it is comparatively easy to form lenses into truly spherical surfaces.

Fig. 10.



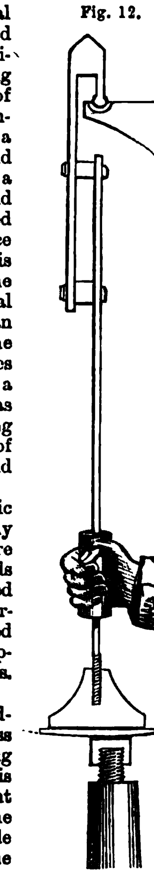
The concave and the convex tools grind each other true with the assistance of emery and water, although Mr. Ross thinks greater accuracy is attained by using the emery dry. The glass for the lens is brought to the circular form by means of *shanks* or flat pliers of soft iron, or to save the material (since good optical glass is more precious than gold) selected fragments of glass blocks are softened by heating to redness, moulded to nearly the required form, and then carefully annealed. Each lens is then coated on one side with a layer of cement, which is run into a hemispherical mass sufficiently thick to be grasped, so as to form a handle: but if the lens is of large size it is cemented to a metal handle, as a wooden one would swell. The cement is made by mixing wood-ashes with melted pitch. The glass is first rough ground within the metal shell or basin (*fig.* 11), either with river-sand and water, or coarse emery and water, until the surface is brought nearly to the curve of the shell. The glass is rubbed with large circular strokes, and when the grinding has been carried far enough, the glass is warmed, the cement handle is shifted to the other side, and the grinding is continued on the second surface of the lens. The parallelism of the two sides is obtained by observing that the edge of the glass is of equal thickness all round. The grinding is then continued with washed emery, six sizes being used, the last size being the fine powder collected after one hour's subsidence, and which leaves so smooth a surface that when the lens is held between the eye and the light it shows a semi-polish. Grinding the lens to the true figure or *trueing* the lens, as it is called, is generally done upon a post with the concave brass tool, much in the same manner as the concave and the convex brass tools are made to correct each other. The grinding is continued with each size of emery, until the marks made with the previous size are removed; everything being carefully washed between the changes of sizes; for should a speck of a larger size get into the work it might make a scratch which would render it necessary to re-commence the grinding. The polishing is performed with the assistance of putty powder, sifted through lawn and enclosed in a box with a lid perforated with small holes; or still better, mixed with water in a corked bottle, which is shaken up every time the powder is to be applied, and allowed to subside for a few seconds. A small quantity of the water is then taken out with a clean stick, and thrown upon the polisher, so that only the suspended portions of the putty powder are used. The powder is put upon a piece of thick silk (lute string), cut to the width of about seven-eighths the diameter of the lens, and stretched across the middle of the brass tool. The lens is rubbed backwards and forwards in straight lines along the silk, while at the same time it is twisted round in the hand, and also traversed gradually sideways, until the centre of the lens is brought to the edge of the silk, when the direction of the traverse is reversed. For the most carefully finished lenses, however, a pitch tool is prepared as described under SPECULUM.

Fig. 11.



Mr. C. Varley has described ('Trans. Society of Arts,' vol. xlix.) a lathe for grinding and polishing lenses in which instead of the lower tools being mounted on a fixed post they are mounted on a revolving axis placed vertically. Mr. Grubb, of Dublin, has an apparatus for figuring and polishing lenses, which is said to be very successful. For very accurate work, the arrangement shown in *fig.* 12 may be adopted. After grinding in the metal basin (*fig.* 11), the lens is attached to the lower end of a vertical rod, of which the upper end terminates in a steel ball, working in a cup and fitting accurately, so that every point of the surface of the lens may move in a spherical surface concentric with the steel ball. The rod is grasped by a woollen holder, to prevent the heat of the hand from elongating the rod. Below the lens is a small polisher of pitch, spread on brass and covered with a fine polishing powder mixed with water. The polisher admits of nice adjustment by means of a screw. The rod is worked to and fro as well as circularly, and the lens gradually acquires a perfectly spherical and polished surface, the radius of which can be adjusted by lengthening or shortening the rod. In manufactories where large quantities of common lenses are ground and polished, a number are arranged on a convex tool, such as 7, 13, or 21 around a central lens, forming what is called a *block* of lenses. Lenses of medium quality and size are generally ground true and polished seven at a time.

Fig. 12.



In forming the object glasses of achromatic telescopes, it is necessary to measure accurately the radii of curvature of the lenses, which are first tried experimentally, and are afterwards made as nearly as possible to the radii obtained by calculation. In order to measure the curvature of the grinding tools, Mr. Ross invented an instrument called a *spherometer*, a description of which will be found in the 'Trans. Society of Arts,' (vol. liii.)

The edges of lenses are made true by grinding in a lathe by means of a piece of brass supplied with emery and water; but in setting the lenses in the lathe for this purpose, it is cemented upon a chuck, and before the cement has set, the lathe is set spinning, and the reflection of a fixed object, such as a candle flame or a window bar is watched, and the lens is adjusted until the image appears to be quite stationary, notwithstanding the revolution of the lens. This shows that the axis of the lens and that of the mandril of the lathe coincide and consequently that the lens, when its edge is ground circular, and put in the tube of the instrument, will coincide with the axis of such tube.

The centering of the lenses of an achromatic telescope, so that all the centres of curvature of their surfaces shall lie in one straight line, and that coincide with the common axis of the telescope and its eyepiece, is an adjustment of considerable delicacy. Wollaston's method of doing this is described in the 'Philosophical Transactions' for 1822, and depends upon the circumstance that the various images of a candle, of which there are fifteen for a triple object glass, are, if the lenses be exactly centered, all in a right line directed from the candle.

TELESCOPE, HISTORY OF THE. It has been the fate of almost every instrument by which science has been extended, or the well-being of man promoted, that the precise epoch of its invention, and even the name of the individual to whom the world is indebted for it, are alike unknown. This is particularly the case with the telescope, of which the earliest notices are that it existed in England and in Holland near the end of the 16th or in the beginning of the 17th century.

There is in Strabo a passage (iii., p. 180, Falconer's ed.; p. 138, 'Casaub.') in which, speaking of the enlargement of the sun's disc at his rising and setting in the sea, it is stated that the rays (of light) in passing through the vapours which rise from the water, as through tubes, are dilated, and thus cause the apparent to be greater than the real magnitude (of the object); and from this it has been inferred (Dutens, 'Recherches,' &c.), though the inference is probably without foundation, that there then existed tubes furnished with lenses for magnifying objects by refracting the light. It would be needless to make any observations on an inference founded upon an hypothesis so obscurely expressed: the words in Strabo probably signify only that the rays of light might become divergent in passing along the intervals between the particles of vapour.

Omitting then all notice of this, and of the ill-understood passages in Aristophanes ('Clouds') and Pliny (lib. xxxvi., c. 67) concerning transparent spheres, or lenses for concentrating the rays of light, it must be acknowledged that before the end of the 13th century lenses of glass were in constant use for the purpose of assisting the eye in obtaining distinctness of vision. Vitello, a native of Poland, in that century, gave some obscure indications of the apparent magnitudes of objects when viewed through a segment of a sphere of glass; and Roger Bacon, in his 'Opus Majus,' both mentions the like fact, and expresses himself in such a manner as to indicate that in his time (he died in 1292) spectacles were already in use. He may not have actually made combinations of lenses in one instrument, but there is no doubt of his being aware of the fact that lenses might be arranged so that objects seen through them would appear to be magnified.

The idea being known to the learned, it is scarcely possible to doubt that the combination of two lenses, or of a concave or convex mirror and a lens, must have been often made during the three centuries which elapsed between the time of Bacon and that which is generally considered as the epoch of the invention of telescopes. Dr. Dee, in his preface to Euclid's 'Elements,' (1570) having mentioned that some skill is required to ascertain the numerical strength of an enemy's force when at a distance, observes that the "captain, or whosoever is careful to come near the truth herein, besides the judgment of his eye, the help of his geometrical instrument, ring, or staffe astronomical [probably for determining the measure of distances] may wonderfully help himself by *perspective glasses*." These last can only signify some kind of telescope, which therefore must have been then in general use. And in the 'Pantometria' of Digges (1571) it it stated that "by concave and convex mirrors of circular (spherical) and parabolic forms, or by frames of them placed at due angles, and using the aid of transparent glasses which may break, or unite, the images produced by the reflections of the mirrors, there may be represented a whole region: also any part of it may be augmented, so that a small object may be discerned as plainly as if it were close to the observer, though it may be as far distant as the eye can descrie." In the preface to the second edition (1591) the editor, who was the author's son, affirms that "by proportional mirrors placed at convenient angles, his father could discover things far off, that he could know a man at the distance of three miles, and could read the superscriptions on coins deposited in the open fields." There is probably some exaggeration in this account, but it is sufficiently manifest from it that reflecting telescopes, or optical instruments containing combinations of mirrors and lenses, were known in England before the end of the 16th century. The claim of Baptista Porta (between 1545 and 1615) to the invention of the telescope appears to have no other foundation than the circumstance that he perceived a small object to be magnified when viewed through a convex lens.

It is highly probable that the telescope had been invented long before the value of such an instrument was duly appreciated; and it may have been owing to the very gradual discovery of its importance that the name of the inventor sunk into oblivion: about the middle of the 17th century, however, an effort was made to discover the traces of the invention, and Peter Borellus, in his work entitled 'De vero Telescopii Inventore,' which was published in 1655 at the Hague, has given testimonials in favour of two persons; the first of these is Zachariah Jans, or Jansen, and the other, Hans Lapprey, or Lippersheim, both of whom are said to have been opticians, or spectacle-makers, residing at Middleburgh. In a letter written by a son of Jans, it is stated that the epoch of the discovery is the year 1590; but by another account, the year 1610. The same author has also given a letter from M. William Boreel (envoy from the States of Holland to the British Court) which seems to throw some light on the acts. The writer of the letter asserts that he was acquainted with the younger Zachariah Jans, when both of them were children, and had often heard that the elder was the inventor of the *microscope*: he adds that, about the year 1610, the two opticians Jans and Lapprey first constructed telescopes, and that they presented one to Prince Maurice of Nassau, who desired that the invention might be kept secret as (the United Provinces being then at war with France) he expected to obtain in the field, by means of the instrument, some advantages over the enemy. The writer further states that the invention became known, and that soon afterwards Adrian Metius and Cornelius Drebbel went to Middleburgh and purchased telescopes at the house of Jans. This account differs from that which is given by Descartes, ('Dioptrics,' cap. 1) who, writing in Holland, states that about thirty years previously, Metius (who was, he observes, a native of Alckmaer), having always taken pleasure in forming burning-mirrors and lenses of glass and of ice, by chance placed at the extremities of a tube two lenses, one thicker in the middle, and the other thinner, than about the edge (convex and concave); and thus, he adds, was formed the instrument which is called a telescope. The 'Dioptrics' was published at Leyden, in 1637, and therefore the time of the supposed invention by Metius is nearly coincident with that at which, according to Borellus, it was made by Jans. From the papers of Harriot, it appears that this mathematician observed spots on the sun, in 1610, with telescopes magnifying from ten to thirty times; but it is uncertain whether he got them from Holland, or whether they were made in this country; and the only conclusions at which it is possible now to arrive, are, that telescopes were known in England and Holland about the end of the 16th century, and that in both countries they were then in a form which rendered them practically useful.

The two Jansens, father and son, appear to have used their telescopes in observing the heavens; and the latter is said to have remarked four small stars near Jupiter: it has been concluded from thence, that he was the first discoverer of the satellites of that planet; but though this may be, he probably did not continue his observations long enough to enable him to determine their distances from it, or the times of their revolutions.

The use of the telescope, and, probably, even the knowledge of the fact that it had been invented, must have been for many years confined to the north of Europe; for it appears that it was not till the year 1609 that Galileo, who then happened to be at Venice, heard from a German a rumour of the discovery which was said to have been made in Holland. The Italian philosopher states, in the 'Sidereus Nuncius,' that he had then no knowledge of the nature of the instrument, and that he requested a friend at Paris to send him some information concerning it. On being informed, merely, that it was a tube containing glass lenses, his acquaintance with the nature of the refraction of light enabled him, it is said, to discover that one of the lenses must have been convex and the other concave, and also to determine the distance at which they should be placed from one another in order that the objects seen through them might appear magnified and distinct. Without however supposing that Galileo was here guided by theoretical considerations merely, it is easy to conceive that as lenses of different forms were then in use for spectacles, he might have obtained from an optician some which were of different degrees of convexity and concavity; and after a few trials he must have found such as would constitute an instrument possessing magnifying power.

The telescopes which he constructed consisted of one convex object-glass and one concave eye-glass, which were placed at the extremities of a leaden tube; and the first of them magnified the heights and breadths of objects three times only. Soon afterwards he made one which magnified eight times; and subsequently he succeeded in forming a telescope with a magnifying power which caused objects to appear about thirty times as great as they appear to the unassisted eye.

The knowledge which man had acquired of the visible heavens received many important accessions from the discoveries that Galileo was enabled to make by means of the telescope. Except the sun and moon, not one of the celestial bodies had hitherto been observed to have any visible form or magnitude, and it was to the eye of reason alone that those appeared to be anything but plane surfaces. The fixed stars and the planets were alike known only as luminous and ill-defined points; but when seen through a telescope, the planets were found to have certain magnitudes, and some of them to undergo variations of form; while the fixed stars appeared unchanged, or only divested of the radiance with which they seem to be surrounded when seen by the naked eye; and hence it became obvious that the former must constitute a distinct group of bodies infinitely nearer the earth than the others. The sun, from the spots observed on his surface, was found to revolve on its axis, and consequently was ascertained to be globular; and the light and dark spaces on the moon were distinctly perceived to be mountains and valleys, nearly resembling those features on the surface of the earth. Galileo relates, in the work above mentioned, that in the year 1610 he discovered the four satellites of Jupiter, and observed that they revolved about that planet as our moon revolves about the earth. Nearly at the same time he observed that Saturn presented a remarkable appearance: at first he thought it was accompanied by two smaller planets; but on using a telescope of superior magnifying power, these were found to be portions of a vast annulus which surrounds Saturn without touching his surface; and soon afterwards he ascertained the fact that Venus exhibited phases similar to those of the moon.

The species of telescope which was used by Galileo continued for several years unchanged; yet it is extremely defective, on account of the small extent of the field of view which it affords when its magnifying power is considerable; and the Batavian or Galilean telescope, as it was called, is now chiefly used in the form of an opera-glass. It is due to the memory of Kepler to state that he pointed out (in his 'Dioptrics') the possibility of forming telescopes with two lenses, both of which are convex; but he did not reduce his ideas to practice by the construction of such an instrument, and the honour of having been the first to do so is to be attributed to the Jesuit Scheiner, who, in his 'Rosa Ursina' (1650), gives a description of telescopes with one convex eye-glass. He observes that they cause the images of objects to appear in inverted positions; and adds, that thirteen years previously he had used such a telescope in the presence of the Archduke Maximilian.

Telescopes with a single convex eye-glass have been since designated *astronomical*, from the circumstance that they were long employed for celestial observations; the greater extent of their field of view having caused them, notwithstanding the inversion of the image, to supersede for that purpose the telescopes of Galileo. It ought to be remarked, however, that telescopes with two eye-glasses, by which the object might be seen in a direct position, as it appears to the naked eye, were described by Kepler, and constructed by Scheiner; but as they caused the object to appear much distorted and coloured about the margin of the field, they were not esteemed. Père de Rheita, about the same time, constructed for telescopes eye-tubes containing three lenses, which, he observes, afford a better image than those with two. The same person was the inventor of what is called a *binocular telescope*, that is, an instrument which consists of two telescopes having equal magnifying powers, and placed near each other in such positions that an object might be observed with both eyes at the same time. Attempts have been since made to revive this invention; but the advantages, if any there be, are more than compensated by the trouble of directing the two tubes to the object. By combining, however, the stereoscopic principle, some advantages are likely to arise, as in the case of the binocular microscope.

The magnifying power of a dioptrical telescope increasing with the ratio which the focal length of the object-glass bears to that of the eye-glass, and since, by increasing the focal length of the former without increasing its diameter, the coloured border round the image is diminished so that vision is rendered more distinct, the opticians of the 17th century were induced to form, for object-glasses, lenses which were segments of very great spheres—that is, lenses of great focal lengths. Campani, at Bologna, by order of Louis XIV., made telescopes having object-glasses whose focal lengths were as great as 136 feet; and with such, Cassini, in 1671, discovered the satellites of Saturn.

Huyghens, who was an ingenious mechanic, as well as a good philosopher, contrived to use an object-glass of long focus for astronomical purposes without placing the system of lenses in a tube. On the top of a long pole which was planted vertically in the ground, he mounted the object-glass, having fixed it in a frame with joints so that its axis could be moved in any direction by means of a string which was held in the hand of the observer; and the axis being in a line passing through the celestial body, a short tube containing the eye-glasses was fixed to a stand near the ground with its axis in the same direction. An *aërial refractor* (as this kind of instrument was called), having an object-glass 123 feet focal length, was made by Huyghens and presented to the Royal Society; and with it Dr. Bradley made some of his astronomical observations. Pound used it to furnish the diameters of Jupiter and Saturn, and the elongations of their satellites, calculated on by Newton in his 'Principia.' It is described by Huyghens in his 'Astroscopia Compendiaria,' which was printed at the Hague in 1684. M. Auzout is said to have executed an aërial refractor at Paris of 600 feet focal length; but this proved unmanageable. But the chief merit of Huyghens as an improver of astronomical telescopes consists in his construction of an eye-piece with two lenses so combined as both to enlarge the field of view and diminish the aberrations produced by their spherical forms.

There is some probability that the elder Digges had contrived an instrument which constituted a species of catoptric or reflecting telescope; but, on account of the obscure manner in which the instrument is described, it will be scarcely necessary to notice further his claim to the honour of the invention. It appears that Père Mersenne, in his correspondence with Descartes, and in his 'Catoptrics' (1651), suggested the idea of a concave spherical mirror to be used, like the principal lens of a dioptric telescope, for forming in its focus an image of an object; and that this image being viewed through a convex eye-glass of proper curvature, the original object would appear to be magnified. Descartes, in his reply to Mersenne, which is said to have been written in 1639, makes several objections to the scheme, and no effort was then made to put it in practice. But the great length of the dioptric telescopes which were then in use rendering the management of them very inconvenient, ingenious men were induced to attempt a construction in which, with equal magnifying power, much smaller dimensions might be employed. Mr. James Gregory of Edinburgh, in his 'Optica Promota' (1663), published a suggestion for forming a telescope by means of the image at the focus of a concave speculum. The mirror was to be of polished metal with a paraboloidal surface, which by the properties of that curve would cause all rays incident upon it in directions parallel to the axis to converge accurately at one point. It is uncertain whether Gregory had any knowledge of Mersenne's treatise, or whether the idea originated with himself; but this is of little consequence, for not being able to find an artist who could execute such a speculum, though he came to London for the purpose, the suggestion was abandoned, and men of science continued to direct their inquiries to the means of improving dioptric telescopes.

When, however, Newton had discovered the unequal refrangibility of light, and had ascertained that the aberration produced by this cause about the focus of a lens was many hundred times greater than that which was caused by the spherical form of the glass, he gave up the hope of being able to construct refracting telescopes which should be free from this defect, and applied himself to the formation of specula for those of the catoptric kind: the image formed by reflection from a mirror being free from what is called the *chromatic aberration*, and consequently incomparably more distinct than one which is formed by the refraction of light in a lens of any transparent medium.

In the beginning of 1669, Newton having obtained a composition of metals which appeared likely to serve for a mirror, began with his own hands to grind its surface to a spherical form; and early in the year 1672 he completed two telescopes: of the construction and performance of these instruments he sent to the Royal Society an account which was read in the January of that year. The radius of the concave metal in one of them was 13 inches, and the telescope magnified about 38 times. The rays, before forming an image in the focus of the speculum, were intercepted by a glass prism, or a plane mirror, and the image formed after this second reflection was viewed by a convex eye-glass which was fixed for the purpose in the side of the tube. In the telescope proposed by Gregory, the rays in each pencil of light, after crossing at the focus of the great speculum, were to fall upon the surface of a small concave mirror; and by this being again reflected, they were to form a second image near the anterior surface of the first speculum: through a perforation in the latter the image was to be viewed; a convex lens being interposed between the image and the eye of the observer. This has been always called the Gregorian telescope; and in 1672, the year in which Newton completed his reflecting telescopes, M. Cassegrain, in France, proposed one which differed from that of Gregory only in the rays reflected from the great speculum being intercepted by a small convex mirror; from this the rays of each pencil were again reflected, and they were made to form an image near the anterior surface of the great speculum; this image was to be viewed through a convex lens behind an aperture in the latter speculum, as in the telescope of Gregory. It does not appear that M. Cassegrain constructed such a telescope, but it may be observed that the image formed after reflection from the convex speculum would be more free from the aberration caused by the surfaces of the mirrors, and would also be rather greater, than that which is obtained from the concave speculum of Gregory, or the plane one which was used by Newton.

The first reflecting telescope, in which the great speculum was perforated so that objects could be viewed by looking directly at them, was executed by Dr. Hooke, and produced before the Royal Society in February, 1674. But the difficulty of obtaining metal proper for the purpose, and of giving it a perfectly spherical form, for a long time prevented reflecting telescopes from attaining the desired degree of perfection. In 1718 Mr. Hadley succeeded in executing two telescopes, each about five feet long, which were considered good; and he gave, in the 'Philosophical Transactions' (1723), a description of the methods employed in their construction. By his advice Dr. Bradley, who was then professor of astronomy at Oxford, in conjunction with Mr. Molyneux at Kew, applied themselves to the construction of these instruments: having executed one which was satisfactory, they in 1738 instructed Scarlet and Hearne, two London opticians, in the processes which they used, and these artists presently succeeded in making good reflecting telescopes for general sale. Mr. James Short of Edinburgh, also soon afterwards distinguished himself by his skill in forming such telescopes: he attempted at first to make the principal speculum of glass, but finding that this material had not sufficient steadiness to preserve the form of its surface, he devoted himself to the improvement of metallic specula, and succeeded in giving them, it is supposed, a correct parabolic figure, by which means his telescopes admitted of larger apertures than any that had before been made.

The processes adopted by Mr. Mudge in grinding and polishing the mirrors for reflecting telescopes, and in giving them the parabolic figure, may be seen in the 'Philosophical Transactions' for 1777. See also SPECULUM.

But the reflecting telescope was carried to a high degree of excellence by Dr. (afterwards Sir William) Herschel. This distinguished astronomer, while residing at Bath, employed his leisure hours in grinding and polishing specula, with which he formed telescopes, both of the Newtonian and Gregorian kinds; and about the end of 1783, that is subsequently to the discovery of the planet which is sometimes called by his name, being aided by the liberality of the king (George III.), he began the formation of a speculum four feet in diameter and forty feet in focal length: the telescope to which it appertains is of the Newtonian kind, the observer being placed in a seat near the open end of the tube, and viewing the image through a system of eye-glasses. With this telescope, which was completed in 1789, objects are magnified about 6500 times; and on the night after it was finished, Dr. Herschel discovered the sixth satellite of Saturn. The attempts that have been made to form a reflecting telescope possessing a higher degree of perfection than that of Herschel will be noticed presently.

While the improvement of reflecting telescopes was in progress, the efforts to combine glass lenses in order to diminish the coloured fringes by which the images in dioptrical telescopes are surrounded were not entirely neglected; and as early as 1729, a private gentleman, Mr. Chester More Hall, of Essex, influenced, it appears, by an opinion that the humours of the eye are combined so as to correct the dispersions which each alone would produce in the different kinds of light, contrived to combine two lenses of different kinds of glass in such a way as to form an image which was free from colours: it is added that telescopes with such object-glasses were in the possession of several individuals many years afterwards. ('Gent. Mag.', October, 1790; 'Phil. Mag.', November, 1798.)

In 1747, Euler, guided also by the constitution of the eye, conceived the possibility of forming a lens compounded of two hollow spherical segments of glass, inclosing water between their concave sides, which should be free from the chromatical and spherical aberrations; and in investigating the curvatures, he assumed that the logarithms of the terms expressing the ratio of the refraction of a mean ray in passing from air into glass, and from air into water, were proportional to the logarithms of the terms expressing the ratio of the refractions of red rays in the same media. He was not able to obtain from any artist a lens of this nature, in which the proposed end was accomplished, and Mr. Dollond, in a short paper which is printed in the 'Philosophical Transactions' (1752), contested the justness of Euler's principle on the ground that it was contrary to one which he conceived to be founded on the experiments of Newton.

But M. Klingenstierna, a Swedish mathematician, having soon afterwards, in a Mémoire which was sent to the Académie des Sciences, pointed out that the principle which had been adopted by Dollond was not conformable to the acknowledged laws of refraction, the latter determined immediately on having recourse to experiment. Either guided by the object-glasses constructed under the direction of Mr. Hall, or from a series of experiments made by himself on the refraction of light in wedges of crown and flint glass, he discovered that by employing a convex lens of the former, in combination with a concave lens of the latter kind, the rays of the different colours in each pencil of light, after refraction through both, might be made to unite at the focus, and thus produce an image of the object nearly free from colour. For this important discovery Mr. Dollond received from the Royal Society the Copleian medal. In 1765 his son, Mr. Peter Dollond, diminished the aberration of light on account of the spherical forms of the lenses by combining together two convex lenses of crown glass with a concave lens of flint glass between them: this construction is particularly advantageous, by the increased aperture which it allows when the focal length of the compound lens is short.

For several years after the telescopes thus improved by Dollond had been in general use, Euler continued to believe that all kinds of glass differed but little from each other with respect to their dispersive power, and he ascribed the success of the English artist merely to a fortunate determination of the curvature of his lenses; but having, in the year 1764, received information that, by the addition of lead, glass had been obtained whose dispersive power was four times as great as that of the common kind, he immediately renounced his former opinion; and from that time the merit of the achromatic object-glasses, as they were called, has been firmly established. The most eminent mathematicians, both on the Continent and in this country, have subsequently investigated, on scientific principles, the curvatures which should be given to the surfaces of lenses, so that, the focal length of the compound lens being assumed, the chromatical and spherical aberrations may be corrected.

The arrangement of lenses for the eye-pieces of telescopes is of no less importance than the formation of the object-glass; and Huyghens proposed ('Dioptrics,' prop. 51), in order to diminish the refraction of light at the surfaces, to substitute for the single eye-glass of the common astronomical telescope two convex lenses, of such curvatures that the whole refraction, or the angle between the incident and emergent ray in the former construction, should be divided between the two lenses.

One mode of effecting this purpose is to place the first eye-glass, or that which is nearest to the object, so as to intercept the pencils coming from the object-glass before the rays are united, and thus the image is formed after the refraction of the light in this lens: the second eye-glass is then placed so that the rays falling on it, after having crossed at the place of the image, are made to enter the eye parallel to one another. A micrometer cannot be applied to such an eye-piece, since any change in the place of the lens which is nearest to the eye would derange its adjustment: these eye-pieces can however be rendered achromatic, and they have the greatest possible field of view; they have therefore been constructed for the purpose of merely viewing the celestial bodies by Dollond, Ramsden, and Frauenhofer. Mr. Ramsden was the first who constructed eye-pieces with two lenses which were capable of being used with a micrometer: this he accomplished by placing the tube containing those lenses so that the rays in the pencils, after crossing at the focus of the object-glass, fell in a diverging state upon the first eye-glass, and, after refraction in both, entered the eye in parallel directions.

With both these kinds of eye-pieces the object appears to be inverted; but eye-pieces with three lenses, by which the object is made to appear in the erect position, had been proposed by Rheita: these being found defective, Mr. Dollond endeavoured to improve upon the construction by dividing the refraction at the first and third eye-glasses between two lenses, according to the method recommended by Huyghens; and thus he formed eye-tubes with five lenses. But some light is always lost by reflection when it falls upon glass; and in order to diminish this evil, Dollond subsequently, retaining the Huyghenian construction in the two lenses nearest to the eye, used but one lens to perform the office of the second and third (in the eye-piece with five glasses), in rendering the rays of each pencil convergent after the first had diminished the divergency caused by the crossing at the focus of the object-glass: he thus succeeded in producing an eye-piece of four lenses which was nearly *aplanatic*, or free both from the chromatical and spherical aberrations; and such are the telescopes now in common use for viewing terrestrial objects.

The chief improvements, if they may be so called, which have since been made in dioptric telescopes, consist in the means which have been adopted to remove those aberrations more completely; and the nature of the different media which have been used for this purpose by Dr. Blair, Sir David Brewster, and Mr. Barlow, are mentioned under TELESCOPE.

We must, however, briefly notice the attempts that have been made of late years to improve what is called *optical* glass. Flint glass is subject to numerous defects resulting from a want of uniform density, which defects are so common as to have obtained distinguishing names, such as *striæ*, or *wreath*, *knots*, *threads*, and *tears*. The striæ are undulating appearances in the glass, whereby the light in passing through it is refracted and dispersed in different directions, producing a wavy effect not always apparent until the glass enters into the construction of an optical instrument. Knots are opaque particles derived from the glass-pot, or particles of glass-gall, or imperfectly vitrified grains of sand. Threads and tears also consist of partially vitrified matter. The glass may also want clearness from the presence of minute bubbles or air, as it is called, diffused through the glass in consequence of its not having been kept sufficiently fluid. It is said that good results have been obtained by horizontal sections of the whole contents of a pot of glass.

Our space will not allow us to do more than indicate the various attempts that have been made to improve optical glass. After the discovery of the achromatic principle, it was seen how important it was to obtain glass of uniform density. Dollond, and the best opticians abroad, had extreme difficulty in obtaining glass adapted to their purpose. The Academy of Sciences at Paris offered prizes in vain for unobjectionable optical glass: some of the best chemists devoted their attention to the subject, but they did not succeed in obtaining larger glasses than from 3 to 3½ inches in diameter. Manufacturers also made the attempt without success. M. Guinand, a watch-maker of Brenets, near Neufchâtel, in Switzerland, was the first to approach the solution of the difficulty. He is said to have got rid of striæ by diligently stirring and mixing the materials while in a state of fusion. His success was such as to induce M. Utzschneider, of Munich, to join him and M. Frauenhoffer in their establishment at Benedictbaüern in Bavaria. He accepted the offer, and remained with them from 1805 to 1814; one of the largest glasses resulting from their experiments (9 inches in diameter) is now in the Observatory at Dorpat. Guinand's presence greatly improved this manufactory, and achromatics of 6, 7, 8, and 9 inches in aperture issued from the establishment, which continued after the death of Frauenhofer to maintain its reputation under the management of Messrs. Merz and Mahler. Guinand, towards the close of his life, had some communication with the Astronomical Society of London. A disc of flint glass, 6 inches in diameter, was reported on favourably by Messrs. Dollond, Herschel, and Pearson. A commission was also appointed, consisting of Messrs. Herschel, Faraday, Dollond, and Roget, to inquire into the manufacture of flint glass. Mr. Faraday pursued the inquiry for some time, and succeeded in producing a borate of lead of remarkable purity. But the excise officers were found to be so obstructive in their regulations, as to make it very difficult to pursue the inquiry, which was, therefore, terminated. Guinand is said to have imparted his secret to his sons before he died, and they endeavoured to sell it on the best terms in England and France. M. Bontemps became associated with one of the sons, and in 1828 they succeeded in producing good flint glass, the largest discs being from 12 to 14 inches. Guinand's widow and another son established works in Switzerland, and were succeeded by M. Daguet, of Soleure, some of whose products appeared at the Great Exhibition of 1851. The Jury Report, Class XXIV., states that these discs "confirm the belief that there are even more impediments in fabricating crown glass of large size, than in making good crystal. In order to render it free from impurity, it becomes more difficult of manufacture, more liable to tension, and to accidents. It requires a higher temperature. By increasing the facility of fusion, the disposition to attract humidity, or to sweat, is increased. In rendering it too hard, the risk of crystallisation and imperfect vitrification in cooling, is incurred."

Soon after 1848, M. Bontemps joined the house of Messrs. Chance, Brothers, and Co., who determined to devote some of their large means to the manufacture of optical glass. They succeeded in producing discs of extraordinary dimensions—in flint of 29 inches in diameter, weighing 2 cwt., and of crown glass up to 20 inches. The large flint glass was ground and finished, and was said to be so uniform in density and otherwise satisfactory, that the Jury recommended a council medal to be awarded to the manufacturers.

Mr. Ross has called attention to a defect in optical glass, which may be detected by the searching agency of polarised light. A glass of not more than 6 inches in diameter, undergoes the annealing process with difficulty, cooling more rapidly at the surface than in the interior, and as this tendency increases with the size, the production of a disc of 29 inches is justly regarded as a very remarkable work.

Sir John Herschel, in a recent article on the telescope ('Ency. Brit.') suggests that the ultimate perfection of the achromatic telescope would be obtained were it possible to manufacture other species of glass with a much lower dispersive power than crown or plate glass, or a different action on the rays of intermediate refrangibility. The fluoric compounds have remarkably low dispersive power, that of cryolite and fluate of lime is only two-thirds that of plate glass, holding nearly the same place with respect to this glass that the latter does to flint. The fluoride of strontium is also suggested as a promising material. It is also stated that M. Jamin, by using oxide of zinc instead of that of lead in flint glass, has succeeded in forming a zinc flint glass of exquisite limpidity, of low refractive and dispersive power, and capable of being wrought into discs of any size.

Attempts have been made by M. Chevalier to diminish the aberrations by means of two achromatic object-glasses placed at a certain distance from each other in the tube; and by Mr. Rogers of Leith, by a single convex lens of plate-glass, in combination with a double achromatic lens, the convex lens being of plate-glass, and the concave lens of flint-glass. This last gentleman proposes to unite the red and violet rays at the image of the object by a proper distance between the single and the double lens, and to correct the spherical aberration either by giving proper curvatures to the surfaces of the compound lens, or by placing the two lenses at a small distance from each other in the narrower part of the converging cone of rays. ('Memoirs of the Astron. Soc.,' vol. iii.)

This was reduced to practice in 1839 by M. Plössl, of Vienna, under the name of the Dialytic Telescope, which is characterised by Sir John Herschel as "a very artificial and beautiful invention, highly deserving further trial." Somewhat resembling this contrivance is Mr. Peter Barlow's plan of placing in the narrowing cone of rays from a plate-glass object-lens a concave lens formed of two plate-glass capsules of equal thickness, inclosing between them a highly dispersive fluid, namely, the bisulphide of carbon, of which the refractive index is 1·678, and the dispersive power 0·115, or more than double that of flint-glass. This fluid lens is concavo-convex. By proper curves the spherical aberration can be destroyed; and by varying the distance between the two lenses, exact achromaticity can be produced. The principle was tested in a telescope of 8 inches aperture and 12 feet focal length, with success: as Mr. Barlow remarks, "less than an ounce of sulphuret of carbon, value three shillings," was made to perform the office of a very costly flint disc of 8 inches. ('Phil. Trans.,' 1828, 1829, 1831.)

Sir D. Brewster has suggested ('Treatise on New Phil. Inst.,' p. 400) that it may be possible to remove, or at least very much diminish, the uncorrected colour in the image by the use of two lenses of the same kind of glass with the same or different dispersive powers. He proposes that the exterior lens should have the meniscus form, the convex side being outwards, in order, from the obliquity of the incident rays to the surface, that the dispersion produced by that lens may increase in a higher ratio than its refraction, so that the dispersion produced by the other lens may be corrected; while in each pencil the rays, after refraction through both, may be convergent.

It would be improper to omit here to mention that M. Amici, at Modena, some years since, invented a species of achromatic telescope by a combination of four prisms, all of the same kind of glass: the refracting edges of one pair of the prisms were parallel to one another, and those of the other pair were also parallel to one another, but perpendicular to the edges of the first pair; and each pair formed an achromatic combination. By the refraction in the first pair, the breadth of the object is magnified, and by that in the second pair the length is magnified in the same ratio: thus the result is an image undistorted and magnified. Sir John Herschel states that, in 1826, he saw in the hands of its inventor one of these telescopes, which magnified about four times.

The success which Sir W. Herschel obtained in the construction of reflecting telescopes was unrivalled during many years; but at length has been surpassed by Earl Rosse, who has erected in the grounds of Birr Castle, Parsonstown, Ireland, two telescopes, in the lesser of which the speculum is of three feet aperture, and in the greater telescope 6 feet, or a reflecting surface of 28·274 square feet, being greater than that of Herschel's large telescope in the ratio of 7 to 3. Its focal length is 53 feet. It can be used either on the Newtonian or the Herschelian principle. The great tube is of wood hooped with iron, and is 7 feet in diameter and 52 feet in length. It is suspended between two lofty meridional walls of solid masonry, between which its upper end is allowed a considerable amount of lateral motion, so as to admit of taking up the view of a celestial object some time before its arrival on the meridian, and following it for some time after, without displacing the lower end. This lower end is supported on a massive universal joint of cast iron, resting on a stone pier buried in the ground, and so counterpoised as to be easily moved in declination. The preparation of the speculum, which weighs 4 tons, is described under SPECULUM. The stairs and galleries for the observers are supported by the western pier. The first gallery commands a view of objects at an altitude of 42°. It consists of a strong light prismatic framing sliding between two fixed ladders; it is counterpoised, and can be raised to the required position by means of a windlass. There are three other galleries at the summit of the western pier, which command the heavens to five degrees below the pole. Each gallery is supported by beams which run between grooved wheels. For some of the achievements of this splendid instrument we may refer to a Memoir by Lord Rosse, 'Phil. Trans.' 1850. See also NEBULÆ.

Mr. Lassells' reflector has a clear diameter of 2 feet, and 20 feet focal length; it was originally erected at his residence near Liverpool, and in 1852 was removed to Malta, for the advantage of a clearer atmosphere and a lower latitude. By means of this instrument, Mr. Lassells discovered two of the satellites of Uranus, one of Saturn, and one of Neptune. This instrument is erected under a revolving cupola 30 feet in diameter, carrying a stage for the observer. The image may be deflected towards the eye-glass, either by a small two-inch speculum, or by a prism. To prevent dew forming on the latter, a small piece of heated lead is placed in a case near it. Metal does not contract dew, but glass is peculiarly liable to deposit it; hence achromatics are generally furnished with a dew-tube, which is merely a brass cylinder blackened within.

In Mr. Nasmyth's reflector, the rays from the great speculum are received on a small speculum or prism, placed in the axis of the tube, between the focus and the great speculum, by which they are reflected at right angles, and the image is formed in a tube inserted in one of the trunnions, on which the instrument turns. The image is then viewed in the usual way by an eye-piece; the advantage is, that while the great tube is moved in altitude, the side-tube is fixed, and the observer can survey the whole meridian or any other vertical circle without changing his position. The instrument is moved in azimuth by means of a turn-table, on which is the frame of the instrument and the seat for the observer, who can thus command every required motion, both in altitude and azimuth. The great tube has a length of 28 feet, and a diameter of 54 inches.

Telescopes for general astronomical purposes are now almost always mounted equatorially, and great improvements have been made in the mounting, the method of the Astronomer Royal being particularly recommended for its lightness, combined with extreme stiffness to resist both flexure and twist.

The history of the telescope may be assisted by reference to the following heads: EQUATORIAL; TRANSIT; SPECULUM; ACHROMATIC; LIGHT; LENS; APLANATIC LENS; ABERRATION; MICROMETER; EYE-PIECE; ASTROLABE; QUADRANT; THEODOLITE; HELIOSTAT; HELIOMETER; OPTOMETER; REFRACTION; DISPERSION.

TELESCO'PIUM (the Telescope), a constellation of Lacaille, in the southern hemisphere, surrounded by Ara, Pavo, Sagittarius, and Ophiuchus. Its principal star is as follows:—

TELLER-BISMUTH. [TELLURIUM.]

TELLERS OF THE EXCHEQUER (*tailler*) were the holders of an ancient office in the Exchequer. [TALLY.] They were four in number; their duties were to receive money payable into the Exchequer on behalf of the king, to give the clerk of the pells (skins or rolls of parchment) a bill of receipt for the money, to pay all money according to the warrant of the auditor of receipts, and to make weekly and yearly books of receipts and payments for the lord treasurer. (4 'Inst.', 108; 'Com. Dig.', tit. 'Court,' D. 4, 14, 15.) The office was abolished by act of parliament (4 & 5 Wm. IV., c. 15), together with that of the clerk of the pells and the several offices subordinate thereto.

TELLURETTED HYDROGEN. [TELLURIUM.]

TELLURIC ACID. [TELLURIUM.]

TELLURIUM (Te) is a rare element, very similar to SELENIUM, and closely allied to SULPHUR. It is sometimes found in the free state, but usually occurs in combination with metals forming *tellurides*. [TELLURIUM, in NAT. HIST. DIV.] From the Nagyag ore, which contains about thirteen per cent., it is obtained by dissolving in nitric acid after the sulphides of lead and antimony have been separated by digestion in hydrochloric acid. The nitric acid solution is evaporated to dryness, the residue treated with hydrochloric acid and filtered, and tellurium thrown down from the filtrate by the addition of sulphite of soda.

Tellurium has a silver-white lustre, and is very brilliant: it is crystalline and brittle, of a lamellar fracture, easily pulverised, and a worse conductor of electricity than antimony or bismuth. Its specific gravity is 6·65. It is nearly as fusible as antimony, and at a high temperature it boils, and may be distilled. When strongly heated in contact with air, it burns with a lively blue flame, green at the borders, and forms a white vapour, which has an acid odour.

The equivalent of tellurium is 64·5.

Tellurium and *oxygen* form two compounds:—

Tellurous acid	TeO_2
Telluric acid	TeO_3

Their constitution is obviously similar to that of sulphurous and sulphuric acids.

TELLURIUM-AMYL. [ORGANO-METALLIC BODIES.]

TELLURIUM-ETHYL. [ORGANO-METALLIC BODIES.]

TELLURIUM-METHYL. [ORGANO-METALLIC BODIES.]

TELLUROUS ACID (TeO_2). It has been already mentioned that when tellurium is heated in contact with air, it burns, and a white vapour is formed: this is oxide of tellurium, or tellurous acid. It may also be obtained by the action of nitric acid on the metal; by adding water to the solution, part of the oxide is precipitated, and the remainder is obtained by evaporation to dryness. It is a white granular anhydrous powder, which slowly reddens moist litmus-paper, and is insoluble in water and acids. It is dissolved by a solution of potash or soda, and by fusing with their carbonates crystallisable salts are formed: when these are decomposed by acids, hydrated tellurous acid is precipitated, which, if washed with very cold water and dried at a temperature not above 53° Fahr., may be preserved without suffering change. The hydrate is soluble in water, acids, ammonia, and the alkaline carbonates, which last it decomposes: the aqueous solution reddens litmus-paper: when zinc, tin, and some other metals are left in a solution of this acid, they deoxidise it, and metallic tellurium is precipitated in the state of a black powder. Its salts are called *tellurites*.

Telluric Acid (TeO_3).—This compound is obtained by fusing tellurous acid with nitrate of potash, which oxidises it completely, and the result is tellurate of potash. When chloride of barium is added to the last-named salt, tellurate of baryta is precipitated, which being decomposed by sulphuric acid, yields a solution of telluric acid, and this solution furnishes hexagonal crystals of the acid. It acts but feebly as an acid, the dilute solution reddening litmus-paper with difficulty, and its taste is rather metallic than sour: the crystals contain water, two-thirds of which they lose at about 212°; the remainder below a red heat becoming a mass of a fine orange colour, which is completely insoluble in water, either cold or boiling, or hot hydrochloric or nitric acids, or solution of potash. It is decomposed at a high temperature, and converted into a white powder, which is tellurous acid. Its salts are called *tellurates*.

Hydrogen and Tellurium form *telluretted hydrogen* (TeH).—When tellurium is alloyed by fusion with tin or zinc, and the compound is acted upon by hydrochloric acid, the hydrogen of the decomposed acid dissolves tellurium, and telluretted hydrogen gas is obtained. This gas has a smell resembling that of hydrosulphuric acid: it is soluble in water, forming a colourless solution, which becomes brown by exposure owing to separation of tellurium. As it possesses acid properties, though to a slight extent only, it has been called *hydrotelluric acid*. It decomposes many metallic salts, yielding an alloy of tellurium with the other metal. Chlorine, nitric acid, and the oxygen of the air, all take the hydrogen from the tellurium.

Chlorine and Tellurium form two compounds. When a feeble current of chlorine gas is passed over tellurium at a high temperature, the *chloride* formed passes over as a violet-coloured vapour, which condenses at first into a black liquid, and eventually into a solid of the same colour. It is decomposed by the action of water into metallic tellurium, which is precipitated, and bichloride of tellurium, which remains in solution.

It is composed of one equivalent of chlorine, and one equivalent of tellurium (TeCl).

The *Bichloride of Tellurium* ($TeCl_2$) is obtained, as above stated, by the action of water on the bichloride, but is better procured by passing a larger quantity of chlorine over tellurium at a lower temperature than in forming the chloride. It is volatile, and any excess of chlorine being separated by agitation with mercury and rectification, it is obtained as a white crystalline solid.

Sulphur and Tellurium combine in two proportions: the *bisulphide* (TeS_2) is obtained when hydrosulphuric acid gas is passed through a solution of tellurous acid, or of a soluble tellurite. It is of a dark brown colour, and is soluble in a solution of potash.

Tersulphide of Tellurium (TeS_3) is obtained by mixing a solution of persulphide of potassium with one of a salt of telluric acid. It is of a deep yellow colour; but it is a very unstable compound, for it speedily becomes black, and is converted into bisulphide.

TEMPERA (Ital. *à tempera*), that method of painting in which the vehicle employed is composed of a glutinous material (usually glue, white of egg, or gum), diluted (or "tempered") with water; gesso, or plaster of Paris, being added to the colours to give them greater consistency, or, as it is termed, body. This was the method employed by the ancient Egyptians, the Greeks prior to the introduction of wax as a vehicle [ENCAUSTIC PAINTING], and by the early Christian painters. [PAINTING.] Distemper-painting, as now practised by scene-painters and decorators, is only a less refined form of tempera, from which it has indeed derived its designation. [DISTEMPER; SCENE-PAINTING.]

TEMPERAMENT (*temperamentum*, *κρᾶσις*) is a vague and unsatisfactory term, but it is one which as Mayo observes ('Pathology of the Human Mind') has been long and generally adopted as a convenient generalisation. The word means literally *a tempering*, or *mixing together*, and may be defined to be a peculiar state of the system common to several individuals, which results from the various proportions in which the elementary parts of the human body are *mixed up together*, and which gives rise to a tendency to certain phenomena. There is, besides, in each individual a further peculiarity of combination, which serves to distinguish his temperament from that of any other person, to whom, however, he may in other respects bear a great resemblance. This individual temperament is called an *idiosyncrasy* (that is, a peculiar mixing together), and, as the two words are sometimes confounded, it may be useful to point out the distinction between them. All the different systems of organs in the human frame are accurately adjusted to each other, so as to produce one harmonious whole. If the disproportion be too great, disease ensues; but there are many gradations, compatible with health, where yet this disproportion is very observable. The predominance of any particular system of organs modifies the whole economy, impresses striking differences on the results of the organisation, and has perhaps almost as great an influence on the moral and intellectual as on the physical faculties. This predominance establishes the temperament: it is the cause of it, and constitutes its essence. The ancients paid considerable attention to the subject of temperaments, and pointed out various peculiarities in the constitution and actions of the human body, which have been seen so far to coincide with general observation, that their nomenclature has continued in very general use even to the present day, although the hypothesis on which it was founded is universally discarded. They described four temperaments corresponding to the four qualities of Hippocrates—hot, cold, moist, and dry. It was supposed that there were four corresponding primary components of the human body, namely, blood (*αἷμα*), phlegm or pituita (*φλέγμα*), and the two kinds of bile (*αἱ δύο χολαί*), yellow bile (*ξανθὴ χολή*), and black bile, or atrabilis (*μέλαινα χολή*); and the preponderance of one or other of these components in different persons produced the different temperaments. These four primary principles of living bodies were supposed to be compounded of the simple elements or qualities of nature thus: hot and moist produce blood; cold and moist, phlegm or pituita; hot and dry, yellow bile; and cold and dry, black bile. Bodies in which blood superabounds are of the sanguine temperament; if phlegm is in excess, the phlegmatic temperament is developed; if yellow bile, the choleric; and if black bile, the melancholic or atrabilious temperament. A minute description of the different temperaments is given by Paulus Ægineta, 'De Re Medica,' lib. i. cap. 61. The due admixture of the different qualities was supposed to constitute the best form of temperament or constitution (*εὐκρασία*), of which the following is Paulus Ægineta's description:—"That man is in the best temperament of body when it is in a medium between all extremes, of leanness and obesity, of softness and hardness, of heat and cold, of moisture and dryness; and, in a word, who has all the natural and vital energies in a faultless state. His hair also should be neither thick nor thin, neither black nor white. When a boy, his locks should be rather tawny than black, but when an adult, the contrarywise." (Adam's 'Trans.,' i. 60.)

Further information respecting the opinions of the ancients on the subject of the temperaments may be found in the treatise of Hippocrates, 'De Natura Hominis,' tom. i., ed. Kühn; in Galen's works, 'De Elementis ex Hippocrate,' tom. i., 'De Temperamentis,' tom. i., 'De Optima Corporis nostri Constitutione,' tom. iv., 'De Sanitate Tuenda,' lib. v., tom. vi., and his 'Ars Medica,' tom. i.; Oribasius, 'Synopsis,' lib. v., cap. 43, sq.; Aëtius, 'Libri Medicinales,' lib. iv., cap. 53, sq.; Haly Abbas, 'Theor.,' lib. i.; Averroes, 'Collig.,' lib. vi.; Alsaharavius, 'Theor.,' tract vi.; and Avicenna, 'Cantica.'

After the revival of letters, this fourfold division was adopted in its most essential parts by all the most eminent physiologists. Stahl ingeniously adapted it to the modern doctrines of the humoral pathology; and even Boerhaave, although he increased the number of the temperaments to eight, and relinquished the erroneous opinions of Hippocrates and Galen respecting the constitution of the blood, yet he still derived the characters of his temperaments from the principles of the humoral pathology, and supposed them to be formed merely by different combinations of the four cardinal qualities. Many late physiologists have been inclined to doubt whether the external characters associated with the four temperaments are real and constant signs of diversity in bodily structure, and enable us to distinguish the principal varieties of constitution which exist. Several attempts have accordingly been made to define in a more satisfactory manner the peculiarities of organisation and the resulting varieties of predisposition, which are chiefly interesting with regard to pathology. Hoffmann and Cullen have, indeed, retained the old division, supposing that the theory of the ancients, as to the peculiarities of constitution, was founded originally upon facts, though subsequently combined with an erroneous theory. Haller seems to have been the first who decidedly opposed the ancient doctrine, not only by showing that there was no foundation for the varieties of the temperaments in the peculiar nature of the fluids, but by substituting in their place the vital actions of the system. Darwin proceeded upon the principle of Haller; and, in conformity with the hypothesis which he adopted of reducing these actions to the four heads of irritation, sensation, volition, and association, he formed four temperaments in which these qualities were supposed respectively to prevail. The only attempt, however, to improve upon the Hippocratic theory and division which has been attended with any degree of success, is that by Dr. Gregory, who, to the four temperaments of the ancients added a fifth, which he called the *nervous*, and bestowed upon three of the others the new appellations of the *tonic*, the *relaxed*, and *muscular* temperaments. Dr. Prichard, however, restricts the number to four, and designates them by their original names; remarking that only four strongly-marked diversities of external character present themselves to observation; that the nervous temperament is not so distinguished; and that, therefore, as this is an essential part of the original scheme for the distribution of temperaments, the improvement proposed by Dr. Gregory is lame and defective. These four varieties, then, of external character really indicate, more or less constantly, well-marked differences of constitution, and, likewise, of morbid predisposition.

There is no doubt that persons having the complexion and other signs of the sanguine temperament, are more liable to certain classes of disorders than the phlegmatic or melancholic, while the latter have their own peculiar tendencies. The sanguine, having a fully-developed vascular structure, and therefore a vigorous circulation of blood, a warm skin, and a high degree of organic sensibility, are more liable to sudden and powerful impressions from external agents than those of more languid vital functions. They are subject in a greater degree to severe inflammatory disorders, and disorders of this class are in them more acute: they bear, however, better than persons of more languid habit, evacuations of blood and the other measures which are found to be the proper remedies for these diseases. The greater fulness of blood-vessels, of those at least which are near the surface, the greater warmth of the skin, and the florid complexion of the sanguine, afford reason to believe that the designation given to this temperament is not wholly unfounded. We likewise find that sanguine persons are more subject to hemorrhages (to those at least which are termed *active*) as arising from excess in the force of circulation through the arteries. Individuals of the phlegmatic temperament are predisposed to disorders arising from, or connected with, a low degree of vital energy. Local congestions of blood arising independently of general excitement come under this category. Glandular and tubercular diseases take place in bodies weak in the structures connected with the vital functions, and are perhaps more frequent in the phlegmatic than in other temperaments. Inflammatory complaints, when they attack the phlegmatic, are less acute and more disposed to terminate in chronic diseases than are those of the sanguine constitution, when at least the latter have been treated by appropriate remedies. The relations of the choleric to the melancholic temperament are similar to the relations which the phlegmatic bears to the sanguine; the former displays greater vigour, both in health and disease than the latter. The choleric and sanguine, when affected by diseases of the nervous system, have complaints of greater violence and acuteness: mania or raving madness belongs particularly (according to the observations of M. Esquirol and many others) to these constitutions. The melancholic temperament is most prone to monomania, attended with depression and melancholy illusions. Hypochondriasis much more frequently affects the phlegmatic and melancholic, though it is occasionally observed in persons who have some of the external characters of the sanguine temperament. The most severe cases of hypochondriasis, adds Dr. Prichard, and those which approached most nearly to the character of melancholia, have certainly occurred in individuals of a dark leaden complexion, fixed and sullen aspect, and lank coal-black hair.

But it is not merely on the body, both in its healthy and morbid state, that the temperament exerts an important influence; the relation of the different forms of physical organisation to the intellectual and even to the moral faculties is equally marked and apparent. The relation of mental peculiarities to the structure of the body has been observed by medical authors of every age, and it has been stated and explained in different ways. Hippocrates said that "the soul is the same in all men, but that the body is different in different individuals. The soul is ever like itself both in greater and in less, for it undergoes change neither by nature nor by necessity; but the body is subject to continual alterations. The affections of the mind depend upon the body; there are many states of the latter which sharpen, and many which obtund it." (Hipp., *De Victûs Ratione*, lib. i., § 21, tom. i., p. 650.) Democritus, in a letter said to have been addressed by him to Hippocrates, asserted that "the intelligence of the mind depends greatly on the body, the diseases of which obscure the mental faculties, and draw the latter into consent." (Hipp., 'Epist.', tom. iii., p. 824.) Among the writings of Galen there is a treatise entitled 'Quod Animi Mores Corporis Temperamenta sequantur' (tom. iv., ed. Kühn), written expressly to establish the connection between the passions and desires of the mind and the temperaments, wherein he has handled the subject very ingeniously and has delivered many profound views of the animal economy. But it is in the works of modern writers that we find this doctrine most fully developed, and made a foundation for a division of human characters, though their views are mingled with many fanciful and unphilosophical speculations.

The doctrine of temperaments is true to a certain extent, and has ever been confirmed by an appeal to experience. States of the mind are so connected with affections of the body, that it is impossible for any person who considers all the physiological facts that present themselves in connection with this subject to doubt that with each temperament particular mental qualities must be associated, although it is manifest that many writers have indulged their fancy on this subject, and have gone into more full and minute details than experience will establish.

TEMPERAMENT AND TUNING. Temperament is the name given to the discussion of the subject of which tuning is the application; and tuning is the art of adjusting the several sounds of a musical instrument so as to make its scale approach to correctness; also that of putting two instruments, each of which has the parts of its scale in proper relative adjustment, into agreement with each other.

Some musical instruments have a permanent relative scale, all the parts of which, if changed at all, change together. Thus a horn or a flute may change its pitch from the heat of a room, but all the parts change together, and the whole effect of temperature is corrected at once by lengthening the pipe of which the instrument consists. Other instruments require to have the parts of their scales compared with each other from time to time, owing to their several parts being unconnected and subject to unequal wear or to separate accident, such as the organ and piano-forte. Others again are so liable to these derangements as to require tuning on every occasion of use, as the violin class, the harp, the drums, &c. It is not our intention to enter into the mode of tuning instruments in detail, but, as promised in the article SCALE, to give some account of the difficulties which are met with in the actual construction of any scale, and the ordinary modes of meeting them.

In the article just referred to we have pointed out the mathematical commencement of this subject, and have made it evident, from first principles, that *a perfect* scale* is impossible; that is to say, one in which all the intervals, or even all the principal intervals, in every key, shall be perfect. Let additional notes be introduced to make existing keys perfect, and those additional notes would themselves become the key-notes of new keys, requiring additional notes to make *them* perfect. Again, the conditions of the ordinary musical instruments require that the octave shall consist of only twelve semitones; and though some organs have been constructed with more, it is not worth while to embarrass the subject by treating of any other scale than that of the twelve semitones. We shall use the same notation as before, namely, expressing the following note of the treble scale,

by C, we shall denote the successive Cs in ascent by C^1, C^2, &c., and those in descent by C_1, C_2, &c.: thus, C_3 is three octaves below C, and C^4 is four octaves above it.

The first point is to fix upon some one note, by the pitch of which all others may be determined. The only way of retaining a permanent pitch for use is by having an instrument which time will not alter. It is true that the pitch of a note depends only upon the number of vibrations in a second, and can, by the description of this number, always be recovered by acoustical experiments. But we might as well expect a carpenter to ascertain his own foot-rule for himself by the pendulum as an ordinary musician to appeal to the theory of musical vibrations. A standard pitch is usually obtained, or professed to be obtained, by the tuning-fork, an instrument consisting of two steel prongs growing out of a steel handle. When these prongs are sharply struck they vibrate; and if the instrument be then held to the ear, or placed upon the flap of a table or any other sound-board, a low and very pure sound is heard, if the prongs be perfectly equal. These tuning-forks are usually made to sound either C^1 or A, and they would answer their purpose exceedingly well if there really were in existence any standard from which they were made. But this there is not; and the consequence is, that not only do the tuning-forks of different makers frequently vary a little from each other, but the new forks are sensibly higher than the old ones. We have already seen how much the pitch used in different places varies [ACOUSTICS], and also how very much what is now called concert-pitch is higher than it was a century ago. [PIPE.] This rise, it appears, is still going on, and, unless measures be taken to stop it, will not finish until all the compositions of the old masters are played and sung two or three notes higher than they were really written.

There was, we are told, a few years ago, a standard, so called, constructed under the direction of those who manage the Philharmonic Concerts; but we are not aware that any account was given of the method of selection, or that any experiments were instituted with a view to its perpetuation. We are also told that this mysterious standard was committed to the charge of one particular tradesman, and that the rest of the craft had difficulty in obtaining it. We have seen another promulgation of a standard tuning-fork, for the especial use of singing-classes. The prospectus of the seller states that careful experiments have determined that the Philharmonic C (the C^1 of our notation) vibrates less than 512 times in a second; how much less is not stated. These new tuning-forks are asserted to have had their pitch raised to vibrate 512 times in a second; avowedly for no other reason than that 512 is a good number for calculation, and intermediate between those of tuning-forks now in use; and it is stated that every fork is tuned to the true standard by a "scientific process." But directors of concerts and publishers of music should be aware that

* This means, of course, impossible so long as only twelve sounds are allowed in the octave. General Perronet Thompson, a warm advocate of the total abolition of temperament, has constructed an enharmonic organ, which is publicly exhibited, having fifty-four sounds in the octave, and perfect in twenty-one keys. All that can be said about the subject is exhausted in his 'Principles and Practice of First Intonation,' 4th edition, 1860 (Effingham Wilson), a shilling tract of 112 very full pages. We think that he overrates the admitted inconvenience; and we despair of seeing a pianoforte with fifty-four sounds which shall stand in tune, so as to preserve the minute differences of neighbouring sounds. But we decidedly approve of the attempt: and we can only say that if there shall be a general demand for the abolition of temperament, we have no doubt the thing is practicable. But a change of musical scale requires great concerted action: want of instruments puts difficulties in the way of concert, and want of concert puts difficulties in the way of getting instruments.

no attention is ever paid by those who understand such matters to scientific secrets; and that until a full account is published, and authenticated copies of the standard are made secure and accessible, the science of the standard-makers will rank no higher than that of the tailors who cut "on unerring geometrical principles."

Mr. Woolhouse, who made experiments on this subject ('Essay on Musical Intervals,' p. 64), finds the "common pitch-note A" to make 424 double vibrations in a second, from whence he infers that C^1 gives 509 such vibrations; but whence he got this pitch-note he does not state, nor whether he was aware of the existence of a so-called Philharmonic standard. As matters stand, we should recommend every one not to be led into the belief of the existence of a standard without some better account of it than yet exists, and also in the mean time to do what he can to *keep down concert-pitch*, so as at least to prevent its rising higher than it now generally is.

There is another matter connected with the tuning-forks which requires some attention. These forks (in England, not on the Continent) are differently manufactured: there are C forks and A forks—that is, forks which sound C^1 and A. In the orchestra, which must follow the violins, the A fork is always used; while in tuning a pianoforte, harp, &c., the C fork is used. It is much to be wished that only one, the A fork, should be used. Even if the scale were perfect, it would still be desirable not to run the risk of error arising from the use of different forks; add to which, that, without extreme care,—such care as never is taken,—it is impossible to avoid making the temperament depend somewhat upon the note which is first tuned, and which must be that sounded by the fork. We do not certainly much believe in the temperament of an orchestra; the characters of the instruments are various, and the disposition of most of the wind instruments to be a little out of tune, each in one or more particular parts of the scale, gives them each something so like a temperament (or dis-temperament, if the reader please) of its own, that the united body disobeys temperament to a degree which sets the slight differences between one system and another altogether aside. In the full passages there is too much noise for the ear to be very nice on this point, and in the solos the leading instrument marks its own temperament upon the whole orchestra. But when a few instruments come together, some of which are tuned from A and others from C, the disadvantage of different temperaments may be sensibly felt. But all this must be said with much deference, for circumstances connected with the scale or its adjustment may produce very different effects on different ears.

We leave the above as it stood in the 'Penny Cyclopædia.' In 1859 the French ministry made the settlement of the musical pitch a government business: the C^1 was settled at 522 vibrations per second, which, so much had the pitch risen even in very recent time, was a considerable abatement. Also in 1859, the Society of Arts took up the subject in England, and a committee ascertained that C^1 had actually reached 546 vibrations per second. Looking at the love of singers and concerto-players for brilliancy,—which, we should explain to those unversed in music, means *squeakiness*,—there was much reason to fear that the rise was not near its end. Since 1840 the pitch had risen a semitone. For practical reasons, connected with the state of musical instruments and the want of power to enforce, the society recommended that 528 should be the number of vibrations in C^1. This proposal was generally approved of, and tuning-forks (A and C, the interval being that of equal temperament) were constructed accordingly. There is then some hope that at least all further rise will be stopped; and we cordially recommend the proposal, not without a hope that in course of time a still further fall may be found practicable.

The leading note being settled, the tuner must learn to tune that note in perfect unison with his fork, and then to tune the octaves of that note both above and below. This seems to be the most plain and straightforward part of the whole operation; nevertheless, easily as tuners take it, and readily as they refer to one of their octaves as being as good an authority as the original note itself, we cannot help thinking that more pains than is usually taken might be well bestowed. A note and its octave, when the consonance is perfectly well tuned, should sound like one note: now considering that in a grand piano there are six strings to be tuned before an octave is ready, three unisons with the lower note and three with the upper, it is not so very easy to present that perfectly indivisible effect which a good artist ought to strive for. There is a method (given in Jousse's work) of tuning the twelve semitones of one octave-interval first, without tuning the octave of any note, by proceeding upwards by fifths and downwards by fourths, until the whole is completed, and this purposely to avoid depending upon notes in the adjacent octaves. This mode, however, or any other, must be matter of individual selection: it cannot be supposed that any one method would be best suited to all ears.

Those who are acquainted with the mathematical theory of the scale know that all the concords cannot be made perfect: others may learn it in the following way:—Suppose twelve perfect fifths to be tuned upwards from C, and give the results the names of the notes which they would represent in the scale of twelve semitones, and in the nomenclature of sharps, if the scale were perfect. We should then have

C, G, D^1, A^1, E^2, B^2, $F^3\sharp$, $C^4\sharp$, $G^4\sharp$, $D^5\sharp$, $A^5\sharp$, $E^6\sharp$, $B^6\sharp$.

Now since $B^6\sharp$ is the same note as C^7, it appears that twelve perfect fifths should be the same as seven octaves; and if we pass to the octave below, as soon as we get out of the octave beginning with C, we should have C, G, D, A, E, &c., the last being C^1. It will be found, however, that this is not true, but that the note obtained from twelve ascents by fifths intermixed with six descents by octaves is sharper than C^1. Again, if the perfect thirds be tuned from C, we should have C, E, G♯, C^1; but it will be found that C^1 obtained in this way is too flat. The octave derived from the fifths vibrates 223 times where it should vibrate 220; and that derived from the thirds vibrates 125 times where it should vibrate 128. The slight alterations which are made in order that any one of the twelve notes of the octave may be fit to be used as a key-note, without any shock to the ear, constitute the *temperament* of a scale; the altered consonances are said to be *tempered*. Some writers call the interval from the false octave obtained by the fifths to the true one, by the name of the *wolf*; and using the word in this sense, Lord Stanhope contends (and justly) for five *wolves*, one from the fifths, and one from each of the sets of thirds beginning with C, C♯, D, D♯; and three more might have been got from the minor thirds. But by the term *wolf* other writers mean the bad fifth which exists in the worst key, when the temperament is allowed to favour some keys at the expense of others. Simple as this little variation in the meaning of a term may be, it is worth while to notice it. A writer on tuning charges some of the pianoforte-makers of his time with utter ignorance of the scale, in stipulating with the tuners whom they employed that there should be no wolf. In all probability they only meant that no key should be worse than another, or that the temperament should be equal. This term *wolf* is said to be derived from the jarring of a badly-tuned consonance, supposed to resemble the distant howling of the animal: we rather suspect it was so called because it was hunted from one part of the scale to another like a wild beast, in hopes of getting rid of it.

Two systems of temperament suggest themselves: the first, *equal*, in which the necessary defects of the scale are distributed equally throughout it; the second, *unequal*, in which some mode is adopted of distributing the imperfection so as to make some keys feel it less than others. The most common practice of our day is to endeavour at equal temperament. The two systems have their advocates, and the arguments for one and the other are as follows. In favour of equal temperament it is urged that all the keys are made equally good, and that in no one does the imperfection amount to a striking defect: also that in the orchestra there is little chance of any uniform temperament among the various instruments, if it be not this one. Against equal temperament it is urged that it takes away all distinctive character from the different keys, and leaves no one single key perfect. All these arguments have force, both for and against: for ourselves, we consider those against equal temperament much the stronger. We have often felt that a pianoforte newly tuned has, with much correctness, a certain insipidity, which wears off as the effect of the tuning gradually disappears; insomuch that the best phase of the instrument, to our ears, is exhibited during the period which precedes its becoming offensively* out of tune. At this time the progress towards the state of being out of tune (for which there is no single word, *maltonation* would do very well) can only be called a change of the temperament; and the several keys begin to exhibit varieties of character which, until maltonation arrives, render the instrument more and more agreeable. But it must be remarked with respect to equal temperament, that it cannot be obtained in the ordinary way of tuning. The only way, unless beats be used, of obtaining a given temperament, equal or unequal, with certainty, is to take a monochord, and having calculated the proper lengths of the different strings, to form the successive notes on the monochord, and to tune the several notes of the instrument in unison with them. No tuner can get an equal temperament by trial: so that the question lies between the having all sorts of approximations to equal temperament, according to the propensities of different ears, or as many sorts of approximations to some other systems. Had the English nation been as musical as it is mechanical, a portable monochord, or system of monochords, would have been invented, on which any given system of temperament could have been readily laid down by rule, and thence transferred to the instrument.

The mode of proceeding by approximation to equal temperament is simply to tune the fifths a little too flat, and the following order of proceeding is the most usual, and has often been given. The first letter represents the note already tuned, the second the one which is to be tuned from it: a chord interposed in parentheses represents the trial that should be made upon notes already in tune, in order to test the success of the operation as far as it has gone. The first step is to put C^1 in tune by the tuning-fork:—

C^1; C^1C; CG; GG_1; G_1D; DA; AA_1; A_1E; (CEG); EB; (CEG, DGB); BB_1; $B_1F\sharp$; (DF♯A); $F\sharp F_1\sharp$; $F_1\sharp C\sharp$; ($A_1C\sharp E$); C♯G♯; (EG♯B); C^1F; (FAC^1); $FA_1\sharp$; ($A_1\sharp DF$); $A_1\sharp A\sharp$; A♯D♯; (D♯GA♯; $D\sharp G_1\sharp$; ($G_1\sharp CD\sharp$).

We have written all the semitones as sharps, whether tuned from above or from below. Of course, since the fifths are all to be a little

* A musical critic has stated that we avowedly prefer an instrument *out of tune*. His mistake probably arises from his confounding *equal temperament* with *perfect tune*, average sin with perfect holiness: perhaps he did not know that any scale with twelve sounds cannot be in perfect tune in every key.

too small in their intervals, the upper note must be flattened when tuned from below, and the lower note sharpened when tuned from above. In the preceding, the octave CC^1 is completely tuned, and also the adjacent interval F♯C. The rest of the instrument is then to be tuned by octaves. The thirds should all come out a little sharper than perfect, as the several trials are made: when this does not happen, some of the preceding fifths are not equal. The parts which are first tuned by the fifths, and from which all the others are tuned by octaves, are called *bearings*.

We shall now show how, by means of the theory of the scale, to examine a system of temperament: the rest of this article is therefore only for those who have some mathematical knowledge of the scale. Everything will be expressed in mean semitones, and the following additions will be convenient:—A major tone is 2·039100 mean semitones; a minor tone, 1·824037; a diatonic semitone, 1·117313; a comma, ·215063; the excess of twelve perfect fifths above seven octaves, ·234600, a little more than a comma, frequently called a comma; the excess of an octave above three perfect thirds, ·410689. Various modes of dividing the octave have been proposed—that is, of creating imaginary subdivisions—by means of which to express the various intervals required. None is so convenient, in our opinion, as the expression by means of mean semitones and their fractions.

We prefer to show a complete examination of one system, in such a manner that any one may apply it to another, instead of briefly noting the peculiarities of different systems. We shall take as an example Dr. Young's first system, which is as follows:—Tune downwards, from the key-note, six perfect fifths, ascending into the octave interval CC^1 when necessary: then tune upwards, from the key-note, six equally imperfect fifths, throwing the whole error of ·2346 of a mean semitone equally among them. In the equal temperament the wolf is made to bear twelve cubs: here only six—larger ones of course. Now a perfect fifth, being two major tones, a minor tone, and a diatonic semitone, is thus composed:—

Two major tones . .	4·078200 mean semitones
Minor tone . . .	1·824037
Diatonic semitone . .	1·117313
Perfect fifth . . .	7·019550

The imperfect fifth of this temperament is to be flattened by the sixth part of ·234600, or ·039100, and 7·019550 – ·039100 is 6·980450, the imperfect fifth required. We are then to proceed as follows:—

Six fifths downwards perfect.

	C^1	12·00000
		7·01955
1.	F	4·98045
	F^1	16·98045
		7·01955
2.	A♯	9·96090
		7·01955
3.	D♯	2·94135
	D^1♯	14·94135
		7·01955
4.	G♯	7·92180
		7·01955
5.	C♯	0 90225
	C^1♯	12·90225
		7·01955
6.	F♯	5·88270

Six fifths upwards imperfect.

	C	0·00000
		6·98045
1.	G	6·98045
		6·98045
	D^1	13·96090
2.	D	1·96090
		6·98045
3.	A	8·94135
		6·98045
	E^1	15·92180
4.	E	3·92180
		6·98045
5.	B	10·90225
		6·98045
	F^1♯	17 88270
6.	F♯	5·88270

There is no doubt, at least in this world,* much surplusage in carrying the results to five decimals, or the hundred-thousandth part of a mean semitone; but all calculators are aware of the desirableness of using more places than will ultimately be wanted. Collecting the above results, we have, for the interval of every note from C, as far as C^1, as follows:—

C	0·00000	E	3·92180	G♯	7 92180
C♯	0·90225	F	4·98045	A	8·94135
D	1·96090	F♯	5·88270	A♯	9·96090
D♯	2·94135	G	6·98045	B	10·90225

We shall now examine the effect upon the several keys. We have remarked [SCALE], that the effect of making an interval too small is to render the consonance of a more plaintive character; while we may suppose that too large an interval has a somewhat contrary effect. As the most important chord of every key is that of the key-note, its third, and fifth, we must form our idea of the effect of each key from observing the effect of the temperament upon the common chord of the key-note, judging of the character of the key by the amount and direction of the temperament of the third and fifth. Now a major third is made of a major and minor tone, and is therefore 3·86314 mean semitones; while a minor third, or a major tone, and a diatonic semitone, is 3·15641 mean semitones. Hence the principal chord of a key, according as it is major or minor, has the following intervals from the key-note:—

Major	3·86314,	7·01955
Minor	3·15641,	7·01955

* Mr. Marsh, the author of a treatise on tuning, is seriously of opinion that a perfect scale is one of the blessings reserved for a future state, in which "it will be part of the enjoyment of the blessed to chant the praises of their Creator in extatic hallelujahs, *when systems of tuning shall no longer perplex us, and temperament shall be no more.*"

To examine any particular key, take out the numbers from the preceding table opposite to the notes of the principal chord (adding 12 to make the octave when necessary); subtract the number of the key-note from each of the other two, and the remainders will give the tempered intervals. Compare the tempered intervals with the preceding correct intervals, and the amount and direction of the temperament will be seen. For instance:—

Key of A major.

A 8·94135	C^1♯ 12·90225	E^1 15·92180
	8·94135	8·94135
Tempered intervals . . .	3·96090	6·98045
Perfect intervals	3·86314	7·01955
Temperaments . . .	+·09776	–·03910

and + means sharper than perfect, — flatter than perfect. We might describe this chord (keeping three decimals, which is more than sufficient) as having a temperament expressed by the following symbol (+ ·098 — ·039); and if we examine all the keys in the same manner, we shall have the following account of this system of temperament. (A person who is used to the subject, and to calculation, might proceed more shortly by considering the law of the system, but the beginner had best take each key by itself. We have preserved the use of sharps only, for the sake of symmetry.)

Major Key.	Temperament.	Minor Key.	Temperament.
C, D, G	(+·059, –·039)	A, B, E	(–·098, –·039)
C♯, F♯, G♯	(+·215, 0)	A♯, D♯, F	(–·215, 0)
D♯	(+·176, 0)	C	(–·215, –·039)
E	(+·137, –·039)	C♯	(–·137, 0)
F	(+·098, 0)	D	(–·137, –·039)
A	(+·098, –·039)	F♯	(–·098, 0)
A♯	(+·137, 0)	G	(–·176, –·039)
B	(+·176, –·039)	G♯	(–·176, 0)

The rules for the verification of every such process are six in number, and as they express relations which may be made of signal use in searching for systems of temperament, we give them at length. In all these rules it is supposed that the fifths and minor thirds are tempered flat, the major thirds sharp, and that the signs are neglected.

1. The sum of the temperaments of all the fifths in the twelve keys must be the excess of twelve fifths above seven octaves, or ·23460 of a mean semitone.

2. The sum of the temperaments of all the thirds in the twelve major keys must be the excess of the octave above three major thirds taken four times, or 1·64236 mean semitones; the sum of the temperaments of the thirds in any three keys whose tonics are successive thirds being the excess above mentioned, or ·41059 of a mean semitone.

3. The sum of the temperaments of all the thirds in the twelve minor keys is three times the excess of four minor thirds over an octave, or 1·87695 mean semitones; the sum of the temperaments of the thirds in any four minor keys whose tonics are successive minor thirds being the excess above mentioned, or ·62565 of a mean semitone.

4. The temperament of the third in any major key, increased by the temperaments of the fifths *in that key and* the three succeeding dominant keys, makes a comma, or ·215063 of a mean semitone. The *dominant* of a note is the fifth above it; so that the successive dominant keys of C major, for instance, are those of G, D, A. Thus, in the above system, the temperament of the third in A♯ major is ·137, and those of the fifths in A♯, F, C, G, are 0, 0, ·039, ·039: put these together, and we have ·215, a comma, as asserted.

5. The temperament of the minor third in any key, together with the temperaments of the fifths *in the three succeeding* subdominant keys, make a comma, or ·21506 of a mean semitone. The subdominant of a note is the fourth above it; so that the successive subdominant keys of C, for instance, are those of F, A♯, D♯. Thus, in the above system, the temperament of the third in A♯ minor, for instance, is ·215, and the temperaments of the fifths in D♯, G♯, C♯, are severally 0: these put together of course give ·215, a comma, as asserted.

6. The temperament of the flat seventh in any key is the difference of those of the fifth in that key and the minor third in the dominant key.

The algebraist may easily see how these rules are deduced, and also that they are all which can be obtained. They amount altogether to 25 equations of condition; for the first, fourth, and fifth rules contain the second, third, and sixth. Now, the pitch note c^1 being given, there are eleven notes to be determined, and there are 3×12 or 36 equations between the values of those notes and the temperaments of the major thirds, minor thirds, and fifths. But 36 equations between the eleven values of the notes should give 25 equations between the values of the temperaments; and these 25 equations are contained in our first, fourth, and fifth rules.

In every system of temperament which deserves the name, the fifths must be flattened, and also the minor thirds; while the major thirds must be sharpened. In any other case, the algebraist might use the preceding rules by considering as *negative* the temperament of a sharpened fifth or minor third, or of a flattened third. In this sense, these rules are always true, from the instant when the strings of the instrument are put on, and throughout its existence as a sounding body.

It is now easy to determine the temperaments of the thirds, major and minor, from those of the fifths. From a comma subtract the sum of the temperaments of the fifths in any one key and the three following dominant keys, and the remainder will be the temperament of the major third in that key. Again, from a comma subtract the sum of the temperaments of the fifths in the three subdominant keys following any given key, and the remainder will be the temperament of the minor third in that key. Hence we may, without any trouble, lay down at pleasure the temperaments of the fifths, and deduce those of the thirds. But we cannot, from the temperaments of the thirds, deduce those of the fifths. It must be remembered that a succession of fifths, setting out from a given note, runs through every note of the scale before it reaches that note again; while the major thirds are brought up, so to speak, by the original note, in three successions, and the minor thirds in four. There are then four distinct parcels of major thirds, and three of minor ones, so that it is impossible to pass out of one into another by thirds alone. It would be possible to temper *all* the major thirds equally, and yet to retain an unlimited number of modes of tempering the fifths, depending upon the manner in which one system of thirds is joined on to the others; and the same of the minor thirds.

We have, from the scale, shown how to construct the temperaments: we now take the inverse question, namely, from the temperaments to construct the scale. Let the sharps be denoted by accents placed above the letters: thus A′ represents A♯, and so on. Let the temperaments of the fifths, in the several keys, be denoted by the small letters: thus a represents the temperament of the fifth in the key of A, or is the portion of a mean semitone by which the interval from A to E falls short of a perfect fifth. And, for abbreviation, let simple commas denote addition: thus a, b may mean $a+b$. Also let the notes themselves be descriptive of their intervals from C: thus C means 0; G′ means the interval between G♯ and C: we have, then, V meaning the number of mean semitones in a perfect fifth,

$$\begin{aligned}
\text{C} &= 0 \\
\text{G} &= \text{V} - c \\
\text{D} &= 2\,\text{V} - 12 - c, g \\
\text{A} &= 3\,\text{V} - 12 - c, g, d \\
\text{E} &= 4\,\text{V} - 24 - c, g, d, a \\
\text{B} &= 5\,\text{V} - 24 - c, g, d, a, e \\
\text{F}' &= 6\,\text{V} - 36 - c, g, d, a, e, b \\
\text{C}' &= 7\,\text{V} - 48 - c, g, d, a, e, b, f' \\
\text{G}' &= 8\,\text{V} - 48 - c, g, d, a, e, b, f', c' \\
\text{D}' &= 9\,\text{V} - 60 - c, g, d, a, e, b, f', c', g' \\
\text{A}' &= 10\,\text{V} - 60 - c, g, d, a, e, b, f', c', g', d' \\
\text{F} &= 11\,\text{V} - 72 - c, g, d, a, e, b, f', c', g', d', a'
\end{aligned}$$

That is, the interval from C to B, for example, is found by deducting from the excess of five perfect fifths above two octaves the sum of the temperaments of the fifths in the keys of C, G, D, A, and E. Towards the end, in isolated questions, trouble will be saved by remembering that the sum of all the temperaments of the fifths is ·2346 of a mean semitone, and that we thus have—

$$\begin{aligned}
c, g, d, a, e, b, f', c', g', d', a', &= \cdot 2346 - f \\
c, g, d, a, e, b, f', c', g', d', &= \cdot 2346 - f, a', \text{\&c.}
\end{aligned}$$

We shall now take an example of this, and our instance shall be the proposal of a system of temperament which we should like much to see tried. We are for variety in the several keys, and against equal temperament; but we do not like variety without law. We do not like, for example, to find the greatest temperament in one key, and the least in an adjacent key, as that of the dominant or subdominant. Suppose, then, we ask what can be done towards an ascending and descending temperament, which, proceeding, say from the key of C, shall increase through the keys of C, G, D, A, E, B, and diminish through those of F′, C′, G′, D′, A′, F. And, as a first step, let the increments and decrements of the temperaments of the fifths be equal, or let $c = m$, $g = 2m$, $d = 3m$, $a = 4m$, $e = 5m$, $b = 6m$, $f' = 7m$, $c' = 6m$, $g' = 5m$, $d' = 4m$, $a' = 3m$, $f = 2m$. Here, as far as the fifths are concerned, the effect of modulation into the dominant or subdominant keys is the same everywhere, as much as in equal temperament. And, from the first rule, we have $48m = \cdot 2346$, or $m = \cdot 0048875$, and the greatest temperament of a fifth is seven times this, or ·034. Now, if we compute the temperaments of the thirds, major and minor, from the fourth and fifth rules, we may exhibit the temperaments of all the keys, as follows :—

Key.	Temperament.			Key.	Temperament.		
	−	+	−		−	+	−
C	·166	·166	·005	F♯	·127	·108	·034
G	·191	·147	·010	C♯	·122	·127	·029
D	·186	·127	·015	G♯	·127	·147	·024
A	·171	·108	·020	D♯	·142	·166	·020
E	·156	·098	·024	A♯	·156	·176	·015
B	·142	·098	·029	F	·171	·176	·010

The three columns contain the temperaments of the minor third, major third, and fifth. The effects of modulation into adjacent keys are everywhere very small, nowhere amounting to more than about the tenth of a comma, in alteration of temperament; while the fifths are in different keys so differently tempered, that in C that interval may be called perfect; while in F♯ there is nearly twice as much temperament as in the equal semitone system. There is then variety without sudden change. In the system of equal semitones, the temperaments of the minor third, major third, and fifth, are always

$$-\cdot 156, + \cdot 137, - \cdot 020.$$

Now, to form the scale in this system. Proceeding by the table given above, of which we take a few steps as an example, we have—

$$\begin{aligned}
\text{C} &= 0\cdot 000000 \\
\text{V} &= 7\cdot 019550 \\
&\overline{\ 7\cdot 019550} \\
c = m &= \ \ \cdot 004888 \\
\text{A} &= 7\cdot 014662 \\
\text{V} &= 7\cdot 019550 \\
&\overline{\ 2\cdot 034212^{*}} \\
a = 2m &= \ \ \cdot 009775 \\
\text{D} &= 2\cdot 024437, \text{\&c.}
\end{aligned}$$

Proceeding in this way, we find for the intervals of the several semitones from the key-note, expressed in mean semitones, the following table :—

C	0·000	E	4·029	G♯	7·990
C♯	1·000	F	4·990	A	9·029
D	2·024	F♯	6·015	A♯	9·985
D♯	2·985	G	7·015	B	11·024

To carry this or any other system strictly into practice without comparisons with the monochord, or the use of beats, presently described, would be impossible; but the following might be suggested as an approximation. In tuning by fifths, let the intervals C G and F C be made perfect, or all but perfect; let there be greater temperament in G D, D A, and D♯ A♯, A♯ F; and most of all, decidedly, in the remaining intervals.

The system of temperament is sometimes described by giving the number of vibrations made by the several semitones, or numbers proportional to them. It is easy enough to deduce the number of mean semitones in each interval from such data, either by the common tables of logarithms, or by that given in SCALE.

First, by the common table of logarithms. From the logarithm of the number answering to the higher note, subtract that answering to the lower; from the result take its three-hundredth part, and multiply the remainder by 40. The product is the number of mean semitones in the interval, with an excess of very little more than the thousandth of a mean semitone in an octave. For example, to find the intervals, in mean semitones, of a fifth and of a comma; in the former of which the lower note makes two vibrations while the higher makes three, and in the latter 80, while the higher makes 81 :—

For the Fifth.		For the Comma.	
log. 3 =	·47712	log. 81 =	1·90849
log. 2 =	·30103	log. 80 =	1·90309
300)	·17609	300)	·03540
	·00059		·00002
	·17550		·00538
	40		40
Result	7·02	Result	·2152
More exactly	7·01955	More exactly	·2151
Error	0·00045	Error	·0001

Next, by the table in SCALE. If the numbers be in the table, simply subtract the logarithm of the lower number from that of the higher, and the result is the answer required, within about the hundredth of a mean semitone. But if the numbers be not in the table, divide both by any number which will bring them within the table, accurately or approximately, and then subtract as before: inter-

* Throw out the twelves as fast as they arise.

polation may of course be employed, but if the skill of the computer do not reach so far, he must be content with a less accurate result, or must use the common table, in the manner just explained. For instance, one note makes 4622 vibrations, while another makes 5033; required the interval between them. Divide both by 30, which gives 154·1 and 167·8; if without interpolation, say 154 and 168. Opposite to 168 is 88·70, and opposite to 154 is 87·20, differing by 1·5, or a mean semitone and a half. The interpolated logarithms are 88·68 and 87·21, differing by 1·47. The more accurate result of the former rule is 1·4752.

The tuning of a piano-forte is generally done by ear, but in that of an organ recourse is had, though not very often, to the beats which imperfect consonances always give. In the temperament of this last-named king of instruments, less liberty is allowable than in that of the stringed instruments; for not only do the beats become unpleasantly frequent when a consonance is too imperfect, but the imperfection of the consonance itself is more perceptible when notes are held, as in the organ, than when they die rapidly away, as in the piano-forte. These beats are described in ACOUSTICS, and when the lower note is known, and also its number of vibrations, the number of beats which are made in a given time, as ten seconds, a minute, or any other which is convenient, can be calculated from the known imperfection of the consonance, and the number of vibrations of the lower note. Theoretically speaking, it makes some little difference whether the consonance be tempered sharp or flat, but not to an extent which it is worth while to consider. The rule for determining the beats is as follows: let the lower note of the (perfect) consonance make n vibrations, while the upper note makes m, the fraction $m \div n$ being in its lowest terms, and let N and M be the actual numbers of vibrations in the lower and higher notes, per second: then $mN = nM$. Let μ be the fraction of a mean semitone by which the consonance is tempered; then the number of beats in a minute is found by taking the fraction μ of the production mN or nM, multiplying by 1109 and dividing by 320, or by 4, 8, and 10. The algebraical formula is

$$\frac{1109}{320}\,\mu m N \text{ or } \frac{1109}{320}\,\mu n M \left(\frac{1109}{320} = 3{\cdot}4656\right)$$

For example, let the note C^1 make 512 vibrations; it is required to find the number of beats per minute in the consonance C^1G^1, when tempered as in the system of mean semitones. Here $N = 512$, $m = 3$, $mN = 1536$. The perfect fifth is 7·01955 mean semitones, whence the fraction μ is ·01955, since the tempered fifth has seven semitones exactly. Multiply ·01955 by 1536, which gives 30·0288; multiply by 1109 and divide by 320, which gives 104·07 (say 104) beats in a minute.

Tables for facilitating the calculations might easily be made, but it is hardly worth while to insert them here. These beats are usually, we believe, simply counted with a watch, but it would be both convenient and exact to have some such machine as Dr. Smith recommended, a pendulum which could be easily altered in vibration, and first adjusted to move exactly with the beats; the pendulum might then be subsequently compared with the watch. Without such a contrivance it is very difficult to tune the piano-forte by beats, since they do not last long enough in sufficient intensity; with it the last-named instrument might easily be tuned on any system of temperament; and those who practise the art would have the advantage of hearing different systems, knowing at the same time what those systems are. At present the few organ-builders who use beats are the only tuners who make any approach to science: all the rest judge only by the ear, which may vary from time to time, or even with the state of the body, or the weather. We have many reasons for thinking that the ear alone is a variable judge in so nice a matter as temperament.

Persons desirous of information on this subject may consult Jousse 'On Temperament,' London, 1832; Hamilton, 'Introduction to the Art of Tuning' (no date); Stanhope, 'Principles of Tuning,' 1806; Marsh, 'Theory of Harmonics,' 1809; Woolhouse, 'On Musical Intervals,' 1835; Sir J. Herschel, 'On Sound' (*Encyclop. Metropol.*); Young's 'Lectures,' vol. i., cap. 33; Smith, 'On Harmonics,' first edition, 1749; second edition, 1759. This work of Dr. Smith is most difficult and confused, but is still the most extensive separate treatise on the subject; that of Mr. Woolhouse is sufficient, and much more intelligible. On the subject of beats, and on several proposals as to temperament, see a paper by Professor De Morgan, 'On the Beats of Imperfect Consonances' (*Camb. Phil. Trans.*, vol. x., part i.).

TEMPERATURE. [ATMOSPHERE; CLIMATE; ISOTHERMAL LINES.]

TEMPERATURE OF THE SEA. [SEA.]

TEMPERATURE, TERRESTRIAL, DISTRIBUTION OF. [TERRESTRIAL TEMPERATURE.]

TEMPERING OF STEEL. [STEEL MANUFACTURE; CUTLERY.]

TEMPLARS, KNIGHTS TEMPLARS, or KNIGHTS OF THE TEMPLE, are the popular designations for the Brethren of the Temple of Solomon at Jerusalem, also called the Soldiery of the Temple (*Militia Templi*) and the Soldiers of Christ. The three great religious military Orders, the Knights of the Hospital of St. John of Jerusalem (commonly called the Knights Hospitallers), the Templars, and the Teutonic Knights of St. Mary of Jerusalem (or German Knights of the Cross), all originated in the 12th century; the two former towards its commencement, during the first crusade, the last not till near its close. The founders of the Order of the Templars, which is held to date from the year 1118 or 1119, were nine knights, all French, of whom the two chief were Hugues de Payens (or de Paganes) and Geoffroi de St. Omer (or St. Ademar). One account makes all the nine to have been previously members of the Order of St. John; but it is at least doubtful if this were the case. At all events, the Hospitallers were not yet a military order; their distinguishing profession was to entertain pilgrims and to attend the sick and wounded: the idea of adding to the three common vows of chastity, poverty, and obedience, an engagement to fight against the Infidels, appears to have been first put in practice by De Payens and his brethren. Up to this time, when a knight entered the society of the Hospitallers, he seems to have laid aside his arms. Nor probably did the nine knights forming the new association at first contemplate either the extensively military character which their order eventually assumed, or even the establishment of an order which should extend and perpetuate itself. Their original vow was simply to maintain free passage for the pilgrims who should visit the Holy Land; and they did not proceed to add to their number till six or seven years after their association. In another respect, also, their early condition and pretensions were remarkably contrasted with their subsequent state; for at this time they made the greatest show of poverty, even De Payens, who was styled Master, and his friend De St. Omer, keeping only one horse between them, a circumstance commemorated in the seal of the order, which represents two armed knights mounted one behind the other on the same horse. Indeed, the name which they took, and by which they were commonly known, was the Pauper Soldiers (*Pauperes Commilitones*) of the Temple of Solomon; and they professed to have no source of subsistence but the alms of the faithful. The king of Jerusalem, Baldwin II., gave them their first place of residence—a part of his palace; to which the abbot and canons of the church and convent of the Temple, which stood adjoining, added another building for keeping their arms, whence they acquired the name of Templars.

The new principle of their association, however, immediately drew general attention; so much so, that in 1120 the Hospitallers got their order remodelled by Pope Calixtus II. on the same principle. The first regular embodying of the Templars was by Honorius II., who in 1128 confirmed a rule for them which had been drawn up and decreed that same year by the Council of Troyes, on the requisition of Hugues de Payens and several of his brethren. Honorius at the same time, to distinguish them from the Hospitallers, who were arrayed in a black mantle, assigned the brethren of the new order a white mantle for their peculiar dress, which they wore plain till Eugenius III., in 1146, appointed them to wear a red cross on the left breast, in imitation of the white cross worn by the Hospitallers. This bloody cross was also borne upon their banner, which was formed of cloth striped black and white; whence it was called *Bauseant*, an old French term applied to a horse marked with these colours. This word consequently became the famous war-cry of the Temple chivalry.

The new order speedily rose into consideration. Members of the noblest families in every nation of Christendom eagerly sought to be joined to it; legacies and donations in lands and money were showered upon it by persons of all ranks; and in course of time it acquired ample possessions in nearly every country of Europe. At the head of the order was the Master, or Grand Master (*Magister*, or *Magnus Magister*), who was, however, not only elected by the Chapter, or general body of the Knights, but very much controlled by that body. The Grand Master had immediately under him his Seneschal, or lieutenant, and other high officers were the Marshal, the Treasurer, &c. The several countries in Asia and Europe in which the order had possessions were denominated Provinces; and each of them was presided over by a resident chief, called, indifferently, a Grand Prior, Grand Preceptor, or Provincial Master. Under the provincial masters were the Priors, otherwise called Bailiffs, or Masters, who had charge each of one of the districts into which the province was divided; and, finally, under the priors were the Preceptors, each of whom presided over a single house of the order (or sometimes over two or three adjoining houses which were considered as one establishment), hence called a Preceptory. The head province was that of Jerusalem; the affairs of the order, in fact, were for the most part directed by the chapter of this province, which was invested by the constitution with all the powers of a general chapter at all times when such a chapter was not assembled. The Grand Prior of Jerusalem was ex-officio treasurer of the order; and in this province the Grand Master resided so long as the Christians retained any footing in the country; and on the fall of Acre, and the final extinction of the Latin power in Palestine, in 1192, the Knights took refuge in the town of Limisso (otherwise called Limasol) in Cyprus. The other provinces in the East were Tripolis and Antioch; to which Cyprus, till then included in one of these, was added after that island became the head-quarters of the order. The western provinces were Portugal, Castile and Leon, Aragon, France and Auvergne, Normandy, Aquitaine or Poitou, Provence, England (in which Scotland and Ireland were included), Germany, Upper and Central Italy, Apulia, and Sicily.

For some time after its institution, the Order of the Templars consisted exclusively of laymen; but in the year 1162, the famous bull entitled 'Omne Datum Optimum,' issued by Pope Alexander III., among other important privileges which it bestowed upon the order permitted it to receive as members any spiritual persons who were not bound by previous vows. These spiritual members were called Chaplains. They did not fight, nor take the military vow; but, in lieu of that duty, they not only celebrated mass and other religious offices in the houses of the order, but usually also acted as secretaries to the chapter. Alexander's bull also allowed the order to have its own burial-grounds; released it from all spiritual obedience, except only to the holy see; freed it from the payment of tithes, and even authorised it to receive them if the bishop gave his consent; and prohibited any one who had once become a Templar from ever leaving the order unless to enter into a stricter one.

At a date a little later the society still farther extended its scheme and its influence, by admitting as members many persons who were not knights or of noble birth, but who were desirous of participating in the advantages of belonging to so powerful a body, on condition of acting as the squires and servants of the knights. These were styled Serving Brethren; and in this class were sometimes found individuals both of great wealth and eminent station, though not of high birth or knightly rank. The serving-brethren, however, could not be preceptors, or hold any of the higher offices in the order. Latterly, they were divided into two classes—those of arms and those of trades; the former attending the knights to the field as esquires; the latter exercising various handicrafts in the houses or on the lands belonging to the order. The order also associated to itself many persons under the name of Affiliated Members, who took no vows, assumed no peculiar dress, nor became subject to any duties or services; but, continuing to pursue their ordinary secular occupations, merely purchased enrolment in the ranks of the powerful and highly-privileged soldiery of the Temple for the sake of the protection and other advantages, both temporal and spiritual, which even such a mere nominal membership ensured. The affiliated comprehended women as well as men. Finally, there were the *Donati* and the *Oblati*, consisting of children dedicated to the order by their parents or other relations; and also of persons of all ranks, both laity and clergy, who, without entering the order, pledged themselves to stand by it, and to maintain its rights.

The history of the Knights Templars would embrace the history of the wars of the Christians against the Infidels in the East for all the time they lasted after the establishment of the order. For more than a hundred and seventy years the soldiers of the Temple formed the most renowned portion of the Christian troops, and almost every encounter with the enemy bore testimony to their unequalled prowess and daring. But it may nevertheless be questioned whether the establishment of this and the other religious military orders proved advantageous to the attempt so perseveringly made to wrest the Holy Land from the dominion of the Infidels. The Templars and Hospitallers probably damaged and weakened the cause for which they fought, as much by their rivalry, jealousies, and frequently open contention, as they aided it by their valour. Then, the immense wealth and worldly power which the Templars in particular speedily acquired, altogether changed the original character and spirit of their institution long before it was half a century old. Within thirty or forty years from the origin of the order, two at least of the four vows which the members still continued to take had become a mockery and a profanation; instead of poverty and chastity, they were already distinguished by their pomp and pride, and the general luxury and licentiousness of their lives. But the vast material forces of the association, the extent to which it had projected its ramifications in all directions, and its other elements of strength, might have long withstood the principle of corruption thus at work within it, if it had not drawn upon itself an assault from without by which it could not fail to be overpowered.

The destroyer of the Templars was the resolute and vindictive Philip IV. of France. Philip, who came to the throne in 1285, at the age of seventeen, was the enemy of the church by education, by temper, and by circumstances. He had already proceeded to extremities in a quarrel with Pope Boniface VIII., which was terminated only with the life of that pontiff. His successor, Benedict XI., is supposed to have been poisoned at the instigation of Philip. Benedict was succeeded by Clement V., who is believed to have purchased his elevation from Philip on condition, among other compliances, of co-operating with him in the destruction of the Templars. This was in 1305. In 1306, Jaques de Molay, the Master of the Temple, was drawn to Europe by a summons from the pope, who professed a desire to consult with him on the expediency of a union of the two orders of the Templars and the Hospitallers. The following year, while Molay was at Paris, the first distinct accusations against the Templars were made by two individuals lying in prison under sentence of death; Squin de Flexian, who had formerly been a member of the order and prior of Montfaucon, but had been ejected for heresy and other offences, and a Florentine called Noffo Dei, also, according to one account, a degraded Templar, by general admission a person of the worst character. They made their revelations to Philip himself, and were immediately liberated from prison. Their charges, imputing to the order the systematic practice and encouragement of all sorts of secret immoralities, as well as the strangest confusion of heresy, idolatry, and infidelity, are far too absurd for examination. Very soon after this, on the 12th of September, 1307, royal letters were issued, sealed, to all the governors of towns and other officers of the crown in authority throughout the kingdom, and transmitted along with orders to them to arm themselves and the persons under their command on that day month, and then to open the letters in the night, and to act as they should find themselves therein directed. The result was, that the next day (Oct. 13) nearly all the Templars in France, De Molay included, were in custody. Their houses and goods were also everywhere seized; the vast stronghold of the Temple at Paris, the chief seat of the order in that kingdom, was entered and taken possession of by Philip himself.

An act of accusation was forthwith published; and Philip at the same time wrote to the pope, and also to the king of England, intimating what he had done, and calling upon them to second him. Edward II., on receiving letters from Clement, yielded, and the English Templars were seized and thrown into confinement about the end of December. Meanwhile, the examinations had been going on in France under the direction of the king's confessor, Imbert, a Dominican priest, and, as such, the inveterate enemy of the order of the Templars. Confessions, in many cases incredible from their inherent absurdity, were extracted from many of the knights at Paris and elsewhere by the most savage tortures. This went on for many months. In August, 1308, Clement, whose person Philip had now contrived to get completely into his power, issued a bull, calling upon all Christian princes and prelates to aid him in examining into the guilt of the order; and about the same time his holiness appointed a commission, consisting of the archbishop of Narbonne and other prelates and dignitaries of the church, to meet at Paris to try the case. This commission, however, did not commence its sittings till the 7th of August, 1309. A few months later, examinations under judges, deputed or nominated by the pope, commenced in England and other countries. Altogether many hundreds of knights were examined by these commissions during the years 1309, 1310, and 1311; but it was only in France, where torture was made use of, that any admissions were obtained of the crimes laid to the charge of the order, except such as were manifestly unworthy of regard. Even the Paris commission, however, did not satisfy the impatience of Philip: on its requisition a great number of knights stood forward to defend the order, among whom were several of those who had confessed and afterwards retracted. Philip, having forced the pope to nominate Philip de Marigni, bishop of Cambray, the brother of Enguerrand de Marigni, his prime minister, to the archbishopric of Sens, which had just become vacant, and then included the diocese of Paris, got the new archbishop to convoke his provincial council in the capital, on Sunday, the 10th of May, 1310; and this body, on the Wednesday morning following, had fifty-four of the defenders of the order, who had formerly made confession, brought out as "relapsed heretics" to a field behind the abbey of St. Antoine, and there committed to the flames. They all died asserting their innocence and that of the order. These proceedings and others of a like kind in the provinces of Rheims and Sens, put a stop to the attempt at defending the order: the rest of the knights who had undertaken this task now all declared their renouncement of it. Meanwhile, a general council met by order of Clement at Vienne, October 13, 1311, but it was not found so compliant as Philip and the pope had expected; and Clement, having put an end to the session, assembled the cardinals and a few other prelates upon whom he could depend, in a secret consistory, and abolished the order by his own authority, on the 22nd of March, 1312. The bull of abolition was formally published on the 2nd of May following. On the 18th of March, 1314, Molay, the grand master, and Guy, commander or grand prior of Normandy, who had all this while remained in prison at Paris, were brought before the archbishop of Sens, condemned to death, and burned on one of the small islands in the Seine, about the spot where the statue of Henry IV. is now erected on the Pont Neuf.

After all, Clement and Philip, the former of whom died suddenly about a month, and the latter, of a fall from his horse, within a year after the martyrdom of De Molay, were able to secure to themselves only a small portion of the plunder which they had probably hoped for. The king of France seized and kept, or divided with his confederate, the moveable property of the Templars in that country; but there, and also in England, and throughout the rest of Europe, with the exception of Spain and Portugal, it was found necessary to transfer their landed possessions to the Hospitallers, or Knights of St. John (at this time commonly known, from the place where they had fixed their head residence, as the Knights of Rhodes). In Spain, the lands of the Templars were bestowed upon the Knights of Our Lady of Montesa, a new order, founded in 1317; and in Portugal the society merely took the new name of the Order of Christ, which still subsists.

It has been calculated that the entire revenues of the order when it was dissolved did not fall short of six millions sterling, though it seems impossible that this should not be a great exaggeration. Their possessions in England were even at a comparatively early period of great extent and value, as may be seen from an "inquisitio," or account of their lands, taken by royal authority in the year 1185, which Dugdale has printed in his 'Monasticon' (vol. vi., pt. ii.). They are supposed to have been settled in the Old Temple, at London, which stood on the south side of Holborn, near the present Southampton Buildings, by the beginning of the reign of Stephen: they removed to their new house at the western extremity of Fleet Street, the site of which still retains the name of the Temple, in 1185. This was the chief seat of the order in England.

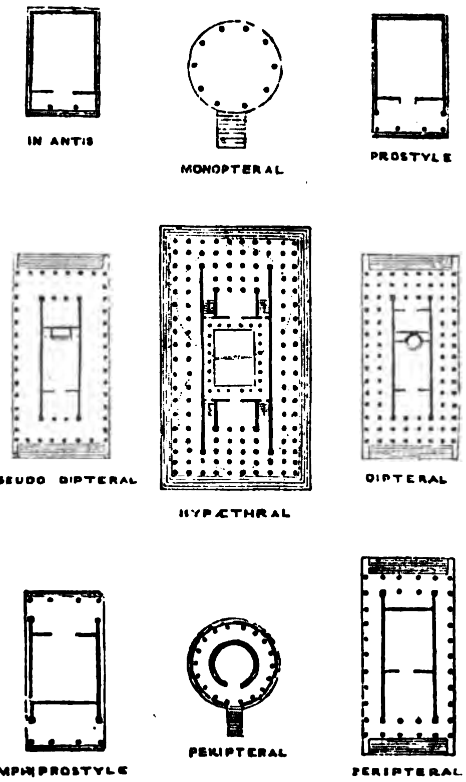
The question of the guilt or innocence of the Templars has been much discussed in modern times; and although it may be said to be now almost universally admitted that the particular charges upon which they were condemned were for the most part entirely unfounded, some attempts have been made to show the probability that the order nevertheless was held together by certain secret principles or doctrines which made its existence dangerous to society, and called for its suppression. Von Hammer, for instance, in a disquisition printed in the sixth volume of his 'Mines de l'Orient,' has attempted to convict the order of a participation in the apostacy, idolatry, and impiety of the Gnostics and Ophianites. Von Hammer's Essay was answered by M. Raynouard, in a long note printed in the fifth volume of Michaud's 'Histoire des Croisades,' &c.; and also in two articles in the 'Journal des Savans' for March and April, 1819; and in two others published in the 'Bibliothèque Universelle,' tom. x. The documents relating to the condemnation of the Templars were first published in a work entitled 'Traitez concernant la Condemnation des Templiers,' par M. Du Puy, 8vo, Paris, 1654; reprinted, with additions, under the title of 'Histoire de la Condemnation des Templiers,' &c., par Pierre Du Puy, 2 vols. 8vo, Bruxelles, 1713; and under that of 'Histoire de l'Ordre Militaire des Templiers, avec les Pièces Justificatives,' 4to, Bruxelles, 1751. Other works on the subject are—'Nicolai Gürtleri Historia Templariorum,' 8vo, Amst., 1691, and, with large additions, 1703; 'Christiani Thomasii Dissertatio de Templariorum Equitum Ordine Sublato,' 4to, Halae, 1705; Raynouard, 'Monumens Historiques relatifs à la Condamnation des Templiers,' 8vo, Paris, 1813; Munter, 'Statutenbuch des Ordens der Tempelherren;' Wilike, 'Geschichte des Tempelherrenordens;' and 'The History of the Knights Templars, the Temple Church, and the Temple,' by C. G. Addison, 4to, London, 1842.

TEMPLE (the Latin "Templum") a building set apart for religious uses. What is known of the columnar architecture of the nations of antiquity is derived chiefly from their temples. In the temples of the Egyptians, it may be said to display itself exclusively, and likewise much more extensively than in the temples of the Greeks or Romans, with this further difference as regards the general design and character, that in the Egyptian edifices the columns are placed *internally*, that is, so as to form colonnades along the sides of an enclosed fore-court, and the portal or frontispiece of the temple itself. Of this disposition of the entire plan, with a walled-in cortile or cloister, an example is shown in EGYPTIAN ARCHITECTURE. To that article and the articles GREEK ARCHITECTURE and ROMAN ARCHITECTURE we refer for other particulars relative to Egyptian temples and some of the characteristic differences between them and those of the Greeks and Romans; and to NINEVEH, ARCHITECTURE OF, for notices of the temple-palaces of the Assyrians; and proceed to give in this place some further particulars respecting the temples of Greece and Rome.

Instead of being composed of a variety of parts grouped and combined together, Grecian temples consist only of a simple parallelogram, a *cella*, or body of the temple itself, either *in antis*, or else *peripteral*, that is, entirely surrounded with an external colonnade; for to these two distinctions may be reduced all those subordinate ones for which separate technical terms have been invented: but whatever be their technical designation the general shape and outline still remains a simple unbroken parallelogram, either with or without external colonnades along its sides. Still simple as are the plans of Grecian temples, there are many terms required to express their varieties in regard to the application of columns, besides those denoting the number of columns in front, that is, beneath the pediment. Thus, if there were columns only in front, the building was termed *prostyle;* if at each end, *amphiprostyle;* if there were also colonnades along the sides, it was said to be *peripteral*, that is, with wings (aisles) or colonnades quite round it. When there were two rows of columns, one behind the other, it was termed *dipteral*. Again, where a range of columns was placed between antæ, forming the extremities of walls at right angles with such colonnade, it was said to be *in antis*. This was generally the case with the pronaos, the vestibule or inner portico behind the columns in front. According to the number of columns in front, porticos are said to be *tetrastyle*, that is, with four columns; *hexastyle*, with six; *octastyle*, with eight; *decastyle*, with ten; and *dodecastyle*, with twelve, the greatest number that can very well be brought beneath a pediment; and even of these two last the examples are exceedingly rare. If instead of columns at the angles there were antæ, then the number of columns alone was reckoned as before, and would denominate what would be equivalent to a portico containing two more: thus a *distyle in antis*, that is, two columns between two antæ, would be equal to a tetrastyle, as in both there would be three intercolumns; a *tetrastyle in antis* would be equal to a hexastyle, and so on. When the cella was without a roof, and in part, at least, open to the sky, the temple was termed *hypæthral*.

The following diagrams will render these terms more intelligible, and at the same time serve as examples of the different forms of plan as regards *columniation*, or the arrangement of the columns.

Though so exceedingly small as to show little more than the position of the columns, without any regard to exactness in other respects, these slight diagrams will both serve to render evident many circumstances that cannot else be fully explained, and also to exemplify the respective denominations of temples and porticos according to the number of columns in front. The one "in antis" is a *distyle in antis*, there being only two columns between the antæ, or three intercolumns,



as in the two tetrastyle examples (prostyle and amphiprostyle); whereas were there four columns between the antæ, it would become *tetrastyle in antis*, and have as many intercolumns as a *hexastyle*, of which last the peripteral figure is an example. The dipteral and pseudo-dipteral are both *octastyles;* and the hypæthral a *decastyle*. This last may also be taken as an example (though an imperfect one) of a *diprostyle*, for it will be seen that if the portico were a mere prostyle, it would project forward two intercolumns from the body of the temple. In this figure the pronaos may also be termed *polystyle*, on account of the great number of columns in successive rows between the side walls enclosing that part of the plan (pronaos), which may be described as a dipteral or double *tetrastyle in antis*, having a distyle in antis behind it, and a *diprostyle decastyle* in front of it.

Still there is no variety whatever as to external form, no individual character as to outline or even the general proportions, nothing of combination or of design, as the last term is usually understood; but the difference of effect depended altogether upon the actual dimensions of the structures, upon material and execution, upon circumstances of detail and finish, and on the degree and particular kind of decoration in regard to sculpture and polychromic embellishment. The only instance of combination and grouping is that afforded by the Erechtheion, or triple temple on the Acropolis at Athens, which has two distinct porticos, namely, an Ionic hexastyle monoprostyle at its east end, and a tetrastyle diprostyle of the same order on its north side, and upon a lower level; besides which there is a smaller attached or projecting structure at the south-west angle, forming a tetrastyle diprostyle arrangement of caryatic figures, raised upon a screen-wall or podium. In this combination no regard has been paid to symmetry; for which reason however it is the more striking, as forming a decided contrast to the unvaried and even monotonous uniformity pervading the temple-architecture of the Greeks. It is almost the only Grecian structure that can be said to be as much distinguished by picturesqueness as by elegance of architectural detail. This edifice moreover affords almost the only instance in the Grecian style of distinct porticos or prostyles projecting from a building [PORTICO], other porticos being either in *antis*, so as to be *recessed* within the main walls forming the sides of the edifice; or are only the end or ends of the colonnades continued throughout the whole exterior: consequently in neither case does such portico show itself as an actual prostyle. The only other known examples of Greek prostyles are the two small Ionic temples at Athens, that on the banks of the Ilissus, called the temple of Panops; and that dedicated to Nike Apteros, or Wingless Victory. Both these were amphiprostyle, and not *in antis*, consequently had a projecting portico at each end; and in both the porticos were tetrastyle. Of the former nothing now remains, but it is well known from

Stuart's delineations, and the order itself—of plain and bold but elegant character—has been adopted as the type of most of our modern Grecian Ionic. Though amphiprostyle, the porticos were not exactly similar in plan; for while the one was a mere monoprostyle, that forming the entrance end was also deeply recessed within the main walls, after the manner of a portico in antis without columns. The other temple, that of Nike Apteros, was a very small structure, a mere votive chapel, close by the west front of the Propylæa of the Acropolis, with its hinder portico facing the south wing of that edifice, but turned obliquely from it. For although they carried regularity almost to excess, the Greeks seem to have paid no regard to it whatever in disposing buildings relatively to each other, for there is a similar and apparently intentional want of parallelism between the Parthenon and Erechtheion on the Acropolis itself; nor are either of them in a line with the Propylæa, or equidistant from such line or axis.

This inattention to uniformity of arrangement, where different buildings are brought together on one general plan, shows a striking difference of taste in that respect between the Egyptians and the Greeks. The temples of the Egyptians consist of various architectural parts subordinate to the principal structure, but combining with that and with each other to form a whole; which scheme was sometimes further extended by an architectural avenue of sphinxes in front of the buildings. The Greeks, on the contrary, certainly did not attempt to imitate or rival the Egyptians in the extent and complex arrangement of their temples, though there can be little doubt that they were originally indebted to them for much of their architectural knowledge. Their temples were almost invariably single structures, not only detached from but altogether unconnected with adjacent ones, instead of forming with them a symmetrically arranged assemblage or group. It seems however to have been in some degree the practice with the Greeks as well as with the Romans to erect several temples in the immediate neighbourhood of each other, and in a particular district of a city, as was the case in the Forum and Capitol at Rome, where temple succeeded to temple almost uninterruptedly; and the ruins of Pæstum, Agrigentum, Selinus, and other places show a somewhat similar concentration of sacred edifices about the same spot. Temples were frequently surrounded by a sacred grove or plantation of trees, *temenos*, or else placed within an enclosure, *peribolos*, formed either by mere walls or by colonnades, but there are scarcely any examples of the kind now remaining; and they are chiefly Roman works, namely, the temples at Baalbec and Palmyra. Similarly enclosed and standing in the centre of a peribolos or piazza (therefore very different in plan from an Egyptian temple preceded by a fore-court), were the temples of Jupiter and Juno, Venus and Roma, at Rome [ROMAN ARCHITECTURE, col. 145]; that of Jupiter Olympius at Athens, a work completed in the time of Hadrian; and also, among Græco-Asiatic examples, the temples Athena Polias at Priene, and Apollo Didymæus at Miletus.

Similar as it is upon the whole to that of the Greeks, the temple-architecture of the Romans differs from it in many other circumstances besides those of style; which latter was, with very few exceptions, Corinthian—the national style of the Romans, as the Doric was of Greece and its Italian colonies. One leading distinction in regard to general arrangement is, that Roman plans were hardly ever *in antis*, and not often *peripteral*, but generally prostyle, with the portico projecting out from the *cella*, or body of the structure, three or more intercolumns, so as to be *triprostyle*, &c. [PORTICO.] Such façade was generally further distinguished by having a flight of steps enclosed within pedestals at its ends, which were continued as a podium or moulded basement along the sides of the edifice; whereas the Greeks raised the temples only three steps or so above the ground, and carried those gradini quite round the structure, wherefore each elevation or side of their peripteral temples was uniform in design, having no other variety than that produced by greater extent and number of columns in one direction, and by the pediments at the extremities. The Romans certainly evinced greater taste for both contrast and picturesque combination than the Greeks, although decidedly inferior to them in beauty of detail and finish of execution. In order to give greater dignity to the whole temple or to the principal structure in an architectural group, they elevated it upon not a mere basement or substructure with an ascent in front or at both ends, but upon a spreading-out platform, constituting a terrace on every side. They appear to have occasionally formed a succession of terraces of flights of steps, leading up to if not continued on every side of the building. The celebrated Temple of Fortune at Præneste, usually supposed to have been originally founded by Sulla, was a very remarkable example of the kind. Very little now remains of it, except the terraces themselves; neither have we any account of the architecture, but besides the principal edifice or temple there were several subordinate ones, on the different platforms.

Circular and polygonal plans for temples are peculiar to the Romans, and occasion a diversity of character not to be met with in those of the Greeks. Besides the two simplest forms, the monopteral and peripteral, which have been shown above, there were other varieties and combinations. For a notice of some of them we refer to ROMAN ARCHITECTURE.

Instead of entering into formal descriptions of particular temples, we subjoin a synopsis with accompanying remarks. Some of the

TABLE OF SOME OF THE PRINCIPAL GREEK AND ROMAN TEMPLES.

Athens	Theseion	Doric	Hexastyle, peripteral, with 12 intercolumns on sides, 46 × 105 feet.
,,	Parthenon	Doric	Octastyle, peripteral, hypæthral, 100 × 228 feet; Ictinus and Callicrates, architects. [ELGIN MARBLES.]
,,	Propylæa	Doric	Hexastyle on both fronts, with wings of a smaller order, at right angles to west front. Mnesicles, architect, 437–432 B.C.
,,	Erectheion	Ionic	Hexastyle, prostyle at east end, with a tetrastyle, diprostyle on north side.
,,	Panops	Ionic	Tetrastyle, amphiprostyle. A well-known example, though no longer extant, having been destroyed by the Turks since Stuart's time.
,,	Nike Apteros	Ionic	Tetrastyle, amphiprostyle. Recently rebuilt.
,,	Jupiter Olympius	Corinthian	Decastyle, peripteral, columns 60 feet high, 96 × 259 feet. Enclosed by a peribolus. A Roman work originally begun in the time of Pisistratus, continued by Antiochus Epiphanes, and completed by Hadrian.
Eleusis	Demeter	Doric	A square building of about 180 feet on each side, with a dodecastyle colonnade forming the west front. This temple begun by Ictinus; colonnade added by Philo, architect, about 315 B.C.
,,	Propylæon	Doric	Hexastyle on both fronts, with inner Ionic order as at Athens, 50 × 60 feet. A second and smaller propylæon within the peribolos, distyle in antis. See 'Unedited Antiquities of Attica.' None of these buildings now remain.
Thoricus	. . . . . .	Doric	Eptastyle, peripteral, or with seven columns at each end, and fourteen on each side. No cella remaining; but supposed to have been a double temple, with a passage through the centre, from the sides, dividing the cella into two.
Rhamnus	Nemesis	Doric	Hexastyle, peripteral, 11 intercolumns on sides, 33 × 70 feet.
,,	Themis, or lesser Temple of Nemesis.	Doric	Distyle in antis.
Ægina	Athene	Doric	Hexastyle, peripteral, hypæthral, 41 × 90 feet. [ÆGINETAN MARBLES.]
Olympia	Zeus Olympius	Doric	Hexastyle, peripteral, hypæthral, 95 × 230 feet. Completed about 435 B.C. Libon, architect.
Bassæ	Apollo Epicurius	Doric	Hexastyle, peripteral, hypæthral, 47 × 125 feet. Date about 430 B.C. Ictinus, architect. In interior, Ionic columns.
Tegea	Athene Alea	Ionic	Peripteral, hypæthral. Doric internally; with upper Corinthian order. Scopas, architect.
Nemea	Zeus	Doric	Hexastyle, peripteral.

MAGNA-GRÆCIA AND SICILY.

Pæstum	Poseidon	Doric	Hexastyle, peripteral, hypæthral, 79 × 195 feet.
,,	Demeter	Doric	Hexastyle, peripteral, 47 × 107 feet.
Agrigentum	Zeus Olympius	Doric	Apteral, or with engaged columns, eptastyle, 182 × 369 feet. Wilkins, in his restoration of it, makes this temple hexastyle amphiprostyle.
,,	Hera	Doric	Hexastyle, peripteral, 57 × 124 feet.
,,	Concord	Doric	Hexastyle, peripteral, 31 × 93 feet. Deep pronaos and opisthodomus.
Segeste	,,	Doric	Hexastyle, peripteral, 76 × 190 feet. All the external columns (unfluted) standing, but no remains of cella.
Selinus	Great Temple	Doric	Octastyle, dipteral, 160 × 330 feet. There are remains of five other temples, two of which appear to have been hexastyle peripteral.
Syracuse	Athene	Doric	Hexastyle, 13 intercolumns on sides: now converted into a church with a modern Italian Corinthian façade.

ASIATIC GREEK.

Ephesus	Artemis	Ionic	Decastyle, dipteral, hypæthral, ; columns 60 feet high ; one of the largest Grecian temples, being 220 × 425 feet. Ctesiphon and Metagenes, architects. Date about 340 B.C.
Miletus	Apollo Didymæus	Ionic	Decastyle, dipteral, hypæthral, 164 × 303 feet. Columns 9½ diameters. Pæonius, architect. A peribolos.
Magnesia	Artemis	Ionic	Octastyle, pseudo-dipteral, 106 × 198 feet. Hermogenes, architect.
Priene	Athene Polias	Ionic	Hexastyle, peripteral, 64 × 116 feet. Pytheas, architect, about 340 B.C. The order the best example of Asiatic Ionic. This temple had a peribolos and propylæon ; the latter tetrastyle, with two rows of square pillars within.
Teos	Dionysos	Ionic	Hexastyle, peripteral. Hermogenes, architect ; about the time of Alexander the Great.
Samos	Hera	Ionic	Decastyle, dipteral, 189 × 346 feet.

ROMAN.

Rome	Concord	Ionic	Hexastyle. Appears to have been a diprostyle, but nothing of the cella remains.
"	Fortuna Virilis	Ionic	Tetrastyle, diprostyle, cella pseudo-peripteral, about 24 × 44 feet.
"	Jupiter and Juno	Corinthian	Two separate temples, alongside each other, in centre of a colonnaded peribolos. Similar in dimensions, but the one octastyle, peripteral ; the other octastyle, diprostyle. Erected by Metellus Macedonicus, about 140 B.C. No remains ; but the authority is the ancient plan of Rome in the capitol.
"	Jupiter Stator	Corinthian	Supposed to have been octastyle, peripteral. The celebrated 'Three Columns,' in the Forum, are all that now remain of this very fine example.
"	Jupiter Tonans	Corinthian	Octastyle, dipteral, 92 × 115 feet. Columns 47 feet high.
"	Mars Ultor	Corinthian	Of this temple, sometimes called that of Nerva, only three columns remain ; but it is said to have been octastyle, peripteral.
"	Venus and Roma	Corinthian	Decastyle, pseudo-peripteral, enclosed within a peribolos formed by double colonnades of a lesser order.
"	Antoninus and Faustina	Corinthian	Hexastyle, triprostyle, 33 × 55 feet.
"	Pantheon	Corinthian	An octastyle, triprostyle, attached to a rotunda.
"	Vesta	Corinthian	A circular peripteral of 20 columns.
Tivoli	Vesta, or the Sibyl	Corinthian	A circular peripteral of 18 columns around cella. The order a very peculiar and fine example.
Præneste	Fortuna		No remains of this celebrated temple itself, but merely of the series of terraces and flights of steps on which it was elevated.
Pompeii	Jupiter	Corinthian	Hexastyle, tetraprostyle, about 50 × 110 feet.
Nismes	Maison Carrée, or Temple of Caius and Lucius	Corinthian	Hexastyle, triprostyle ; order continued along the cella, making it a pseudo-peripteral, 38 × 77 feet.
Baalbec	Great Temple	Corinthian	Decastyle, peripteral, 160 × 290 feet.
"	Lesser Temple	Corinthian	Octastyle, peripteral, 118 × 225 feet.
Palmyra	Helios, or the Sun	Corinthian	Octastyle, peripteral, 95 × 180 feet. Enclosed within a peribolus about 740 feet square, formed by an outer wall and two ranges of Corinthian columns, making a double colonnade.

measurements and other particulars stated in it may not exactly accord with other accounts of the respective structures; for so great is frequently the discrepancy between different authorities, whether writers or delineators and restorers, that it is impossible to obtain complete accuracy.

The above table might be rendered more copious and greatly extended; and it might also have been differently arranged in several ways, each of which would have had something to recommend it, according to the purpose for which it may happen to be consulted. Chronological order, for instance, if the respective dates could be ascertained with tolerable accuracy, may be considered preferable by some persons; or the buildings might have been classified according to the number of columns in front, and as being *in antis, prostyle, peripteral*, &c.; or else according to their relative size and dimensions. In fact a separate table is required for each mode of classification and arrangement; but as that could not be done, we have adopted what we consider the most satisfactory upon the whole. We may however render it in some measure more complete by here pointing out that the *decastyle* examples mentioned in it are the Temple of Jupiter, Athens; Artemis, Ephesus; Apollo, Miletus; Hera, Samos; Venus and Roma, Rome; and the great temple at Baalbec. As regards dimensions and relative size, the following are the largest structures, namely:—

	Width of Front.	Length.
Ephesus	220 feet	425 feet
Agrigentum, Great Temple	182 "	369 "
Selinus, Great Temple	160 "	330 "
Venus and Roma	116 "	350 "
Athens, Parthenon	100 "	228 "
Temple of Jupiter	96 "	259 "

By way of affording a standard of comparison, we add the dimensions of St. Paul's, London, and La Madeleine, at Paris, namely: the former, 180 by 500; the other 138 by 328 feet.

TEMPLE, SOLOMON'S. For 447 years after the Hebrews had entered the land of Canaan they continued to worship at the tabernacle which had been framed for their use in the Wilderness. [TABERNACLE.] The incongruity of a settled people having only a tent for the celebration of their splendid ritual service first occurred to the mind of David. It appeared unseemly to him that the Ark of God should still "dwell between curtains," while he abode himself in "a house of cedar," and he therefore proposed to build a temple in which the worship of God might be more becomingly conducted (1 Chron., xvii. 1). The prophet Nathan was however commissioned to inform him that having been engaged in constant warfare, and shed much human blood, he could not be allowed to execute the design he had formed, which was to be reserved for the peaceful reign of his son Solomon. This undertaking was however a principal subject of David's thought and care during the remainder of his reign; and to it he appropriated a large proportion of the immense treasure which his many victories produced. He may be said to have provided all, or nearly all, the materials before his death; consisting of large but variously estimated quantities of gold and silver, brass and iron, stone and timber. He also secured the services of skilful mechanics and artificers for every branch of the work, and furnished the design, plan, and site of the building; so that more of the credit of this work seems due to David than to Solomon (1 Chron., xxi.; xxii.; xxviii. 11-19).

The foundation of the Temple was laid in B.C. 1012, being the fourth year of Solomon's reign; and in seven years and a half it was completed. During this time 183,600 persons were employed on the work. Of Jews there were 30,000 serving by rotation of 10,000 monthly; and of Canaanites there were 153,600, of whom 70,000 were labourers, 80,000 hewers of wood and stone, and 3600 overseers of the others. To save the labour of carriage, the parts were all prepared for use at a distance from the site of the building, and when they were brought together, the structure was reared without the sound of hammers, axes, or tools of iron (1 Kings, vi. 7).

The site of Solomon's Temple was the summit of Mount Moriah, one of the eminences on which Jerusalem stood. This eminence rose to no great height within the city, but was high and steep above the valley of the Kedron, which it overlooked. It faced the Mount of Olives. The Mosque of Omar now occupies the same site; and the imposing figure which it makes in every view of Jerusalem shows that a more advantageous situation could not have been chosen. The top of the hill was levelled, and the sides banked up to afford a sufficient area. This area was divided into two (but in Herod's temple three) courts, in the outermost of which stood the people. It was separated by a low wall (or, as some think, by a latticed fence or trellis) from the inner court, called the Court of the Priests, in which was the great altar of burnt offerings, and where the priests and Levites officiated in view of the people, and in front of the holy house, or proper temple. The proper temple, as previously indicated, was an oblong building. It was 70 cubits in length, 20 in width, and 30 in height: this last was however only the elevation of the house or holy place, for the innermost sanctuary was but 20 cubits high (1 Kings, vi. 20); and although the porch (pronaos) is said, in 1 Chron., iii. 4, to have been 120 cubits high, or four times the height of the main building, the numbers in that text are now generally admitted to be corrupted: 20 cubits, which we find in the ancient versions, is probably the true number; being the same height as the sanctuary. The porch covered the breadth of the building 20 cubits, and was 10 cubits deep: the holy place was 40 cubits long by 20 wide; the sanctuary was a perfect square of 20 cubits. The building fronted the east. Along the north and south sides, and the west end of the structure, was an upper story, or gallery of wood, and certain buildings called "side chambers," in three stories, each five cubits high. This made 15 cubits of total elevation, which was not more than half the height of the main building, in whose walls, above, there was therefore room for the splayed windows which gave light to the temple.

The sacred utensils were of the same description and occupied the same relative position as in the tabernacle. but some of them were larger, as the altar, candlestick, &c., in proportion to the more extensive establishment to which they belonged. The principal of the new utensils was the great brazen laver for ablutions, which rested on the backs of twelve oxen of the same metal.

The inner sanctuary was separated from the holy place by a rich curtain or veil. The whole of the interior was wainscoted with cedar, carved with figures of cherubim, palm-trees, and flowers, and then overlaid with the finest gold. The doors were also covered with gold: all the utensils in the house were of that metal; and even the floor appears to have been overlaid with gold (1 Kings, vi. 30). It is this lavish expenditure of precious metal upon the building, and the elaborate workmanship bestowed upon it, which, rather than its architectural effect, accounts for the reports of its surpassing magnificence, and for the immense wealth consumed in its erection. The popular impression concerning it, however, being based rather upon the exaggerated statements of Josephus than upon the more sober accounts in Scripture, does, no doubt, greatly exceed the truth. More might be said of its richness than of its grandeur. Its wealth is indeed attested by the spoliations of successive kings and conquerors; and it may be well to remember that this was not, as in other nations, one of many temples, but was the sole temple of the whole nation, and in the production of which the whole nation could therefore concentrate its resources.

The Temple of Solomon retained its pristine splendour only for forty years, when its treasures were plundered by Shishak, king of Egypt. After undergoing various other profanations and pillages, it was finally destroyed by the Chaldæans under Nebuchadnezzar, B.C. 588, after having stood 417 years. After the Captivity, the temple was rebuilt, on the same plan, and on a more extensive scale, but with greatly diminished splendour. This temple stood until some years before the birth of Christ, when Herod the Great, to propitiate his subjects, whom most of the measures of his reign had tended to exasperate, undertook to rebuild it on a larger scale and with greater magnificence. In nine years, during which 80,000 workmen were constantly employed, he accomplished his original design; and produced a fabric, which, while the same in its essential characteristics, much surpassed the Temple of Solomon in extent and architecture, although the precious metal may have been less lavishly displayed in the interior decorations. Many years after, the Jews kept workmen employed in embellishing the pile, and in the erection of additional buildings (John, ii. 20). In A.D. 64, nothing remained to be done; but six years later (A.D. 70) the temple and city were involved in one common ruin.

TENACITY (from the Latin *tenacitas*, "the power of holding"), a property of material bodies by which their parts resist an effort to force them asunder.

This property is the result of the corpuscular forces acting within the insensible spaces supposed to exist between the particles of bodies; it is consequently different in different materials, and in the same material it varies with the state of the body with respect to temperature and other circumstances.

Those corpuscular forces consist of attractions which vary according to unknown laws with the distances of the particles from one another, and even at certain distances they become repulsions [ATTRACTION]; but in all bodies except the elastic fluids, the combined actions of all the particles produce that coherence which constitutes the tenacity of the masses. In those fluids the particles have no coherence, and when the pressures to which they are subject are removed, those particles immediately separate from each other with forces depending, probably, upon the quantity of caloric with which they are combined. In non-elastic fluids and in solids, tenacity exists, but in very different degrees; its force depending upon differences in the intensity of the attracting powers between the particles, upon differences in the distances of the particles themselves, upon the action of the caloric, and, in some cases, upon variations in the pressure of the atmosphere.

The molecules of liquids adhere to one another, and generally to those of solid bodies, by attractive forces which decrease very rapidly; and, at insensible distances from the supposed places of contact, the adhesion entirely disappears [CAPILLARY ATTRACTION]: the real tenacity of the molecules being, as Dr. Young observes, equal to the excess of their mutual attractions above the forces of repulsion arising from the actions of the calorific particles. It is on account of the small distance to which the attractions of the fluid molecules extend, and to the freedom with which the particles move on one another, that fluids appear to have so little tenacity; but from the weight of water-support in glass tubes, Dr. Robison has estimated that the mutual attractions of the particles of water on a surface equal to one square inch must far exceed 190 pounds.

Grains of dust or sand, while dry, have no power of adhering together, probably because their forms do not permit a sufficient number of points on their surfaces to be brought within the distance at which corpuscular attractions take place; but, if slightly wetted, the mutual attractions between the dust and the liquid produce a certain degree of tenacity. This is very sensible in clay moistened with water; for, being then drawn into the form of a rod, it is capable of bearing a small weight suspended from it. Tenacity exists in various degrees in viscid fluids, as oil, gum dissolved in water, &c. Sealing-wax and glass also, when heated, lose their brittleness, and acquire *plasticity*, whereby they become capable of being moulded into any form, while their particles retain a considerable degree of adhesive power.

The tenacity of solids constitutes, in part, the subject of the power of bodies to resist strains; and under MATERIALS, STRENGTH OF, will be found a table of the weights which would overcome the force of cohesion in rods immoveably fixed at one end and pulled in the direction of their length. Those weights may be considered as the measures of tenacity in the different kinds of material; and it may be added that, from a mean of several experiments made by Telford on the tenacity of forged iron, the breaking strength, when reduced to that which it would be if the area of a transverse section of the bars had been one square inch, is 29½ tons. The bars were cylinders or parallelopipeds varying in length from 1 foot 5 inches to 2 feet 3 inches, and in area of section from 0·56 to 3·14 square inches: they stretched in length from two inches to four inches before they broke. Telford found, also, that a bar of cast-steel bore, suspended from it, 27·92 tons, a bar of blistered steel 17·27 tons, and of cast-iron (Welsh pig) 7·26 tons; the area of the section in all being one square inch. Tenacity in solid bodies varies greatly with their temperature. Coulomb took a piece of copper-wire, which, when cool, carried 22 lbs. suspended from it; and, upon bringing it to a white heat, it would scarcely bear 12 lbs.

Though, when a piece of metal is fractured, the parts will not by simple adjunction adhere together, yet, in some cases, by hammering them upon one another, so many points on their surfaces may be brought within the limits to which the force of cohesion extends, that they will acquire a tenacity equal to that which the metal had in its natural state.

The tenacity of wood is much greater in the direction of the length of its fibres than in the transverse direction, the fibres being united by a substance having little cohesive power. Few experiments have been made on the tenacity of wood perpendicularly to its grain, as it is called; and from those of Mr. Emerson it appears to vary from one-tenth to one-seventh of the tenacity in the other direction. When a strain takes place in the direction of the fibres, they become disengaged from one another, and thus lose the strength which arises from their lateral cohesion. They then become subject to separate strains; the weaker ones are first ruptured, and at length all give way, leaving an irregular surface of fracture. [ADHESION.]

With respect to metals, the processes of forging and wire-drawing increase their tenacity in the longitudinal direction; the augmentation of friction and lateral cohesion, arising from the particles being forced together in the transverse direction, more than compensates for the diminution of the attraction which may result from the particles being forced or drawn farther asunder longitudinally. Copper and iron have their tenacity more than doubled, while gold, silver, brass, and lead have it more than tripled by those metals being drawn into wire.

Mixed metals have, in general, greater tenacity than those which are simple: the tenacity varies with the different proportions in which the metals are mixed; and the proportions which produce the greatest strength are different in different metals. The only experiments on this subject with which we are acquainted are those of Muschenbroek; and from these we find that a compound of which ⅚ were gold and ⅙ copper, had a tenacity, or force of cohesion, more than double that of the gold or copper alone: brass, composed of copper and zinc, had a tenacity more than double that of the copper, and nearly twenty times as great as that of the zinc: a metal of which ¾ were block-tin and ¼ lead, had a strength more than double that of the tin; and a mixture of which ⅝ were lead and ⅜ zinc, had a tenacity nearly double that of the zinc, and nearly five times as great as that of the lead alone.

TENAILLE, in Fortification, is a rampart raised in the main ditch, immediately in front of the curtain between two bastions; and in its most simple form, it consists of two faces coinciding in direction with the faces of the bastions, and, consequently, forming with each other a re-entering angle. Generally, however, it consists of three faces, of which two have the directions just mentioned, and the third forms a curtain which is parallel to that of the enceinte. See P, *fig.* 1, BASTION, and P (in the plan), FORTIFICATION.

This work was originally proposed by Vauban, in order to serve the purpose, in part, of a fausse-braye [FAUSSE-BRAYE], since the fires of musketry on its faces may be employed, in conjunction with those of artillery and musketry on the flanks of the bastions, to oppose the passage of the enemy across the main ditch when about to mount a breach in the ramparts of the place.

The relief of the tenaille, or the elevation of its crest above the bottom of the ditch, is determined consistently with the intention of thus defending the main ditch; and in order that the defenders of the tenaille may not be injured by the shot fired over their heads, from the flanks of the bastions, it is usual to make the crest of that work coincide with a horizontal plane passing three or four feet below the point where a line of fire from one of those flanks would cut a vertical plane, bisecting the angle of the tenaille or its curtain. The height thus determined will allow the parapet of the work to be elevated from two to four feet above the terreplein of the ravelin in its front;

and, consequently, from the curtain of the tenaille a grazing fire of musketry might be employed to protect the interior of the ravelin, or of its reduit, if there is one, should the defenders of either of those works abandon it (in consequence of an assault being made) before the enemy has time to cover himself in it by a lodgment: that fire will also contribute powerfully to prevent the enemy from attempting to enter the ravelin by its gorge.

Vauban, at first, gave to his tenailles short flanks nearly parallel to those of the bastions, but he soon abandoned that construction, perceiving that though the defenders might thus fire correctly along the main ditch, yet the parapets of those flanks were liable to be destroyed by the fire from the enemy's counter-batteries [H, *fig.* 1, BASTION], and they were enfiladed from the rampart of the ravelin (Q), or from the glacis of the places of arms (L).

Besides affording additional fires for the defence of the main ditch, the tenaille serves to cover, in part, the revetment of the curtain in its rear, and prevent it from being breached by fire from any lodgments of the enemy on the glacis. Its parapet serves also to mask the postern in the curtain of the enceinte, which would otherwise be so much exposed to the fires from the counter-batteries, that the defenders might be unable to communicate through it with the outworks. On this account the breadth of the ditch between the curtain of the tenaille and that of the enceinte is made such only as to allow the parapet of the former, with the relief determined as above-mentioned, to conceal the postern from the view of the enemy on the glacis. This ditch is advantageous in preventing the defenders of the tenaille from being injured by the splinters which may be detached from the flanks and curtain behind it; and, when dry, it serves to cover bodies of troops which may issue from thence and attack the enemy while crossing the main ditch, previously to making an assault. If the main ditch contains water, the tenaille serves to cover the boats and rafts by which the defenders of the enceinte communicate with the outworks.

The tenaille has been considerably improved by Bousmard, who, returning, in one respect, to the original idea of Vauban, has given flanks to the work in order that the main ditch may be directly defended by them. These flanks are raised high enough to cover the revetments of the flanks of the bastions, while their upper surfaces may be grazed by a fire of artillery from thence; and, instead of being formed with open terrepleins, and parapets for musketry, as usual, each flank of the tenaille is provided with casemates, or vaults, for four pieces of artillery which are placed nearly on a level with the terreplein of the covered-way. These guns are consequently capable of being directed against the counter-batteries (H) of the enemy, as well as of defending the foot of a breach in the face of the bastion.

This construction was adopted by Chasseloup de Laubat in the tenailles of the detached works which he executed about Alessandria, in Italy, when Napoleon (after the battle of Marengo) proposed to make that city the base of his operations beyond the Alps. But, in order to avoid the mischief which results from a fire directed against casemates (the shot in striking the cheeks or sides of the embrazures detaching from them splinters, which being driven into the vault do more injury to the defenders than the shot itself), this engineer raised before each flank of the tenaille a mass of earth which was reveted with brickwork, and perforated in such directions that, in defending the ditch, the shot from the casemates could be fired through the apertures, while the mass served as a mask which would prevent the enemy from seeing the embrazures in the flanks of the tenaille.

Any work belonging either to permanent or field fortification, which, on the plan, consists of a succession of lines forming salient and re-entering angles alternately, is said to be *à tenaille*.

TENAILLON, or Great Tenaille, in Fortification, is a species of exterior work which has been occasionally constructed before the faces of a small ravelin, with a view of increasing the strength of the latter, procuring additional space beyond the ditch, or covering the shoulders of the bastions. They were invented by Vauban, who, however, very seldom constructed them; and subsequent engineers have generally considered them as inferior in defensive qualities to a counterguard [Q Q, FORTIFICATION, *fig.*, cols. 171-172,] placed over the faces and salient angle of the ravelin.

The form and position of a tenaillon may be understood, Y being supposed to represent a small ravelin, if beyond the ditch of the latter the ramparts of the right and left faces be produced till each of them meets a rampart nearly perpendicular to the face of the bastion and extending to the place of meeting from the counterscarp of the main ditch at a point opposite the middle of that face. The works thus formed, one over each face of the ravelin Y, constitute a tenaillon; before each line of rampart is a ditch, and part of the general covered-way, the main ditch and that of the ravelin being in the rear. The two faces which are beyond the salient angle of the ravelin would, if produced towards the latter, form with each other a re-entering angle, whose vertex would coincide with that of the said angle.

The objections to tenaillons are, that the besieger would experience little difficulty in establishing a lodgment on that part of the covered-way or glacis which is immediately in front of the salient angle of the ravelin; and in this situation he would be able to breach the faces of the two half-bastions in four places, by fires of artillery directed along the ditches of the ravelin and those on the side faces of the tenaillon. The salient angles of the tenaillon, and of the ravelin which it covers, may be breached at the same time, and, when the ditches are dry, it would be possible to attack and carry the ravelin at the time of making the assaults on the tenaillon: then, the enemy having got possession of the former work, any retrenchments which may have been made in the tenaillon must necessarily be abandoned by the defenders.

The re-entering space between the two faces which are in the prolongation of the faces of the ravelin, and which constitute the head of the tenaillon, is sometimes occupied by a small redout, consisting of two ramparts perpendicular to the faces which have been just mentioned; and thus there may be obtained a good crossing fire for the defence of that part of the covered-way which is concealed by the salient angles of the tenaillons from the defenders of the bastions.

Demi-tenaillons are works placed also on the sides of a ravelin, and consisting of two ramparts which are perpendicular to and nearly opposite the middle of the faces of the bastions and ravelins: these are usually accompanied by counterguards which cover the salient angles of the latter works, and are called *Bonnets*.

TENANCY. [TENANT.]

TENANCY IN COPARCENARY. [ESTATE.]

TENANT. Tenants, in the more extended legal sense of the word, are of various kinds, distinguished from each other by the nature of their estates; such as tenants in fee simple, in fee tail, for life, for years, at will, and at sufferance. [ESTATE; TENURE.]

TENANT AND LANDLORD. The word tenant, in the more limited legal sense, which is also the popular sense, is one who holds land under another, to whom he is bound to pay rent, and who is called his landlord. The word Land means not only land itself, but also all things, such as buildings, houses, woods, and water, which may be upon it. Any one who has an estate in land, provided he is also in possession, may let the land to another. Where the letting takes place by an express contract between the parties, the contract is called a Lease, the nature of which is explained generally under LEASE.

But the relation of landlord and tenant may be created otherwise than by a formal lease. If one man with the consent of another occupies his land, a contract of letting is assumed to have been made between them, and the occupier becomes tenant at will to the owner. Such tenants are, after payments of rent as in annual tenancies, considered to be upon the same footing as if the lands had been let to them for a year dating from the commencement of their occupation. And at the end of the first year, a second year's tenancy begins, unless six months' notice of the intention to determine the contract has been given by either party to the other, and so on from year to year. The same rule of law applies to cases where a tenant continues to occupy land after the expiration of a lease made by deed; but in this case all the covenants of the expired lease as to payment of rent, repairs, insurance, and the like, are in force unless the lease is cancelled by destroying the seal; and even if there should be a verbal agreement for a different rent, still the old covenants subsist, unless the lease is cancelled. [DEED.]

In every case where the relation of landlord and tenant exists, either by express or by implied contract, certain terms are implied by law to have been agreed upon by the parties as forming part of the contract. It is of course in the power of the parties, where the contract is express, to qualify these terms so implied by the language of the contract itself. But it may be observed that as these terms are comprehensive in their nature, and distinctly understood in law, the interests of parties are often better consulted by leaving them to the general protection afforded by these implied terms than by attempts to define by enumeration in detail the respective rights and duties of the landlord and tenant. The terms implied on the part of the landlord are, that the tenant shall quietly enjoy the premises without let or hindrance from the landlord; on the part of the tenant, that he will pay rent, keep the premises in repair to a certain extent, and use the land, &c. in a fair and husbandlike manner.

When the landlord is himself tenant of the premises to a superior landlord, and neglects to pay his rent, and the occupying tenant is called upon to pay it to the superior landlord, he may do so, and set it off against the rent due from him to his own landlord. If a tenant has covenanted without exception or reservation to pay rent during the term for which the lease has been granted to him, he will be bound to pay it even if the premises should be destroyed by fire or other casualty. If he should have assigned his lease to another and ceased to be in possession, he will still remain liable under his covenant to pay rent.

The rules of law as to the repairs of premises may be determined by the terms of the lease. If they are not determined by the terms of the lease, they are somewhat uncertain and depend on a variety of circumstances, which are laid down in law treatises.

No tenant, in the absence of an agreement to that effect, is bound to rebuild after accidental destruction of the premises by fire. But under a general covenant to repair, and *leave repaired*, the tenant is bound to rebuild even in the case of destruction by fire.

In agricultural tenancies the lease generally determines the mode in which the farm is to be treated. [LEASE.] Unless also the lease expressly or impliedly excludes the operation of the custom of the country, the tenant is bound to conform to it. The custom of the country means the general practice employed in neighbouring farms of a similar description, with reference to rotation of crops, keeping up fences, and other like matters. In leases of farms it is often the practice to protect the landlord against certain acts of the tenant, such as ploughing up meadow land, &c., by introducing certain provisions into the lease. These provisions may operate according to the phraseology used, either to assign a penalty or to determine the liquidated damages agreed to be paid for the act done. It is often a matter of great importance and of some nicety to determine under which class the provisions fall. If under the first, the landlord is not entitled to the whole penalty upon the act being done, but he can only recover in an action the amount of the actual damage which has accrued. If under the second, he is entitled to the whole amount of the damages agreed on. A covenant by a tenant not to plough up meadow under a penalty of 5*l.* for every acre ploughed, is an instance of the first class: a covenant to pay 5*l.* rent for every acre of meadow ploughed up, is of the second class. The right to timber and timber-like trees belongs to the landlord; loppings of pollards and bushes, to the tenant. Different definitions prevail in different counties of timber and timber-like trees, and various customs prevail as to what amount of wood the tenant may be allowed to employ (after the landlord has been called on to select it) for the purposes of the farm. No tenant, unless he employs the land as a nurseryman or gardener, can remove any kind of shrub from the soil. Neither can a tenant remove fixtures, though put down by himself. A fixture is a chattel which is let into the soil, or united to some other which is let in. There are some exceptions to this rule in favour of fixtures used for the purpose of trade or agriculture, or merely ornamental purposes, where the removal will cause little or no damage. (Amos and Ferard, 'On Fixtures.')

The tenant in occupation of the premises is, in the first instance, liable for all taxes and rates of every description due in respect of the premises. The party, therefore, who is authorised to collect them may proceed against the tenant in occupation to recover them. It is generally a matter of agreement between the landlord and tenant that the tenant shall pay all rates and taxes except the land tax; and sometimes it is agreed that the landlord shall pay the sewer rate also. If, however, the landlord has undertaken to pay the tenant the rates and taxes, and fails to do so, the tenant may deduct the amount from his rent, or bring an action to recover it; but this should be done during the current year, and if the tenant allows a considerable time to elapse without claiming a deduction or bringing an action, he will be held to have waived his claim to recover them from the landlord.

Where a fixed rent has been agreed upon, has become due, and is neither paid nor tendered, the landlord, with certain exceptions, can distrain growing crops, any kind of stock, goods, or chattels, upon the premises, or pasturing any common enjoyed in right of the premises, whether such things are the actual property of the tenant or not; and if the rent remains unpaid, he may sell them. It follows from this general rule that a landlord can distrain on the goods of a lodger who occupies under his tenant. [DISTRESS; RENT.]

A tenant ceases to be so if he incurs a forfeiture, which may arise either by a breach by the tenant of one of those conditions which are implied by or attached to the relation of landlord and tenant, as where a tenant disclaims or impugns the title of his landlord by acknowledging, for instance, the right of property to be vested in a stranger, or asserts a claim to it himself, or by a breach of a condition which is expressly introduced into the lease, the breach of which is to be attended with a forfeiture of the tenancy, as a condition to pay rent on a particular day, to cultivate in a particular manner, &c. To this head may be referred provisoes in a lease for re-entry by the landlord on the doing or failure in doing of certain acts by the tenant, such as the commission of waste, the failure to repair, &c. The courts are said to be unfavourable to forfeitures; therefore, when the landlord has notice of an act of forfeiture, or an act which entitles him to re-enter, he must immediately proceed in such a way as to show that he intends to avail himself of his strict legal right. If after the commission of the act he does anything which amounts to a recognition of the tenancy, as by the acceptance of rent subsequently due, he will have waived his right to insist upon the forfeiture.

A yearly tenancy, where no period of notice is agreed on, must be determined by a notice to quit at the expiration of the current year, given six months previously. In the case of lodgings, the time, when less than a year, for which they are taken, will be the time for which a notice is necessary. Thus lodgings taken by the month or week require a month's or week's notice.

The notice to quit need not be in writing, though, from the greater facility of proving it, a written notice is always better. It should distinctly describe the premises, be positive in its announcement of an intention to quit or require possession, be signed by the party giving it, and served personally upon the party to be affected by it.

If a tenant, after having given notice to quit, continues to occupy, he is liable to pay double rent. If he does so, no fresh notice is necessary. If he continues to occupy after the landlord has given him notice, he is liable to pay double value for the premises.

At the expiration of the lease, the tenant is bound to deliver up possession of the premises; but if either by special agreement or by the custom of the country the tenant is entitled to the crops still standing on the land, and which are called away-going crops, he may enter for the purpose of gathering them, and also use the barns and stables for the purpose of threshing them. The in-coming tenant may also enter during the tenancy of the preceding tenant to plough and prepare the land.

If the tenant refuses to deliver the possession of the land, the landlord may bring an action of ejectment. [RENT; EJECTMENT.]

TENANT AT WILL, AND FROM YEAR TO YEAR. "Tenancy at will," says Littleton, s. 68, "is where lands or tenements are let by one man to another to have and to hold to him at the will of the lessor, by force of which lease the lessee is in possession. In this case the lessee is called tenant at will because he hath no certain or sure estate; for the lessor may put him out at what time it pleaseth him."

An estate at will may arise by implication, as well as by express words. Thus, where a tenant for years continues in possession after the expiration of his term, and pays rent as before, the payment and acceptance of rent constitute a tenancy at will. So, where a man enters under an agreement for a lease or a contract for the purchase of an estate, he must be considered at law as the tenant at will of the person who has the legal title.

Where a mortgagor continues in possession of his land with the consent of the mortgagee, after default in payment of principal and interest at the time stipulated in the mortgage deed, he is tenant at will. So also, where the legal estate is vested in a trustee, the beneficial owner, or *cestuique trust*, if he be in possession, is considered at law as tenant at will under the trustee.

A tenancy at will may be determined either by express declaration of the lessor that the tenant shall hold no longer, which must be made on the land, or notice given of it to the lessee; or by some act of ownership exercised by the landlord inconsistent with the continuance of the estate, such as entering on the land and cutting down trees demised, making a feoffment, or a lease for years to commence immediately. On the part of the tenant, any act of desertion, an assignment of the land to another, or the commission of waste, is a determination of his estate. A lessor determining the tenancy before the rent is due loses the rent; and on the other hand, the lessee who determines it before the rent is due, must notwithstanding pay it up to that time. If either party die, the tenancy, if it be of a house, continues till the next rent-day; and if of land, until the summer profits are received by the tenant or his representatives.

Where a tenancy at will is determined by the lessor, the tenant is entitled to emblements; but not if it be determined by the tenant himself.

The courts are always inclined to construe demises where no certain term is mentioned, not as estates at will, but as tenancies from year to year; and the circumstance of an annual rent being reserved has been considered sufficient to warrant this construction. Where a remainder-man receives rent from a tenant under a lease for years which is void as against him, before electing to avoid it, a tenancy from year to year is created. Also where an agreement for a lease for more than three years is made by parol, and is therefore void by the Statute of Frauds, there is a tenancy from year to year regulated by the terms of the agreement.

A tenancy from year to year, when once constituted, is binding not only upon the reversioner, but his assignee, and does not cease upon the death of the tenant, but goes to his executors or administrators. The tenant is entitled to six months' notice to quit, ending at the expiration of the year, and thus a new year is continually added to the term as often as the half year's previous notice is omitted to be given at the proper time.

TENANT FOR LIFE. Tenancy for life of lands or tenements is the possession of a freehold estate or interest, the duration of which is confined to the life or lives of the tenant or some other person or persons.

The estate of the tenant for life is either (1) such as is created by deed or some other legal assurance, or (2) such as arises by operation of law.

(1) An estate for life may be created by lease with livery of seisin, or by any other conveyance at common law which might be employed in conveying the fee, or by a declaration of a use, or by will. The estate so limited may be either to a person for his own life, or it may be given to one for the life of another, or for any number of lives mentioned in the grant. In the last case, the estate is in effect one for the life of the survivor of the persons so named. On the other hand, an estate may be granted for the joint lives of A and B, in which case it is in fact an estate for the life of the person who dies first.

When lands or tenements are conveyed by deed, without any express limitation of the quantity of estate to be taken by the grantee, he takes an estate for life only. This however is the case only when the grantor might lawfully create such an estate; for if he be tenant-in-tail, the conveyance, unless it be a lease within the provisions of the statute 32 Hen. VIII., c. 28, will pass only an estate for the life of the grantor. Before the 1 Vict., c. 26, a devise without words of limitation conferred on the devisee a life estate only; but now by sec. 28 of that act, a devise, though without any words of limitation, passes the fee simple, or the whole of such other estate as the testator had power to dispose of, unless a contrary intimation appear by the will.

Formerly, when lands were given to A for the life of B without any words of limitation, if A, or the person to whom he had assigned his estate, happened to die in the lifetime of B, the estate was considered as a kind of *hereditas jacens*, belonging to whoever first took possession; and the person who did so was called the general occupant. [OCCUPANCY.]

A gift to two persons for their lives is an estate in joint tenancy, and for the life of the survivor, if the parties continue joint tenants; but if the jointure be severed, each has then an estate in the moiety for his own life only.

(2) The estates for life arising by operation of law are, the estate tail after possibility of issue extinct, and the estate by courtesy and the estate in dower.

The estate tail after possibility of issue extinct arises when, by the death of one of the persons from whom the inheritable issue is to proceed, it has become impossible that any person should exist upon whom the estate tail can descend. Thus, if the lands be given to A and the heirs of his body by B, his wife, or to A and B and the heirs of their bodies, and B die without leaving any issue of their two bodies living, A, from being tenant-in-tail special, becomes tenant-in-tail after possibility of issue extinct; which is in effect nothing more than a tenancy for life, with certain peculiar privileges remaining to the tenant out of his former inheritance, the principal of which is the right of committing waste.

As to the nature and incidents of tenancy by the courtesy and tenancy in dower, see COURTESY and DOWER.

Tenants for life are entitled to estovers; that is to say, to an allowance of necessary wood for the repair of houses and fences on the land; but no tenant for life, except tenant-in-tail after possibility of issue extinct, can cut down more timber than is necessary for such purposes, or build new houses, or open mines, without being guilty of waste, unless his estate be, as it may be, made expressly without impeachment of waste. [WASTE.]

A tenant for life is not bound to pay off the principal of incumbrances affecting the inheritance, but he is bound to keep down the interest of all such incumbrances. He may convey or demise his tenement by the same means as a tenant in fee, provided he does not attempt to convey any estate greater than his own.

If he convey by grant, lease for years, bargain and sale, or lease and release, he can pass no interest greater than that which he himself possesses, the conveyance for the excess is merely void, and no forfeiture is incurred. But a conveyance by feoffment, or by any assurance equivalent to a fine or recovery, if purporting to exceed the bounds of the life estate, displaces the estates in remainder and creates a wrongful fee simple. The person entitled to the next estate in remainder or reversion becomes then immediately entitled to enter, thereby restoring all the estates which had been displaced by the tortious conveyance, except that of the tenant for life, which becomes absolutely forfeited.

As to the merger and surrender of estates for life, see MERGER and SURRENDER.

The name tenant for life is also applied to the person to whom, in settlements or wills of personal property, is given an interest for life only in the fund which is the subject of the settlement or will. [SETTLEMENT; WILL.]

TENANT FOR YEARS. [ESTATE; LEASE; TENANT AND LANDLORD.]

TENANT AT SUFFERANCE, says Lord Coke, "is he that at first came in by lawful demise, and after his estate endeth continueth in possession, and wrongfully holdeth over." Thus a tenant *pur autre vie*, continuing in possession after the death of *cestuique vie*, a tenant for years holding after the expiration of his term, and a person who, having been tenant at will, continues in possession after the death of the lessor, are all tenants by sufferance.

As the tenant at sufferance holds only by the laches of the owner, there is no privity of estate between them, and therefore the tenant at sufferance is not capable of taking a release of the inheritance. Tenants at sufferance were not bound to pay any rent; till by the 4 Geo. II., c. 28, § 1, it was enacted that "where any tenant holds over after demand made and notice in writing given for delivering the possession, such persons so holding over shall pay double the yearly value of the lands so detained, for so long a time as the same are detained; to be recovered by action of debt, against the recovering of which penalty there shall be no relief in equity."

TENANT RIGHT. It is good policy in the owners of land to give liberal acknowledgement of the tenant's right to the unexhausted improvements of the land which he has held, if he should be forced to leave it; because this will induce him to cultivate it with energy and liberality. Accordingly in some parts of the country, and especially in Lincolnshire, it is the custom to give the tenant on leaving a proportion of his expenditure during the last few years of his tenancy—varying in amount with the number of years which has elapsed since the expenditure, and the character as to permanence of the improvement. The following table may be taken as describing a not uncommon set of allowances:—

Description of Improvement.	Conditions Annexed.	Rate of Compensation to be Allowed on Quitting.
1. Fine ground bone and half-inch bones	On drained or naturally dry tillage land . .	Two-thirds of the cost of what has been used in the last year of tenancy, and one-third of that used in the year preceding.
2. Bone dust and half-inch bones .	On dry or well-drained pasture or meadow land, the same not being afterwards mown	Seven-eighths of the cost of that used in the last year of tenancy, and diminishing one-eighth every previous year subsequent to the application.
3. Dissolved bones or guano . .	On dry or well-drained land . . .	One-fourth of the cost of that used in the last year of tenancy for turnips and rape.
4. Lime . . .	On dry or well-drained land	Three-fourths of the cost of that used in the last year of tenancy, and one-fourth of that used in the preceding year.
5. Linseed-cake .	Consumed on the farm	Three-fourths of the cost of that used in the last year of tenancy. The manure being carefully preserved in the foldyard.
6. Draining — landlord finding tiles	Provided the drains are not less than 3 feet deep at regular distances, and cut under the superintendence of the landlord or his agents, and are in perfect order at the expiration of tenancy	Four-fifths of the expense of cutting, laying, and filling in the drains made during the last year of tenancy, and diminishing one-fifth for every crop grown on the land since it was drained.
7. Draining—tenant finding tiles . .	Same proviso as above .	Six-sevenths of the cost of those made in the last year of the tenancy, and decreasing one-seventh for every crop grown since it was drained.
8. New buildings or walls — landlord finding materials	Provided the same are done under the direction and approved of by the landlord or his agent, according to plan and specification previously agreed upon	Nine-tenths of the cost of those erected in the last year of the tenancy, and decreasing one-tenth for each year's occupation after erection.
9. Ponds . .	Same proviso as above .	Nine-tenths of the cost of those made or filled up in the last year of the tenancy, and decreasing one-tenth for each year's occupation after completion.
10. New walls or buildings — tenant finding all materials . .	Same proviso as above, tenant keeping and delivering up in good repair . . .	Nineteen-twentieths of the cost of those made in the last year of tenancy, and decreasing one-twentieth for each year's occupation after erection.
11. New fences of hawthorn—landlord finding posts and rails . .	Provided they have been properly protected and cleaned . . .	Nine-tenths of the cost of those made in the last year of tenancy, and decreasing one-tenth for each year's occupation after completion.
12. Clover and grass seeds . . .	Provided proper seeds have been sown in a husbandlike and proper manner, and have not been depastured or trod by stock.	The invoice cost of seeds sown in the last year of tenancy.

The advantage of such a set of allowances to the owner of the land consists in its tendency to produce vigorous and intelligent cultivation; its advantages to the tenantry and labourers are obvious.

Tenant Right is the name for a species of customary estates peculiar to the northern parts of England, in which border services against Scotland were anciently performed before the political union of the countries. Tenant-right estates were holden of the lord of the manor by payment of certain customary rents and the render of the services above mentioned, are descendible from ancestor to heir according to a customary mode differing in some respects from the rule of descent at common law, and were not devisable by will either directly or by means of a will and surrender to the use of the same, though they are now made devisable by 1 Vict., c. 26, s. 3. Although these estates appear to have many incidents which do not properly belong to villein-age tenure or copyhold, not being holden at the will of the lord, or by copy of court roll, and being alienable by deed and admittance thereon, it has been determined that they are not freehold, but that they fall under the same general rules as copyhold estates. (Doe *d.* Reay *v.* Huntington, 4 East, 271.)

TENANT IN FEE-SIMPLE. A tenancy in fee-simple is the greatest estate which a subject can have in land. [TENURE.] The possession of an estate in fee-simple involves a complete power of disposition over the land; and after a grant made in fee-simple the grantor has parted with his whole interest.

The words necessary for transferring an estate in fee simple may be reduced to this form: "I give this land to you and your heirs." (Litt., 1.) The addition of the word "heirs" is absolutely necessary in a deed, and no other expression will serve; for any such words as "I give the land to you;" or "to you for ever;" or "to you in fee-simple," would carry to the grantee nothing more than an estate for life. But words of limitation, such as "heirs," are not now necessary to pass a fee-simple by devise. (1 Vict., c. 26, s. 28.)

Lands in fee-simple in the hands of the heir were subject at common law to the debts of the ancestor due to the crown and to specialty debts. By the 11 Geo. IV. and 1 Wm. IV., c. 47, a complete remedy was given for all kinds of specialty debts, both against the heir and devisee; and by the 3 & 4 Wm. IV., c. 104, estates in fee-simple are made liable in the hands of the heir or devisee for payment of the simple contract debts of the ancestor.

Estates in fee-simple are forfeited to the crown for high treason. (Co. Litt., 390 b.) In cases of petty treason and felony the forfeiture to the crown is only for a year and a day, called the *annus, dies et vastum;* after which time the estate escheats (in cases of petty treason and murder) to the lord. By the 54 Geo. III., c. 145, the forfeiture and escheat consequent upon attainder for felony, except in cases of high treason, petty treason, and murder, are limited to the life-interest of the offender. It would seem that this statute leaves the offender the power of disposing of the estate after his decease. Trust-estates in fee-simple may be forfeited to the crown, but are not liable to escheat.

An estate to a man and his heirs may be given upon conditions or limitations, which are capable of abridging or defeating it. The estate cannot then properly be called a fee-simple; but is, according to the circumstances, a conditional, qualified, or base fee. (Co. Litt., 1 b.)

TENANT-IN-TAIL. The origin and general nature of estates tail have been already described. [Estate; Remainder; Settlement.]

The estate of the tenant-in-tail has some essential characteristics. He has a right to commit waste of all kinds by felling timber, pulling down houses, opening mines, and doing other like acts; and this right of the tenant-in-tail cannot in any manner be restrained. The tenant-in-tail is also entitled to the custody of the title-deeds, which the Court of Chancery will order to be delivered up to him. He is not bound to pay off incumbrances affecting the fee of the estate, as he has only a particular interest, and not the entire property in the land; and it seems that he is not in general even bound to keep down the interest on such incumbrances; though if he do pay off such incumbrances, it will in general be presumed to have been done in exoneration of the estate.

By the statute *De Donis* the tenant-in-tail was restrained from alienating his estate in any manner for a longer period than his own life, that is to say, the estate of the alienee, though not *ipso facto* determined by the death of the tenant-in-tail, became thereupon defeasible by his issue or the remainder-man or reversioner.

If the tenant-in-tail conveyed his estate by lease and release, covenant to stand seised, or bargain and sale and grant, the right of entry of the issue and remainder-men was not affected by the conveyance. But a feoffment or fine made or levied by the tenant-in-tail in possession by virtue of the entail, caused what was called a discontinuance of the estate tail, whereby the issue and the persons in remainder and reversion lost their rights of entry and were driven to their action. A fine duly levied with proclamations was an absolute bar to the issue, though not to the remainder-men, creating what was called a base fee; and by means of a common recovery duly suffered, the tenant-in-tail might bar his issue and all the remainders over, and make an absolute conveyance of the estate. [Recovery.]

By the 3 & 4 Wm. IV., c. 74, fines and recoveries were abolished; and by the Statute of Limitations (3 & 4 Wm. IV., c. 27) it was enacted "that no discontinuance or warranty should thereafter defeat any right of entry or action for the recovery of land. It seems therefore that no discontinuance, properly so called, can now be produced by any mode of conveyance, for, whatever may be the form of discontinuance, the last-mentioned statute takes away its effect. [Fine; Recovery.]

In accordance with the principle which prevented a tenant-in-tail from alienating his estate for more than his own lifetime, leases by tenants-in-tail might be avoided after their death by the issue in tail. But by the 32 Hen. VIII., c. 28, tenants-in-tail were enabled to make leases for three lives or twenty-one years, which should bind their issue, though not the persons in remainder or the reversioner.

The estate of the tenant-in-tail is not subject to any of the debts or incumbrances of his ancestor, except debts due to the crown, by the 32 Hen. VIII., c. 39, s. 75.

Estates tail are subject to the bankrupt laws, and to forfeiture for high treason by the 26 Hen. VIII., c. 13. By attainder for high treason, the estate of the tenant-in-tail, of his issue, and of all such of his collateral heirs as would have been entitled to take under the estate tail, are forfeited, but not the estates in remainder or the reversion.

The 26 Hen. VIII. extends only to cases of high treason, and therefore as to felonies the statute *De Donis* is still in force, and the forfeiture by attainder for felony extends only to the life interest of the tenant-in-tail. (Co. Litt., 392 b.)

TENANTS or TENANCY IN COMMON. [Common, Tenancy in.]

TENDER. A tender is the offer to perform some act. In practice it generally consists in an offer to pay money on behalf of a party indebted, or who has done some injury, to the creditor, or to the party injured.

A tender to the amount of 40s. may be in silver; but beyond that amount it must be in gold, or in Bank of England notes payable to bearer on demand for any sum above 5*l.* (3 & 4 Wm. IV. c. 6.) If a tender be made of a larger amount in silver, or in country bank-notes, and no objection be taken at the time to the silver or notes, the objection to the tender on that ground is waived, and the tender is good to the amount to which it is made. The money must be produced and shown, or the bag or other thing which contains it shown, to the party to whom it is intended to be given, unless this is dispensed with by some declaration or act of the creditor. This is insisted upon with such strictness, that even though a party tell his creditor that he is about to pay him so much, and put his hand into his pocket to produce the money, yet if the creditor leave the presence of the debtor before the money is actually produced, no tender will have been made: but if the creditor refuse to receive the money mentioned on the ground that it is insufficient in amount, the actual production of it is not necessary to constitute a valid tender. The offer must be absolute and without conditions. An offer of a larger amount with a request of change; an offer with a request of a receipt, or on condition that something shall be done on the part of the creditor, are not valid tenders; but an offer of a larger sum absolutely without a demand of change is good. A tender may be made either to the party actually entitled to receive it, or to an agent or servant authorised to receive it, or to a managing clerk; and a tender will not be invalidated even though before it is made the creditor has put the matter into the hands of his attorney and the managing clerk of the creditor refuses to receive it, and assigns that circumstance as his reason for doing so. If the attorney write to the debtor demanding the money, a tender afterwards made to him or to his managing clerk is good, unless at the time when it is made they disclaim authority to receive the money. A tender ought to be made on behalf of the party from whom the money is due; if the agent appointed by him to make the tender offer a larger sum than he is authorised to do, the tender will nevertheless be good for the full amount to which the tender is made.

If the defendant in an action plead a tender, he must state that he has always been ready to pay the money, and he must also pay it into court. The effect of the plea is to admit the existence of a cause of action in the plaintiff. The plea goes only in bar of damages. The plaintiff, therefore, in such case can never be nonsuited: but if issue is taken on the mere fact whether or not the tender has been made, and that fact is found for the defendant, it is a good defence to the action.

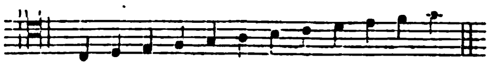
By various statutes, magistrates, officers of excise, &c., are empowered, after notice of action to be brought against them, to tender amends; and if the amount tendered is sufficient, the tender is a defence to the action.

TENEMENT, in its usual and popular acceptation, is applied only to houses and other buildings; but in its original, proper, and legal meaning it includes everything of a permanent nature that may be an object of tenure, or may be held in the legal sense, whether corporeal or incorporeal. It is sometimes applied in a more confined sense to objects of feudal tenure; in general, however, it includes not only land, but every modification of right concerning it. Thus the word "Liberum tenementum," frank-tenement, or freehold, is applicable not only to lands and other solid objects, but also to offices, rents, commons, and the like. [Estate; Tenure.] (Harg., 'Co. Litt.', 154, a. n. 7.)

TENNIS, a game in which a ball is driven to and fro by several persons striking it alternately, either with the palm of the hand, naked or covered with a thick glove, or with a small bat called a racket, held in the hand; the aim being to keep the ball in motion as long as possible without allowing it to fall to the ground. Perhaps the first historical notice of the game in England is that which Shakspere has introduced, almost in the words of Holinshed (who, however, called them Paris balls) in his 'Henry V.' (act i., sc. 2), where the Dauphin sends a present of tennis-balls in answer to Henry's demand for the sovereignty of France. Henry VII. was a tennis-player; and, as an entry in a MS. register of his expenditure in the thirteenth year of his reign mentions an item of twelve-pence for his loss at tennis and three-pence for the loss of balls, it may be inferred that the game was played abroad, as the loss of balls is not likely to have happened in a tennis-court. Be this as it may, in the 16th century tennis-courts were common in England, and the game was very popular with the nobility, which it continued to be down to the reign of Charles II., who frequently diverted himself by playing at tennis with his courtiers. A similar game was sometimes played with a hollow leather ball, inflated with air, and called a *balloon*, which was driven from one player to another by striking with the hand, or with a wooden bracer fixed upon the hand and lower arm. Further particulars respecting these and other old games played with a ball may be found in Strutt's 'Sports and Pastimes.'

TENOR, the name of the most common of adult male voices, that which is between the extremes of highest and lowest, or Contratenor [Alto] and Base. [Base-Voice.] The compass of the Tenor is from

C, the second space in the base, to G, the second line in the treble. Example, in the tenor clef:—



Hence it will be seen that the tenor and treble are reciprocally at the distance of an octave; consequently, what is calculated for the one voice, as relates to compass, will, at a distance of eight notes, invariably suit the other.

The word is derived from *Teneo, to hold;* for in ancient part-compositions, the plain-song, or air, if it may be so denominated, was given to, or *held* by, the Tenor. [CLEF.]

Tenor-Clef is the C, or mean clef, placed on the fourth line for the use of the tenor-voice, as in the above example.

It is also occasionally used for the violoncello: and the part of the tenor trombone is written in this clef.

Tenor is also the English name for a larger instrument of the violin kind. See VIOLA.

TENSION (Mechanics), the name given to the force by which a bar or string is pulled, when forming part of any system in equilibrium or in motion. Thus, when a weight is supported by a string, the tension of the string is the weight which is suspended to it. Every point of the string may be considered as a point of application of two equal and opposite forces, downwards and upwards, each equal to the weight applied.

TENSION, ELECTRICAL. [VAPOUR.]

TENT, MILITARY, is a temporary dwelling-place made of canvas, which is supported by one pole, or more, and distended by means of cords, which are made fast to pickets driven into the ground: tents are set up when an army is encamped in the field either for actual service or for the purpose of performing military exercises.

The tents of the private soldiers, whether infantry or cavalry, are of a conical form with circular bases, the supporting pole or *standard* of each being planted vertically in the ground, in the centre: the standard is 10 feet 3 inches long, and the whole diameter of the tent, between two opposite pickets, is 17 feet 3 inches; but from the lower extremity of the cone, at about 2 feet from the ground, the canvas hangs down vertically and forms a cylindrical *wall*, therefore the diameter of the tent within the canvas is 13 feet 3 inches. Fifteen infantry, or twelve cavalry soldiers occupy such a tent. The round tent of an officer is 12 feet 6 inches in diameter within the walls. The marquees of officers, as well as the hospital and laboratory tents, are of oblong forms on the plan; and, in these, the canvas is supported by two standards, which are connected together at their tops by what is called a *ridge pole* 6 or 7 feet long. The length of an officer's marquee is 19 feet, and the breadth 13 feet, both dimensions being taken within the walls: tents of the two other kinds are still larger.

For the rules of modern castrametation, or the dispositions of tents in an encampment, see ENCAMPMENT.

TENTHS are the tenth part of the yearly value of all ecclesiastical livings. They were formerly claimed by the pope; and his claim was sanctioned, in this country, by an ordinance in the 20th year of Edward I., when a valuation of all livings was made, in order that the pope might know the amount of his revenue from this source. The possessions afterwards acquired by the church were not liable to the payment of tenths to the pope, as all livings continued to be charged according to that valuation. (Coke, 2 'Inst.', 627.) When the authority of the pope was extinguished at the Reformation, Henry VIII. transferred the revenue arising from tenths to the crown, and had a new valuation of all the livings, so as to obtain the tenth of their true yearly value at that time. (36 Hen. VIII. c. 3, s. 9-11.) By royal grants under 1 Eliz. c. 19, s. 2, the Archbishop of Canterbury and the Bishop of London were exempted from tenths, and were also authorised to receive the tenths of several benefices as a compensation for certain estates which were alienated from their sees. By the 6 Anne, c. 24, all benefices were discharged from the payment of tenths which, at that time, were under the annual value of *50l.*, except those of which the tenths had previously been granted by the crown to other parties. There are also some other special exemptions. Queen Anne gave up the revenue arising from tenths, as well as from first-fruits, which had been enjoyed by her predecessors since the Reformation, and by act 2 & 3 of her reign, c. 11, assigned it to the augmentation of poor livings; for which purpose she erected a corporation by letters patent in 1704 to administer the funds, called the Governors of Queen Anne's Bounty. This act declared that episcopal sees and livings not exempted should continue to pay in such rates and proportions only as heretofore, or according to the valuation of Henry VIII., commonly known as the "King's Books." Tenths under the act 1 Vict. c. 20, are collected by the treasurer of the Governors of Queen Anne's Bounty. Payment is enforced by Exchequer process, when not duly made, and the treasurer is required to give notice of arrears within one month after the proper time of payment. In case of a living being vacated, the Exchequer is empowered by act 26 Hen. VIII., c. 3, s. 16, to recover arrears of tenths, not only from the executors and administrators, but also from the successor of the last incumbent. [BENEFICE; FIRST-FRUITS.]

TENURE. The general nature of tenure and its origin and history in England are explained in the article FEUDAL LAW.

All land was and is held of the crown either mediately or immediately, the tenure being either free or base; Frank-tenement or freeholding, and Villeinage. The act 12 Car. II. c. 24 abolished military tenures, which were one kind of free services, and changed them into the other species of free services, namely free and common socage; socage tenure being thus established for all lands held by a free tenure, which comprehended all lands held of the king or others, and all tenures except tenures in frankalmoigne, copyhold, and the honorary services of grand-serjeanty.

Tenure is still therefore a fundamental principle of the law relating to land in England; for the owner of land in fee simple, which is the largest estate that a man can have in land, is not absolute owner: he owes services in respect of his fee (or fief), and the seignory of the lord always subsists. This seignory is now of less value than it was, but still it subsists. The nature of the old feud was this: the tenant had the use of the land, but the ownership remained in the lord; and this is still the case. The owner of a fee has in fact a more profitable estate than he once had; but he still owes services, fealty at least, and the ownership of the land is really in the lord and ultimately in the crown. For all practical purposes the owner's power of enjoyment is as complete as if his land were allodial; but the circumstance of its not being allodial has several important practical consequences.

No land in England can be without an owner. If the last owner of the fee has died without heirs, and without disposing of his fee by will, the lord takes the land by virtue of his seignory. If land is aliened to a person who has a capacity to acquire but not to hold land in England, the crown takes the land; this happens in the case of lands being sold to an alien. If a man commits treason, his freehold lands are liable to be forfeited to the crown, and his copyhold estates to the lord of the manor. And if a man commits a felony, his freehold and copyhold lands are also subject to certain forfeitures, these forfeitures being all consequences of tenure.

Church lands are held by tenure though no temporal services are due. This is the tenure in frankalmoigne, which is now exactly what it was before the 12th of Charles II. was passed. Church lands, however, owe spiritual services, and the lord of whom they are held must be considered the owner; but the beneficial ownership can never revert to the lord, for all spiritual persons are of the nature of corporations, and when a parson dies, the corporation sole (as he is termed by an odd contradiction in terms) is not extinct, and it is the duty and right of some definite person to name a successor. When then the parson dies, the freehold may be considered to be in abeyance till the appointment of his successor, one of the few instances in the English law in which it is said that a freehold estate can be in abeyance.

No seignory can now be created except by the crown; for it was enacted by the statute Quia Emptores (18 Edw. I. c. 1), that all feoffments of land in fee simple should be so made that the feoffee held of the chief, that is, the immediate lord of the aliening tenant, by the same services by which the tenant held. But tenure of an imperfect kind may be created. Thus wherever a particular estate is created, it is held of the reversioner by an imperfect tenure: as in the common case of landlord and tenant. If no rent or other services are reserved from the tenant of the particular estate for life or years, the tenure is by fealty only, and he may be required to take the oath of fealty. But the right of the reversioner to whom services are due is solely incident to the reversion, and is created at the same time with it. The perfect tenure originated in the pure feudal system, in which the seignory of the lord was the legal ownership of the land, and the tenant owed his services for the enjoyment of it. The only perfect tenure now existing is Socage tenure, the services of which are certain, and consist, besides fealty, of some certain annual rent. And if the services due in respect of it are not rendered, the lord may distrain, that is, take any chattels that are on the land in respect of which the services are due. An imperfect tenure so far resembles a perfect one, that a reversioner can distrain for the services due from the tenant of the particular estate.

A right still incident to a seignory such as a subject may have is that of escheat, which happens when the tenant in fee simple dies without leaving any heir to the land, and without having incurred any forfeiture to the crown, as for treason. Forfeiture is another right incident to a seignory, and it may happen in consequence of any act by which the tenant breaks his fidelity (fealty) to his lord of whom he holds. It therefore extends to other cases than treason and felony. COPYHOLD; ESCHEAT; FEUDAL SYSTEM; FORFEITURE; MANOR; RENT.

TE'RAPHIM (תְּרָפִים; Sept., εἴδωλα). This is a word of somewhat uncertain etymology and signification. That the teraphim were of human form seems evident from 1 Sam. xix. 13. They appear to have been superstitiously, if not idolatrously, reverenced as penates, or household gods. (Gen. xxxi. 19, 34, 35; 1 Sam. xix. 13-17; 2 Kings xxiii. 24.) In some shape or other they were used as domestic oracles. (Comp. Zech. x. 2; Judg. xvii. 5; xviii. 5, 6, 14-20; Hos. iii. 4.) This is confirmed by 1 Sam. xv. 23, where teraphim are mentioned in connection with the arts of divination.

TERBIUM, (Tr) a peculiar metal discovered by Mosander in the state of oxide in gadolinite, orthite, &c., associated with yttria, and with oxide of erbium, another new metal.

The oxide of terbium has not yet been reduced to the state of metal; it is distinguished from that of erbium in not becoming of a dark orange-yellow colour when heated in the air. The oxide of terbium is insoluble in water and in the caustic alkalies; it is soluble even after heating to redness in a boiling solution of carbonate of soda, but after a few days it separates from solution in the state of a double salt; the carbonate of terbium is soluble in solution of carbonate of ammonia, and after saturation forms with it in a few hours a double salt, which separates in such quantity that very little of the oxide remains in solution; the salts of this oxide are colourless and have a sweetish taste. The sulphate is more soluble in cold water than in hot; the nitrate yields by evaporation a crystalline mass which deliquesces in a moist atmosphere.

The oxide of terbium has hitherto been obtained in small quantity only, and its properties are but little known.

TERENTIAN METRES. Few subjects connected with Latin literature have been treated with less success than the principles and laws which govern the metres of Latin comedy. The majority of readers seem to look upon the writings of Plautus and Terence as mere humble prose arbitrarily distributed so as to present to the eye the appearance of verse without its realities. For them it would be better if the whole were printed consecutively, and such an arrangement would in fact be supported by not a few of the existing manuscripts. On the other hand, there have been writers who have laboured to remove the difficulties that obscure the subject, among whom none before Bentley and Hermann appear to have had any success. Since their time, Bothe, Ritschl, and Fleckeisen have done good service, although the first and second of these recent critics have too frequently been rash in their innovations. Even the writer of the Life of Terence, in the 'Biographie Universelle' (published in 1826), gave the following extraordinary criticism upon the metres of Terence:—"The sole rule which he observes with tolerable regularity is to end each verse with an iamb; and even this limitation he often disregards, as, for instance, in the terminations *hic consiste; si vis, nunc jam; audio violenter; huc adducam; hanc venturam*, &c. With regard to the other feet, he freely substitutes for the iamb or spondee, a trochee, anapest, dactyl, double pyrrhic, or four short syllables, and a cretic or short between two longs," &c. This writer thus started with the false impression that all the verses of Terence are reduced by critics to the single metre, called trimeter iambic; whereas in fact all who have dealt with the subject, except himself, are aware that the poet has at least three forms of verse which end trochaically; and his second exception is disposed of by the more correct orthography *nunciam*. In England, again, so late as the year 1837, we had a scheme of the Terentian meters, which for the commonest of those metres, the trimeter-iambic, gave us the following scale:—

⏑ –	⏑ –	⏑ –	⏑ –	⏑ –	⏑ –
– –	– –	– –	– –	– –	– –
– ⏑ ⏑	– ⏑ ⏑	– ⏑ ⏑	– ⏑ ⏑	– ⏑ ⏑	
⏑ ⏑ ⏑	⏑ ⏑ ⏑	⏑ ⏑ ⏑	⏑ ⏑ ⏑	⏑ ⏑ ⏑	
⏑ ⏑ –	⏑ ⏑ –	⏑ ⏑ –	⏑ ⏑ –	⏑ ⏑ –	
	⏑ ⏑ ⏑ ⏑		⏑ ⏑ ⏑ ⏑		

with the additional remarks that *quo quid hunc* may be a dactyl, that *hic quidem est, studet par*, and the three first syllables of *voluptati*, may pass for anapests, &c., &c. All this is exceedingly unsatisfactory, and it would be better to abandon the problem as insoluble, than to give currency to extravagancies which would enable us to find in any given chapter of Cæsar a series of trimeter-iambics.

It must be admitted that the metres of the Greek dramatists, and more particularly of the tragedians, gratify the ear with rhythms which, comparatively speaking, are smooth and appreciable. But it should be recollected, in the first place, that the Greek language is distinguished from among other languages by its abundance of words which end in a short syllable, and the advantage to the poet is increased by the large number of instances where these short final syllables have a vowel ending. Compare, for instance, the accusatives singular μουσαν, δουλον, πολιν, δαιμονα, with the Latin *musam, servom, navim, leonem*; the nominative and accusative plural δαιμονες, δαιμονας, with the Latin *leonēs*; the numerals ἑπτα, δεκα, with the Latin *septem, decem*; the verbs τυπτετε, τυπτουσι, with the Latin *scribitis, scribunt*; the pronouns με, σε, ἑ, with *mē, tē, sē*. In fact the Latin language exceeds the Greek in the number of long syllables, as much as the English and German languages exceed the Latin.

A still more important matter is the question whether, and how far, the written language of the Romans is an exact representative of the spoken language. It seems to be a condition of language in general that its pronunciation should always be passing through a series of changes, and that those changes should consist for the most part in the gradual omission of letters and even syllables. Thus the Roman phrase *mea domina* is in Italian *madonna*; in French, *madame*; in English, *madam, ma'am*, and even *mum* and *mim*. Meanwhile, for the most part, the changes in orthography are slow, and consequently nearly always in arrear of the orthoepy. Thus it will be found that the sounds of English and German words which appear to the eye so weighed down with consonants, are in the mouth of a native tolerably harmonious. Was such the case with the Roman also? We answer with little hesitation in the affirmative, partly because the laws which now govern language can scarcely have been wanting in ancient Italy, and partly because we find the point established by several incidental remarks in Latin writers. Thus Suetonius says, in his 'Life of Augustus (c. 88), "Orthography—that is, the laws and principles of writing laid down by grammarians—he was not very observant of, but seems rather to follow the opinion of those who hold that we should write as we speak. For as to his hābit of changing or omitting not merely single letters, but even whole syllables, that is a common error." It should be observed, too, that Suetonius had himself seen the handwriting of the emperor. (Ibid, c. 87.) Again, Quintilian ('Inst.,' xi. 3, 33) says, "As, on the one hand, it is essential that every word should be clearly articulated, so, on the other hand, to reckon up, if we may so speak, every separate letter, is painful and wearisome." In the same chapter he further observes, "Not only is a coalition of vowels very common, but *some* too of the consonants are disguised (*dissimulantur*), when a vowel follows;" where he must refer to some other letter than *m*, probably the final *s* generally and the final *d* of neuter pronouns. Moreover, Priscian, who by the way appears to have written when the Latin language had ceased to be spoken as a living tongue, at times throws out such conjectures as the following:—"I think that *vigil, vigilis*, should rather be pronounced *per syncopam*." We might appeal to Cicero's authority for the fact that a final *s* was frequently omitted in pronunciation. But there are still other arguments in support of the principle for which we are contending. Within the limits of the Latin language itself we find such changes actually in progess—as, *magis, nisi, ipsus, neque, atque, sive, neve, videris, viderunt, providens, mihi, nihil, quibus, populus, tegumen, opera, potesse, mavolo, noverit, novisti, coventio*, becoming severally *mage, ni, ipse, nec, ac, seu, neu, vidēre, vidēre, prudens, mi, nil, quis, poplus* (compare also *poplicus*), *tegmen, opra, posse, malo, norit, nosti, contio*. Principles of etymology would enable us to carry the list out to a vast extent, and this still more, if we employed the analogies of the Greek tongue.

Again, the languages which are acknowledged to be derived from the Latin, such as that of the Troubadours, the Italian, French, Spanish, Portuguese, and one portion of the English, by their shortened forms, confirm our views. And this will be found to be specially the case with the French. To those who may express their surprise that the French should thus take precedence in our argument of the Italian, the answer is, that the French is probably derived from the Latin more completely than even the Italian; for the Celtic, Teutonic, and Iberic languages spoken in France before the Roman conquest of that country were of too foreign a character to mix with the language of conquerors or to supply the place of it in the intercourse of the provincials with their masters; whereas in Italy there already existed dialects which were intelligible to those who came from Rome, and for that very reason were not supplanted by that particular form of the Italian language which happened to prevail in the metropolitan city. In the same way the authorised dialect of our own tongue is more likely to become the current language of Calcutta than of Yorkshire. Add to this that the language now called Italian belongs to Tuscany, not to Rome.

Lastly, we find much to strengthen our present argument in the abbreviated forms of writing which were in use among the Romans, and are still found in manuscripts. Thus the word *consul* is written *cos*, because the *n* was not pronounced before *s*, as Diomedes expressly tells us. (Putsch.,'428.) Again, the word *modo* not unfrequently occupies such a position in the verses of Terence as to seem to require a monosyllabic pronunciation, such indeed as seems also more consistent with its enclitic character. This very word enters into the composition of the Latin *quomodo*, which again in the languages derived from Latin assumes various forms: in the Romance, *com*; in Spanish, *como*; in Italian, *come*; and in French, *comme*. To this we now add the fact that the Romans themselves represented the simple word by the abbreviation *mō*. Again, ·*n*· is the manuscript mode of denoting the conjunction *enim*, a word which must often be pronounced like *en* to fulfil the conditions of Terence's metre. We may observe of this word, as of *modo*, that an enclitic should not attract the attention of the ear. A third example shall be a third enclitic, namely, *quidem*. Bentley himself observed the trouble caused by this word in the verses of Terence ('Andr.,' i. 3, 20), and his remedy is to drop the final *m*, which however still leaves the verse encumbered with a superabundance of syllables. We contend that this also is commonly a monosyllable, and on the following grounds:—First, the metre of Terence requires it. Secondly, if *ĭtidem* has a reduced form, *item*, analogy will give us *quem* for *quidem*. Thirdly, the Romans, like the French, did not pronounce the vowel *u* after *q* (otherwise such words—*ăqua*, or *nĕque*, for instance—would have had the first syllable long), and they also disguised the final *m*, as Quintilian implies in the passage to which we have already referred. Thus we have arrived at a sound *ke*. Now the

Greek language has a word of precisely the same power and character, *γε*, which we strongly suspect to be the very same word; so that, if our suspicions be right, *equidem* and *εγωγε* are of one origin, as well as of one meaning. Lastly, there are reasons still remaining which demand a monosyllabic pronunciation for *quidem*. We have already called it an enclitic, and it appears beyond dispute in that character in the words *equidem, siquidem, quandoquidem*. Now an enclitic should in its nature sacrifice itself to give tone to the word which precedes it. Yet if we believe the ordinary teachers of Latin prosody, *equidem*, though a corruption from *egoquidem*, or *egquidem*, has the first syllable short. Again, *quando* by itself has the final *o* common, to take the most unfavourable view; for in the poets of the Augustan age it would be difficult to find a single example where *o* is short; and in *quandoque, quandocunque*, the vowel is always long. But add *quidem*, and they say *quandoquidem* has the same vowel always short. So also *si* in *siquidem*, according to their views, loses its length the moment the enclitic attaches itself to it. If our views be right, the true pronunciation of these three words may be represented by something like *ēke, quandōke, sike;* the last corresponding to the Greek *ειγε*. We will here observe, in passing, that our pronunciation of *quidem* suggests a correction of a corrupt passage in Persius, Sat. i. 10:—

"Littera. Per me quidem sint omnia protinus alba."

The current reading is *equidem;* and, relying upon one error, the editors have allowed the same *equidem* to stand with *dubites* in Sat. v. 45, when the context, as well as grammar, requires *dubitem*. It may also be noticed that Ritschl, in his 'Parergon,' says that the employment of *quidem* as a monosyllable is a very ordinary occurrence.

But to return to the subject before us. It is not uncommon with critics to imagine to themselves that the laws of Greek and Latin verse are based upon principles essentially different from those of modern languages; the former depending, they say, upon the length of syllables, the latter upon accent. This distinction we believe to be wholly without foundation. We rely little upon the fact that Priscian's treatise headed 'De Accentibus' is only a schoolboy-like scanning of the first lines in the 'Æneid,' because, as has been already said, that writer's authority is not of great weight in what concerns the spoken tongue; and in fact, for the same reason, there is little dependence to be placed upon the dogmas of the other so-called grammarians, such as Diomedes. Our views upon this subject are rather derived from the perusal of Terence and Plautus themselves, and are confirmed to a considerable extent by the hexameters of Virgil and the lyrics of Horace. They also seem to be supported by the general principles of language. We will endeavour briefly to state the results at which we think we have fairly arrived.

I. In words of more than two syllables, if, according to the received prosodies, two or more short syllables, exclusive of the final syllable, occur together, the second of those short syllables, counting from the beginning of the word, was slurred over. For instance, in some cases the changing a vowel *i* or *e* into the sound of a *y*, or of a vowel *a, o*, or *u* into the sound of a *w*, would be the simplest mode of effecting such a result. Thus, *adtrĭbŭĕre, pĕrĭĭmus, consĭlium*, would, upon our theory, be pronounced *adtribwere, peryimus, consilyum*, the last of which is confirmed by Horace's use of the same word in his odes, and the Italian *consiglio*, Fr. *conseil*, Sp. *consejo;* and at any rate our pronunciation of the two former is more consistent with the quantity of the vowels than the mode usually adopted, namely, *per-ĭ-imus, adtribúere.* Bentley has himself observed ('Eun.,' ii. 2, 36) that the words *mulier, mulieris*, &c., are always so placed in Terence as to have the accent on the first syllable; which, by the way, is consistent with the Italian *moglie*, and the Spanish *muger*. We doubt, however, whether the dative and ablative plural would be found to obey the law laid down by Bentley. In those cases where the second short vowel is followed by a consonant, the abbreviation proposed becomes impracticable, if at least that consonant be really to be sounded. In such cases the right course is probably to drop the syllable altogether. Thus *miseria, familia*, and such words, Hermann ('De Re Metrica') truly says, are to be pronounced with the accent on the first syllable, and this in defiance of the law laid down by all the grammarians, that the accent cannot be carried farther from the end of a word than the antepenult. Hermann has not attempted to reconcile the two assertions, but they fall at once into agreement if we are right in dropping the second syllable, for then the first becomes virtually an antepenultimate; and we are only doing what is common in our own language, as in *évery, lóvely*. This principle, moreover, may be clearly traced in forms acknowledged to be Latin. Thus, from *populus* should be formed *populicus*, but that becomes *poplicus* or *publicus*. If *pello* has a perfect *pepuli, cado* a perfect *cecidi;* the compounds with *re* should strictly give us *repepuli, rececidi;* but we find *reppuli, reccidi*. Again, in connection with *opifex* we ought to have *opificium* and *opificina;* but these have been supplanted by *officium, officina*. So, too, the Greek *επιπεδον* becomes in Latin *oppidum*, as opposed to the *arx*, or citadel; and the adverb *επιπεδως* takes the form of *oppido*, an equivalent in meaning to *plane*.

II. The accent of a Latin dissyllable or polysyllable will fall upon the penult, if long. Where that penult is long by the nature of the vowel, and at the same time the final syllable is short, the accent upon the penult is called a circumflex; in other cases an acute accent. Secondly, if the penult be short, put an acute accent upon the antepenult, always performing the previously mentioned abbreviation, if need be; the necessary effect of which is to give a long antepenult, if the penult itself be short.

III. The preceding rules dispose of every case except two classes of words, namely, dissyllables with a short penult, and monosyllables. The former are either to be pronounced as monosyllables, or else to be attached to the preceding or following word; and the double word thus formed to be accentuated as a polysyllable. When a word is attached in pronunciation to that which it precedes, it has already received in common use the name of enclitic. Hermann, who first observed that there are also words which attach themselves to those which follow, has proposed to give them the name of proclitics. The Greek article, for instance, belongs to this class, as also not unfrequently the Latin *hic, hæc*, &c. The same is true of prepositions, when really prepositions, that is, when they precede their noun; and the Latin *non* or *ne*, like the Greek *ου*, should perhaps in many cases be pronounced in immediate connection with the following verb, just as we, who are accustomed to place our *not* after a verb, write *cannot* as a single word. Many little conjunctions also may probably require such treatment, as *si, ut*, &c.; in confirmation of which it should be observed that Latin manuscripts, even of a late date, almost habitually write these little words in immediate connection with the following word. Again, the list of enclitics should be extended so as to include most of the conjunctions which require to be placed second in a sentence, and even conjunctions in general, together with the relative itself when they are forced, if the word may be used, into a second place, as, for instance, in the first line of the 'Æneid,' which acquires additional power by the pronunciation *Troiaé-qui*. In the same way a postponed preposition becomes an enclitic, as in the phrase *altís-de montibus*. In this way many dissyllables and monosyllables will coalesce into polysyllables, and be accentuated accordingly. We even entertain a strong suspicion that a verb in the middle of a sentence must often be treated as an enclitic, to give tone to some important word before it. Such a pronunciation was indeed demanded by Carey, in his 'Prosody,' for the Virgilian *levis-volat*. The verb *est*, again, is known to have been very generally an enclitic; and the best Sanskritists have held that the verb must very frequently in verse be so attached to the word which precedes it. We trace the same law in a fact which governs the order of words in the Latin and Hungarian, and probably many other languages, namely, that when a verb occupies a place in the middle of its clause, it is safe to infer a strong emphasis for the word which precedes it.

IV. The principle of elision will often modify the accent of a word. Thus, *cumprímum, scribéndum, argeménto*, would in ordinary circumstances have the accent as marked. But if elision take place, they sometimes have the accent displaced. In this way the first and eleventh lines of the Prologue to the 'Andria' should be read: "Poéta cúm-prim, âm' adscríbend' ádpulit;" and "Non it' dissím'li sunt argúment' ét-tamen." It should also be observed that elision often destroys the initial vowel of the second word, instead of the final syllable of the preceding word, as *nunc tuúmst offícium*, rather than *nunc tu' ést offícium*.

V. The pronunciation of Latin words in the days of Plautus and Terence differed in several respects from that which holds good for the later poets, and this for the most part in one direction—syllables being long in the old Latin drama, which afterwards became short. Thus, *lārŭă* and *milŭŭs, gratiīs* and *nunciam*, were always trisyllabic. The first syllable of *Acheruns* was already in a state of transition, generally long, yet at times short; *cacula* is another word of varying quantity in the same syllable. Then, again, nominatives in *or*, as *uxōr* (Plaut., 'Stic.,' v. 140), *stultiōr* (Ibid., 'Bacc.,' v. 123), may have the last syllable long, and this with the more reason as they really stand for *uxors, stultiors*. In the same way, *pater*, like the Greek *πατηρ*, has a long final syllable in the 'Trin.,' v. 645, if we follow the Ambrosian palimpsest. Then, again, in verbs we have a long final in the first person of the reflective, as *perpetiōr* ('Most.,' v. 621), and in the third person singular of the active, provided the other parts of the tense in question prove the vowel to be in itself long, as *sīt* ('Mil.,' v. 242), *adflictāt* ('Merc.,' v. 648), *habēt*, not *aut habet* ('Trin.,' v. 206), *desiderēt, expectet*, for so the MSS. ('Mil.,' 244), and, above all, in perfect tenses, as *optigit* ('Stic.,' v. 384), *astitīt* ('Mil.,' v. 213), *repperīt* ('Stic.,' v. 462), *vendidīt* (Capt. Prol. 9). Indeed, Virgil and the later poets furnish not a few examples where such syllables retained their original length, as, *patēr, amōr*, in Virg., *perrupīt, subiīt*, Hor., *rediīt, prœteriīt*, Ov. On the other hand, a short vowel in what is called doubtful position, remained invariably short in Plautus and Terence, although the later poets took the liberty of treating such a syllable as long. Thus, *lacruma, sacrum, lucrum, patrem*, have always a short first syllable in Latin comedy; and if *mediocris* has a long *ō*, it is because the *o* vowel of this word is in itself long.

If now the principles we have assumed on the grounds above mentioned be applied to the plays of Terence, we arrive at the result, that the verses, with very few exceptions, acquire the desired rhythm; and that there should be exceptions must be expected where the text of an author is not yet established upon a careful comparison of manuscripts, and where even the transposition of two words will often alter the accent. Moreover, it should always be recollected that in the comic drama it may be even desirable to avoid the purer rhythm of verse, and approach somewhat to the prose of natural conversation, as Cicero has himself remarked ('Orator.,' 55). That what we now say may be put to the test, we will give a list of those words requiring abbreviation which most commonly occur, observing at the same time that a word at the end of an iambic trimeter, or after a monosyllable, is often to be pronounced with all its syllables, though elsewhere liable to contraction. Of this an example may be seen in the tenth line of the prologue already referred to, which contains both *noverit* and *norit* :—

senex	= *sen.* Compare the genitive.
pater	= *père.* Compare *parricida.*
soror	= *sœur*, as in French.
voluntas	= *vountas.* Compare *vīs* = *vŏlīs* and *invitus* = *involitus.*
lacruma	= *larma.* Compare the French *larme* and *serment,* from *sacramentum.*
hodie	= *oggi,* as in Italian.
dies	= *jes.* Compare *jour, journée.*
ego	= *yo.* Compare Italian *io.*
cave	= *cau.* Compare Cicero's story about the word *cauneas.*
tace	= *tai,* as in French, *tais.*
quibus	= *quis.* Compare the loss of *b* in the dat. pl. of the first and second declensions.
tibi	= *ti.* } Compare the Romance, Italian, Fr., Sp., and *mihi* = *mi.*
sibi	= *si.*
ibi	= *i* or *y.*
ubi	= *ou.*
abi	= *ai.*
jube	= *ju.* Compare the perfect *jussi.*
inde	= *in.* Compare the French *en,* and Latin *dein, exin,* for *deinde, exinde,* &c.
redi	= *rei.*
magis	= *mais.* Compare *mai* It., *mais* Fr., *mas* Sp,
minus	= *mins.*
alius	= *alyus.* Compare Greek *αλλος,* and Sanskrit *anya.*
facere	= *fare.* Compare Fr., It., Sp.
vigilare	= *vigliare.* Compare Fr., It.
vide	= *vi.* Compare Fr. *voi-ci, voi-la.*
novos	= *nous.* Compare Greek *νεος,* English *new.*
sine	= *sin.* Compare Fr., It., Sp.
duo	= *do.* Compare Greek *δω-δεκα,* Fr., Eng.
ille, &c.	= *il* or *le,* &c. Compare It., Fr., Sp.
bonus	= *bon,* } as in French.
sumus	= *sommes,*
bene	= *ben.*
male	= *mal.*
homo	= *homme,* as in French.
rei	= *re.* Compare the forms of the fifth declension used by Cæsar, Virgil, &c.
puer	= *pur* or *por.* Compare Greek *παις,* Spartan *ποιρ,* Latin *Lucipor.*
suus, &c.	= *sus* or *sos.* } Compare It., Fr., Sp., and also the forms used by Ennius, and in Greek.
meus, &c.	= *mus,* &c.
tuus, &c.	= *tus,* &c.
fuit	= *fut.* Compare It., Fr., and Latin *fore.*
animus	= *âmus.* Compare It., Fr.
asinus	= *ânus.* Compare Fr.
edepol	= *epol.* Compare *ecastor, ecere,* &c.
legere	= *lere.* Compare Fr.
oculus	= *œilus.* Compare Fr.
generis	= *genris.* Compare Fr.
aperire	= *aprire.* Compare It., Fr., Sp.
opera	= *opra.* Compare the form in Ennius, and Fr., Sp.
similis	= *sim'lis.* Compare Fr. *semble,* Eng. *resemble.*
tamen	= *ta'n.* Compare *tametsi* for *tamenetsi,* and *tandem* for *tamendem.*
aliquis	= *alquis.* Compare It. *alcuno,* Fr. *aucun,* from *aliquis-unus.*
hujus	= *his.* Compare the abbreviation of *nullius* into *nullīus* and *nulli.*
ejus	= *is.*

For a more detailed exhibition of these words, see 'Journal of Education,' vol. ii., p. 344; and on the subject of Latin prosody generally, the same work, vol. iv., p. 336.

It should be added, that of modern editors, Hermann, Bothe, Lindemann, Ritschl, and Fleckeisen, alone seem to have a distinct idea of the nature of the metres of Terence and Plautus; for all that has been said applies to Plautus as well as Terence. The author of the 'Varronianus' borrowed his article on the subject, and that without acknowledgment, from the 'Penny Cyclopædia' and the paper in the 'Journal of Education;' all, at least, except the paragraph about *puella,* and that, oddly enough, is the one paragraph in the said chapter which the recent editor of Terence has justly condemned. Among older writers, Bentley certainly possessed a clearer insight into the subject than some of his notes would lead one to suppose. That this is the case is proved by an anecdote in Bishop Monk's 'Life' of that scholar. The reverend doctor, dining at a friend's house in London, kept the gentlemen longer over their wine than was thought proper by the ladies in the drawing-room, and added to the scandal when his voice was heard, even above stairs, in what was supposed to be a song to the tune of 'Unfortunate Miss Bailey.' The doctor was only reading to them some specimen of Terence's Comic Septenarius, or, to use a harder phrase, the Iambic Tetrameter Catalectic.

TEREPHTHALIC ACID. [TURPENTINE.]

TERETINIC ACID. [TURPENTINE.]

TERM (Algebra). A simple term in an algebraical expression means all that involves multiplication, division, and extraction of roots without addition or subtraction. Thus in the expression

$$a^2b^3x^2 - 2abx^3 + \sqrt{ab} \, . \, x^4,$$

the terms are $a^2b^3x^2$, $2abx^3$, and $\sqrt{ab} \, . \, x^4$. But compound quantities are also called terms when they are put in such a form that additions and subtractions are subordinate to subsequent multiplication, division, or extraction. Thus,

$$(a+b)\, x^{c+d} + \sqrt{(a^2-b^2)} \, . \, xy$$

has two terms, $(a+b)$, x^{c+d}, and $\sqrt{(a^2-b^2)} \, . \, xy$. If the form be altered into

$$ax^{c+d} + bx^{c+d} + \sqrt{(a^2-b^2)} \, . \, xy,$$

the expression then has three terms. Most frequently, however, there is one letter in powers of which the whole expression is arranged, and then all that involves any one power of this principal letter is a term. Thus $a + bx + cx + ex^2$ has three terms, namely, a, $(b+c)\,x$, and ex^2.

When one quantity is said to be expressed in terms of another, it generally means merely that the first is to be an explicit FUNCTION of the second. Thus, in $x+y=a$, we have expressed $x+y$ in terms of a: deduce $y=a-x$, and we have y expressed in terms of a and x. This is the distinction between y being expressed in terms of x, and y being a function of x: if, for instance, $y=a-z$, $z=x^2+x$, y is a function of x, but it is not expressed in terms of x, but of z; substitute for z its value, and y is then expressed in terms of x. It is to be remembered that by saying that a quantity is expressed in terms of x, it is not meant that x is the only letter which enters, but that no other letter if there be any, is a function of x. Thus, in the preceding, where we obtain $y=a-x-x^2$, y is expressed in terms of x if a be no function of x. But if a be a function of x, say x^3+x, then y is not expressed in terms of x, until the value of a has been substituted, giving $y=x^3-x^2$.

TERM. The law Terms are those portions of the year during which the courts of common law sit for the dispatch of business. They are four in number, and are called Hilary Term, Easter Term, Trinity Term, and Michaelmas Term: they take their names from those festivals of the Church which immediately precede the commencement of each. Various acts of parliament have been passed relative to the regulation of the Terms. The statute which now determines them is the 11 Geo. IV. & 1 Wm. IV. c. 70, amended by 1 Wm. IV. c. 3, which enacts that Hilary Term shall begin on the 11th and end on the 31st of January; Easter begin on the 15th of April and end on the 8th of May; Trinity begin on the 22nd of May and end on the 12th of June; Michaelmas begin on the 2nd and end on the 25th of November. Monday is in all cases substituted for Sunday when the first day of Term falls on Sunday. During Term four judges sit in each court, and are occupied in deciding pure matters of law only, without the intervention of a jury. The courts are empowered however to hold sittings out of Term for the purpose of disposing of the business then pending and undecided before them.

TERM OF YEARS signifies the estate and interest which pass to the person to whom an estate for years is granted by the owner of the fee. [ESTATE.]

TERMINAL. We cannot say that this term *is* used in mathematics to the extent to which we shall carry it; but the very great convenience which would arise from an extension of its use is sufficient justification for coining a few new meanings. Term is a word of geometry very little used, and signifying boundary or extremity; the words terminal value and terminal form are sometimes used to signify the last and most complete value or form. When a finite expression, added to a certain number of terms of a series, makes up the equivalent of the expression from which the series is deduced, or stands for all the subsequent terms of the series, this finite expression might be called the terminal expression. Thus in Taylor's Theorem we have one terminal expression in D'Alembert's form, another in that of Lagrange.

There is also another use of the word, which would convey a distinction much wanting words to express it: we allude to what might be called *terminal language.* All the use of the words infinitely small and infinitely great [INFINITE; LIMIT] is entitled to this name; as follows:—When we say, for example, that a circle *is* a regular polygon with an infinitely great number of infinitely small sides, the language used is that of an end arrived at, a transformation actually made; the circle is described as actually consisting of straight lines; and the language is *terminal* (expressive of a boundary actually attained). But the meaning of this language is, or is generally held to be, false: no polygon is a circle, how great soever the number, or how small soever the magnitude, of the sides. The proposition which is really true, that is, over which all shake hands, whatever their notion of infinity may be, is that the terminal proposition, true or false, is one to which an interminable and unlimited degree of approximation may be made. An inscribed regular polygon may, with sides enough, be made to coincide with the circle within any degree of nearness we please to assign: or the following proposition—"the area of the inscribed polygon may be made to differ from that of the circle by less than the nth part of the latter"—may be made true for every value of n that can be named, however great. Terminal language, properly employed, may be made the means of abbreviation of all those truths whose announcement contains interminable approximation: the development of this sentence is the object of the article INFINITE.

TERMINALIA, the festival of Terminus [TERMINUS], celebrated at Rome annually on the 23rd of February, the last day of the old Roman year. The festival was either public or private, according as it was held at the boundaries between the fields of private persons, or at the boundary of the Ager Romanus. In the former case persons possessing adjoining lands met with their families and servants at the stone which divided the properties, adorned it with garlands and offered sacrifices, and a feast in which the neighbours partook was intended to renew the friendly relations existing between them. (Ovid., 'Fast.' ii., 643, &c.) Dionysius states that down to his time the Romans did not offer any bloody sacrifices on this occasion, but only cakes and fruit. But we have authentic statements which show that the assertion of Dionysius can only apply to the early period of the republic, and that subsequently a lamb or a sucking pig was sacrificed. (Dionysius ii., 74; Plutarch, 'Numa' 16; 'Quaest. Rom.' 15; Horatius, 'Epod.' ii. 59.) The public Terminalia were solemnised in a similar manner by the whole people on the boundary of the Ager Romanus. (Ovid., 'Fast.' ii. 679, &c.)

TERMINUS, a Roman deity whose worship was said to have been introduced by Numa Pompilius, when he ordered the fields of the citizens to be separated from one another, and the boundaries to be marked by stones which were to be considered as sacred to Terminus, or as Dionysius calls him Ζεὺς ὅριος. (Festus, s. v. 'Terminus,' Dionysius, ii. 74). A careful examination of the worship of this god shows that Terminus was only a surname of Jupiter, who was worshipped under this name as the guardian of boundaries. The stone pillars were regarded as symbolical representations of the god himself, and hence perhaps the severe law mentioned by Festus, that whoever displaced such a pillar should, together with his oxen, be devoted to the god. In the same manner in which the boundaries between the lands of private individuals were marked, the original territory of Rome (Ager Romanus) was separated by pillars from the territory of neighbouring tribes. In the direction of Laurentum there was such a pillar (terminus) between the fifth and sixth milestones from Rome on the Laurentine road. This was the public Terminus. The god had a temple on the Capitol, and the part of the roof just above the symbolical pillar was left open. (Festus; Servius, 'Ad Aen.' ix. 448.)

TERMINUS, or TERM, signifies, in sculpture and architecture, a pillar statue, that is, either a half statue or bust, not placed upon, but incorporated with, and as it were immediately springing out of the square pillar which serves as its pedestal. If they be mere busts, figures of this kind are usually distinguished by the name of HERMÆ (Ἑρμαῖ); and busts which, instead of having a circular moulded base, resemble the upper part of a terminus, are called terminal busts. There are many such busts and also some termini in the Græco-Roman Saloons of the British Museum; among others a terminal bust of Dionysus, and a double terminal bust of Bacchus and Libera, both of which are engraved under DIONYSUS; also a terminal statue of PAN. The terminus, or pillar part, is frequently made to taper *downwards*, or made narrower at its base than above, which mode of diminution, the reverse of that employed for columns, was no doubt intended by way of similarity to the general outline of the human figure, whose greatest breadth is at the shoulders. By modern artists the pedestal part is usually made tapering downwards or narrowest just above its base; when it is called the *gaine*, from its resemblance to the scabbard of a sword.

In architectural design *Terms* are employed in lieu of Caryatides, not however as insulated pillars, but as pilasters forming a small order or attic, or a decoration to gateways, doors, &c. They frequently occur in the Renaissance and our own Elizabethan style.

TERMS, ATTENDANT AND SATISFIED. The assignment of satisfied terms on the purchase of property being frequently accompanied by great difficulty and expense, the Act 8 & 9 Vict. was passed to render the assignment of Satisfied Terms unnecessary.

TERRESTRIAL LIGHT. Aurora borealis, or northern lights, as they have hitherto been called, is now generally admitted to be a magnetic phenomenon. [TERRESTRIAL MAGNETISM.] As lightning shows a restoration to equilibrium from a disturbance in the electrical condition of the atmosphere, so these northern and southern lights denote the conclusion of a magnetic storm which has foretold its approach by its universal influence on a freely-suspended magnet, even at places far distant from the place where the phenomenon itself is visible.

Fig. 1.—Aurora Borealis.

The appearances which ordinarily present themselves during a display of terrestrial light are thus graphically described by Humboldt with his accustomed accuracy:—"Deep in the horizon, nearly in the situation where it is intersected by the magnetic meridian, the heaven, up to this moment clear, grows black. There is a kind of hazy bank or screen produced, which rises gradually and attains an altitude of from 8° to 10°. The colour of the dusky segment passes over into brown or violet. Stars are visible in it, but they are seen as in a portion of the sky obscured with dense smoke; a broad bright luminous arc or seam, first white, then yellow, bounds the dusky segment. The highest point of the luminous arc, when it has been carefully measured, has been found to be not exactly in the magnetic meridian, but to vary between 5 and 18 degrees from it, towards the side on which the magnetic declination of the place of observation lies. The luminous bow, in constant motion, flickering and changing its form incessantly, sometimes remains visible for hours before anything like rays and pencils of rays shoot from it and rise to the zenith. The more intense the discharges of the northern lights, the more vividly do the colours play from violet and bluish-white, through every shade and gradation, to green and purplish-red. The magnetic fiery columns shoot up, at one time singly from the luminous arch, even mingled with black rays like thick smoke; at another, many columns arise simultaneously from several and opposite points of the horizon, and unite in a flickering sea of flame, to the splendour of which no description can do justice, and whose luminous waves assume another and a different shape every instant. The intensity is at times so great that Lowenörn perceived its oscillations, in bright sunshine, on the 29th of January, [illegible]. The motion increases the brilliancy of the phenomenon. Around the point of the vault of heaven which corresponds with the direction of the dipping-needle, the rays at length collect together, and form the corona or crown. This surrounds the summit, as it were, of a [illegible] canopy, the dome of heaven, with the mild radiance of its streaming but not flickering rays. It is only in rare instances that the phenomenon proceeds the length of forming the corona completely. With

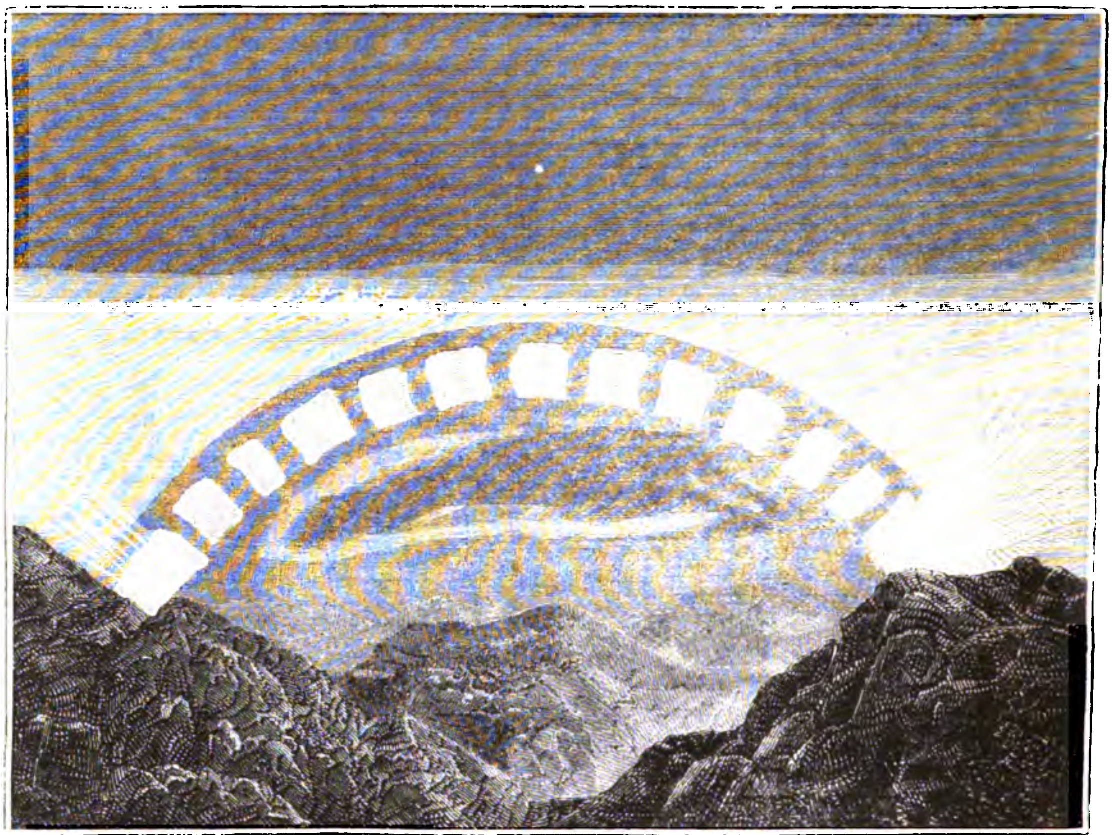

Fig. 2.—Aurora Borealis.

its appearance, however, the whole is at an end. The rays now become rarer, shorter, less intensely coloured. The crown and the luminous arches break up. By-and-bye nothing but broad, motionless, and almost ashy-gray pale gleaming fleecy masses appear irregularly dispersed over the whole vault of heaven: these vanish in their turn, and before the last trace of the murky fuliginous segment, which still shows itself deeply on the horizon, has disappeared. Of the whole brilliant spectacle, nothing at length remains but a white delicate cloud, feathered at the edges, or broken up, as a cirro-cumulus, into small rounded masses or heaps, at equal distances." ('Cosmos,' v. i.)

The two illustrations given above are selected, for their dissimilarity, from the work of M. de Mairau. *Fig.* 1 represents an aurora as seen at Breuillepont, in Normandy, nearly in the latitude of Paris, on September 26th, 1726. It consisted entirely of streams of light, without any darker meteor. *Fig.* 2 shows an aurora as observed at the same place, and which lasted for several minutes, on Oct. 19, 1726.

It has been a subject of some dispute whether any sound accompanies the development of the terrestrial light. The Greenland sledgers and Siberian fox-hunters are positive in their assertions that there is; and intelligent observers engaged in the Arctic magnetical and meteorological expeditions have recorded their evidence in the affirmative. On the other hand, Parry, Franklin, Richardson, and others state to having witnessed thousands of auroræ without perceiving any attendant sounds.

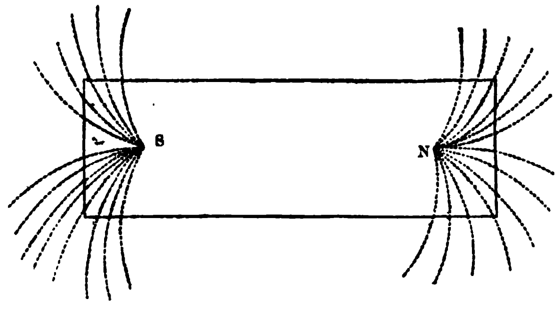
According to Dalton, the southern lights have been frequently seen in England; and the northern lights were seen in 45° S. lat. on January 14, 1831. Humboldt remarks, however, that "It is necessary to distinguish between the sphere of a simultaneous apparition of the phenomenon and the zone of the earth in which the phenomenon is displayed almost every night of the year. As each observer sees his own rainbow, so also, doubtless, does he see his own polar light. A great portion of the earth engenders the radiating light-phenomenon at the same time."

The intensity of the terrestrial light diminishes with the decrease of latitude, or, more strictly, with the decrease of magnetic latitude. In Iceland, Greenland, and on the banks of the Slave Lake, it appears at certain seasons every night. In Italy it is rare. On the shores of Siberia there appear to be "special regions of the northern lights."

There is great difficulty in determining the altitude of the terrestrial light, in consequence of the incessant oscillations of the luminous rays; so that the results of different observations "vary between several miles and three or four thousand feet." Moreover, it is probable that its altitude differs at different times.

Our observations and knowledge of the terrestrial light leads us to the important and interesting conclusion that our earth itself is luminous; and it is supposed that the degree of luminosity is a little greater than that of the moon in her first quarter. These considerations, compared with the observed fact that the planet Venus "glows occasionally with a proper phosphorescent gleam" in those parts which are not illuminated by the sun, lead us to inquire whether the moon and planets may not likewise be magnetic, thus keeping up a mutual influence between themselves and our earth.

Why the phenomenon of the terrestrial light should confine itself especially to the polar regions is readily explained on the supposition that it is a luminous discharge of superabundant magnetism; and since heat is destructive of magnetism, the magnetic intensity will be greater in the colder regions of the earth. [TERRESTRIAL MAGNETISM.] An illustration of this may be given by taking a bar-magnet and dipping it in iron filings, when the filings will be found to arrange themselves near the poles of the magnet, presenting the appearance as shown in the following figures.



Whether the magnetic condition of our earth has undergone any recent change we cannot say; but it is remarkable that we can find no very early accounts of the phenomenon we have been describing. It

Aurora Borealis.

Aurora Australis.

certainly appears to have been less frequent before the 18th century than it has been since. Torfœus, who wrote in 1706, relates that even in his own time the aurora was an object of terror in Iceland. For some time it was thought that there was no aurora australis, or terrestrial lights in the south; and though the fact is now well established, yet the earliest account we have of such an occurrence is given by Don Antonio Ulloa, who saw it at Cape Horn in 1745.

From the writings of Aristotle, Cicero, Pliny, and others, we read of appearances in the heavens which we conclude to have been auroræ, and which were viewed with the same superstition as comets.

For further information on this subject, the reader is referred to the writings of M. de Mairau (1754); Dalton; Humboldt's 'Cosmos;' Halley; Forbes; Expeditions of Parry, Franklin, Richardson, and Henderson; Kaemtz's 'Complete Course of Meteorology' (Lond., 1845); Reports of the British Association for the Advancement of Science; and the Philosophical Transactions of the Royal Society.

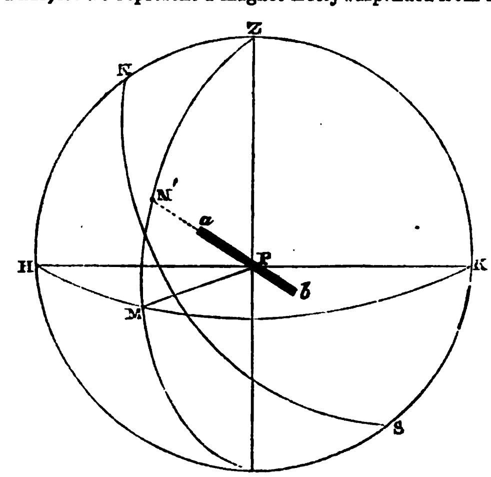
TERRESTRIAL MAGNETISM. If a magnetised bar of steel be suspended by a fine thread attached to its middle point, one extremity always points *nearly* to the north, the other end towards the south. Again, if a bar having a fine axle through its centre of gravity, and perpendicular to the axis of the bar, be placed with the axle resting on two highly polished surfaces, it will be found to make an angle with the horizon, and the magnitude of this angle will depend upon the place at which the experiment is made. The unknown influence which produces these phenomena is derived from the earth itself, and is called Terrestrial Magnetism. Hitherto no one has succeeded in reducing terrestrial magnetism to a theory, although various attempts have been made—and some with partial success. But the labours of mathematicians and observers have not been lost, for a mass of evidence on this important subject has been accumulated, which in due time will form the basis of a theory more wonderful even than that of gravitation, since it is not too much to assert that this unseen power, which for years has been known only, and thought of, for its practical utility, will one day prove to be the key to all the other phenomena in the universe. Terrestrial magnetism then is known by its effects upon the artificial magnet, and it is the province of the philosopher to observe, compare, and reduce these effects after they have been freed from all incidental and extraneous sources of error.

Until the year 1828, there were no systematic observations of magnetical phenomena; but since that time different countries—and especially our own—aided by their respective governments, have established observatories in all the most advantageous positions on the earth's surface; and sent out expeditions to the antipodes and places where a permanent observatory could not be maintained.

The object of these observations has been to determine the absolute value of what are called "the magnetic elements," and the periodical changes they undergo. The observations thus made, having been carefully corrected and reduced, are printed with such comments as seem necessary, and a description of the instruments and methods employed; and these enormous collections of facts are widely distributed throughout the scientific world under the title of Magnetical Observations.

There are three magnetic elements – namely, *the Intensity*, *the Inclination*, and *the Declination*.

If a magnetic needle be freely suspended from its centre of gravity, one extremity is drawn from the horizontal position by a force called the *Magnetic Intensity*, and the direction of this force is inclined to the horizon at an angle called the *inclination* or dip. These two elements appear to be independent of each other, and to vary with the position of the place of observation. Again, the needle does not point exactly north and south, but to points situated at some little distance from the poles of the earth—which points are called the magnetic poles. The angle between the meridian of the place of observation and the vertical circle in which the axis of the needle lies—that is, the vertical circle passing through the magnetic poles—is called the *Declination or Variation*. Thus, let $a\,b$ represent a magnet freely suspended from its centre



of gravity at any place P, whose zenith is Z. Let Z N H K represent the meridian of the place, H M K the horizon, Z N′ M the magnetic meridian, or the great circle in which the axis of the needle lies: N and N′ the true north pole and magnetic north pole respectively. Then the magnet $a\,b$ is forced from a horizontal position into the position $N'\,a\,b$ by the intensity of the latter's magnetism. The angle $N'\,a\,P\,M$ is the inclination: and the angle between the circles Z N H, Z N′ M, which is measured by the angle H P M, is the declination.

The first object of the magnetic observer is to determine the absolute values of these magnetic elements, and then to trace the laws which regulate their hourly, daily, annual and secular changes.

It would be a difficult matter to construct an instrument which should at once give the absolute value of the *intensity*, and its periodical changes; but this object is readily attained by the application of the principle of the resolution of forces. For let F be the absolute value of the magnetic intensity, X and Y its horizontal and vertical components, θ the inclination or dip:

Then $F = X \sec \theta$
and $Y = X \tan \theta$

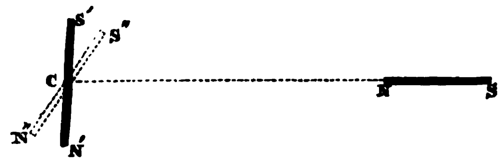
Now, as we shall see, there is no difficulty in determining the horizontal component X, and the inclination θ: hence, also, the vertical component Y and the total force F may be found.

Determination of the Horizontal Component of the Magnetic Force.—This element is obtained by a combination of two experiments made with an instrument called the Unifilar Magnetometer. In the first experiment, the time of vibration of a suspended magnet is observed. In the second experiment we observe the amount of deflection which the same magnet produces in a second magnet suspended by a single thread.

Let T denote the time of vibration of a suspended magnet, determined much in the same way as the oscillation of a pendulum might be observed, that is, by observing the time of the passing and repassing of a fixed point on the magnet past a vertical line placed in the focus of a fixed telescope. Let m be the magnetic moment of the bar, K its moment of inertia, then by the principles of Dynamics we have

$$m X = \frac{\pi^2 K}{T^2} \qquad (1)$$

Next let this same bar N S, be placed on a support in such a position that its axis lies in a straight line, passing through the centre of



another magnet N′ S′, suspended by a single thread, and its direction perpendicular to the axis of the latter magnet. Then the magnet N S will deflect the magnet N′ S′ from its normal position into a position N″ S″. Let u denote this angle of deflection N′ C N″, r the distance between the centres of the two magnets. Then the condition of equilibrium will be given by the equation

$$\frac{m}{X} = \frac{1}{2} r^3 \sin u \qquad (2)$$

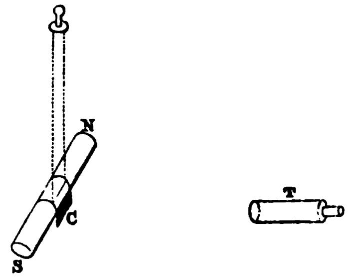
combining this with equation (1), we have

$$X = \frac{\pi}{T r} \cdot \sqrt{\frac{2 K}{r \sin u}} \text{ and } m = \frac{\pi r}{T} \sqrt{\tfrac{1}{2} r K \sin u}.$$

It is to be observed that the units of time, space, and mass referred to in these investigations, are by universal consent taken to be, a second, a foot, and a grain respectively.

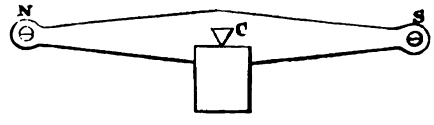
But though we are thus enabled to determine the absolute value of this horizontal component X, and, therefore, also the changes it undergoes from time to time, yet it is not adapted to give those very minute changes which take place from hour to hour, and day to day. Such changes are called horary and diurnal variations; and the instruments by which they are observed are called differential instruments. The variation in the horizontal force is denoted by the symbol Δ X; and is observed by means of an instrument called a Bifilar Magnetometer.

N S is a magnet suspended by two threads hanging from a screw



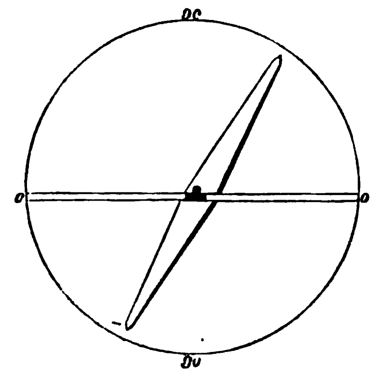
which can be turned horizontally, so that the axis of the magnet can be constrained to assume a position approximately perpendicular to the magnetic meridian. Beneath the magnet, a graduated transparent scale, C, is suspended, and the readings of this scale are viewed by means of a telescope, T, whose axis is in the magnetic meridian. Now the horizontal force, X, evidently acts perpendicularly to the magnet, hence every change that it undergoes will cause the magnet to be deflected from its normal position. These deflections are read off by means of a vertical wire placed in the focus of the telescope; hence, having determined the change in the horizontal force which corresponds to one division of the scale, the reading of the scale at any time will show us the increase or decrease of the horizontal intensity—the zero reading of the scale corresponding to the normal value of the horizontal force.

The Vertical Force Magnetometer is another differential instrument



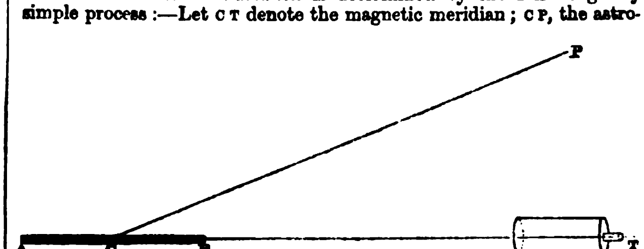
for observing Δ Y, a small variation in the vertical component Y. It consists of a light magnet, N S, with small holes at its extremities, across which fine threads are drawn in a horizontal position. Through the centre of the magnet is a knife-edge, C, perpendicular to the axis of the bar. This knife-edge is supported by two smooth agate planes, so as to free the motion of the magnet, as far as possible, from the effects of friction. The axis of the bar is placed in a position perpendicular to the magnetic meridian, thus rendering it independent of the inclination or dip. A small shifting weight is attached to the magnet, and is so adjusted as to bring the axis into a horizontal line for its normal position. Now it is evident that any change in the vertical force will deflect the bar from its horizontal position, and this deviation is viewed by means of two ordinary micrometers directed to the holes at N and S. The change in the vertical force which corresponds to any number of revolutions of the micrometer screw may be found by absolute determination; hence, also, the changes due to one or more divisions are known—the zero reading of the micrometer corresponding to the normal position of the axis of the magnet, for which position the absolute value of the vertical component Y has been carefully determined from the formula $Y = X \tan \theta$.

The Inclination or Dip is determined by means of a light magnet whose extremities taper to a point, and through the centre of which is



a smooth cylindrical axle perpendicular to the plane in which the axis of the magnet moves. This circle rests on two smooth agate planes, and thus the magnet moves freely in a vertical circle whose rim is graduated through each of the four quadrants from 0° to 90°. When used, the instrument is adjusted so that the plane of the graduated circle, together with the axis of the magnet, is in the plane of the magnetic meridian, previously determined. The needle now assumes the *direction* of the magnetic force at the place of observation, and the reading of the graduated circle opposite to either extremity of the magnet indicates the *inclination* of the axis of the needle to the horizon. In practice, the means of both readings are taken, and several pairs of observations made. These and many other precautious are adopted in order to eliminate, as far as possible, the mechanical defects in the instrument, and errors of observation.

The Declination or Variation is determined by the following very simple process:—Let C T denote the magnetic meridian; C P, the astronomical meridian.



Then the axis of a magnetic bar, A C B, suspended by a single thread attached to a point *above* its centre of gravity, will assume a horizontal position in the line C T; and a graduated glass scale being attached to the magnet, its zero-reading, which is taken to indicate the normal position of the magnet, is made to coincide with a vertical wire in the focus of the fixed telescope T. The angle P C T is the declination or inclination of the magnetic to the astronomical meridian, and is measured by a theodolite which is placed so that its axis is made to coincide with the line C T; and being then turned in azimuth until a distant object is seen which is *known* to be in the meridian of the place, the azimuthal angle thus measured is the normal declination.

This instrument, which is sometimes called the Unifilar Magnetometer, likewise serves to make differential observations of the declination; for there is no difficulty in determining the angular value of each division of the scale attached to the magnet: hence, if the vertical wire in the telescope coincides with the zero-reading of the scale at any specified time, when the needle is supposed to be in its normal position, any other reading will denote the angular deviation of the magnet from its original position, and therefore determines the corresponding variation of the magnetic meridian.

Such is a brief outline of the methods employed in determining the absolute value of the magnetic elements, and in watching the periodic changes they are constantly found to undergo. It is obviously beyond the limits of this article to enter into the numerous and elaborate details of the cautions which must be adopted by the observer; the methods employed to diminish the effects of instrumental errors; and the corrections which are applied to many of the observations to counteract the influence of temperature, which has the effect of changing the magnetic condition of the bars. For a more complete description of the magnetometers, and all the practical details necessary for observing and computing the observations, the reader is referred to the 'Instructions of the Royal Society to the Directors of Magnetical and Meteorological Observatories.'

We now proceed to notice some of the most prominent phenomena in connection with terrestrial magnetism. It has been already stated that the magnetic elements are subject to periodic changes. These changes are generally slow, and exhibit a certain amount of regularity, though the laws which govern them have not yet been arrived at. One of the most apparent, perhaps, of these fluctuations is seen in the declination magnet, that end which is towards the north moving slowly westward during the forenoon, and returning to its normal position about ten in the evening. It then moves towards the east, and returns to its former position about ten in the morning. These changes evidently establish the fact that the motion of the magnetic meridian is in some way connected with that of the sun. The other magnetic elements also undergo similar though less striking changes; and it is to be observed that each succeeding day will not show exactly the same set of hourly variations as its predecessor, nor are the observations of one year identical with those of another.

But, besides these known periodical fluctuations, which past experience teaches us to look for from time to time, there are sudden and unaccountable disturbances in the magnetic elements arising, it is supposed, from some sudden derangement in the magnetic condition of the earth.

This phenomenon exhibits itself in a sudden and sometimes violent agitation of the suspended magnets. During these magnetic storms, as they are called, the magnets oscillate to and fro, sometimes slowly and regularly, at other times with such rapidity that the observer is unable to note the time or arc of the vibration; and often the scale by which the position of the magnet is viewed is completely carried out of the field of the telescope. On some occasions the magnet seems to be acted upon by a succession of rapid jerks; at other times a quivering motion is detected, so much so as to render the scale indistinct. These unusual disturbances, the particulars of which have, when observed, been carefully recorded at the different observatories, do not appear to have electricity as their origin, since they do not necessarily take place during an electric storm. The most remarkable feature attending them is the fact that simultaneous disturbances of the magnets at different places are found to take place during a display of the aurora borealis [Terrestrial Light], thus connecting that phenomenon with terrestrial magnetism.

Some philosophers have supposed that earthquakes are accompanied by magnetic disturbances; but the great Humboldt doubts this, though he was startled by observing, during the violent earthquake of Cumana in 1799, "that the dip was diminished by 48'."

Magnetic phenomena appear to be immediately connected with meteorological changes. Hence it is that meteorology forms an important part of the work of a magnetic observatory; and observations of the thermometer, barometer, wind, and weather are made simultaneously with those of the magnets. Violent gales, sudden changes of temperature, and rapid barometric fluctuations are generally accompanied by magnetic disturbances.

Each place on the earth's surface has its own distinct magnetic elements. We have already stated that the freely suspended needle does not point exactly north and south, but to two points near the terrestrial poles. These points are called the magnetic poles. When the meridian of any place likewise passes through the magnetic poles, it is evident that the magnetic meridian coincides with the terrestrial, and there is no declination or variation; and the locus of all such places is called "the line of no variation." Again, at places near the equator, the dip needle is horizontal, and the locus of all such places, which locus does not coincide with the equator, nor is it an exact circle, is called the "line of no dip." As we proceed towards either of the terrestrial poles, the needle becomes more and more inclined to the horizon, until we reach the magnetic poles, where it assumes a vertical position.

Likewise, also, the absolute intensity of the magnetic force depends upon locality. It appears to increase as we proceed from the equator to the poles, and the curves which pass through all those places where the intensity is the same, are called "isodynamic lines." These lines do not coincide exactly with parallels of latitude, nor with lines of *equal dip*. According to the most recent determination, the north magnetic pole is situated very nearly in latitude 70° 5', and west longitude 96° 47'. Some have supposed the existence of two magnetic poles in each hemisphere, the position of the second northern pole being in Siberia, about 60° north latitude, and 102° east longitude. The positions which have been assigned to the southern poles are a little to the south of Australia, and south-south-east of New Zealand. This hypothesis, however, must be adopted with caution.

The following is a comparative view of the value of the magnetic elements at some places where they have been determined with the greatest accuracy:—

	Declination.	Dip.	Total Force.
Greenwich	22° 51' west	68° 59'	10·4
Toronto	1° 27' ,,	75° 17'	13·9
St. Helena . . .	22° 46' ,,	21° 37'	6·3
Cape of Good Hope . .	29° 8' ,,	53° 35'	7·6
Hobart Town . . .	9° 47' east	70° 36'	13·5

The causes of terrestrial magnetism have still to be developed. Various theories have been from time to time proposed, some of which have indeed successfully accounted for a few of the known magnetical phenomena, but fail under the tests which science and observation supply us with. The elaborate theory founded on the supposition that the earth is an actual magnet, is overturned by the discoveries of Faraday, Arago, and other philosophers. Although there does not appear to be a simultaneous occurrence of magnetic and electric storms, yet there can be little doubt of the connection between these phenomena, even if magnetism be not "one of the numerous forms under which electricity developes itself." The experiments of Faraday and Oersted have shown, not only that "electricity induces magnetism in the vicinity of the body which conducts it," but that "free magnetism gives rise to electricity." Assuming, what is highly probable, that the interior of the earth is a mass of liquid fire, then the idea of a magnetic nucleus in the earth must be abandoned, for it is found by experiment, that the magnetism of a body is destroyed when it reaches a white heat. It is, therefore, the earth's crust only which we may assume to be the seat of magnetic currents. That such currents do exist, is by no means improbable, and experiments seem to show that they are immediately excited by unequal distribution of heat. If we regard the aurora borealis [Terrestrial Light] as a luminous discharge of superabundant magnetism, we can understand how this phenomenon should be confined to the vicinity of the colder regions, where the earth's surface is least heated, and the magnetic intensity, therefore, the greatest. No less than 146 years ago, Halley ('Philosophical Transactions') had boldly ventured to conjecture, that the terrestrial light was a magnetic phenomenon. But when the fact became established, that the aurora indicated its appearance by the disturbed state of the magnet in all parts of the globe, and the brilliant discovery was made by Faraday, that light could be evolved by magnetic power, then a passing conjecture acquired a degree of probability amounting almost to certainty.

It is curious that Galileo was inclined to account for the parallel direction of the earth's axis, on the supposition of a distant magnetic point of attraction in space. Without entering upon the consideration of a question which we usually refer to dynamical principles, yet it is pretty certain from recent observations, that both the sun and moon do exert an influence upon the magnet, and philosophers are strongly disposed to connect the variable phenomenon of the spots on the sun with the magnetic condition of our earth.

For further and more complete information on this subject, and subjects closely allied to it, the reader is referred to the following authorities: Humboldt's 'Cosmos,' Sabine's translation; Somerville's 'Connection of the Physical Sciences;' Young's 'Lectures on Natural Philosophy;' Brewster's 'Magnetism;' Faraday's 'Researches;' 'Reports of the British Association for the Advancement of Science, on Magnetism and Meteorology;' 'Philosophical Transactions' of the Royal Society; Barlow on 'Magnetic Attractions;' 'Annuaire Magnétique,' St. Petersburg, 1836; Gauss, on the 'General Theory of Terrestrial Magnetism,' in Taylor's 'Scientific Memoirs,' August, 1839; Gauss and Weber's 'Magnetic Atlas,' Leipzic, 1840; 'Report of the Committee of Physics of the Royal Society;' 'Magnetical and Meteorological Instructions of the Royal Society;' 'Magnetical and Meteorological Observations made at different Observatories, and printed by direction of the British and Foreign Governments, and the Honourable East India Company.'

Amongst those who have enriched this science by their investigations and observations, we may make especial mention of General Sabine, to whom, in conjunction with Sir John Herschel, and the present Astronomer Royal, is due the establishment of magnetic observatories and well organised expeditions, which have furnished upwards of 2,000,000 of observations in the course of three years, and who has, ever since the year 1819, devoted himself to the cause of terrestrial magnetism.

But terrestrial magnetism it still in its infancy; much remains to be done; and so simple and inexpensive are the methods and instruments of observation, that many would find a delightful and profitable amusement in the study—especially in the observance of magnetic storms—and thus contribute their mite towards the discovery of "the great ocean of truth."

TERRESTRIAL TEMPERATURE, DISTRIBUTION OF. The subject of the earth's temperature has already been treated of at some length under different headings. Generally, it was shown under Climate and Meteorology, that the temperature of the air in any region depends on the inclination of the sun's rays to the surface of the earth in that region; on geographical position and physical conformation, the distribution of land and water, the state of the countries from which come the prevailing winds, the vicinity of the sea, the elevation of the land, the electrical state of the atmosphere, and numerous other circumstances and phenomena. Under REFRIGERATION OF THE GLOBE, the question of the influence of the proper, or internal, heat of the globe on its superficial temperature is examined. The condition and properties of the ATMOSPHERE are investigated under that title. Under SNOW, PERENNIAL, the decrement of temperature on ascending into the atmosphere is noticed. Under SEA, the temperature of the ocean is considered. Whilst the effects of oceanic currents, glaciers, deserts, &c., are treated under those heads either in the present division, or in the NATURAL HISTORY and GEOGRAPHICAL DIVISIONS of this Cyclopædia. The important subject of Terrestrial Magnetism is reserved for a distinct article. Here it only remains to speak of some of those general deductions of recent investigators in climatology which have not been specifically mentioned; and especially have we to do so in reference to isothermal lines, or lines of equal temperature, for an account of which, reference has been made to this article from ISOTHERMAL LINES; and to the temperature of the atmosphere over the sea, a branch of the subject which has been referred to the present article from SEA.

In the primitive condition of the earth, when the globe was a fluid mass, or in remote geological periods, when its central fluid mass was covered with a comparatively homogeneous crust, the effect of the radiation of its heat on the superficial temperature must, as Mr. Hopkins has shown, have been almost unlimited. But as by this radiation it would continue to part with heat till the superficial temperature approximated to that of the circumambient space, unless the radiation were compensated by the generation of heat on the surface, which is known not to have been the case, it must necessarily happen at some indefinite time (it has been shown to require many millions of years), that the internal heat of the globe would cease to exert any appreciable influence on its superficial temperature. And this is what has now very nearly come to pass [REFRIGERATION OF THE GLOBE]; this influence, according to the calculations of Mr. Hopkins, being now reduced to less than the twentieth of a degree Fahrenheit. In fact, whilst volcanoes, thermal springs, borings for artesian wells, the continuous increase of temperature in descending deep mines, and other phenomena, afford irrefragable evidence of the higher temperature of the interior of the globe, it is as clearly seen that for a short distance from the surface the temperature of the earth is dependent on external heat and moisture, and varies with the seasons of the year and the hours of the day, whilst at a greater, but still small depth—which varies according to the latitude of the place, and the conducting power of the rock, but nowhere probably exceeds 100 feet—a point is reached at which there is no sensible change of temperature, and which has accordingly been designated the *Invariable Stratum*. The present influence of the internal heat of the globe, although almost inappreciable, may, however, acording to Dove, be regarded as constant; "lessening the extremes, but not affecting the periods of the variations of temperature at the surface."

When the influence of the internal heat ceased to be paramount on the surface, changes of temperature must have been in a large measure due to the altered conditions of land and water—the elevation of mountain regions, the subsidence of extensive areas, and the consequent changes of oceanic currents—to glacial action, &c.: circumstances of which the results are clearly traceable in the animal and vegetable remains preserved in the various strata which compose the crust of the earth, and some of which (as notably in the case of the Gulf Stream and the Arctic Current) are shown by the remarkable inflections of isothermal lines to be distinctly operating now. (Hopkins, 'Trans. of Geol. Soc.,' and 'Cambridge Phil. Trans.')

In considering the present temperature of the earth, the sun must be regarded as the only source of heat and the ultimate cause of all climatic change, and hence we arrive at the possibility of ascertaining, amidst all casual fluctuations, a regularly recurring periodicity, annual as well as diurnal, for every variety of geographical position. The bearing of this periodicity on a theory of the general distribution of heat appears to have been first distinctly observed by Kirwan, who (in vol. viii. of the Irish 'Transactions') constructed a table of monthly temperatures for all parallels of latitude between 10° and 80°. Before the difference of temperature on the same parallel of latitude in the old and new continents was known or regarded, a simple formula was thought sufficient to express the temperature at any parallel of terrestrial latitude. The celebrated Tobias Mayer, from such mean temperatures as had in his time been observed, found that the temperature t (on Fahrenheit's scale) at any place might be represented by $\text{T} - 52^\circ \sin.^2 \text{L}$, where T is the mean temperature at the equator, and L the geographical latitude of the place; and in 1819 M. Daubuisson ('Traité de Géognosie') proposed the more accurate formula $t = 27^\circ \cos.^2 \text{L}$ (centigrade scale); which being adapted to Fahrenheit's scale, considering the mean temperature at the equator to be 81°, becomes $32^\circ + 49^\circ \cos.^2 \text{L}$. This formula has been found to serve for temperatures in Europe as far north as the latitude of 60°; but beyond that parallel it is useless, as it supposes the temperature at the geographical pole to be 32°, which is much too high.

It was however reserved for Humboldt to determine (1817) from the registers of observed temperatures in Europe, and from the numerous observations made by himself and other travellers in different regions of the world, the constancy of the mean annual temperature of places, and to "connect graphically by lines those points where accurate observations indicated equality of mean periodic temperature." Those lines (or curves supposed to be traced on the surface of the earth) which connect the places where the mean annual temperature is the same he called *Isothermal lines*. In order to ascertain with the utmost possible precision the mean temperature of any place from the tables there kept, Humboldt divided the sum of all the temperatures observed in each day at intervals of one hour by the number of observations; and the sum of all these mean daily temperatures being divided by 365, gave the mean annual temperature. And in determining the series of points for his lines of equal temperature, when there existed no observations on which he could depend, he interpolated the temperature and geographical position between the values of those elements at two or more places where they were well known.

The diagram on next page represents an orthographical projection, on the plane of the equator, of the principal meridians and parallels of latitude in the northern hemisphere of the earth; and the strongly marked curves represent the nine isothermal lines whose forms were determined by Humboldt. Their distances from one another are such as correspond on the earth to a change of mean annual temperature equal to 2·5 degrees of the centigrade thermometer (4·5° of Fahr.), and the most northern curve is that on which the mean temperature is expressed by zero on the former, or 32° on the latter scale. The number on each curve in the diagram expresses, according to Fahrenheit's thermometer, the mean annual temperature, at the level of the sea, of all the places through which the curve passes. The centre P represents the pole of the earth, and the longitudes of the meridian lines are numbered eastward and westward from the meridian of Greenwich.

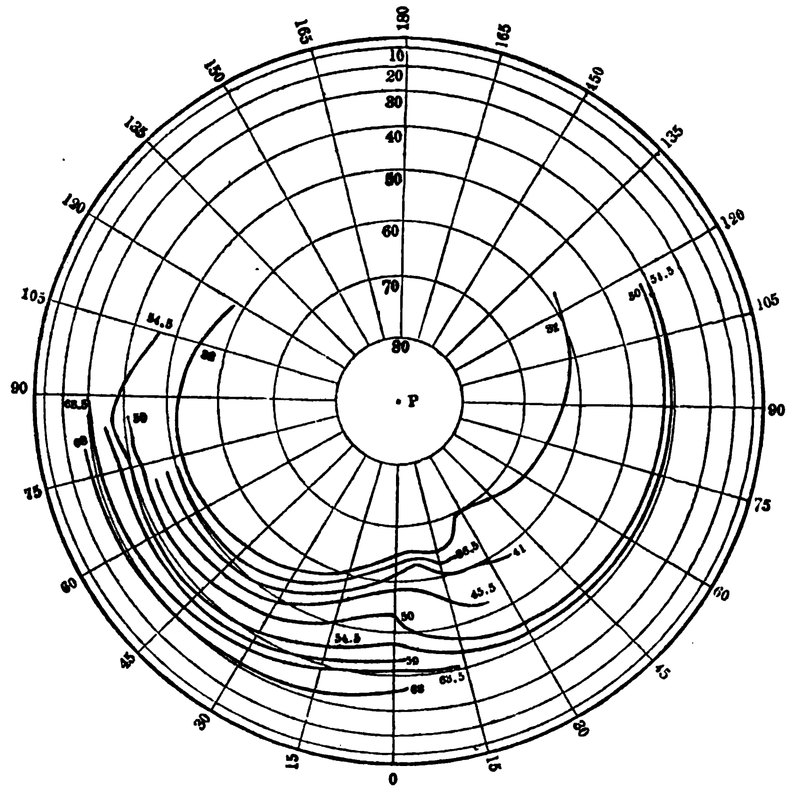
The isothermal line of 32° passes about 4° southward of Nain, a Moravian settlement on the coast of Labrador; and under the influence of the gulf stream, makes a remarkable inflexion, ascending as high as North Cape in Lapland, where it abruptly returns southward, and attains its lowest limit in the eastern parts of Asia, about 50° N. lat. Proceeding westward from Labrador the curve crosses the lower extremity of Hudson's Bay, from whence it again tends northwards to the Great Slave Lake, reaching its northern maximum in about 70° N. lat. The positions of the other curves seem to be affected in a greater or less measure by the same influences as act upon the curve just mentioned. In their progress from the western coast of Europe to the eastern coast of America they incline towards the terrestrial equator, yet so that the southern curves approach near to parallelism with that great circle of the earth. Within the territory of the United States they assume a form which is convex to the equator, and farther west they appear to reascend towards the north. In the isothermal lines of 50° and 60° westward, and those of 40° to 10° eastward of the meridian of Greenwich the curves have their convexities turned northwards; and farther eastward they descend towards the equator. The isothermal line of 54·5° is one that has been traced nearly round the earth: commencing at the mouth of the Columbia, on the western coast of North America, it passes south of Council Bluffs, and near the city of Washington with its convexity towards the south; and after crossing the Atlantic it runs between Paris and Bordeaux, from whence it continues to a point a little north of the city of Pekin, where it is again convex towards the equator.

But it must be remembered that in every country the mean temperature varies with the height of the place above the level of the sea; and Humboldt, from observations made as well on the Cordilleras as in Europe, having determined that at every 343 feet the mean temperature of the air is diminished by a quantity equal to that diminution which is consequent on an augmentation of latitude equal to one degree, calculated a table of the corrections which should be made in the curvatures of the isothermal lines at the level of the sea, in order to obtain the forms of those which appertain to points at any given elevation, but this calculation, as pointed out under CLIMATE (col. 968) does not hold with strict accuracy for places situated without the tropics.

The differences between the mean summer and mean winter temperatures Humboldt found to be very considerable at places whose mean annual temperature is the same; and these differences are not equal in the Old and New Continent. On the isothermal line of 32° in Europe, that difference proved to be equal to 39·6°, and in America to 54°; and on the isothermal line of 68° the differences were respectively 21·6° and 27°. He also remarked that the differences between summer and winter are least near the northern, and greatest near the southern bends of the curves. To indicate these variations, Humboldt laid down other lines. The curves formed by connecting, on the isothermal lines, points at which the mean temperature of summer is the same he called *Isotheral* lines; and those formed by connecting points at which the mean winter temperature is the same *Isocheimal* lines: both these systems of lines he found to deviate more than the isothermal lines from the parallels of terrestrial latitude.

Humboldt, in the first volume of his 'Cosmos,' expressed a hope that not only a clearer insight had thus been gained into the distribution of heat in the atmosphere, but that this "system of Isothermal, Isotheral, and Isocheimal lines, if gradually perfected by the united efforts of investigators, may prove one of the chief foundations of a

Comparative Climatology." In this hope he was no doubt fully justified, but one of the most profound of his followers, Professor Dove of Berlin, was led to the conclusion, as the result of the tabulation of an enormous mass of observations, ('Meteorologische Untersuchungen,' Berlin, 1837; 'Temperaturtafeln,' 1849; 'Die Verbreitung der Wärme auf der Oberfläche der Erde,' 2nd edit., 1853; 'Klimatologische Beiträge,' 1857, &c.,) that it was necessary, in order to understand the true climate of a place, to carry this system of lines of equal temperatures much



beyond those of annual and semi-annual periods, there being between places of nearly the same mean annual temperature sometimes very remarkable monthly variations, and to which are due the most marked differences in the general character of the climate and natural productions of the respective places. Dove in short concluded that it was necessary to have a complete series of *Monthly Isothermals*,—a name he judiciously adopted for the curves connecting places having equal temperatures in the same month, instead of carrying further the terminology of Isotheral and Isocheimal: the lines of equal annual temperatures he proposed to call *Yearly Isothermals* instead of simply *isothermals* with Humboldt. Of these Monthly Isothermals, Dove has given separate maps on the equatorial projection for each month, and combined polar and equatorial maps for January and July. He has also carefully observed and laid down in a series of maps the monthly thermal anomalies, uniting them by lines which he terms *Isabnormals*. Indeed his maps, tables, and memoirs altogether present a surprising mass of information on this branch of science, with the greatest precision and clearness. In his essay on 'The Distribution of Heat over the Surface of the Globe,' translated for the British Association, he arranges the different Monthly Isothermals which he has established into four classes:—

"1. Isothermals which are always found in pairs, intersecting both hemispheres: this class includes all between 32° and 77° Fahr.

"2. Isothermals which are sometimes single and sometimes in pairs, that is, sometimes intersecting one or other hemisphere only, and sometimes both: to this class belong many of the isothermals below the freezing point, and some of those of highest temperature which do not pass through all meridians, for example, 81°·5 Fahr.

"3. Isothermals which always occur singly (or in one hemisphere only), at a particular season, not touching it in other parts of the year: to this class belong the isothermals of lowest, and also those of highest temperature (40° and 90°·5 Fahr.) which are only developed at particular seasons, and enclose detached spaces.

"4. Lastly, the isolated patches of highest temperature which are developed at particular places in the torrid zone, without passing through all meridians, and are enclosed by isothermals that fork, that is, divide into two branches, (79°·25, and 81°·5 Fahr.)."

Having thus briefly indicated the character of the several Isothermal lines, we refer back to the articles CLIMATE and METEOROLOGY, where, and in the connected articles there referred to, the circumstances which appear chiefly to regulate the temperature of the earth will be found discussed at length; also various details illustrative of the temperature of different parts of the earth's surface; together with tables of the mean temperatures in different latitudes, as well as formulæ expressive of the most important general results. We shall in this place merely add that Dove has deduced as the result of his tabulation of innumerable observations, that the mean annual temperature at the surface of the earth is in January 48°·9 Fahr. in the Northern, and 59°·5 in the Southern hemisphere, giving a mean of 54°·2 for the whole earth; while in July it is 70°·9 Fahr. in the Northern and 53°·6 in the Southern hemisphere, or 62°·3 for the whole earth, thus showing an increase of 8° Fahr. from January to July. Again if we take "the mean between the temperatures of January and July for the northern and southern hemispheres respectively, we find for the northern hemisphere 59°·9, and for the southern 56°·5 Fahr., being 58°·2 for the whole earth." Further he has found that in all seasons of the year there is encompassing the whole earth a zone having a temperature above 77° Fahr.

The following tables, by Dove, show the mean annual temperatures at different degrees of latitude in the two hemispheres, and the mean annual decrease of temperature from the equatorial to the polar regions:—

MEAN ANNUAL TEMPERATURE OF THE NORTHERN AND SOUTHERN HEMISPHERES.

Latitude.	Northern Hemisphere.	Southern Hemisphere.	Difference.	Mean.
0°	79°·7	79°·8	0°·1	79°·8
10°	79·9	78·8	2·1	79·0
20°	77·5	74·1	3·4	75·8
30°	69·8	66·9	2·9	68·3
40°	56·5	54·6	1·9	55·6

DECREASE OF TEMPERATURE FOR THE ENTIRE EARTH.

Latitude . . .	0°—10°	10°—20°	20°—30°	30°—40°	0°—40°
Northern hemisphere .	—0°·2	2°·5	7°·7	13°·3	24°·3
Southern hemisphere .	1·8	3·8	7·2	12·4	25·2
Earth	0·8	3·2	7·4	12·8	24·8

We now turn to the distribution of the atmosphere over the sea. [SEA.] It is a well established fact, that places near the sea have a more uniform climate than those which are at great distances from it, though in the same latitude. Inland places experience a much greater degree both of heat and cold than places on the coast, and the difference between these degrees of heat and of cold increases with the distance of the place from the sea. This phenomenon has been variously explained. The explanation is now pretty clear, since it has been proved by observation that the temperature of the air over the sea is less subject to changes than, or rather does not undergo such great changes as, that of the air which is over the land. But as the temperature of countries situated between the tropics is not subject to so great changes as that of countries in the temperate zone, and these again are less affected by them than the frigid zone, so it is found to be the case on the sea also. Beginning with the smallest natural division of time, the day, it is found that between the tropics the difference of temperature within 24 hours seldom exceeds 2 degrees of Fahrenheit, and rarely amounts to more than 3 degrees. The following table, from Meyen's 'Reise um die Welt,' shows the changes of temperature on the sea during 24 hours between the tropics:—

1830, October 25; lat. 14° 17′ N., long. 26° 37′ W.

1h.	79·88°	9h.	80·96°	5h.	81·14°
2	80 06	10	80·96	6	81·14
3	80·06	11	80·96	7	81·14
4	80 06	12	80·96	8	80·96
5	79·88	1	81·14	9	80·78
6	79·70	2	81 50	10	80·96
7	79·70	3	81·96	11	80·24
8	79·70	4	81·68	12	80·24

The difference between the highest and lowest temperature is only 2·26°. The mean temperature of the day is 80·65°, which is only 0·95° above the lowest and 1·31° below the highest temperature. It must, however, be remembered, that during the day to which these observations refer, the vessel on which they were made advanced through nearly 1½ degrees of latitude, which of course must have had some effect on the temperature.

There is a greater difference in the daily temperature of the sea within the temperate zone: though when compared with the changes which occur in any place situated in the same zone, but not immediately on the shores of the sea, it will be found considerably less than in the latter. The following table from Berghaus, of the changes on the sea, may be compared with the changes in the temperature of London in the middle of March:—

March 16; lat. 31° 0′ N., long. 64° 11′ W.

1h.	43·7°	9h.	44·6°	5h.	43·7°
2	43·7	10	44·6	6	42·8
3	43·7	11	44·6	7	41·0
4	43·7	12	44·6	8	41·0
5	44·6	1	46·4	9	41·0
6	44·6	2	45·5	10	41·9
7	44·6	3	44·6	11	41·9
8	44·6	4	43·7	12	42·8

The difference between the maximum and minimum of the daily temperature in this table amounts to 5·4°, and the mean temperature of the day is 43·7°. The maximum is 2·7° above the mean temperature, and the minimum is 2·7° below it.

We come to the same conclusion that the temperature of the air over the sea is subject to less considerable changes than that which surrounds the land, when we compare the changes that occur during the seasons. Looking at the difference of temperature between the hottest and coldest season in Berghaus's tables, we find that this difference is much greater, and at the same time more irregular, in the northern than in the southern hemisphere. But this seems to be due, in a great measure, to the influence of the Arctic current and to the difference between the winter and summer temperature, owing to the presence of vast masses of ice, which during winter extend as far south as 40° N. lat.; between 55° and 25° the increase of the mean temperature of the spring is tolerably regular, rising from 4½° to 5° for every 5 degrees of latitude. The other irregularities are evidently produced by a greater increase of the heat in summer. The mean temperature of the summer increases pretty regularly between 55° and 45° by from 2 to 4 degrees for every 5 degrees of latitude. But between 45° and 40° it rises suddenly to more than 6 degrees. This sudden rise is, no doubt, produced by the warm vapours arising from the Gulf-stream [ATLANTIC OCEAN, in GEOG. DIV.], which in these parts runs across the Atlantic. Another rise of more than 6 degrees occurs between 40° and 35° N. lat. The air of the Sahara, when raised to the highest degree of heat by the continuance of the sun near the northern tropic, seems to affect the mean temperature of the summer between 40° and 15°, and to raise it nearly to the mean temperature of that season under the equator. The effect of this heated air has been distinctly traced for an immense distance, we may, however, suppose that it ceases near Cape Verde; but the effects of another phenomenon begin to operate. The region of calms [CALMS] frequently extends in summer to 12° and 13° N. lat. Of these three agents, the heated air of the Sahara seems to have the greatest effect in raising the summer temperature of the Atlantic. Again, the fact that most of the isothermal lines run in a north-eastward direction from the western side of the Atlantic towards the eastern, and then bend downwards towards the south, indicates, as Maury remarks, the presence along the African shores in the North Atlantic of a large volume of cooler waters, the return current of the Gulf stream.

When two elements, such as air and water, approach each other, there can be no great difference in their temperature. Still there must be some difference, as the air is the better conductor of heat, and the water, as a more dense body, is capable of retaining it for a greater length of time. Many observations have been made for the purpose of establishing this difference more precisely. It has been found that the temperature of both is subject to regular changes during the day, but that the air attains its highest temperature about two o'clock, whilst the sea attains its highest temperature in some parts at three o'clock, in others not before four o'clock. Further, it appears that the temperature of the air is greater shortly before and after noon, and that of the sea about midnight; but in the morning and evening the two elements have nearly the same temperature. On the land, again, the coldest and hottest months are February and August, but on the sea the vast amount of observations collected by Maury ('Physical Geog. and Meteorology of the Sea,' ch. xvii., ed. 1860), show distinctly that the extremes occur in March and September. It has further been found, that "at sea the climatic conditions of the land are reversed, for the coldest side of the ocean is next the warmest side of the continent, and *vice versâ*" (Maury), conditions, however, which a little reflection will render readily comprehensible. When these slight changes are excluded, it is found that the difference of temperature in both elements is inconsiderable, but differs in different latitudes.

The great preponderance of water in the southern hemisphere is, as Dove has pointed out, the prime cause of the southern hemisphere being a region of warm winters and cool summers, while the northern is characterised by cool winters and hot summers; an increasing quantity of the sun's heat becoming latent, as, in passing from north declination and entering the southern signs, it is employed in evaporating an increasing quantity of aqueous vapour. And, as he observes, "the mild winter of the southern hemisphere, plus the contemporaneous hot summer of the northern, necessarily gives a higher sum of temperature than the cool summer of the southern plus the cold winter of the northern hemisphere." These relations, he suggests, appear to furnish, in the periodical conversion of the aqueous vapour into a liquid form, the motive power in the machinery of the general atmosphere of the earth. "The unequal distribution of land and sea in the northern and southern hemispheres appears to supply an effectual provision, from whence it necessarily follows that the aqueous vapour, which from the autumnal to the vernal equinox is developed to an immense extent over the southern hemisphere, returns to the earth in the other half of the year in the form of rain or snow. And thus the wonderful march of the most powerful steam-engine with which we are acquainted, the atmosphere, appears to be permanently regulated. . . . It is probable that the northern hemisphere may be regarded, comparatively speaking and to a considerable degree, as the condenser in this great steam-engine, and the southern hemisphere as its water-reservoir; that the quantity of rain which falls in the northern hemisphere is therefore considerably greater than that which falls in the southern hemisphere; and that one reason of the higher temperature of the northern hemisphere is, that the large quantity of heat which becomes latent in the southern hemisphere in the formation of aqueous vapour is set free in the northern in great falls of rain and snow." ('Essay on Distribution of Heat,' p. 26, Eng. translation.)

TERRIER, from the French word *terrier*, a land-book, a register or survey of lands. Those best known in this country are the ecclesiastical terriers made under the provisions of the 87th canon. They consist of a detail of the temporal possessions of the church in the parish. They ought to be signed by the parson, and are sometimes also signed by the churchwardens and some of the substantial inhabitants of the parish. Their proper place of custody is the bishop's or archdeacon's registry: a copy also is frequently placed in the parish chest. If a terrier is proved to be produced from the proper custody, and therefore may be presumed to be genuine, it is in all instances evidence as against the parson. And in those instances where it has been signed by churchwardens elected by the parish or by the inhabitants, it is also evidence as against the inhabitants generally; even against those occupying lands other than the lands occupied by the inhabitants who signed it. The questions in respect of which a terrier is generally employed as evidence are those relating to the glebe, tithes, a modus, &c.

TERSTEARIN or TRISTEARIN. [STEARIC ACID.]

TERUNCIUS. [AS.]

TESSELATED PAVEMENTS. [TILES; PAVEMENTS.]

TE'SSERA, a small cube or square resembling our dice, which was used by the ancients for various purposes, and accordingly it consisted of different materials, as marble, precious stones, ivory, glass, wood, or mother-of-pearl. Such small tesseræ of different colours were used to form the mosaic floors, or pavements in houses [MOSAICS], which were hence called tesselata pavimenta. (Sueton., 'Cæsar,' 46.) The same kinds of cubes, usually made of ivory, bone, or hard wood, and marked on all their six sides, were used by the ancients as dice in games of hazard, just as in our times. In the earlier times three dice were used in a game, but afterwards only two.

The word tessera was also employed to signify any token which was given to persons by which they might recognise one another. In this case however the tesseræ were probably small tablets marked with certain signs. Thus we find mention of a *tessera hospitalis*, which strangers when forming a connection of hospitality gave to one another, that they or their children might afterwards recognise one another, and it appears that a tessera in this case was marked with the figure of Jupiter hospitalis. (Plautus, 'Poenul.,' v. 1, 25; 2, 87, &c.) Tesseræ frumentariæ, or nummariæ, were occasionally given at Rome to the poor to serve as a token or ticket, on the presentation of which they received a certain amount of corn or money. (Sueton., 'Aug.,' 40; 'Nero,' 11.) The Roman soldiers also, before they commenced a battle, received a tessera containing the watchword by which they recognised their comrades, and were enabled to distinguish them from strangers. (Virgil, 'Æn.,' vii. 637, with the note of Servius.)

TEST PAPERS. Strips of paper impregnated with certain reagents as litmus or turmeric, and used by chemists for detecting the presence of certain bodies. [TESTS, CHEMICAL.]

TESTAMENT. [WILL.]

TESTAMENT, OLD AND NEW. Some critical disputes have arisen respecting the meaning of the word *Testament*, as applied to the Canonical Scriptures. These, under the name of the two Testaments, comprise the revelations of God to man, which, being imparted under two principal conditions—the Law and the Gospel—are divided into two corresponding classes. The word translated by *covenant* is the Hebrew *berith*, so used in the first division of the sacred writings, and rendered in the latter by *diatheke* (διαθηκη). But a further notion than that conveyed by the Hebrew is contained in the Greek term (and which belongs also to the ecclesiastical Latin one, *Testamentum*, the original of the ordinary designation of the two portions of the Scriptures, the Old and New *Testaments*). No more appropriate designation than that of the New Testament can be applied to the second portion. Its application to the books of the Old was defended by St. Jerome (among other authorities of equal weight), on the ground that "Testamentum non voluntatem defunctorum sonat, sed pactum viventium." The books of the Old and New Testament are noticed at length under their respective titles; their inspiration is treated of under REVELATION: see also SCRIPTURES; BIBLE; APOCRYPHA, &c.

TESTAMENTS OF THE TWELVE PATRIARCHS, a Greek work which professes to contain the last words of the twelve patriarchs, the sons of Jacob, but which is considered to be undoubtedly spurious by all writers except Whiston, who accepts it as a part of the canon of the Old Testament; but no weight can be attached to his judgment on the matter.

The age and authorship of this work are much disputed. It is once quoted by Origen, who flourished about A.D. 230. The most probable opinion is that of Cave and Lardner, who suppose it to have been written by a Jewish convert to Christianity about the end of the 2nd century after Christ.

It appears to have been the writer's object to foist his work into the Canon, since, though he makes frequent quotations from the books of the Old Testament, he never mentions any of them by name. The only book which he quotes by name is 'the book of Enoch the Righteous.'

These testaments have been frequently published in Latin. They were first printed in Greek by Grabe in his 'Spicileg. Patr.,' and afterwards by Fabricius in his 'Cod. Pseudepigraph.,' and Whiston published an English translation of them in his 'Authentic Records.'

(Lardner's *Credibility*, part ii., c. 29, § 3, and the authorities there quoted.)

TESTE OF A WRIT. [WRIT.]

TESTIMONY. [EVIDENCE.]

TESTIMONY, PERPETUATION OF. [PERPETUATION OF TESTIMONY.]

TESTONE or TESTOON. [MONEY.]

TESTS, CHEMICAL, or Chemical Re-agents, are those substances which are employed to detect the presence of other bodies, by admixture with which they are known to produce certain changes in appearance and properties: thus, for example, as the blue colour of litmus is turned red by acids, it is considered as and used for a test to determine their presence when uncombined or in excess: so also litmus which has been reddened by an acid has its blue colour restored by the action of an alkali: reddened litmus is therefore used as a test of the presence of free or uncombined alkalies.

We give these examples from thousands which might have been selected, merely to explain the meaning of the term chemical test, observing that change of colour is one only of the many alterations adduced in proof of chemical action: thus the solubility of certain substances in some re-agents and not in others, constitutes another criterion or test of the nature of bodies.

We cannot enter particularly into this subject, for its extent is equalled only by its importance; and it is the less requisite that we should do so, since, in describing the various metals, &c., the tests of their presence are usually given with the properties of their salts. See also CHEMICAL ANALYSIS.

TE'TANUS (τέτανος, derived from τείνω, *to stretch*) is both a generic and a specific term: generically, it may be defined to be a more or less violent and rigid spasm of many or all of the muscles of voluntary motion; the name is also particularly applied (as will be seen hereafter) to one of the species of this affection. Both the disease and also its name are as old as the time of Hippocrates; and, as it is proved by experience to be much more frequent in warm climates, the ancient physicians probably had peculiar advantages in observing it, and accordingly seem to have paid particular attention to it.

"Tetanic spasms," says Aretæus ('De Caus. et Sign. Morb. Acut.,' lib. i., cap. 6, p. 6, ed. Kühn), "are attended with severe pain, and prove rapidly fatal, and by no means readily admit of relief; they make their attack on the muscles and tendons of the jaws and neck, but impart the disease to every other spot, for all parts become sympathetically affected with those which were primarily assailed. There are three forms of the convulsions: the straight, the backward, and the forward. The straight one is true *Tetanus*, when the patient is stretched straight and inflexible; the backward or forward varieties have their name from the direction and locality of the tension; hence the deflexion of the patient backwards is termed *opisthotonos* (ὀπισθότονος), from the nerves being affected in this direction; while, if the bending be forward, by the nerves in front, it is termed *emprosthotonos* (ἐμπροσθότονος), for *tonos* (τόνος) is a term which signifies both *a nerve* and *tension*."

The three forms of the disease mentioned by Aretæus are described by most of the ancient writers: the species called *trismus*, or *locked-jaw* (which is the name applied to it when the spasms are confined to the muscles of the jaw or throat), forms a fourth in modern authors; and to these has been added a fifth, under the name *pleurosthotonos* (πλευροσθότονος), which signifies that the body is drawn to one side. These different terms applied to tetanic affections do not imply so many particular diseases, but only the seat and various degrees of one and the same complaint. Trismus is invariably a part of each of the other varieties. This subdivision of the disease is of little or no practical importance; but a much more essential division is into *acute* or *chronic*, according to its greater or less intensity. The former kind is exceedingly dangerous and usually fatal; while the latter, on account of the more gradual progress of the symptoms, affords more opportunity of being successfully treated. (Larrey, in 'Mém. de Chirurgie Militaire' tome i.) Tetanus is also divided into *traumatic*, or that arising from a wound, which is also occasionally termed *symptomatic*; and into *idiopathic*, or that which proceeds from other causes.

Traumatic tetanus sometimes comes on in a surprisingly sudden manner, and quickly attains its most violent degree. The most rapidly fatal case that has ever been recorded is one that we have on the authority of the late Professor Robison of Edinburgh. It occurred in a negro, who scratched his thumb with a broken china plate, and died of tetanus a quarter of an hour after this slight injury. Most commonly, however, the approaches of the disorder are more gradual, and it slowly advances to its worst stage. In this sort of case the commencement of the disorder is announced by a sensation of stiffness about the neck, a symptom which, increasing by degrees, renders the motion of the head difficult and painful. In proportion as the rigidity of the neck becomes greater, the patient experiences in the throat a sense of dryness and soreness, and about the root of the tongue an uneasiness, soon changing into a difficulty of mastication and swallowing, which after a time become totally impossible. The attempt at deglutition is attended with convulsive efforts, especially when an endeavour is made to swallow liquids; and so great is the distress which accompanies these convulsions, that the patient becomes very reluctant to renew the trials, and occasionally refuses all nourishment; sometimes it even inspires him with a dread of the sight of water, and a great resemblance to hydrophobia is produced.

With respect to the causes of tetanus, "it must ever be regarded," says Dr. Gregory ('Theory and Practice of Med.'), "as a very singular fact in pathology, that an affection of so peculiar a character as this should have its source in causes apparently so dissimilar; that the puncture of a nerve, the laceration of a tendon, or an extensive burn, should bring on the same *kind* of nervous affection as that which is the occasional consequence of *cold*." Every description of wound, no matter how inflicted, or in what part, or in what stage, may be the occasion of tetanic symptoms which form the species denominated *traumatic*. Cases are on record wherein the patient was attacked with the disease in consequence of a bite on the finger from a tame sparrow; in which it supervened on the mere stroke of a whip-lash under the eyes, though the skin was not broken; in which it was occasioned by a small fish-bone sticking in the pharynx; by a slight solution of continuity in the external ear from a musket-shot; by the application of a seton to the thorax; by the stroke of a cane across the back of the neck; by a blow on the hand from the same instrument; by the extraction of a tooth, &c. In short, according to Sir James M'Grigor, "it occurs in every description and in every stage of wounds, from the slightest to the most formidable, from the healthy and the sloughing, from the incised and the lacerated, from the most simple and the most complicated."

Next in frequency to wounds as an exciting cause of tetanus is exposure to cold and damp; indeed there are but very few cases of true idiopathic tetanus which are referrible to any other. The irritation of worms and other disordered states of the alimentary canal have been considered by some authors as the cause of tetanic affections. To generate this form of disease, however, it would appear that a certain *predisposition* is also requisite, and it is doubtless the same with that which operates as an *accessory cause* of the traumatic tetanus. The predisposition to tetanic affections is given, in the first place, by warm climates and warm seasons. Within the tropics therefore it prevails to an extent unheard of in colder latitudes. Secondly, tetanus is chiefly observed to prevail when the atmosphere is much loaded with moisture, and particularly where this has suddenly succeeded to a long course of dry and sultry weather. Even in this country exposure to the cold and damp air of the night has occasionally been followed by an attack of tetanus. In tropical climates children are particularly subject to this complaint, and with a few peculiarities which, though producing no specific difference, have been thought sufficient to constitute a variety known by the name of *trismus nascentium*. The disease in this case is vulgarly known by the absurd name of *falling of the jaw*. It occurs chiefly between the ninth and fourteenth day after birth, and seldom after the latter period. Without any febrile accession, and often without any perceptible cause whatever, the infant sinks into an unnatural weariness and drowsiness, attended with frequent yawnings, and with a slight difficulty of moving the lower jaw. This last symptom takes place in some instances sooner, in others later, and soon increases in intensity. Even while the infant is yet able to open its mouth, there is occasionally an inability to suck or swallow. By degrees the lower jaw becomes rigid, and totally resists the introduction of food. There is no painful sensation, but the skin assumes a yellow hue, the eyes appear dull, the spasms often extend over the body, and in two or three days the disease proves mortal.

The prognosis of this disease is mainly to be determined by the nature of the exciting cause, and by the type of the seizure. Tetanus of the idiopathic kind has certainly been cured in a larger proportion of cases than that which follows external injury. The type of the disease as acute or chronic is a no less important guide as to the probable termination. It may be said that recovery in a case of acute tetanus is almost, if not altogether, hopeless: the chronic form, however, is of a much milder character. The usual termination of the disease may be stated to occur on the third or fourth day; and if the patient survives that time, there are good hopes of his recovery; it is rarely protracted beyond the eighth day. Mr. Cooper, however, mentions ('Surg. Dict.') that he had a patient (who had been wounded, and suffered amputation of the thigh) who lingered five weeks with chronic tetanus before he died.

The dissection of patients who have died of tetanus has thrown little or no light upon the real nature of the complaint, as is indeed the case in almost all spasmodic or neuralgic disorders. Sometimes slight effusions are found within the cranium, but in general no morbid appearance whatever can be detected within the head. There is always more or less of an inflammatory appearance in the œsophagus, and in the villous coat of the stomach about the cardia. These appearances, however, are common to a great number of diseases, and are uniformly met with in every case of rapid or violent death. Besides the redness and increased vascularity of these parts, Baron Larrey found the pharynx and œsophagus much contracted, and covered with a viscid reddish mucus. He also found numerous lumbrici in the bowels of several of the patients who died; but this, as Mr. Cooper remarks, could only be an accidental complication, and not a cause. In several cases Dr. M'Arthur found the intestines much inflamed; and in two of them a yellow waxy fluid, of a peculiar offensive smell, covered their internal surface; but whether the inflammation was primary, or only a consequence of the pressure of the abdominal muscles, which contract so violently in this disease, he is unable to decide. ('Med. Chir. Trans.,' vol. vii., p. 475.)

The treatment of tetanus is confessedly a subject of infinite difficulty, as the disease frequently baffles every mode of practice, and, in certain instances, gets well under the employment of the very same remedies which decidedly fail in other similar cases. Upon the whole it will probably be universally admitted that no effectual remedy for tetanus has yet been discovered, as every plan has occasionally succeeded, and every plan has still more frequently failed. An excellent abstract of the opinions of the ancients on this point is given by Mr. Adams in his Notes to Paulus Ægineta.

The general principle of cure, as Dr. Good remarks, is far more easily explained than acted upon: it is that of taking off the local irritation, wherever such exists, and of tranquillising the nervous erethism of the entire system. The former of these two objects is of great importance in the locked-jaw, or trismus, of infants; for, by removing the viscid and acrimonious meconium, or whatever other irritant is lodged in the stomach or bowels, we can sometimes effect a speedy cure without any other medicine. Castor oil is by far the best aperient on this occasion, and it may be given both by the mouth and by injections. If this, however, do not succeed, we should have recourse to powerful anodynes: of these the best is opium, which should be administered in doses of from three to five drops of the tincture, according to the age of the patient. Opium has also been more extensively resorted to in the cases of adults than almost any other remedy; and Dr. Good, Dr. Gregory, and others profess that it is that on which they place their chief, if not their only reliance. To give it a fair chance of success, we must begin its use from the earliest appearance of tetanic symptoms. It must be given in very large doses; and these doses must be repeated at such short intervals as to keep the system constantly under the influence of the remedy. It is astonishing to observe how the human body, when labouring under a tetanic disease, will resist the operation of this and other remedies, which, in its healthy state, would have been more than sufficient to overpower and destroy it. It is advisable to begin with fifty drops of laudanum, and to repeat this at intervals of two or three hours, or even oftener if the urgency of the symptoms require it, until some effect has been produced on the spasms. In the early stage of the disease we are to bear in mind the approaching closure of the jaw and difficulty of deglutition; and our remedies are accordingly to be pushed before such serious obstacles to their administration arise. When they have occurred, and are found to be insuperable, opiate enemata and frictions may be tried; but we must not anticipate much benefit from such feeble means. Such are Dr. Gregory's remarks; but Dr. Symonds considers that the employment of opium is recommended chiefly by systematic writers, and for theoretical, rather than for practical reasons; while most of those who give the results of their own experience express the greatest dissatisfaction with the remedy.

Probably a much more efficient class of remedies than the preceding is that of purgatives; both on account of the obstinate costiveness which attends the disease, and also because we have in daily practice such convincing proofs of their strong revulsive influence on diseases of the cerebro-spinal centre. The testimony of the army physicians, as we learn from the report of Sir James M'Grigor, is highly in favour of a rigid perseverance in the use of purgatives, given in adequate doses to produce daily a full effect. Dr. Forbes states that a solution of sulphate of magnesia in infusion of senna was found to answer better than any other purgative; and it was daily given in a sufficient quantity to produce a copious evacuation, which was always dark-coloured and highly offensive; and to this practice he chiefly attributes in one severe case the removal of the disease. ('Med. Chir. Trans.,' vol. vi., p. 452, quoted by Mr. Cooper.) Dr. Good condemns drastic purgatives, forgetting apparently that mild ones have no effect. Strong cathartics have indeed frequently proved of great service, and none has higher repute than croton oil.

The employment of the warm bath has been recommended by numerous writers, but it would be difficult to trace in their accounts any facts which decidedly show that its adoption was ever followed by unequivocal benefit. Cold bathing has also been advised, but it has generally been found to be worse than useless; and there are several cases upon record of almost instant death having followed its employment.

The practice of bleeding is another that has been tried, but most frequently without effect. In some few cases amputation of the limb, from the injury of which the tetanus has arisen, has been successful; but as this extreme measure is also very uncertain, it is not likely to be ever extensively adopted.

Numerous other remedies have been tried, with no, or very imperfect, success; for instance, acupuncture, strychnia, mercury, caustics, blisters, tobacco, oil of turpentine, ether, camphor, musk, bark, wine, sesqui-oxide of iron, &c., &c. However, it must, after all these have been tried, be confessed that tetanus is one of the most formidable and unmanageable of disorders, and that the recovery in the acute form still continues to be almost hopeless.

TETRACHORD, the Greek name for any part of the scale consisting of four notes, the highest of which is a perfect fourth to the lowest. Thus in the common diatonic SCALE (we assume a knowledge of this article throughout) we have the following tetrachords:—

CDEF, DEFG, EFGA, GABC, ABCD, BCDE.

We despair of giving anything like a satisfactory account of the Greek music; not that we think the difficulty lies in the Greek writers, but in the manner in which they have been treated. It was an assumption that the nation which produced models such as the moderns could not surpass in architecture, sculpture, and perhaps in painting, was to be considered as necessarily possessed of a system of music approaching to perfection. Their writers on the subject were to be taken as having an agreement with each other, which was to be detected and established, any apparent discrepancy, however evident, notwithstanding. The numerical relations which were the objects of inquiry in the settlement of the parts of the scale gave the subject the air of an exact science; and explanations which required the assistance of the scholar, the mathematician, and the musician, were undertaken by persons who were deficient in one character, if not in two. The consequence has been such a mass of confusion as the world never saw in any other subject; writers whose undertakings required them to say something, copying absolute contradictions from different other writers; others glad to adopt anything intelligible, whether true or not; others again, unable or unwilling to state the simplest facts of their own premises, so that their readers are not even made aware which of the most remarkable opposite opinions they mean to adopt.

We intend in the present article, without looking into any modern writer, to draw from Ptolemy and Euclid, writers who are known to be trustworthy on other subjects, all concerning the tetrachord that we can find to bear the character of certainty and precision, and to be likely to aid an unbiassed reader in approaching, should it please him so to do, the mass of different accounts which have been given.

All parties seem agreed that the Greek scale, which at first consisted of only two or three leading consonances, was gradually enlarged until it comprehended two octaves, or fifteen notes. It is generally stated that this scale, when it was what we now call diatonic (a word which means the same with us as with the Greeks), was minor in its character, so that in fact it would be represented by

$$A\,B\,C\,D\,E\,F\,G\,A^1B^1C^1D^1E^1F^1G^1A^1.$$

It is also known that the Greeks were early in possession of the mode of dividing a string so as to produce their several notes; and that, by the time of Ptolemy at least, they took the rapidity of the vibrations (on which they knew the pitch to depend) to be inversely as the lengths of the strings.

Their scales were numerous: three were considered classical, if we may use the word, and were called enharmonic, chromatic, and diatonic; the two first words not having the same meaning as with us. The remaining scales had names of locality attached to them, Lydian, Dorian, &c. The distinction between these lay in the different modes of dividing the octave, as seems to be now generally agreed, though there have been those who have thought that these terms, Lydian, &c., were the names, not of scales, but of single notes.

Of enharmonic, chromatic, and diatonic scales, Ptolemy lays down fifteen from his predecessors, and eight from himself. In each of them is an octave, and all of them agree in two particulars: first, each has the fourth and fifth of the fundamental note perfect; secondly, each has the tetrachord made by the fundamental note and its fourth divided in precisely the same manner as that of the fifth and the octave. That is, if we call the notes of this octave—

$$C\,P\,Q\,F\,G\,R\,S\,C^1;$$

then CF is a fourth, and CG a fifth, always; and the interval CP, PQ, QF are severally equal to the intervals GR, RS, SC^1. Thus it appears that the fourth was to the Greeks what the octave is to us, the unit, as it were, of the scale, in the subdivision of which consisted the differences of their systems. We now give a tetrachord from each of these twenty-three scales, assigning the intervals first by the ratios of the vibrations, next by the number of mean semitones they contain, as in the article SCALE. We prefix the Latin rendering of Ptolemy's appellatives from Wallis.

And first as to enharmonic scales, which are mentioned first, and seem to have been ancient, and regarded with high approbation.

	Ratio of Numbers of Vibrations in each Interval.			Mean Semitones in each Interval.		
	CP	PQ	QF	CP	PQ	QF
Archytas	5 : 4	36 : 35	28 : 27	3·86	·49	·63
Aristoxenus Eratosthenes . .	19 : 15	39 : 38	40 : 39	4·10	·44	·44
Didymus	5 : 4	31 : 30	32 : 31	3·86	·57	·55
Ptolemy	5 : 4	24 : 23	46 : 45	3·86	·74	·38

It seems then that the enharmonic system would allow only of the following notes in an octave—

$$C\,E\,P\,F\,G\,B\,Q\,C^1;$$

where P means a note about half way between E and F, and Q one half way between B and C^1. An odd scale truly for a modern musician to look at; but, it may be, not incapable of pleasing effects to ears not accustomed to music in parts.

The chromatic scales come next in order, as follows:—

	Ratio of Numbers of Vibrations in each Interval.			Mean Semitones in each Interval.		
	CP	PQ	QF	CP	PQ	QF
Archytas	32 : 27	243 : 224	28 : 27	2·94	1·41	·63
Aristoxenus, mollis Chromatica	56 : 45	29 : 28	30 : 29	3·79	·61	·58
Do., Sesquialterius Chromatica	37 : 30	77 : 74	80 : 77	3·63	·69	·66
Do., tonici Chromatica Eratosthenes . . .	6 : 5	19 : 18	20 : 19	3·16	·94	·88
Didymus	6 : 5	25 : 24	16 : 15	3·16	·71	1·12
Ptolemy, mollis Chromatica .	6 : 5	15 : 14	28 : 27	3·16	1·19	·63
Ptolemy, intensi Chromatica .	7 : 6	12 : 11	22 : 21	2·67	1·51	·80

To make something as like as we can to these scales, we should write down in modern music

C E♭ E♯ F G B♭ B♯ C^1

The diatonic scales, Ptolemy allows, are more agreeable to the ear, and his specimens are as follows: we shall now write the scale with the usual letters throughout.

	Ratio of Numbers of Vibrations in each Interval.			Mean Semitones in each Interval.		
	CD	DE	EF	CD	DE	EF
Archytas	9 : 8	8 : 7	28 : 27	2·04	2·31	·63
Aristoxenus, mollis Diatonica .	7 : 6	38 : 35	20 : 19	2·67	1·43	·88
Do., intensi Diatonica . .	17 : 15	19 : 17	20 : 19	2·17	1·93	·88
Eratosthenes* . . .	9 : 8	9 : 8	256 : 243	2·04	2·04	·90
Didymus	9 : 8	10 : 9	16 : 15	2·04	1·82	1·12
Ptolemy, mollis Diatonica .	8 : 7	10 : 9	21 : 20	2·31	1·82	·85
Do., tonici Diatonica . . .	9 : 8	8 : 7	28 : 27	2·04	2·31	·63
Do., intensi Diatonica . .	10 : 9	9 : 8	16 : 15	1·82	2·04	1·12
Do., æquabilis Diatonica . .	10 : 9	11 : 10	12 : 11	1·82	1·65	1·51

These scales have all so far the diatonic character that they divide the tetrachord into two larger intervals followed by a smaller one: the scale of Didymus would have been exactly the modern untempered diatonic scale, if he had inverted the order of the two larger intervals in his second tetrachord. As to the other modes, the Dorians, &c., there is much confusion in Ptolemy respecting them, arising from the corruptness of the text, which Wallis has endeavoured to remedy. According to him, there are divisions of the octave, somewhat more fantastic than those which precede. In more recent times the idea has been started of their being simply different keys, or rather answering to different variations of the diatonic scale, by using intermediate semitones instead of some of the notes: it would be difficult, we think, to produce authority enough for this conjecture.

If it were true, as supposed, that the two octaves of the Greek scale, beginning, say with A, were minor, it would follow that Ptolemy, in his diatonic scales, exhibited the octave from C to C^1, as we have supposed. Accordingly, the principal mode of exhibiting the formation of the octave from two tetrachords and a tone would be the one we have taken, namely,

(C D E F) (G A B C^1)

But it is frequently supposed that it was the following:—

C {D E F (G} A B C)

or the following—

A {B C D (E} F G A)

On this point we shall only say that there never was, we believe, so strong a union of the three characters of scholar, mathematician, and musician, as was seen in Dr. Smith, the author of the Harmonics. He had studied the Greek scale attentively, and to him the first of these methods was a matter of course. "The Greek musicians" ('Harmonics,' 1749, p. 45), "after dividing an octave into two-fourths, with the diazeuctic or major tone *in the middle between them*, and admitting many primes to the composition of musical ratios, subdivided the fourth into three intervals of various magnitudes placed in various orders, by which they distinguish their kinds of tetrachords."

We do not, we confess, though admitting that it is exceedingly hard, and probably impossible, to reconcile the Greek writers with themselves and each other, find that sort of difficulty which Dr. Burney owned to, when he said that he neither understood those writers himself, nor had met with any one who did. He was a musician, and was looking out for an intelligible mode of arriving at and distributing the most agreeable concords, with a strong predetermination to arrive at musical truth or nothing. But the Greek writers were arithmeticians, with as strong a determination to find natural foundations in integer numbers: they did not ask how to find sounds which would best suit the ear, but how to discover triplets of fractions which multiplied together should produce four-thirds of a unit. Pleased with the simplicity of the ratios which give the fourth, fifth, and octave, their efforts at musical improvement were confined to the attempt at discovering magic numbers to fill up the intervals. It was not until one of these philosophers had laboured at his abacus, and tasked his metaphysics to find *à priori* confirmation of some question in arithmetic, that he strung his monochord and tried how his scale sounded: it would have been hard indeed if his ear had refused to sympathise with his brain. In all probability the musicians, whose object was simply to please, laughed at the arithmeticians, as Tycho Brahé did at Kepler, when the latter had discovered reason for the distances of the planets in the properties of solid bodies: they had motive enough, and, beyond all question, reason more than enough.

TETRAGON (properly a four-angled figure), a term usually applied to the square only, when used, which it seldom is. [REGULAR FIGURES.]

TETRAHEDRON (a solid of four faces), a term usually applied to the regular tetrahedron. [REGULAR FIGURES.]

TETRAMETHYLAMMONIUM. [ORGANIC BASES, *Methylamine.*]

* This is also Ptolemy's Ditonici Diatonica.

TETRAMYLAMMONIUM. [ORGANIC BASES.]

TETRARCH (τετράρχης), from two Greek words, signifying *four* and *to govern*, a title used by the Greeks at a very early period to describe the ruler of each part of a country which was divided into four parts, either on account of its occupation by different tribes, or merely as a political division. Each of such four parts was called a tetrarchy (τετραρχία or τετραδαρχία). In process of time the title came to be applied to the rulers of different divisions of the same country, or to the chiefs of different tribes inhabiting the same country, without any reference to the number four. In this sense it was equivalent to the titles *ethnarch* and *phylarch*. Under the Roman government, in the later ages of the republic and under the emperors, there were several such petty princes, independent of each other, but tributary to Rome. These *tetrarchs*, *ethnarchs*, or *phylarchs*, were either the legitimate governors of their subjects, or persons who had received the title and government from Rome as a mark of honour. They ranked below those other subject princes who were permitted to retain the title of king.

The principal examples of tetrarchies are those of Thessaly, which was anciently so divided, and the division was again made by Philip, the father of Alexander the Great: of Galatia, which was peopled by three Gallic tribes, each of which was divided into four tetrarchies: of Syria, many of the petty princes of which bore the title of tetrarchs, especially certain princes of the family of Herod the Great. Concerning the tetrarchs of Syria, see Niebuhr's 'History of Rome,' ii., pp. 134-5.

TETRATHIONIC ACID. [SULPHUR.]

TETRETHYLAMMONIUM. [ORGANIC BASES.]

TETRYL. [BUTYL.]

TETRYLAMINE. Synonymous with *butylamine*. [BUTYL.]

TETRYLENE. *Butylene*. [BUTYL.]

TETRYLHYDROSULPHURIC ACID. Synonymous with hydrosulphate of butyl. [BUTYL.]

TETRYLSULPHURIC ACID. *Sulphobutylic Acid*. [BUTYL.]

TEUTONIC NATIONS is the general name under which are comprised the different nations of the Teutonic race. These are divided into three branches. The first branch contains the High Germans, to whom belong the Teutonic inhabitants of Upper and Middle Germany, those of Switzerland, and the greater part of the Germans of Hungary; it is subdivided into the Suabian and the Franconian minor branches. The second is the Saxon branch, which is divided into three minor branches: the first of which contains the Frisians; the second, the Old Saxons or Low Germans, with the Dutch, the Flemings, and the Saxons of Transylvania; and the third, the English, the Scotch, and the greater part of the inhabitants of the United States of North America. The third branch is the Scandinavian, to which belong the Icelanders, the Norwegians, the Danes, and the Swedes. It has been estimated, but on no very exact data, that nearly 100,000,000 individuals belong to the Teutonic race. The Germans amount to above 42,000,000, 33,000,000 of which live in Germany, the remaining 9,000,000 form a greater or less part of the population of East Prussia, of Switzerland, of Hungary, of Transylvania, of France, (in Alsace and north-east Lorraine), of Russia (in the Baltic provinces, in the kingdom of Poland, in the Crimea, in Bessarabia, and in the German colonies in the environs of Saratov on the Volga), of the duchy of Sleswig, and of the United States of North America, especially Pennsylvania. The English amount to about 33,000,000, there being about 18,000,000 of English and Scotch in Great Britain and Ireland, nearly 3,000,000 in the English colonies, and 11,000,000 or 12,000,000 of Anglo-Americans in the United States. The number of the Frisians is about 130,000, in the province of West Friesland in Holland, in the islands in the German Ocean along the Dutch and the German shore, in the Saterland (near Oldenburg), and in the islands along the west coast of the duchy of Sleswig. There are about 3,000,000 of Dutchmen in Holland and in her colonies and the Cape of Good Hope; and there are about 2,500,000 Flemings in the north part of Belgium, in the south part of Holland, and in the north-east part of France. The number of individuals belonging to the Scandinavian branch amounts to at least 6,000,000, among whom there are—50,000 Icelanders; 1,500,000 Danes in Denmark, in her colonies, and in the north part of the duchy of Sleswig; 1,250,000 Norwegians; and about 3,200,000 Swedes in Sweden and in the present Russian province of Finland, especially along the coast of the Gulf of Bothnia, in the districts of Abo and Nyland, and on the Aland Islands, which are entirely inhabited by Swedes.

Light hair and blue eyes in the northern countries, and brown hair and brown or blue eyes in some of the southern countries, are characteristics of the Teutonic race. Their stature is generally tall, although in those provinces where the Germans are mixed with Wends, Suabians, and Bohemians, many of the people have the broad shoulders and the short square form of the north-western Slavonians. The straight black hair of some Slavonian tribes also sometimes appears. The mixture of Germans with the south-west Slavonians, such as Wends and Croatians, whose stature exceeds that of the Wends and Bohemians, is more difficult to be distinguished, the black straight hair and a darker complexion being almost the only indication of such a mixture. The mixture of Germans with Celts in Belgium and in the adjoining part of France has formed a tall race which differs from their Teutonic neighbours only in the dark colour of their hair and their black eyes. (Plató, 'Scenen aus dem Volksleben in Belgien.')

It is very difficult to distinguish the descendants of English and Irish parents as belonging either to the Teutonic or the Celtic race, though it appears that wherever aquiline noses are seen among the lower classes they are a proof of Celtic origin, the true Teutonic nose not being aquiline, but either straight or curved only in its upper part. In general, also, the Teutonic forehead is broader between the temples than the Celtic. (Clement, 'Die Nordgermanische Welt;' Herder, 'Ideen zur Philosophie der Geschichte,' vol. i.)

The moral and intellectual difference between the Teutonic nations is less remarkable than that which exists between other European nations of the same race with one another. Capable of strong and violent passions, they do not easily lose their self-control, the intellectual functions being more developed than in most other races. Southern nations, confounding liveliness of feeling with intensity, and nervous excitability with moral sensibility, have been deceived by the cool character of the Teutonic nations, and have accused them of indifference. But the most superficial examination will show their sensibility—a fact which is proved by their poetry. The Teutonic nations are less excitable than the Celtic, the Slavonian, and other races, but capable of deeper thought. Southern nations have accomplished great things by sudden efforts; the Teutonic nations have reserved their enterprise for vast plans, which it requires centuries to carry into effect. Thus they destroyed the Roman empire after a struggle of three centuries, and they formed new kingdoms in Europe upon new social principles, which have maintained their vigour to the present day. The Normans became powerful wherever the sea permitted them to effect a landing. The Germans, diminished in number after they had sent their swarms to Western Europe, turned back towards the east part of their country, then occupied by Slavonian nations, which they conquered, and Germanised upon a plan of colonisation which enabled them to civilise the east of Europe. And lastly, the English colonies have spread over the world: their dominion in the east and in the west is the result of plans which imply more boldness of conception, more prudence in execution, and more reflection, than the conquests of Alexander the Great and the ephemeral power of Napoleon.

The same character of deep and patient reflection exercised on great objects appears in German philosophy and in the inventions of the Teutonic nations. The watch, the gun, and the art of printing are Teutonic inventions. They have subjugated the power of steam; and the first model of the modern sea-vessel was constructed at the mouth of the Eider by the hands of an old Saxon or Frisian ship-builder. (Clement, *ibid.*)

The name of the Teutones was made known to the ancients by Pytheas of Massilia (Marseille), who, in the age of Alexander the Great, about 320 B.C., discovered a nation of that name in the Chersonesus Cimbrica, and on the adjacent islands, or in the present countries of Holstein, Sleswig, Denmark, and perhaps also in the southern extremity of Sweden. It seems that they had long been settled there, for they lived in houses, and were acquainted with agriculture and commerce. Other traces of the name appear later. Among the Celtic tribes which invaded Greece and besieged Delphi under the second Brennus (278 B.C.), there was a people called Teutobodiaci, who afterwards passed the Hellespont and settled with the Celts in Galatia, in Asia Minor. About 160 years later, the Romans were attacked by the Cimbri and Teutones, who came from the same country, where they had been seen by Pytheas. The Teutonic origin of the Cimbri has been disputed: some historians consider them identical with the Celtic Cymri, but this error has been long since refuted, although it has been reproduced in our days by Thierry, in his 'Histoire des Gaulois.' It is said, and it is not improbable, that inundations of the sea compelled the Teutones and their neighbours the Cimbri to leave their country and to seek other abodes. The choice was soon made. The wealth of Rome and the arts of Greece were not unknown to them. From the most remote times adventurous merchants, starting from the shores of the Black Sea, followed the course of the Dnieper towards its sources, and reaching the Düna and the Niemen, descended these rivers to their mouths in the Baltic, where they exchanged the commodities of the south for amber, the electrum of the ancients. The same trade, as it seems, was carried on by the merchants of Massilia along the Rhône and the Rhine, and therefore Schlözer, in his 'Nordische Geschichte,' says that but for the amber Germany would have remained unknown to the ancients for five centuries more. Their acquaintance with Rome and Massilia was perhaps the principal cause which led the Cimbri and the Teutones to the south of France and to Italy (B.C. 113–99). Their destruction by Marius has been related. [MARIUS, in BIOG. DIV.; CIMBRI.]

When the Romans first heard the name of the Teutones, they thought that they were a single tribe. They did not know that it was also the general and ethnographic name of all those nations to which they afterwards gave the vague designation of Germans.

Origin of the name Teutones.—The root of the word Teuton is *thu* or *do*, which originally represented the idea of "activity," of "living, procreating, nourishing," and also of "taming, educating, and ruling." From this root are formed the following words, some of which are still used in the popular dialects:—*Teut*, god, creator, ruler, father, nourisher (*Thor, Tuisco*); *thut* or *thiud*, earth; *tott döte, dote*, godfather; *toda*, nurse; *thiod*, father of the people, lord, ruler, king, in Gothic *thiudans*, in old Bavarian *theodo*; *diet*, people, in old Swedish, *thiaut* and *thyd*; *thiudinassus*, in Gothic, kingdom. (Fulda, 'Wurzel-Wörterbuch.') The idea of ruling, expressed by the root *Teut*, explains why this word occurs so frequently in the names of the ancient Teutonic kings, dukes, or chiefs, such as Teutoboch, Theudorix, Diorix, Theodorix, Theodoric, Theodomir, Theodimir, Teutagon, &c. It is likewise contained in the general name of all the Teutonic nations, and in those of various tribes, as the Teutones, the Teutonoarii, Thaifali, and the Dithmarses or Dietmarses. *Teuton* is identical with *Deutsche* or *Teutsche* (in Low German, *Dütsch*; in Dutch, *Duitsch*; in Danish, *Tysk*; in English, *Dutch*), which from the remotest time has been and is still the general name of that part of the Teutonic nations which we now call Germans, who considered the god or hero Tuisco as their common ancestor. There are no direct proofs of the word Teuton having had this extensive meaning in the earliest German history, but this is perhaps the result of the political state of the Teutonic nations, which were originally divided into numerous tribes, each of which became separately known to the Romans.

Origin of the Teutonic Nations.—The Teutonic race is originally from Asia. The Teutones immigrated into Europe at different periods unknown to history, although it appears that the last of them entered Europe during the migration of nations in the 4th and 5th centuries. Some account of their Asiatic origin is given in their ancient national songs, principally in the Sagas of the Scandinavians. It is also said that Benedict Goesius (Goez), a Jesuit, found in 1603, in the mountains of the Hindu Kush, north-east of Cabul, a people with fair hair like the Dutch, and who are perhaps identical with that tribe of which Pliny speaks, and which was settled in the Montes Emodi. But all this is of little value, unless it is corroborated by other facts. Such facts have been furnished by the learned philologists of our age, especially by Friedrich von Schlegel, Adelung, Bopp, Grimm, and Hammer-Purgstall. A comparison of the Teutonic languages with the Persian, the Zend, and the Sanskrit, has shown the relationship which exists among these languages [LANGUAGE; SANSKRIT LANGUAGE and LITERATURE], and by means of these facts, the Mythes and Sagas become important for history.

When the Teutonic nations appeared in history, they were divided into many bodies or confederations of tribes, such as, at a later period, the Franks, the Suevi, the Saxons, the Marcomanni, and the Alemanni. Long before these names were known, there was a similar confederation of tribes which came from the north-north-east and conquered the countries on the left bank of the Rhine, then inhabited by Celtic nations, which fled to their brethren in Central Gaul. The epoch of this invasion is not known, but the event happened a long time before the age of Cæsar, who found those countries settled by a Teutonic population. Tribes of the Condrusi, the Eburones, the Caeraesi, and the Paemani, were united in a confederation, and had adopted the name of Germani, or "war-like men." This name was gradually used by the Romans to designate other nations which belonged to the Teutonic race (Tacitus, 'Germ.,' c. 2), and subsequently it was adopted by the English as a name for the "Deutsche," while this very name, changed into Dutch, now designates the inhabitants of Holland.

The Teutonic Nations after Cæsar.—When Cæsar reached the Rhine, Northern Germany, Holland, Belgium, and a part of the countries on the Middle Rhine were inhabited by Teutonic nations which belonged to the northern, now Saxon, branch. They had been settled in fixed habitations for several centuries, and they must be considered as the first of this race which settled in Germany. The southern part of this country was then inhabited by Celts and Rhaetians, except the tract between the Upper Rhine and the Upper Danube, which was conquered by the Suevi, who belonged to the Teutonic race. The word "Suevi," which comes from "schweifen," may be translated "wanderers," or people who rambled about for the purpose of settling in any convenient country. It was adopted by a great number of tribes, the majority of which belonged to the High Germans, and came from the countries on the Baltic between the Oder and the Niemen. Cæsar was obliged to fight with their leader Ariovistus (B.C. 58), who had invaded Gaul. Ariovistus was compelled to go back to Germany.

Tacitus divides the Germani into three great bodies: the Ingaevones, in the north; the Istaevones, in the west, from the mouths of the Rhine upwards to Basel; and the Hermiones, in Middle Germany and towards the north-east. This division seems to have an ethnographic and still more a political value. The position of the Ingaevones corresponds to that of the later Saxons, and both the names have one meaning, Saxon signifying a settled people, and In-gae-vones a people who live in a cultivated country divided into districts (In-gau-wohner or Inwohner). The Istaevones, or Western Germani (West-wohner), correspond to the later Franks, and the Hermiones to the Suevi, including the Alemanni. Further, the name of Hermiones is undoubtedly identical with Hermunduri, one of the greatest Suevian or High-German tribes, the name of which is generally supposed to be the same with Doringi or Thuringi, the present Thuringians.

From the time when Cæsar first met with the Suevi under Ariovistus, there was a deadly enmity between the Romans and the Germans. The Romans wished to make Germany into a province, and the Germans aimed at the possession of Gaul: on both sides there was the passion of conquest and the necessity of self-defence. Ambition pushed the Romans into Germany, and want of fertile lands, and perhaps some great revolution among the nations of Eastern Europe, led the Germans into Gaul and Italy. The Roman eagles were seen in the wilds of the Hercynian forest, but Arminius saved his nation from slavery in the forest of Teutoburg, in Detmold, where Varus was slain with three legions (A.D. 9). The campaign of Germanicus, who advanced as far as the Elbe, led to no results, though he gained a complete victory over the Germans on the field of Idistavisus near the Weser (A.D. 16); when he celebrated his triumph in Rome (A.D. 17), the Germans between the Rhine and the Weser were as free as before. These tribes made a confederation, and chose Arminius for their leader. A war arose between him and Maroboduus, king of the Marcomanni, who was defeated and obliged to implore the assistance of the Romans (A.D. 19). Being attacked by Catwald, or Catualdus, the chief of the Gothones, he lost his crown, and the confederation of the Marcomanni was broken. Arminius, the hero of Germany, fell by the hands of his jealous kinsmen, in his thirty-seventh year. (Tacitus, 'Annal.,' ii. 88.)

Notwithstanding the civil wars in Germany, the Romans gave up the idea of conquering the country, and Tiberius ordered a defensive system to be observed on the frontiers, which were formed by the Rhine from its mouths to the Moselle, and from the junction of this river with the Rhine they followed the Lahn as far as the present district of Wetterau. The frontier then took a southern direction, passed the Main at Obernburg, the Jagst at Jagsthausen, the Kocher at Hall, and joined the Danube near Pföring, from which town it ran along the Danube as far as Pannonia. The rivers were defended by castles, and the tracts between them by a strong rampart with towers, the Vallum Romanum of Hadrianus, a considerable part of which, the Pfahlgraben, is still visible. The Germans west and south of this barrier became Roman subjects, but those who lived east and north of it enjoyed their ancient liberty.

All the German tribes practised agriculture, but warfare being their favourite occupation, they abandoned their fields and their flocks to the care of bondsmen. The fine arts were not exercised among the Germans, but they were acquainted with the art of writing [RUNES], although only for religious purposes. (Rhabanus Maurus, in Goldast, 'Script. Rer. Alem.,' ii. 1; Hickesius, 'Thes. Ling. Septentr.') The groundwork of their social and political constitution was the union of a certain number of families into a community, "Marcha," "erdmarcha," now "Mark-Genossenschaft." Mr. Kemble, in his 'Saxons in England,' has shown the prevalence and the importance of the divisional mark in England. Several marchas formed a "gow," now "gau," a district which had its own administration. Twice a month, and sometimes every week, the members of a gow assembled and held the "gowding;" the gowdings were civil and criminal courts, and also meetings for legislation, and war and peace were decided on in them. Besides the gowdings there were "graven" or "greven" (graviones, comites), or delegates of the gowding, who were assisted in their judiciary functions by a certain number of freemen. The magistrates were chosen from the nobles (edelings or adelings), the "principes" of Tacitus, who had also the right of forming a kind of senate, where they deliberated on important affairs previously to their being brought before the gowding, and they despatched matters of little importance, which did not come before the gowding. The nobles had also the privilege of keeping a "dienst-gefolge," or a band of freemen who served them in their feuds and wars; and they had individually the right of protecting unfree people in the gowding, a right which also belonged to the community as a body, but not to individual freemen. The privileges of the nobles were probably connected with the religious institutions, of which we have no positive knowledge, although it appears that priests and nobles formed only one class, an opinion which is corroborated by the fact that wherever Christianity was introduced into Germany, it met with no opposition from the common people as soon as the nobles were converted. Some of the earlier Teutonic nations had hereditary kings, the "reges" of Tacitus, who however had a very limited authority. The greater part of them chose princes only as commanders of the army in time of war. The name of these commanders was "herzog," in low German "hertog," or "hartog," in Latin "dux."

Besides the freemen and the nobles, there were bondsmen, "lazzi," "lati," or "liti," now "leute;" in low German "lüde," or "lide;" who were either the primitive inhabitants of a conquered territory, or prisoners of war, or freemen who had lost or sold their liberty. Their condition was in no way like that of the Roman servi, who, legally speaking, were not considered as persons, but in most respects things. Domestic and personal services, and especially agriculture, were their exclusive occupations.

The military organisation of the Teutonic nations was founded on two principles. When a gow, or a confederation of several gows, determined on war, every freeman was obliged to take up arms for the defence of the commonwealth. But war was sometimes made for the private interest of some powerful noble, who carried it on with his "dienst-gefolge," which was a numerous body when the military renown of the chiefs, or the hope of easy conquests, promised rich rewards to the adventurous band.

We know little about the religion of the ancient Teutonic nations. They worshipped a supreme being under the name of Woden or Odin, but the true character of their religion was the worship of Nature in her different manifestations. Thor, Hertha, and Freya were personifications of the power of heaven, of earth, and of love and procreation. [SCANDINAVIAN MYTHOLOGY.]

Such was the moral, social, and political state of the Teutonic nations when they began their wars with Rome. The Vallum Romanum prevented them from invading the Roman empire during the 1st and 2nd centuries. In the 3d century they often crossed it. In the 4th they conquered a considerable part of the countries on the Danube; and in the 5th they invaded and conquered all the European provinces of the Roman empire.

Alemanni. [ALEMANNI, in the GEOG. DIV., under which head the political history will be found.]—The *Lex Alemannorum* was revised in the time of Dagobert, king of the Franks, and again by Lantfried, the Frankish duke of Alemannia, in the beginning of the 8th century. There is no trace of the Roman law in it except in one single case (tit. 80). The Lex Alemannorum, as well as all the other earlier codes of the Teutonic nations, are contained in Ferdinand Walter's 'Corpus Juris Germanici.' Sichard published an edition of it in the 'Leges Ripuariorum, Bajuvariorum, et Alemannorum,' 1530, 8vo. Besides these collections, the Teutonic laws are in the collections of Herold, Lindenbrog, Eccard, Heineccius, Georgish, Canciani, and Baluzius.

Burgundians. [BURGUNDIANS, KINGS OF THE, in BIOG. DIV.]—The Burgundians came from north-east Germany, and first assisted the Alemanni against the Romans; but they left Germany as early as the beginning of the 5th century, penetrated into Gaul, and formed the powerful kingdom of Burgundy on both sides of the Jura, which was incorporated with the kingdom of the Franks in 534. The collection of the Burgundian laws, Lex Burgundionum, 'Gundobada,' 'Gundobarda,' 'Loi Gombette,' was made towards the end of the 5th century, under king Gundobald, who died in 516, and was augmented (517) by king Siegmund, who died in 523. The legislation of Gundobald goes as far as title 42. The following titles, although they contain laws and regulations of Gundobald, were added by Siegmund, who completed the code by two "additamenta," containing his own laws. Charlemagne made a third additamentum, without altering the code itself. The Lex Burgundionum, which is written in much purer Latin than most of the other Teutonic codes, contains several of the rules of the Roman law concerning donations, and especially testaments (tit. 43 and 60). A separate edition was published at Lyon in 1611.

Franks. [FRANCE, in the GEOG. DIV., gives the political history of the Franks.]—In the very countries which the Romans traversed on their way to the woods where Varus was slain, the Usipetes, the Tencteri, the Sicambri, the Bructeri, the Ansibarii, the Marsi, the Tubantes, the Chamavi, and the Chatti—all tribes belonging to the northern, now Saxon branch (Ingaevones) of the Germani—formed a confederation and called themselves Franks, either because they were particularly "free and bold," or on account of their "barbed lances" (frameæ). The Franks were divided into Franci Salici, who lived in the Low Countries between the Zuider Zee, the Maas, and the Somme; and Franci Ripuarii, who were settled along the Rhine between Nymegen and Bonn. Each of them had their code. The *Lex Salica* was written in very barbarous Latin, under Clovis, between 484 and 496, and was never revised, although it contains some laws by the sons of Clovis, which begin with the 62nd (63rd) title. Except one rule in title 14, about the rape of free persons, and another concerning marriage within the prohibited degrees, this code contains no trace of the Roman law. It is very important for the history of the laws of the Teutonic nations. The ancient Lex Salica is often confounded with the present Salic Law, which regulates the right of succession in several sovereign and noble families in Europe. But this latter Salic law is only a single rule of the *Lex Salica*, and originally concerned the succession to the tax-free estates of free or noble Franks (*terra Salica*), which belonged to the male issue, to the exclusion of females. It is contained in title 62, 'De Alode,' l. 6: "De terra vero Salica nulla portio haereditatis mulieri veniat: sed ad virilem sexum tota terrae haereditas perveniat."

This law was not peculiar to the Franci Salici: it occurs in the greater part of the other ancient Teutonic laws. (Wiarda, 'Geschichte und Auslegung des Salischen Gesetzes;' Heineccius, 'Ant. Germ.', i., p. 265, 285; a separate edition of the Lex Salica was published by Pithou, Paris, 1602, 8vo.) The *Lex Ripuaria* was collected by Theodoric, the son of Clovis, between 511 and 534. It was several times revised, especially by Dagobert. It resembles the Lex Salica, and contains no traces of the Roman law.

Goths. [GOTHS, GOTHI, GOTHONES, for the history.]—The Code of the Ostro-Goths, 'the Edictum Theodorici,' which was composed by order of Theodoric in 500, is a collection of Roman laws. This king wished to form one people of the Romans and the Goths ('Edictum,' § 30), and he therefore adopted the laws of the most civilised of his subjects. Leaving the Gothic laws exclusively to the memory of the people, he knew that they would soon fall into oblivion without being formally abolished. In some cases, however, he supplanted Gothic customs by Roman laws. The *Wehrgeld*, or *Wehre*, —that is, the fine for crimes,—was entirely abolished, and in place of it the punishment of death was introduced in many cases, an innovation which seemed very hard to the Goths, who, like all the other Teutonic nations, inflicted the punishment of death only for high treason and a few such crimes. Pithou published a separate edition of the 'Edictum Theodorici' (Paris, 1579). Rhon, 'Commentatio ad Edictum Theodorici, Reg. Ostrogoth.', Halae, 1816, 4to.

The *Visi-Goths* settled in the southern part of Gaul in 412, and invaded Spain in 414. This country was then in the hands of the Suevi, the Alani, and the Vandals, who became subject to the Goths, or were forced to emigrate. In 451 the Visi-Goths, together with the Franks, defeated Attila and his 700,000 Huns, Goths, Gepidae, and other vassals, in the plain of Châlons-sur-Marne. Their king, Alaric II., lost Gaul, except the eastern part of Languedoc and Provence, in the battle of Vouglé against Clovis, king of the Franks, in 507. The kingdom of the Visi-Goths lasted for three centuries, when it was overthrown by the Arabs in 712.

Among all the Teutonic nations the Visi-Goths were the first who had written laws. (Isidorus Hispalensis, 'Chron. ad annum Aer. Hisp. 504, A.D. 466.') A collection of them was made by their king Euric (466-484), which is written in Latin and has the title of 'Lex Visigothorum.' Its present form dates from king Egica, whose new code was translated into the Gothic language under King Receswind. It contains many traces of the Roman law, and is the only early Teutonic law which may be considered as a code in the modern signification of the word. The Lex Visigothorum must not be confounded with the Breviarium Alarici (Alaric II., in 506), or the Code for the Romans, who were subjects of the Visi-Goths, and continued to live under their own laws until they were abolished by the kings Chindaswind and Receswind, who declared the revised Lex Visigothorum obligatory on all the inhabitants of the kingdom of the Visi-Goths.

The Goths, the most civilised among the Teutonic nations, were the first who adopted the Christian religion. They had a literature from the time when Ulphilas translated the Bible. The Ostro-Goths soon disappeared among the Longobards, while the Visi-Goths preserved their language and nationality till the invasion of the Arabs; and another portion of them maintained their nationality until a very recent period.

These were the *Gothi-Tetraxitae*, who, after the emigration of their brethren to the western countries, retired to the eastern part of the Chersonesus Taurica, now the Crimea, and the opposite island of Taman. There they lived for eleven centuries under the successive dominion of Huns, Bulgarians, Greeks, Khazars, Tartars of Kiptshak, and Tartars of the Crimea, and, lastly, of Turks Osmanlis. Their part of the Crimea was called Gothia during the middle ages. Busbequius, who was the ambassador of the emperor Rudolph II. at Constantinople, towards the end of the 16th century, is the last writer who mentions them. It appears that they afterwards adopted the language, the customs, and the religion of the Tartars. Russian scholars have traced the Gothic language among the Tartars of the Crimea. ('Journal de St. Pétersbourg,' 1829.)

Another part of the Goths invaded Sweden, and founded the kingdom of Gothland (Gautland), which was afterwards divided into East Gothland and West Gothland (Eystra-Gautland and Vestra-Gautland). They mixed with the Scandinavians, and it became a general opinion that they were originally the same people. But a comparison of the Gothic of Ulphilas and the old Scandinavian language shows that this opinion is unfounded. (Olaus Verelius, 'Gothici et Rolfi Westrogothiae Regum Historia,' Upsalis, 1664; Antonius, 'Bibl. Hisp. Vet.', i.; Michael Geddes, 'Miscellaneous Tracts,' vol. ii. diss. 1; vol. iii., diss. 1; 'Manso, 'Geschichte des Ostgothischen Reichs in Italien;' Mascov, cited below, ii.)

Suevi.—From the country east of the Black Forest, between the Upper Danube and the Alps, the Suevi, by which name the Quadi and the Hermunduri were perhaps likewise meant, spread over Gaul and forced their way into Spain (406-409). Their king Hermanaric or Hermanrich became master of Portugal, Galicia, and the western parts of Asturias, and Leon: he resided at Bretonia, near the mouth of the Miño, now a small village named Bretaña. His successors were independent kings, but in 585 the Suevi became subjects of Leovigild, king of the Visi-Goths. Their laws have not been collected. They were at first Catholics, but king Remismund (461) professed Arianism; Theodemir (Ariamir) returned to the Catholic faith in 561.

Vandals.—This name, which was known to Tacitus, comprises various tribes of Teutonic and also of Slavonian origin, who lived in Eastern Prussia and Pomerania. The Slavonian tribes were subject to the Teutonic Vandals, who are often confounded with the Wends (Venedi), who afterwards occupied the country of the Vandals. The Vandals left their homes towards the end of the 4th century, and a part of them, after a sojourn in Pannonia, traversed Germany and Gaul, and founded the Vandal kingdom in Spain in 409. In 417 they subjugated the Alani, who had also settled in Spain. In 429 they were forced by the Visi-Goths to abandon this country, and they went over to Africa. Their king Genseric or Geiseric took Carthage (439), all Mauritania, and the islands of Sardinia, Corsica, the Baleares, and the western part of Sicily. On the 12th July, 455, they plundered Rome, and their name became proverbial as that of the most barbarous among the barbarians. Their kingdom lasted till 535, when it was destroyed by Belisarius, and became a part of the Byzantine empire. All the names of the Vandal kings are Teutonic, and resemble those of the Gothic kings, a fact which proves that however numerous the

Slavonians were among them, the Teutonic tribes were the ruling nation. Their name is visible in that of the province of Andalusia or Vandalusia. (Papencordt, 'Geschichte der Vandalen.)

Longobards. [LOMBARDO-VENETIAN KINGDOM, in GEOG. DIV., col. 578.]—The Longobards lived on the right bank of the Lower Elbe, and afterwards on the left side of this river, near Lüneburg and Brunswick: in language and person they resembled their neighbours the Saxons, a strong body of whom appeared with them in Italy. Before they invaded Italy they had lived in the present country of Upper Hungary, in Pannonia, and in Noricum (494–568). Their king Alboin subjugated the Gepidæ in Transylvania (563?), and in 568 he conquered the greater part of Italy. Their last national king, Desiderius, was deprived of his throne by Charlemagne (774), who assumed the title of king of the Longobards: but the Longobards neither lost their constitution nor their estates; the only change was in the reigning dynasty.

When the Longobards were subjugated by the Franks, they had possessed written laws for 130 years. The first collection was made by king Rotharis in 643. The laws of Grimoald were collected in 668, those of Luitprand between 713 and 724; those of Rachis in 746, and those of Aistulf in 754. They contain only a few heads of Roman law concerning prescription and succession. (Muratori, 'Script. Rer. Ital.,' tom. i.; and especially Biener, 'De Origine et Progressu Legum Jurumque Germanicorum,' i.)

These are the Teutonic nations that founded permanent kingdoms within the limits of the Roman empire. Except the Alemanni, they all came in contact with a population the educated part of which was entirely Romanised, although, except Italy and some parts of the south of Spain and Gaul, the inhabitants of the villages were still Celts or Iberians when they were subjugated by the Teutonic invaders. (Fauriel, 'Hist. de la Gaule Méridionale,' vol. i.) The political institutions of the new masters of the civilised world rested on two great principles.

The Teutonic laws were not territorial, as they now are, but personal: a Frank was judged after the Frankish law, a Burgundian after the Burgundian, wherever he lived. This principle being applied also to the Romans, gave rise to a double legislation, one for the ruling Teutonic nation, and the other for the subject Romans. The second principle was that the sovereignty belonged to the body of the conquerors, and not exclusively to their kings. This sovereignty not only comprised the supreme authority in legislation and administration, but it was considered as comprehending a right to the private landed property of the vanquished nation. Every free Frank or Goth became the master of a considerable portion of land which he took from the Romans. The rights and duties of the kings towards their Teutonic fellow-conquerors remained the same as before; the kings had no right to punish any freeman, unless in time of war and for neglect of military duties. The freemen also could not be forced to serve in any war to which they had not given their consent; and they did not pay any taxes to their kings, who were only the first among their equals. As to the subject Romans, the Teutonic kings became the lords of a numerous civilised nation: as successors to the rights of the Roman emperors, and with regard to the Romans, they had absolute power, and they became proprietors of the extensive private estates of the emperors. They maintained the provincial administration, which was established by Constantine the Great and his successors, but they often conferred various functions on one person in order to render that complicated administration more easy to manage. As the conquerors lived among the subject people, each province had a double administration, one for the ruling nation and the other for the subject nation. But there resulted so much confusion from this circumstance, that the kings were obliged, especially in Gaul, to sacrifice the principles of the Roman administration, and to govern in the Teutonic way, although the names of the higher public functions were Roman. The first functionary in each province in the Frankish kingdom was the Dux, who had the supreme military command, and sometimes also the authority of a judge. The second was the Comes, who was chief judge and director of all affairs concerning taxes and the revenue of the fiscus. From the 8th century the functions of the Dux and the Comes were conferred upon one person, who is sometimes styled Dux, and sometimes Comes.

The fate of the Romans in the Frankish empire was threefold. One part of the Romans entered into the private service of the king, and preserved a portion of their estates on condition of obedience to him. The great landowners belonged to this class, which had the name of "Romani convivæ regis." A second part, the "Romani possessores," remained in possession of their lands, but they were obliged to pay taxes for them, a duty from which the conquerors were exempt: this class principally consisted of small landowners. The third class were the "Romani tributarii," who lost their liberty, although they did not become Servi in the Roman sense of the word: these were the ancient "coloni." In many towns the Romans continued to enjoy their municipal institutions, while a Teutonic community gradually arose within the same walls, and had its separate constitution. In other towns the richest among the Romans lost their liberty and became "ministeriales," a kind of privileged vassals; but the poor were treated as the Romani tributarii in the villages.

The Teutonic nations which became subject to the Frankish kings were treated with less severity. The Burgundians, the Longobards, and the Bavarians only changed their dynasty, but the greater part of the Thuringians and of the Alemanni lost a considerable portion of their lands, which were given to Frankish nobles, of whom they became vassals.

Besides those nations which founded permanent kingdoms within the Roman empire, many tribes maintained their independence there only for a short period, or came and went rapidly without leaving further traces, or were subjugated by others, and adopted the names of their vanquishers. Many among them were of Slavonian or other origin.

The *Alani* came from the Caucasus, traversed Europe, and lived independent in southern Spain under their king Respendial, from 409 to 417, when they were subjugated by the Visi-Goths and carried into the south of Gaul. Another part of them settled between Orleans and Nantes under their chief Goar (406), but in 452 they were defeated and dispersed by the Visi-Goths. The Alani were not of Teutonic origin; the names of their kings (Respendial, Utaces, Goar) have no resemblance to Saxon, Frankish, or Gothic names. They are probably identical with the Ossetes, an old Persian tribe in the central part of the Caucasus. The country of Albania, north of the Caucasus, was known to the Greeks and Romans. The Byzantines called the tract between the Terek and Shirwan, Alania. (Procopius, 'De Bello Goth.,' l. iv.; Stritter, 'Memoriæ Populor,'—Alania, in tom. iv.; Suhm, 'Geschichte der Dänen,' übersetzt von Gräter, i. 1; Zeuss, 'Urgeschichte der Deutschen,'—Alanen.)

The *Quadi*, who lived in Silesia and Moravia in 375, were a Suevian people. The *Gepidæ* perhaps were of Gothic origin; their kingdom in Transylvania was destroyed by Alboin, who killed Kunimund, the last king of the Gepidæ.

Odoacer, the commander of a band of *Scyrri* or *Sciri*, *Rugii*, and *Heruli*, put an end to the Roman empire in Italy, and was acknowledged as emperor, but he was put to death by order of Theodoric the Great in 493.

The *Rugii* were Germani; the origin of the *Scyrri* and of the *Heruli* is uncertain. It has been pretended that the Heruli were a Lithuanian tribe.

Tribes within the limits of Germany which lost their independence under the Franks.—The *Bojoarii*, *Bojobari*, *Bajuvarii*, or *Bavarians*, whose name became known towards the year 480, were a confederation of Suevian tribes: they lived between the Danube, the Lech, and the Ens. In 540 they were forced to yield to the Frankish kings, and were governed by dukes of the dynasty of the Agilolfingians. Their laws, which were collected between 613 and 638, resemble the laws of the Alemanni, though they contain many traces of the Roman law. (Mederer, 'Leges Bajuvariorum, oder ältestes Gesetzbuch der Bajuvarier,' &c., 1793-8.) The *Thuringians* occupied the country north of the Bavarians as far as the Unstrut, and even beyond that river. They were related to the Goths, and their name seems to resemble that of the Thervingi, the Hermunduri, and Hermiones. Their last king, Hermanfrid, was deprived of his crown by the Franks in 531. Charlemagne is said to have made the first collection of their laws, but there is no evidence in support of this statement. Their code is known under the title of 'Lex Angliorum et Werinorum, hoc est Thuringorum.' These Angles and Warini or Werini were settled in the northern part of Thuringia, but it does not appear why their names are mentioned before that of the Thuringians, who were the more numerous nation. This collection is brief and incomplete. (Leibnitz, 'Script. Rer. Brunsvic.,' i.)

The *Saxons* dwelt north of the Thuringians. On the east their frontiers were the Elbe, the Stecknitz, and the Baltic; on the north, Denmark, the German Ocean, and Friesland; on the west, they corresponded to the western frontiers of the present province of Westphalia. When they had sent numerous settlers to Britain, their power became less formidable to their neighbours—the Wends in the east, and the Franks in the west. The Franks were formerly united with them against the Romans, but when they had conquered Gaul, the Saxons were obliged to desist from their incursions into this country, and hence arose jealousy and hostility. The south-western parts were conquered by the Franks as early as 555; the rich landowners were compelled to give a considerable part of their lands to Frankish nobles, and the common freemen to bend under the yoke of servitude. The remaining and greater part of the population was free, though from time to time the Saxons paid tribute, until, after the memorable war with Duke Wittekind (772-803), Charlemagne became master of all Saxony. But the Saxons were not subjugated like the Romans. They promised to adopt Christianity, to acknowledge Charles as their king, and to obey his governors (greves) and bishops. On the other hand, Charles granted them equal "Wehre" (value of their body and liberty in case of wounds, murder, &c.), and the same privileges which the Franks had, especially freedom from tribute, and the privilege of being tried in their own country, according to their own laws, and by their equals. (Leibnitz, 'Script. Rer. Brunsv.,' i.; Compare Möser, 'Osnabrückische Geschichte,' i.)

Charlemagne was the first king of the Saxons who formed a great confederation of free communities; they appointed dukes for their wars, and only acknowledged obedience to the "gowding" and to "greves" chosen by the freemen among the "edelings" of the communities. The laws of the Saxons were collected by order of Charlemagne. They consist of nineteen titles, and are so short and incomplete as to justify the opinion that only a part of them has been preserved. Two "Capitularia" of Charlemagne concern the political and ecclesiastical condition of those parts of Saxony which were conquered at the time of their publication (788 and 797). This 'Lex Saxonum' must not be confounded with the 'Sachsen-Spiegel,' the 'Mirror of the Saxons,' a code of Saxon law which was written in Latin, and afterwards translated into the Saxon language by Eicke van Rebgow, between 1215 and 1218. (Gärtner, 'Saxonum Leges Tres. Accessit Lex Frisionum,' 1730-4.)

Frisians. [FRISIANS.]—The laws of the Frisians were collected by Charlemagne under the title of 'Lex Frisionum.' (Gärtner, 'Saxonum Leges Tres. Accessit Lex Frisionum.') The 'Statuta Opstalbomica,' the laws of the Seven Sealands, which are written in the Frisian language, are a different collection. The dialect of this language, which most resembles the Anglo-Saxon language, is that of the northern Frisian islands on the coast of Sleswig.

Anglo-Saxons.—An account of their history has been given under SAXONS; and under ENGLAND in GEOG. DIV. The first settlement of Teutonic tribes in Great Britain previous to the arrival of the Anglo-Saxons, has been treated with great learning by Dr. Clement, in his work 'Die Nordgermanische Welt,' Copenhagen, 1840; and much valuable information respecting their laws and social habits will be found in Kemble's 'Saxons in England,' and the works of Palgrave and other recent writers on Anglo-Saxon history.

The following works contain full information concerning the history of the Teutonic nations:—Mascov, 'The History of the Antient Germans,' translated by Thomas Lediard; Gibbon, 'Decline and Fall;' Eichhorn, 'Deutsche Staats-und Rechts-Geschichte;' Savigny, 'Geschichte des Romischen Rechtes im Mittelalter;' Grimm, 'Deutsche Rechts-Alterthümer;' and his 'Deutsche Grammatik.'

The Scandinavian branch of the Teutonic nations appears late in history. The Sagas tell us that in the fifth century B.C. Odin led the Scandinavians to Sweden and Norway; but this Odin is a god. Less fabulous is the history of a second Odin, who, in the beginning of our era, came from Asia to Scandinavia, accompanied by his "Asen" or perhaps "Ansen," or fellow-warriors. The name of the Suiones or Swedes was known to Pliny and to Tacitus, and Pliny knew the name of Scandia, now Scania, the southern extremity of Sweden, which name gradually acquired its present general meaning. Goths came to Scandinavia at a very early period, and the second Odin was perhaps their chief. They mixed with the Scandinavians, and traces of their language have been found in the dialects of the provinces of East and West Gothland in Sweden, and their name is still preserved in many localities. The aborigines of Sweden and Norway belonged to the Finnish race. They fled towards the north, but not without leaving their traces in the mountains of the Kjœlen and the Dovre Fjeld.

The Scandinavians, Northmen, or Normans, became known to the southern nations by their piracies, and they were often leagued with the Saxons. In the wars between Charlemagne and Wittekind, the Danes assisted Wittekind, who had married Gera, the daughter of their king, Siegfried. As early as the beginning of the 8th century the Danes and Jutes appeared in the north of England; in the beginning of the 9th century the Danes settled on the south-east coast of Ireland. Normans or Norwegians occupied the Orkneys before the end of the 9th century: in 861 they came to the Faroe Islands, and they sent colonies to Iceland as early as 870. The northern parts of North America were known to these bold navigators four centuries before the time of Columbus. Other Normans conquered Normandy, Apulia, Sicily, and the opposite coast of Africa. From the 8th century the Waregians, who came from Norway and Sweden, penetrated into Russia, and founded the Norman dynasty of the grand-dukes of Kiew. Some of the first families of the Russian nobility are of Norman origin.

The Swedes conquered the coast of Finland as early as 850, and settled in great numbers in the districts of Abo and Nyland. Although Finland is chiefly inhabited by a nation of Finnish origin, and though it has become a Russian province, the Swedish language is the only language used for public acts and legal documents.

Suhm is one of the best authorities for the critical history of the Scandinavians. He has written in Danish on the origin of the Scandinavians, on their mythology, a critical history of Denmark, a history of Denmark, and several other works concerning this country.

(Müller, in his 'Kritisches Examen der Däuischen und Norwegischen Sagengeschichte,' examines the historical truth of the Sagas; Peringskjöld, 'Monumenta Sueo-Gothica,' Stockholm, 1710, fol.; Peringskjöld, 'Wilkina Saga, sive Historia Wilkinensium,' contains an account of the exploits and conquests of the Scandinavians in Russia, Italy, &c.)

Table of the modern Teutonic Languages and their Dialects.

I. HIGH GERMAN LANGUAGES.

(The German language as it is written or spoken by the well-educated Germans, belongs to the High German languages, but is not a dialect.)

A. *Suabian* branch.

a. Suabian, subordinate branch, containing the dialects of

1, *Suabia*, that is, of the Black Forest, of the Neckar, and of the country between the Danube and the Lech.
2, *Bavaria*, that is, of the Alps, of Salzburg, and of the Danube.
3, *Tyrol*, that is, of Vorarlberg, of the Inn, of the Etsch (Adige), and of the Puster-Thal.
4, *Austria*, that is, of the archduchy of Austria, of Styria, of Carinthia, of Carniola, of Southern Bohemia, and of Moravia.

b, Alemannic, subordinate branch.
1, *Alemannic*, commonly so called in the south-west corner of the Black Forest.
2, Dialects of Switzerland, that is, of Bern, of the Oberland of Bern, of Wallis, of the country of the Grisons, and of Appenzell, &c.
3, Dialects of Elsass (Alsace), and of Baden.

c. Old Thüringian, subordinate branch, containing the dialects of the Thüringer Wald, of part of the Fichtelgebirge, and of the northern part of the Böhmerwald. These dialects are generally confounded with those of the adjacent flat countries of Thüringia and the Upper Palatinate, which belong to the Franconian branch.

B. *Franconian* branch.

1, Dialects of Franconia, of the Palatinate, of the Middle Rhine, and of Southern Hesse.
2, Dialects of Thüringia, except the Thüringer Wald, of Northern Hesse, and of the Eichsfeld.
3, Dialects of Lorraine and Luxemburg, which are much mixed with Low German.
4, Dialects of Upper Saxony, of Meissen, of the Erzgebirge, and of Lusatia.
5, Dialects of Northern Bohemia, of Silesia, and of part of the German colonies in Hungary.
6, Dialects of the nobles, the clergy, and the citizens in Curland, Livonia, and Esthonia.

II. SAXON LANGUAGES.

A. *Frisian* branch, which contains the dialects of West Friesland, of Saterland, of the islands along the Dutch and the German coast, and of the islands along the coast of Sleswig.

B. *Low German* branch, divided into six sections, namely:—
1, Of *Lower Saxony*, containing the dialects of Sleswig, of Holstein, of Hamburg, of Bremen, of Brunswick, of Hanover, of the country between the Harz and the Weser, and of the Marshes with East Frisia.
2, Of *Westphalia*, with the dialects of Upper Münsterland, of Lower Münsterland, of Osnabrück, of the Upper Weser, of Sauerland, of Mark, and of Eastern Berg.
3, Of the *Lower Rhine* between Neuwied and Düsseldorf, especially the dialects of the Eifel, of Cologne, and of Aix-la-Chapelle.
4, Of the *Netherlands*, containing the Dutch language, the Flemish language, and the dialects of Jülich, of Cleve, and of Geldern in Germany.
5, The dialect of the Saxons in *Transylvania*.
6, Of the ancient *Wendish* countries, colonised by the Saxons, containing the dialects of Mecklenburg, of Pomerania, of Brandenburg, of the Marks, and of East Prussia.

C. *English* branch. [SAXON LANGUAGE AND LITERATURE; ENGLAND, in GEOG. DIV.]

III. SCANDINAVIAN LANGUAGES.

A. *Old Norman* branch, containing the dialects of the mountaineers of Norway, the Icelandic language, and the idiom of the Faroe Islands.

B. *Danish* branch, containing the Danish language, with the dialects of the islands, of Jutland, and of Northern Sleswig, and the modern Norwegian language.

C. *Swedish* branch, containing the Swedish language, with the dialects of Gothland, of Dalecarlia, of Stockholm and the adjacent country, of Finland, and of the Aland Islands.

(Adelung und Vater, 'Mithridates;' Balbi, 'Atlas Ethnographique;' Ober-Müller, 'Atlas Ethno-géographique de l'Europe.')

TEXTILE MANUFACTURES. [COTTON.]

THAMES, a certain jurisdiction, though not undisputedly exclusive, appears to have been immemorially exercised over both the fisheries and navigation of a large portion of the Thames by the mayor and corporation of London. In early times, when fisheries were probably of much greater importance than they are at present, the same kind of encroachments upon them by private individuals which were so often made the subject of complaint in other parts of the kingdom were also practised in this river. In 1405 an order was issued from Sir John Woodcock, then lord mayor, enjoining the destruction of wears and nets from Staines to the Medway, in consequence of the injury which they did to the fishery and their obstruction of the navigation. By 4 Hen. VII., c. 15 (1487), the mayor of London and his successors were invested with the same authority as conservator of the fish in "all the issues, breaches, and ground overflown as far as the water ebbeth and floweth from out of the river Thames," as he had within the river itself. Before the river was artificially embanked and the adjoining lands drained, this extension was probably of considerable importance. During the reign of Elizabeth, in 1584, an order was put forth by the mayor for the purpose of settling the proper times in which various kinds of fish were to be taken. It prohibited fishing in certain parts of the river, and forbade the taking of the white-bait or "bloodbag." The right of the corporation, however, to the conservation of the river about this time was disputed by the lord-high-admiral, and some litigation took place, in which the corporation was uniformly successful. James I. in the third year of his reign granted a charter to the city, in which the immemorial right of the city to the office of bailiff and conservator of the Thames is recited and confirmed. The same rights are also confirmed and settled by various other charters and acts of parliament. The result was to vest in the corporation the conservation of the river, the regulation of the port and harbour of London, and, as is said, the actual property in the soil of the river, subject only to the jus regium of the crown. The commencement of the city's jurisdiction was marked by a stone, with an apocryphal date, called London Stone, placed on the north bank of the river, a short distance above the present bridge of Staines, and its termination on the south shore, by the formerly navigable creek of Yantlet, separating the Isle of Grain from the mainland of Kent, and on the north shore by the village of Leigh, in Essex, placed directly opposite, and close to the lower extremity of Canvey Island, thus extending a distance of eighty miles, over nearly the entire course of that river through the metropolitan valley.

After much litigation between the City of London and the Crown, the conservancy of the river, which involves the control of the fisheries, the regulation and control of the watermen and of the shipping, the cleansing of the river, the removal of obstructions, erection of stairs, licensing mills, and other such duties, has been vested, by act of parliament, in a Board of Conservancy, to whom the powers of the corporation have been transferred.

(Griffiths, *Conservancy of the River Thames*; Stow, *Survey of London*; Pulling, *On the Laws, &c. of the City and Port of London*.)

THAMMUZ, in Hebrew תַּמּוּז, is the tenth month of the Jewish civil year, coinciding with our June or July; it has twenty-nine days, and in the present year (1861), it will begin on the 9th of June and end on the 7th of July. The name does not occur in the Bible, as a month at least; the passage in Ezekiel viii. 14, "women weeping for Tammuz," having no known connection with the month. Benfey, who has a short dissertation on the name in his 'Monatonamen,' p. 164, seq., denies the identity of Thammuz and Adonis, first advanced by St. Jerome in his commentary on Ezekiel. In the copies of the calendar of Heliopolis the name is written Θαμιζα, Θαμμουζ, and Θαμα. A fast is kept on the 17th day of Thammuz, in memory of the capture of Jerusalem by Titus, according to most authorities, though some say it was instituted to commemorate the breaking of the Tables of the Law by Moses, Exod. xxxii. 19. In some calendars a feast is mentioned on the 14th day, to celebrate the destruction of a pernicious book tending to discredit the traditions of the Rabbins. In the Syrian calendar now in use, Thamuz is the fourth month, as it was among the Hebrews when the year began with Nisan.

THANE, in Anglo-Saxon *thegn*, from *thegnian*, or *thenian*, "to serve," the same word with the modern German *dienen*, is frequently, in conformity with this origin, translated *minister* in the Latin charters of the Anglo-Saxon period. In other cases its equivalent is *miles*, or *fidelis miles*. So king Alfred, in his translation of Bede's 'Ecclesiastical History,' renders the king's minister, the king's thane, and uses thane wherever Bede has *miles*. The exact meaning of the term when employed as a title of honour is involved in considerable obscurity: the rank or dignity which it denoted was possibly not the same at different times, and there were also thanes of more than one kind. After the Conquest thanes (*thaini* or *taini*) are frequently classed with barons (barones): in the laws of Henry I., the two words are apparently used as synonymous; and where the Saxon Chronicler has thanes (*thegenas*), the Latin annalists have commonly *barones*. The class of common or inferior thanes seems to have answered nearly to that of the barones minores, or landed gentry. One of the few things that are tolerably certain with regard to the rank of a thane is, that it implied the possession of a certain amount of landed property. Such a qualification indeed seems in certain circumstances to have conferred the dignity of thane. One of the laws of Athelstane declares that if a ceorl (or commoner) shall have obtained five hides of land in full property, with a church, a kitchen, a bell-house, a burghate seat (or office of magistrate in a burgh), and a station in the king's hall (the meaning of which last expression is doubtful), he shall henceforth be a thane by right. Five hides of land was probably the amount demanded even for a thane of the highest order; although it appears from Domesday-Book that this was also the quantity which made the owner a miles, or liable to be called out on the king's military service. Many lands are mentioned in Domesday-Book as thane-lands (terræ tainorum); and it is probable that the dignity, like the oldest of the Norman baronies, was sometimes attached to a particular estate. Thanes were among the members of the Saxon Witenagemot, or parliament. The principal facts connected with this dignity in England have been collected by Mr. Sharon Turner, in his 'History of the Anglo-Saxons,' 8vo., London, 1823, vol. iii.; by Sir Francis Palgrave, in his 'Rise and Progress of the English Commonwealth,' 4to., 1832, and by Mr. J. M. Kemble in his 'Saxons in England,' 1849.

There is little mention of the thanes in England after the time of Henry II.; but Lord Hailes has shown ('Annals,' i. 28) that in Scotland thane was a recognised title down to the end of the 15th century: the 'Chartulary of Moray' mentions a thane of Cawdor in 1492. It appears from the first to have implied in Scotland a higher dignity than in England, and to have been for the most synonymous with earl, which was a title generally annexed to the territory of a whole county.

THAW is the reduction of ice or snow to a liquid state in consequence of an increase in temperature. In the ordinary succession of the seasons, this effect is produced on the surface of the earth or in the atmosphere during the spring by the return of the sun to the hemisphere of the observer, the solar rays then falling in greater abundance than before on a given extent of ground; or it is produced by accidental currents of warm air which pass over a frozen mass. The dissolution of particles of ice or snow floating in the atmosphere, and the universal liberation of moisture previously frozen up, are the causes of the humidity which accompanies a thaw.

As the conversion of a liquid into ice always commences at the surface of the former, and about the sides of the vessel containing it, or about those of a solid body immersed in it, so in ice surrounded by air which has acquired a higher temperature than the ice has, the process of liquefaction commences at the sides and extends gradually from thence inwards; ice being a bad conductor of heat, the central parts of it, under ordinary circumstances, are the last which are dissolved. It is observed that when solid bodies, whose temperatures are equal to one another and higher than that of ice, are applied to the latter, the ice is dissolved most rapidly by those which have the greatest power of conducting caloric: thus a piece of ice being laid on a plate of polished metal, and a piece of equal magnitude on wood, the ice on the metal will be dissolved before that which is laid on the wood, not only when the temperature of the metal and wood are equal, but even when the temperature of the wood considerably exceeds that of the metal, the latter conveying more abundantly to the ice the caloric which it is continually receiving from the atmosphere.

A severe and long-continued frost abstracts so much caloric from terrestrial bodies, as the walls of buildings which are not exposed to the sun, that these are often cooled below the temperature of freezing water; and while in this state, if a current of warm air pass over their surfaces, the aqueous vapour which the air contains deposits itself on the walls, where it is converted into ice or snow: it remains thus frozen for a time after a thaw has commenced, but at length, the temperature increasing, the ice is melted and the walls are then covered with moisture.

It is often remarked that, at the time of a thaw taking place, there is felt a degree of coldness greater than that which is experienced during the continuance of the frost; this has sometimes been ascribed merely to the evaporation of the moisture which is then on the skin, as the thermometer at the same time indicates an elevation of temperature in the atmosphere. But the evaporative power of the skin must depend both upon the temperature of the air and the amount of aqueous vapour which it already contains, and in part also on the local heat of the human body. The sensation alluded to arises, in all probability, from the continual conversion of the sensible heat of the atmosphere and the surface of the earth and bodies resting upon it, into a latent form during the process of thawing, the latent heat of water being greater than that of any other substance. Dr. Faraday has shown that the conversion of a cubic yard of ice simply into water at 32°, or ice-cold, would absorb or render latent the whole heat emitted during the combustion of a bushel of coal. [Hail; Ice; Water.] The amount of heat thus required in the liquefaction of ice renders a thaw so gradual. This is an important provision of nature; but for it, "the ice that had accumulated during a long winter would at the first breeze from the south be instantly converted into water, and sweep before it, not merely the habitations of man and their tenants, but trees, rocks, and hills;" every thaw, in fact, would occasion a frightful inundation. Conversely, frost is rendered gradual by the evolution of the latent heat of water in a sensible form.

For a remarkable case of slow thawing, and illustration of the principle on which the gradual nature of that process depends, we may refer to some experiments made by Dr. Faraday for the investigation of a different subject, that of regelation. He prepared a bath of water, which could be retained, by appropriate contrivances, at the unchanging temperature of 32° Fahr., or the melting-point of ice, for a week or more; but a small piece of ice floating in it for that time was not entirely melted away. Yet the temperature was adequate to the liquefaction of ice, for a very slow thawing process was really going on in the bath during the whole time, as was rendered evident by the state of this very piece of ice; but the glass jar containing the water being surrounded by a system of bad conductors of heat, including dry flannel and broken ice, the heat of the atmosphere and exterior surrounding bodies could only very slowly penetrate to the ice in the bath, and there supply the heat required to become latent in the process of thawing it, and hence the rate of thawing was so slow as not to dissolve a cubic inch of ice in six or seven days. (See 'Proc. of Royal Society' for April 26, 1860, vol. x., pp. 442, 449.)

A phenomenon observed at Inspruck, in the Tyrol, which has been referred to the contrary operation of local winds, probably admits of explanation upon the principle of the absorption or rendering latent of heat in the thawing process. At that place the snow is often seen melting on the mountains above the town, at an elevation of 3000 feet, while it continues very cold and there is not the least sign of thaw in the valley of the river Inn below. It is then popularly said that the south wind is driving the cold into the valley; and this saying seems to involve the truth. The air above will be greatly cooled down by the abstraction of its heat in the melting of the snow, and, thus becoming heavier, will descend in the atmosphere and maintain for a time the low temperature in the valley below.

The overflowing of rivers by the dissolution of the snow and ice on the mountains above their sources is well known [RIVERS, col. 119], and to the liquefaction of the ice formed by the previous congelation of water which has introduced itself into the fissures of rocks is to be ascribed the occasional severance of large masses from the sides of mountains; the expansion of the water in freezing having destroyed the cohesion, so that the parts are only held together by the ice, and on the liquefaction of this the disunion is complete.

Two pieces of thawing ice, if brought into contact, adhere and become one; at a place where liquefaction was proceeding, congelation suddenly occurs. This is the phenomenon and process of *regelation*, already treated of in the article ICE. The view of the thawing or melting of ice taken by M. Person, that it is a gradual process, resembling that of wax and metals, and not really a sudden one, and its adoption by Professor James Forbes, as well as the objections to it urged by Professor James Thomson, have been noticed in the article ICE. Person's original paper, 'On the Latent Heat of Fusion of Ice,' will be found in the 'Comptes Rendus' of the Royal Academy of Sciences of Paris, for April 29, 1850, vol. xxx., p. 526. The evidence he adduces of the supposed viscosity of ice, intermediate between the states of rigid solidity and perfect fluidity, consists solely of an amount of latent heat which a high authority agrees with us in considering to be much within the probable errors of the delicate experiments required. The application made by Professor Tyndall of the principle of regelation, renders the plasticity of ice in the mass quite intelligible, without the necessity of attributing a viscous property to that substance, the existence of which is negatived by all the other properties which it possesses.

Although the terms thawing and freezing were originally applied only to the solidification and re-liquefaction of water, by variations of temperature, and derivatively to those of other fluids in ordinary use, their sense has become extended in the progress of that more precise knowledge of natural things which is called science, to denote also, generally, the solidification and re-liquefaction of liquids not commonly observed in the solid condition. We speak, for example, of the freezing and thawing of mercury; and not only so, but the terms thawing and freezing are sometimes used to express the circumstances of the melting and re-solidification of bodies which are ordinarily solid—solid, that is, at common temperatures, an expression which, as usually employed, includes a considerable thermometric range from above the freezing to below the boiling point of water, and is even extended, though indefinitely, somewhat below the former and considerably above the latter, though not to a red heat, or a temperature at which light is evolved. Thus these terms have been applied to the melting and crystallisation of glass. In like manner, the term fusion, originally employed with reference to the liquefaction of bodies which are solid at common or much higher temperatures, has come to be applied, as equivalent to that of thawing, to the melting after solidification of substances which are ordinarily liquid. In this manner we speak of the fusion of ice, as well as that of wax or of copper; and Dr. Faraday has described, in the paper referred to above, an experiment in which layers of ice are produced "of greater and less fusibility."

THEA. [TEA.]

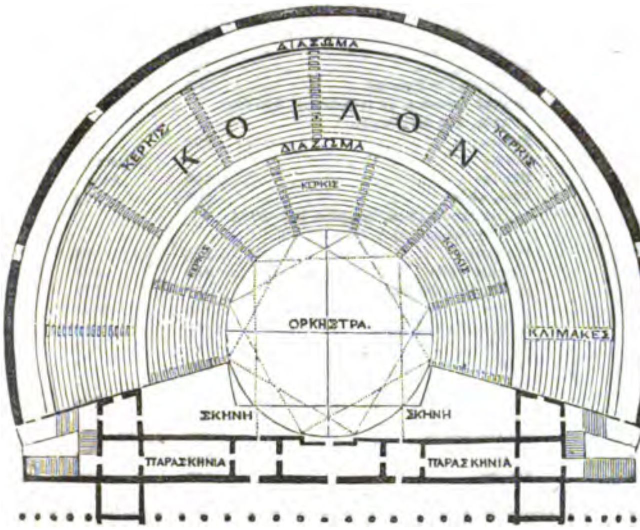
THEATINS, or TEATINS, an order of monks founded at Rome in 1524, principally by Gianpietro Caraffa, who was then archbishop of Chieti, in Naples, the Latin name of which is Teate, and who afterwards became pope under the title of Paul IV. The institution was confirmed at the time of its foundation by the reigning pope, Clement VII.; and a final rule, or code of regulations, drawn up by a general chapter of the order, was authorised by Clement VIII. in 1604. The Theatins were principally established in Italy and in France, into which latter country they were brought in 1644, and where they subsisted till the Revolution of 1789. Their dress was a black cloak and cassock with white sleeves; and the principal peculiarity of their institution was that they affected to subsist not only upon alms, but upon alms bestowed upon them without being asked for. They procured, however, considerable support in this way, and they were at one time enabled to maintain missions in Georgia, Circassia, Mingrelia, and other parts of Asia. Their history has been written by John Baptist Tuffins, under the title of 'Annales Theatinorum.' There were also Theatin nuns (in French, *Theatines*), so called from having been placed by Pope Gregory XV. under the direction of the Theatin monks, their original and proper designation having been Sisters of the Immaculate Conception. A notice of a controversy between the Theatins and the Jesuits, which was kept up for a great part of the 17th century, is given by Bayle, in a note to his article on 'Ignatius Loyola.'

THEATRE (from the Latin *theātrum*, which is from the Greek θέατρον, 'a place for seeing'), a word adopted in all modern languages to signify a building appropriated to dramatic representations. The oldest edifices of this class are those of the Greeks and Romans, for it was with them that the European drama originated, and, in point of magnitude, the Greek and Roman theatres surpassed the most spacious of their temples. The enormous extent of many of the ancient theatres, and the prodigious solidity of their construction, are attested by the numerous remains of such edifices, which have been explored not only in Greece and Italy, but also in Asia Minor. Of some of them indeed little can now be traced, but others are sufficiently perfect to convey a clear idea of the arrangement and general appearance of the structure in its original state; that is, however, merely as regards the space appropriated to the spectators, for scarcely anything remains to explain what is most difficult, and, as regards the dramatic exhibitions, most important of all to understand, namely, the stage itself, including under that term the whole space requisite for the accommodation of the performers, and for the preparation of the exhibition before the audience. Owing to the want of any evidence of the kind afforded by the buildings themselves, and to the very little that can now be gathered from the scanty notices of ancient writers, we have no certain knowledge of many things which now can only be conjectured. The character of the performance has been spoken of under DRAMA.

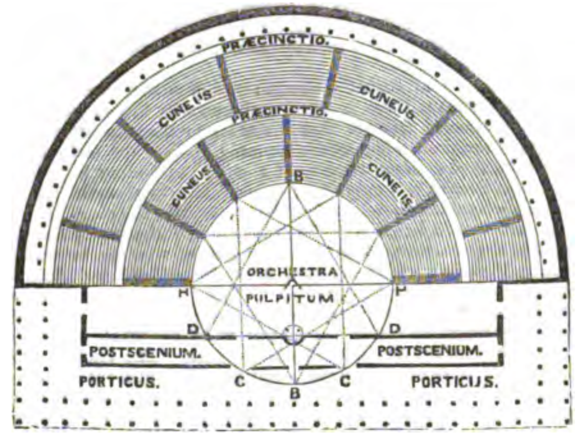
The circumstances that are mentioned for our admiration, and as proofs of the magnificence and sumptuousness of some of the ancient theatres, prove how deficient in scenic illusion and stage effect the performances must have been. Whether it be at all exaggerated or not, it is evident from what Pliny ('Nat. Hist.,' xxxvi., c. 15) says of the theatre of Scaurus, at Rome, that the *scena* was a mere architectural façade, unmeaning in itself, though lavishly embellished with marble columns and statues—with no fewer than 360 of the former, arranged in three tiers, and 3000 of the latter, a most incredible number, surpassing that of a modern audience. Pliny puzzles us still more when he says that the middle of the scena (meaning the second of the three orders) was of glass, "*vitro*." The actors it is evident must have appeared mere pigmies upon a stage of such enormous extent, with a number of statues behind them. This must always have been in some degree the case, since even in moderate-sized ancient theatres the stage was enormously wide in comparison with what it is in the very largest modern theatres. The scena too was always a permanent architectural erection, incapable of change. It has been supposed that, besides the permanent scena, the ancients employed, occasionally at least, moveable painted scenes, capable of being let down before it. Yet while this can be only vaguely inferred, the presumption against it is founded both on its impracticability and its extreme improbability. If they even did, as some suppose, practise scene-painting, it is scarcely conceivable that they should have had painted moveable scenes on canvas, which on the average must have been 200 feet in width, especially where the stage itself was so shallow and confined at its sides, and without any space for apparatus or machinery over it. Vitruvius does indeed mention, in the proem to his seventh book, Agatharchus as a scene-painter, and Democritus and Anaxagoras as writers on scenography and perspective; but it is with such vagueness of expression, that it is difficult to draw any conclusion from his words. Of the former he merely says "scenam fecit," which probably means no more than that he was one of the first who introduced some sort of decoration on the scena, or back wall of the stage, where, if there was at any time painting at all, it could only have been very partial, and as accessory embellishment to that general façade. The fixed arrangement of the scena itself, with three distinct entrances assigned to the performers according to their rank in the piece, the centre one being for the principal characters, the others for those supposed to arrive on one side from the port, on the other from the country, was not only an awkward conventionalism in itself, but an expedient which shows how imperfect the ancient stage must have been, notwithstanding its alleged magnificence. What there was of painted scenery at all was probably confined to two *Versuræ* (περίακτοι) at the sides or ends of the stage, which served as "wings," and which were upright triangular frames made to revolve upon a central pivot, so that any of the three sides could be turned towards the audience; a very scanty change of scenery at the best, and only sufficient to *hint* where the action was supposed to take place.

From the use of the term *Aulæa* it has been generally concluded that the whole stage was concealed by a curtain, both previous to the commencement of the performance and whenever it was requisite to make any change in the decorations. But we agree with Winckelmann, that such could not possibly have been the case, because in the first place it could hardly have been practicable, and in the next it was unnecessary as regarded the permanent scena or architectural façade. But even admitting that there was painted scenery, and that it was not inferior to that of our own theatres, either in regard to truth of perspective or to anything else, it still must have fallen far short of the latter in effect, if only for the reason that the performances took place by daylight. At the best the illusion could have been but exceedingly imperfect—a strange mixture of the artificial with the real. The natural lights and shadows and the painted ones must frequently have been in contradiction to each other; nor was it possible to manage any effects of light, as in our theatres, by either increasing or diminishing it, or by concentrating it on any particular part of the scenery. The only thing in favour of the ancient stage in this respect, is that there were no "foot-lights," and consequently the faces of the performers were not lighted from beneath. Yet even this comparatively unimportant advantage was nullified by the use of masks, some of them so extravagant as to bear scarcely any resemblance to the human countenance, whilst in all a fixed expression of countenance was substituted for what could properly be only a momentary one. This was however of the less consequence, because, owing to the vast extent of the theatres, the faces of the actors could hardly have been distinctly seen, or even seen at all by the great majority of the spectators. The whole space was so great, that in regard to it the actors could have been little more than as the figures put by a painter into a landscape.

On considering the audience part, and the accommodation provided for the spectators, although there the arrangement of an ancient theatre was nearly perfect, and in some respects preferable to that of modern ones, it was not free from many inconveniences. The most obvious one is, that as there was no roof, there was no shelter from the weather, on which account awnings were sometimes made use of to screen from the heat of the sun, while in case of sudden and heavy rain the spectators were obliged to take shelter in the corridors behind and beneath the seats, where there were any, and in the porticos at the back of the theatre. Besides interruption to the performance, this must have occasioned considerable confusion in so numerous an assemblage of persons. Beautiful too as the arrangement of all the seats in concentric rows is in itself, it is attended with some disadvantage, as will be perceived on referring to the annexed plans, for instead of being placed, as in the pit of a modern theatre, parallel to and immediately



Greek Theatre.



Roman Theatre.

facing the stage, a considerable portion of the audience must have sat sideways to it, with part of it behind them; and those at the ends of the further or upper benches could hardly have had any view of the scena at all, at least not in the Greek theatre.

The Greek and Roman theatres so very nearly resemble each other in their general form and principal parts, that it is only by comparing the plans, for the purpose of seeing wherein they vary, that the difference between them can be clearly understood. Such difference however is exceedingly slight, the general arrangement and the essential parts being the same in both,—the *Coelum* (Κοῖλον), *Orchestra* (Ὀρχήστρα), and *Scena* (Σκηνή) in the one, and the *Cavea*, *Orchestra*, and *Scena* in the other. The cavea was the general term for the whole of the space appropriated to the seats of the spectators, which were all concentric with the orchestra, and which were intersected, in one direction, by ascents or flights of steps (*κλίμακες*) dividing the seats into so many compartments, termed *κερκίδες*, or *Cunei*, and separated into two or more "flights" or "tiers" by broader spaces or landing-places, called *Διαζώματα*, or *Præcinctiones*. The number of the *κλίμακες*, or ascents, and that of the *Διαζώματα*, or Præcinctions, and also the breadth of the latter, appear to have been regulated entirely according to the extent of the theatre and other circumstances. In general there seems to have been only one Præcinction between the seats, dividing them into two "flights," not however so as to give an equal number of rows of seats to each. In the theatre near Epidaurus, for instance, there were 54 rows of seats, divided by a single Præcinction, and 34 of them formed the *first* or lowest tier nearest the orchestra; while in that at Syracuse there were 62 rows, with only a single Præcinction between them, and 41 were given to the *second* or upper flight, furthest from the orchestra. In the theatre at Dramyssus, again, there were two Præcinctions, dividing the entire number of rows, 54, into 18, 16, and 20 respectively, reckoning from the orchestra. As regards the distinct "flights," or series of seats, there were two modes of disposing them: the more usual one was to break into separate slopes, retiring from each other, like the "flights" in an ascent of steps; the other was to place them in a continued slope from the lowest to the highest seats, whereby at each præcinction the next "flight" was considerably elevated above the level of that landing, being raised upon a podium or wall, which showed itself between the lower and upper "flight." Besides the præcinctions *between* the seats, there was another surrounding the whole *coelum*, or auditory of the theatre, forming either an upper uncovered terrace as a standing-place for spectators, or a covered gallery with columns, as is shown in the plan of the Roman theatre, where such portico was assigned to females.

Between the Grecian and Roman orchestra there was a very wide difference as regards the purpose to which that space was appropriated. In the Roman theatre it was merely a continuation of the rest of the auditory, being occupied with seats and spectators, with no other difference than that the spectators were senators and other persons of dignity, and that benches or chairs must have been ranged parallel to the stage. The Greek orchestra, on the contrary, was, as its name imports, made use of for the dancers, musicians, and singers, whose performances constituted so important a part of the entertainment; and so far nothing could have been better planned than the Greek theatre, for the orchestra was visible from every part, whereas the scena could not have been distinctly seen, or hardly seen at all by those on the upper seats at either extremity of the coelum. By referring to the plans it will be seen that while the Roman orchestra does not exceed half a circle, the Greek forms three-fifths of one, or an arc of 216 degrees, its proportions and the depth of the stage being ascertained by merely inscribing a square within a circle, taking one side of that square as the boundary of the stage, and drawing parallel to it a tangent to the circle, which tangent coincides with the scena or back of the stage. Such plan therefore is simple enough, complex as it may appear in the cut, where two other squares are also drawn within the circle, and the points of the three squares determine how far the seats extend, and the situation of the steps (*κλίμακες*) between the seats,—a fanciful operation, nothing more being required after the first one than to divide the arc or curved portion of the orchestra into as many equal parts as would be requisite according to the number of ascents. In fact this last appears to have been the mode practised, for there are as many examples which differ from as agree with that established by Vitruvius for the Greek theatre. According to that, the divisions, the number of cunei and steps between them, would be uniformly the same, namely, seven of the former, and eight of the latter, including those next the stage, as shown in the cut. This however is so far from being the case, that very material differences occur in that respect. At Epidaurus, for instance, there are ten cunei in the lower tier, and eleven ascents, consequently an even number of the former and an odd one of the latter. At Dramyssus again there are nine cunei and ten ascents; and at Syracuse and Tauromenium the same. The Roman orchestra and scena were also defined by a circle, within which was inscribed an equilateral triangle, one of whose sides D D formed the scena, while the diameter H H of the circle, parallel to the scena, formed the boundary between the pulpitum or stage and the orchestra, the last being always a perfect semicircle. The other three triangles are merely for the purpose of determining the points where the scalæ, or steps between the cunei, are to be, for which nothing more is requisite than to divide the semicircle of the orchestra into as many equal parts as there are to be cunei, whether the number be six or any other; and the diameter of the orchestra H H being given, the distance of the scena from it would be ascertained by making it equal to one-fourth of that line. After all, as has been remarked by Wetter in his work on theatres, there is something more whimsical than rational in such an arrangement. In addition to the disadvantages already pointed out, as regards the want of moveable scenery, it was no slight inconvenience that the stage could never be occasionally extended in depth, shallow as it was. Taking 70 feet as the diameter of the orchestra alone, which dimensions are equal to the whole of the largest of our modern theatres, the depth of the stage in a Grecian theatre would be a little more than 10 feet, or one-seventh of that diameter; and in a Roman one 17½ feet, or just one-fourth. While so confined a space would admit of very little dramatic action, it would scarcely admit of any change of scenery. Yet shallowness of the stage was in some measure matter of necessity, in order that the performers might be as near to the front of the stage as possible, separated as they were, in the Grecian theatre at least, from the audience by the intervening orchestra.

Strict as were the rules for proportioning the depth of the stage to the size of the orchestra, the relative size of the orchestra to the coelum or whole auditory does not appear to have been subject to any regulations: it varies considerably in different theatres, being in some nearly one-half, in others only one-fifth, or even little more than one-sixth of the entire diameter of the interior, as in the theatres of Epidaurus and Dramyssus, or Janina.

When it is said that the Grecian orchestra was considerably larger than the Roman, there is some ambiguity in the expression, for it might be inferred from it that it was larger than the other in proportion to the coelum, whereas the meaning is that the orchestra of the Greeks formed a larger portion of a circle, extending to 220 degrees, while the Roman was only 180 degrees, or an exact semicircle. In the Greek theatre, therefore, the orchestra cuts into the stage, and renders that part termed Logeion by the Greeks, and Pulpitum by the Romans, considerably narrower than the extremities, whereas in the Roman theatre the stage was of the same depth throughout, pulpitum being a mere technical distinction applied to that portion corresponding with the orchestra, and to which the actors confined themselves, in order that they might be better seen and heard by the whole of the audience than would otherwise have been the case. The ancients also had recourse to what seems a strange expedient for transmitting the actor's voice to the furthest part of the theatre, namely, that of placing in cavities for the purpose beneath the seats hollow metal or earthen vases, termed Echeia (ἠχεῖα), that is, "sounding thing," which augmented the sound. The plans above given are not drawn to any particular scale, but supposing them to be upon the same scale, and the diameter of the orchestra in the Greek plan to be 100 feet, the diameter of the coelum or whole auditory will be 300 feet, the width of the stage and scena 180 feet, and the depth of the logeion only 15 feet, while in the other the dimensions will be, orchestra 100 feet, auditory 270 feet, scena 195 feet, depth of stage and pulpitum 25 feet.

Another point of difference between the Grecian and Roman theatre is that in the former the stage was considerably elevated above the orchestra, 12 feet or upwards, consequently there was a wall of that height at the back of the orchestra, to which was given the name of Hyposcenium (ὑποσκήνιον), or Lower Scena, and which appears to have formed a sort of architectural basement to the stage, and was adorned with niches and statues.

Little more remains to be said on the subject of ancient theatres, except to remark that the form of the orchestra also determined that of the exterior of the building; while the Roman theatres, therefore, did not exceed a semicircle, those of Greece had a greater curve. In the Greek theatres, however, the orchestra was not always extended beyond a semicircle by the curve being continued, but sometimes by straight lines at right angles to the chord (or parallel to B B, in the plan of the Roman theatre, whose general form is so shaped, the external semicircle being prolonged by the colonnades). Grecian theatres were almost invariably built on the sloping side of a hill, so that, as regards the coelum, it was merely necessary to shape it out, and erect the seats; consequently there was no other architectural exterior than that formed by the Parascene (Παρασκήνη) and colonnade behind the stage; for which reason the degree of curvature did not manifest itself. The Roman theatres, on the contrary, were erected on level ground, and, therefore, the curved part of the exterior was confined to a semicircle, a form which unites better with the rectangular one and its straight lines.

The theatre at Athens (called that of Dionysus) was by no means so spacious as many others, its diameter being only 250 feet, and that of the orchestra 72 feet, which are very moderate dimensions in comparison with those of some of the Asiatic theatres. The Odeion of Regilla, also at Athens, though similar in its general plan to the usual theatre, was a music-hall, and was covered in with a tent-like roof, with a semicircular *eye* or opening for light. Both structures were situated at no great distance from each other on the south side of the Acropolis; therefore the scena of the theatre had a northern aspect, and must have been in shadow while the performances took place.

The following is a list of such ancient theatres as are known, together with the respective dimensions of their general diameter and of their orchestra; which we have for the most part taken upon the authority of a similar table given by Colonel Leake, in his 'Tour in Asia Minor,' to which several other examples are here added.

	Diam.	Orchestra.
Anemurium	197 feet.	
Aspendus (scena Ionic and Corinth.)	400	25 rows of seats.
Athens, Theatre of Bacchus	250	72 feet.
,, Odeion	90	36
Cnidus	400	
Delos	175	
Dramyssus, or Joannina	440	78
Ephesus	660	240
Epidaurus	370	55
Herculaneum	180	16 rows of seats.
Hierapolis	346	100
Laodicea, Great Theatre	364	136
Limyra	195	not known.
Mantineia	227	not known.
Miletus	474	224
Myra	360	120
Nicopolis [in Epirus)	360	120
Orange (scena only remaining, 336 feet wide, 114 feet high).		
Patara	265	96
Perga		25 rows of seats.
Phellus	400	Scena 150
Pola, about (destroyed 1636, but plan preserved by Scamozzi)	200	68
Pompeii	190	62
Pompeiopolis	219	138
Rome, theatre Marcellus	517	172
Sardes	396	162
Selinus (in Cilicia)	114	
Sicyon	313	100
Side	390	120
Sparta	453	217
Stratonicea	390	106
Syracuse	440	
Tauromenium	330	width of scena 132
Teos	285	70
Tralles	540	150

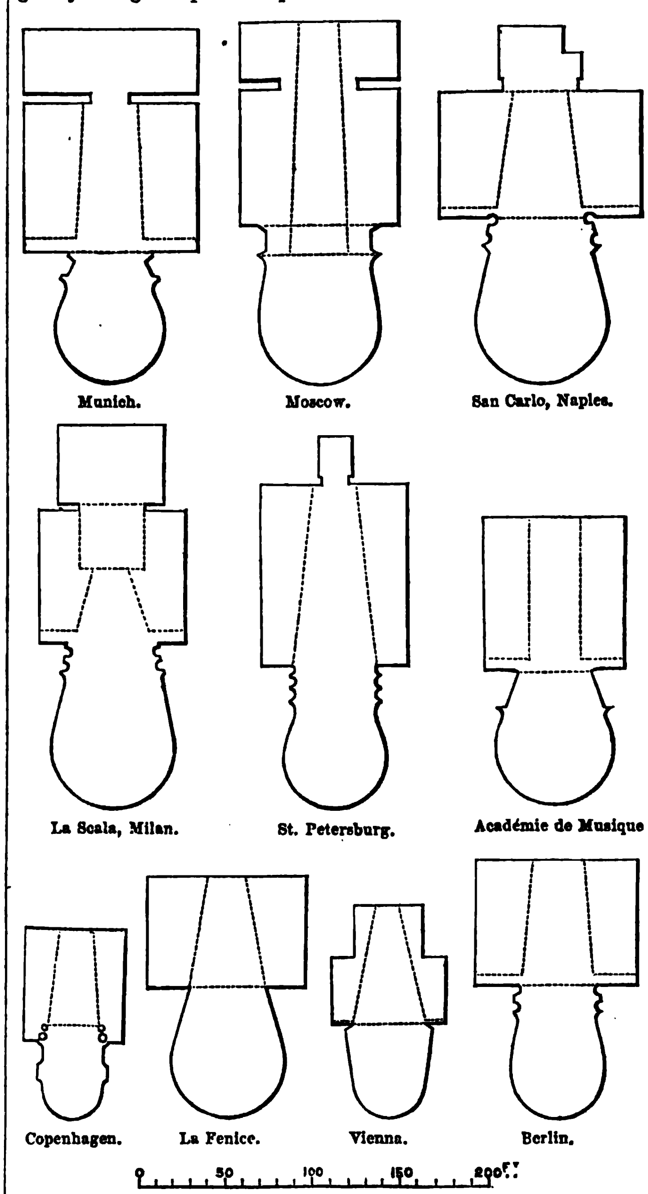
Of some of these theatres scarcely anything remains, little more than their general shape and extent being now distinguishable; accordingly the statements of their dimensions are not to be strictly relied upon, though they are sufficient to enable us to estimate their comparative size.

Fortunately the ancient theatre was not taken as a model for modern structures of the kind. The revival of theatrical representations took place before anything was known relative to that branch of archæology, and under very different circumstances. Dramatic entertainments were in the middle ages either partly religious, and performed within churches, convents, and colleges; or were acted for the amusement of princes and nobles on occasions of state and festivity, in halls merely temporarily fitted up for that purpose; consequently spacious and permanent structures, as public theatres, were not required until long afterwards, when the drama had become a distinct profession. In the meanwhile a taste for scenic display had developed itself, which required a very different arrangement of the stage and its apparatus from that of the ancients. Imperfect as they were in many respects, the dramatic pageants and recitations performed before Leo X. were "got up" with great magnificence, and some of the greatest artists were employed upon the decorations; among others Baldassare Peruzzi [PERUZZI, in BIOG. DIV.], whose skill in architecture and perspective carried scene-painting almost to perfection at once. Even in the preceding century dramatic exhibitions had been produced at Florence in a style then unprecedented; and we are told that the first Italian theatre was one erected in that city by Bernardo Buontalenti in 1581; but it does not appear to have been a public theatre, nor could it have been very spacious, as it now forms merely a saloon in the building called the Uffizi. Theatres on the present system were not built until the early part of the 17th century: just before which time an attempt had been made to restore the form of the ancient theatre and stage, with the permanent architectural scena and its entrances, by Palladio, whose celebrated Teatro Olimpico at Vicenza is one of those things which have gained a traditional reputation far beyond their real merits. Admired at first, because then superior to anything of the kind, it has continued to be admired since, partly on account of the character attached to it, which few care to dispute; and partly perhaps on account of its singularity, and because it shows the peculiarities of the ancient theatre. By no means, however, is it a very accurate imitation, though its chief merit lies in being a mere imitation; it is semi-elliptical instead of semicircular, with the stage on the longer axis of the ellipse; and on this account it looks too much squeezed up one way, and stretched out the other, and produces the same kind of disagreeable effect which would arise from placing the stage on the longer side of a parallelogram of the same extent (96 × 45 feet). It is said that the space to which the architect was restricted compelled him to adopt that form, yet it hardly appears so from the published plans of the building, for it would not be difficult to show how a semicircle might have been brought in. The scena, for which unlimited admiration is claimed, abounds in architectural barbarisms and solecisms. It is, however, the avenues seen beyond the scena through the centre arch and other openings which attract notice, and have been extolled by some as greatly superior to the "flimsy" painted decorations upon canvas used in modern theatres. Those avenues represent as many streets, the fronts of the buildings being modelled or carved in relief, and attempted to be shown in perspective by the floor and ceiling sloping very much upwards and downwards, and the other horizontal lines accordingly, and by the passages themselves being narrower at the further end. The contrivance is puerile at the best; and instead of being more deceptive or natural than painted scenery, the imitative perspective becomes distorted when viewed from any other situation than the centre of the theatre and the level of the stage. It is also difficult to understand how these narrow enclosed passages could have been properly lighted at the time of a performance; and although they are, in stage language, "practicable," they could hardly have been made use of, at least not for their whole extent, because at their further end an actor would appear gigantic. We are not aware of more than one other attempt to revive the ancient theatre in all its strictness, which was that built in 1588 at Sabbionetta, for the Duke Vespasiano Gonzaga, by Scamozzi, who completed the Teatro Olimpico after Palladio's death.

In claiming a decided superiority for the modern theatre over that of the ancients, we speak only as regards the respective systems; and as Ugoni, in his Life of Milizia, observes, to prefer the Grecian theatre, with all its inconveniences and the awkward expedients resorted to in it, as being of more classical and dignified character than our own comparatively small and fragile yet greatly improved structures of the kind, is to wish to limit art and science within their first bounds. There certainly was good reason at one time for exclaiming against modern theatrical architecture as very defective in regard to the audience portion of the "house." Till within a comparatively late period, scarcely any study was bestowed on beauty and convenience of plan. The accommodations were hardly so good as those in many very ordinary playhouses, where for want of space, there are no other seats than what directly face the stage. The "house" was usually an oblong, either rectangular or elliptical, so that the greater part of the audience,—at least those in the boxes,—were placed quite on the sides. Where the "house" contracted towards the proscenium, as was frequently the case, the side-boxes were actually turned *from* the stage; and whether such was the case or not, they were allowed to encroach upon the stage itself in such manner, that when the actors advanced to the front of the stage or beyond the line of the curtain, they may be said to have mingled with the audience, and those in the boxes on the *avant-scene* were actually behind them. If we may judge from the plans and other drawings of them, the two principal theatres in London were, even less than a century ago, both as inconvenient and as ugly as can well be imagined. The approaches, too, used formerly to be exceedingly bad; not only mean and inconvenient, but in many places most dangerously narrow. Such is strikingly the case in most of the modern Roman theatres, for instead of the box-corridors following the curve of the "house," and being of the same width throughout, they are so contracted where the other is widest, that more than two persons cannot pass.

Very great reforms have now taken place, yet there is still room for further improvements, obvious, though not likely to be adopted so long as it is considered a matter of course that the space before the curtain must be made to contain as many persons as can possibly be packed into it, and that an audience must be piled up around the whole house to the very ceiling. We do not say that modern theatres are too lofty; the error does not lie there, but in carrying up the boxes, tier after tier, to such a preposterous height that the uppermost box is several feet above the top of the curtain or stage-openings, and the back seats of the upper gallery are actually on a level with the ceiling over the pit. Such accumulation of diminutive stories gives a crowded appearance to the whole, and leaves no space for architectural decoration around the upper part. No doubt a very striking appearance of a different kind presents itself from the pit and from the stage, when the house is entirely filled to the very top; and if we consider merely the *coup-d'œil* from such points, it may be allowed to be imposing. But then, as regards that part of the audience who occupy the upper part of the house, the arrangement is bad. From the seats which are at all above the level of the top of the curtain, there is only a bird's-eye view of the stage and the scenery, and that only from the front seats, and also facing the stage; for from those on the side of it it is impossible at that height to obtain a sight of the scene or even of the actors, unless when they come forward towards the foot-lights. There should be no seats at a greater height than that of the centre of the curtain, or the level of what is now the second tier of boxes in our large theatres; for, as the scenery can be painted only to one horizon, —generally that of the stage itself,—its perspective effect is more or less impaired when it is seen from either very much above or below that level. No less preposterous is the practice of continuing the side-boxes up to the proscenium, and sometimes (as in Her Majesty's Theatre at London) quite up to the very curtain, so that there is no proscenium at all, unless the space on the floor of the stage, between the curtain and foot-lights, can be so called. While those so seated

lose the scenery altogether, they have the disadvantage of seeing between the wings on the side opposite them; and although the positive inconvenience resulting from such arrangement is felt only by a portion of the audience, the bad effect occasioned by it extends to the whole theatre. Not only ought there to be a distinct proscenium, serving as an architectural frame to the stage and its scenery, dividing that part of the theatre from the rest, but it ought to be of much ampler proportions than are now given it. It should extend so far as to leave some interval—a sort of neutral ground—between the curtain and the boxes, so as to remove the nearest spectator in them to a tolerable distance for properly viewing the stage as a picture; for it is possible to be as inconveniently near the stage as to be inconveniently distant from it. When, in order to contract the stage, or to render the pit and general diameter of the house considerably greater than what is required for the width of the curtain, the plan is made to approach a circle (as is the case in nearly every theatre built within the last forty years), the boxes should be confined to the semicircle facing the stage; and, so far from being a blank, the curved space on each side between them and the curtain might be made to contribute very much to the architectural appearance of the whole house. This would not take away anything from the pit; and if it materially diminished the number of the boxes and seats in them, it would be only where there ought to be nothing of the kind. The banishing of boxes from such situations, and making also no more than two tiers, would certainly greatly abridge the present capacities of theatres: a house of the same



size would not contain the same number of persons as at present, when a large part of the audience are put where they cannot well see the performance. It is likely, therefore, to be objected that such a system would be too expensive, since a large house would be requisite for a comparatively moderate audience; but curtailments might very well be made elsewhere, for at present the whole building is frequently much larger and more costly than actual necessity requires, the "house" itself, be its dimensions what they may, taking up a comparatively small area of the entire plan, while the rest is occupied by stately approaches and saloons, which, where economy rendered it expedient, might be greatly abridged, and much plainer in style, and some of them omitted altogether as superfluous appendages.

In some of the modern Continental theatres, plans of which are given on the previous page, the pomp displayed in the accessory parts of the building far exceeds anything of the kind in this country. In that at Berlin, besides several other spacious apartments, is a music-saloon 38 feet high, 44 wide, and 106 feet in length in its upper part, where there is a screen of six Ionic columns at each end; the whole highly decorated, and forming one of Schinkel's richest pieces of interior architecture. The theatre at Münich has two staircases to the boxes, with flights of marble steps 13 feet wide; and besides two saloons for the public (each 82 × 31 feet), there is a very magnificent one communicating with the royal box—not a mere ante-room, but what would be termed a noble room even in a palace, its dimensions being 46 × 44 feet, and 25 in height. In both these theatres, and in that of Genoa, the royal or state box is itself a room of some size, about 15 by 18 feet, more or less; and according to the general custom of the Continental theatres, this box (which occupies the height of two tiers, and is adorned with caryatides in front) is directly in the centre of the house, facing the stage, consequently in the very best situation of all; whereas the situation usually assigned to royal visitors in our theatres is almost the very worst, so far as seeing the stage and the performance is concerned.

In regard to the form of the "house," a decided improvement has taken place of late years; and the circular plan, or one approaching to it (either extended by the curtain being a tangent to the circle or somewhat beyond it, or reduced by the curtain intersecting and forming a chord to the segment), may now be considered the one established as being the most pleasing and commodious—that which is best adapted for affording a distinct view of the stage to the majority of the audience. But there is considerable difference of opinion as to its being the best form in regard to hearing. In fact, the science of acoustics is not yet thoroughly understood as regards practical purposes in building: it is easy enough to ascertain beforehand how much of the stage will be visible from different parts of the theatre, but not so what will be the result as to sound, since that will depend upon a variety of circumstances, some of them counteracting each other, and not every one of them to be guarded against or foreseen. The shape of the house is but one of these circumstances out of many: so much will also depend upon size, upon the depth of the boxes and galleries, and also upon accidental and such trivial matters, that any defect or advantage so occasioned is not likely to be traced to them. Here the chief guide is experience; and experience seems at present to be in favour of, at least not all against, the circular form; for the new theatres at Mainz, Dresden, and other places where it has been adopted, are said to be satisfactory in regard to the actors being distinctly heard in every part of the house.

While in their internal embellishment and fitting up theatres afford very great scope to the architect, though not so much as they might do, they also afford opportunity for accomplishing much in regard to characteristic external design. Magnificent as are the exteriors and façades of the theatres at St. Petersburg, Berlin, Munich, Bordeaux, and Nantes, with their poticoes and colonnades, there is nothing in them that very clearly expresses their particular purpose, because nothing that corresponds with, or indicates, the form of the "house" itself within. Moller, we believe, was the first who made the internal plan discover itself from without, by making the auditory—at least the corridors and saloon surrounding it—project out as a spacious semicircle, in the façade of the theatre at Mainz. The same form of exterior has been given by Semper to the new theatre at Dresden, which is also remarkable for the display it makes of sculpture. The new Covent Garden Theatre, it may be observed, is as deficient in character as any of the earlier structures of the same description mentioned above. Its internal arrangements are also of a very commonplace nature. The forthcoming competition for the new Opera of Paris may perhaps elicit some originality of treatment; but as modern habits interfere with the taste for theatrical amusements, it is to be feared that theatres themselves will hardly inspire any great art.

After all it is the stage, with its multifarious contrivances and complex mechanism, its scenery and pictorial effects, which manifest the extraordinary perfection to which the moderns have carried the scenic art. It does not enter into our purpose, however, to speak of stage mechanism, which is a subject and study by itself, and not otherwise connected with theatres and their architecture than as being made use of in the former. Those who seek for information of the kind will meet with many plates showing the stage construction and mechanism of Plymouth Theatre, in Foulstone's 'Public and Private Buildings, in Cavo's 'Architectonique des Theatres,' &c.; and, with more general and complete instructions, in Stephenson's work on the machinery of theatres. We will only observe that very great improvements and numerous contrivances for producing stage and scenic effects had been introduced into theatres at the commencement of the 17th century.

THEATRE. Before the reign of Elizabeth theatrical representations appear to have been subject to no legal restraint beyond the liability of those who conducted them to the vagrant laws.

But, although players, as such, were subject to no general legal restrictions, it is probable that the practice of granting licences from the crown to such persons prevailed as early as the reign of Henry VIII. The earliest theatrical licence from the crown now extant is that granted by Queen Elizabeth, in 1574, to James Burbage and four other persons, "servants to the Earl of Leicester," which contains a proviso that the performances thereby authorised, before they are publicly represented, shall be seen and allowed by the queen's master of the revels; a stipulation analogous to the licence of the lord chamberlain under the Licensing Act at the present day. These licences from the crown were originally nothing more than authorities to itinerate, which exempted strolling players from being molested by proceedings taken under the laws or proclamations against vagrants, and also superseded the necessity of licences from local magistrates.

Although theatrical representations became much more general in the reigns of James I. and Charles I., no laws were enacted for their regulation, with the exception of the stat. 1 Car. I. c. 1, which suppressed the performance of "interludes and common plays" upon the Lord's Day. An ordinance of the Long Parliament, in 1648, was directed to the suppression of all stage-plays and interludes, but though occasionally enforced with much rigour, it failed to abolish these entertainments. The stat. 12 Ann. stat. 2, c. 23, in general terms, classed players of interludes as rogues and vagabonds; but the stat. 10 Geo. II., c. 28, s. 1, expounded the former statute, by enacting that "every person, who should for hire, gain, or reward, act, represent, or perform any play or other entertainment of the stage, or any part therein, if he shall not have any legal settlement where the offence should be committed, without authority by patent from the king, or licence from the lord chamberlain, should be deemed a rogue and vagabond within the stat. 12 Ann." This provision is now repealed by the stat. 5 Geo. IV. c. 83, and players as such, whether stationary or itinerant, are, at the present day, not amenable to the law as rogues and vagabonds. By the 2nd section of the above statute, 10 Geo. II. c. 28, which, with the exceptions just mentioned, is still in full operation, and forms the law of the metropolitan theatres, it is enacted generally, that "every person who shall, without a patent or licence, act or perform any entertainment of the stage for hire, gain, or reward, shall forfeit the sum of 50*l*." By the 3rd section it is declared, that "no person shall for hire, gain, or reward act, perform, or represent any new interlude, tragedy, comedy, opera, play, farce, or other entertainment of the stage, or any parts therein; or any new act, scene, or other part added to any old interlude, tragedy, comedy, opera, play, farce, or other entertainment of the stage, or any new prologue or epilogue, unless a true copy thereof be sent to the lord chamberlain of the king's household for the time being, fourteen days at the least before the acting, representing, or performing thereof, together with an account of the play-house or place where the same shall be, and the time when the same is first intended to be first acted, represented, or performed, signed by the master or manager." The 4th section authorises the lord chamberlain to prohibit the performance of any theatrical entertainment, and subjects the persons infringing this prohibition to a penalty of 50*l*., and the forfeiture of their patent or licence. The 5th section provides that "no person shall be authorised by patent from the crown, or licence from the lord chamberlain, to act, represent, or perform for hire or reward, any interlude, tragedy, comedy, opera, play, farce, or other entertainment of the stage, in any part of Great Britain, except in the city of Westminster and within the liberties thereof, and in such places where the king shall personally reside, and during such residence only." The 7th section enacts, that "if any interlude, tragedy, comedy, opera, play, farce, or other entertainment of the stage, or any act, scene, or part thereof, shall be acted, represented, or performed in any house or place where wine, ale, beer, or other liquors shall be sold or retailed, the same shall be deemed to be acted, represented, and performed for gain, hire, and reward." Within a few years after the passing of this act of parliament, the clause which restricted the power of granting patents by the crown to theatres within the city of Westminster and places of royal residence, was found to be productive of inconvenience; and special acts of parliament were passed, which exempted several large towns, in which such entertainments were desired, from the operation of that clause, and authorised the king to grant letters for establishing theatres in such places.

A further relaxation of the rule established by the stat. 10 Geo. II. c. 28, for the regulation of theatrical performances, was effected by the statute 28 Geo. III. c. 30, in favour of places which could not be expected to bear the expense of a special act of parliament. By this latter statute, the justices of the peace at general or quarter sessions are authorised to license the performance of any such tragedies, comedies, interludes, operas, plays, or farces as are represented at the patent or licensed theatres in Westminster, or as have been submitted to the Lord Chamberlain, at any place within their jurisdiction not within 20 miles of London, Westminster, or Edinburgh, or eight miles of any patent or licensed theatre, or ten miles of the king's residence or fourteen miles of either of the universities of Oxford or Cambridge, or two miles of the outward limits of any place having peculiar jurisdiction.

The penalties imposed by the stat. 10 Geo. II. c. 28, being found in practice insufficient to prevent the performance of theatrical entertainments without licence, and great evils being alleged to follow from the resort of the lower orders in London to such entertainments, the legislature, in the year 1839, gave additional powers to the metropolitan police for their prevention. By the 46th section of the stat. 2 & 3 Vict. c. 47, "the commissioners of police are empowered to authorise a superintendent, with such constables as he may think necessary, to enter into any house or room, kept or used within the metropolitan police district for stage plays or dramatic entertainments, into which admission is obtained by payment of money, and which is not a licensed theatre, and to take into custody all persons who shall be found therein without lawful excuse." The same clause enacts that "every person keeping, using, or knowingly letting any house or other tenement for the purpose of being used as an unlicensed theatre, shall be liable to a penalty of 20*l.*, or, in the discretion of the magistrate, may be committed to the House of Correction, with or without hard labour, for two calendar months; and every person performing or being therein without lawful excuse shall be liable to a penalty of forty shillings."

THEBAINE. [OPIUM, ALKALOIDS OF.]

THEBET, in Hebrew טֵבֵת, is the fourth month of the civil year, and has twenty-nine days only. The name occurs in the Bible, at Esther ii. 16, where it is called the tenth month, in accordance with the ancient reckoning. It is a winter month, and will vary from December to January; the month Thebet of the year 5621 began on the 14th of December, 1860, and ended on the 11th of January, 1861. Josephus writes the name Τέβεθος, in the eleventh book of his Antiquities, ch. 5, § 4, where he speaks of the command of Ezra to the Jews to put away their strange wives, but Ezra in x. 9, places this in the 9th month, and Josephus himself makes it to correspond with Ἀπελλαῖος, so that we have a clerical error here. On a monument at Palmyra it is written as in Hebrew, but the Samaritan read Tebith, according to Scaliger. Benfey derives the name from some ancient Persian word, meaning "winter," which was probably Tapas, as in the cognate Sanskrit. A fast is observed on the 10th of the month in memory of the siege of Jerusalem by Nebuchadnezzar, as mentioned in ch. xxv., v. 1, of the second book of Kings. Another fast is mentioned, but not generally observed, to show the abhorrence of the Jews for the Septuagint version of the Bible; it is given to the 8th day of the month. Another fast is attributed to the 9th day, without any assigned reason; and a festival for the exclusion of the Sadducees from the Sanhedrim: but all these, except the first-mentioned, are rarely observed.

THEFT. [LAW, CRIMINAL.]

THEINE. [CAFFEINE.]

THEMIS (Θέμις), a Greek divinity, was, according to Hesiod and Apollodorus, a daughter of Uranus (Heaven) and Gaea (Earth), or, according to Tzetzes, a daughter of Helios. She was a favourite of Zeus, and bore him several daughters,—the Horæ, Eunomia, Dice, Eirene, and the Moerae. (Hesiod, 'Theog.,' 135, 901, &c.; Apollodorus, i. 3, 1.) These personified abstractions, which are represented as her daughters, show the ideas which the ancients had formed of her character, and consistently with these ideas she appears in Homer as a personification of the order of things sanctioned by usage or by law, and as the goddess who rules in the assemblies of the people. (Homer, 'Odyss.,' ii. 68, &c.) According to the same poet she lived with the other great gods in Olympus, was on good terms with Hera, and occasionally assembled the gods at the command of Zeus. (Homer, 'Iliad,' xv. 87, &c.; xx. 4, &c.) Diodorus (v. 67) states that she was believed to have made men acquainted with the will of the gods, the mode of their worship, and to have instituted laws, religious as well as civil. As a deity revealing the future she was believed to have been in possession of the Delphic oracle after her mother Gaea, and previous to the time that it came into the hands of Apollo, whence the act of giving an oracle was, even in later times, frequently called by a word derived from her name (θεμιστεύειν). She was worshipped as the goddess of law and order in various parts of Greece, as at Thebes, Olympia, Athens, Tanagra, and Troezen. She is frequently represented on coins in form resembling that of Athena, but carrying the horn of plenty in one hand and a pair of scales in the other.

THENARD'S BLUE. [COBALT.]

THEOBROMA. [CHOCOLATE AND COCOA.]

THEOBROMINE ($C_{14}H_8N_4O_4$). A vegetable alkaloid, homologous with caffeine, found in cocoa. It is obtained by extracting cocoa with boiling water, adding acetate of lead to the clear solution, filtering, removing the excess of acetate of lead from the filtrate, and then evaporating to dryness. The residue is to be treated with boiling alcohol, which deposits crystals of theobromine on cooling. These are to be purified by recrystallisation.

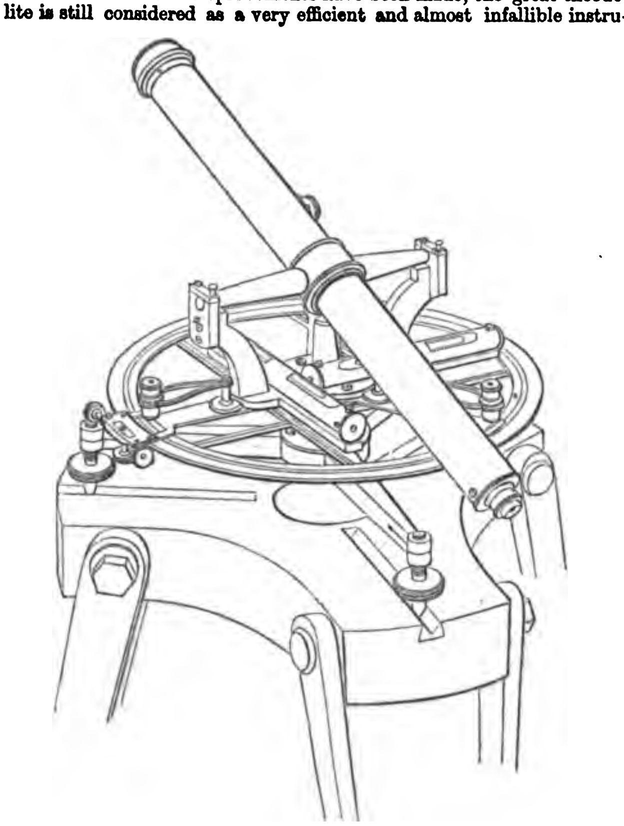
Theobromine is very slightly soluble in boiling water, and still less so in alcohol or ether. It possesses a slightly bitter taste, and can be sublimed without decomposition. It combines with acids, forming salts, which however possess little stability.

THEOCRACY (θεοκρατία, *a government by God*) is a term applied to the constitution of the Israelitish government, as established by Moses, on account of its being under the direct control of God. In fact, in the earliest form of the Israelitish constitution, *God was their king*; and the desire of the people to have a king at the time when Saul was raised to that office is expressly declared to be an act of rebellion on their part. (1 Sam., viii. 7.)

The theocracy did not supersede the establishment of a visible human government, consisting of judges and other officers, but all these officers were considered as subordinate to God as the only supreme ruler of the state.

THEODOLET, or THEODOLITE (the word is found in both forms), is the name generally given to the instrument used for measuring horizontal angles. In its simplest form the theodolet consists of a divided circle, which is to be set parallel with the horizon, and a telescope which has so much motion in a vertical plane as to enable the observer to view any object which he may require above or below the horizon. The derivation of the word is obscure, although the instrument and its name are comparatively of recent date. The earlier observers did indeed use divided circles, which they called *astrolabes*, *armillas*, &c. [ASTROLABE], for the purposes of surveying, but these were, generally speaking, very rude. The quadrant was employed in all accurate surveys up to the latter half of the last century, although Roemer had shown by reason and example the superiority of the entire circle. [CIRCLE.] The first instance of a survey conducted with an entire circle, on a considerable scale, was, so far as we recollect, the Survey of Zealand by Bugge, in 1762-8. (See Bugge's 'Observationes Astronomicæ,' p. 54, where he refers to a description of this instrument in Danish, and p. 61, where he states its merits.) The horizontal circle was two feet in diameter, and constructed by the Danish artist Ahl.

Ramsden finished his great theodolite in 1787, the circle of which is three feet in diameter. This was used for a triangulation, to connect the Observatories of Greenwich and Paris. A very full description of it is given in 'An Account of the Operations carried on for accomplishing a Trigonometrical Survey of England and Wales,' London, 1799, pp. 107-130, with four plates; a reprint, in a great measure, from the 'Phil. Trans.,' vol. 80 *et seq.* The principal triangles of the English, Irish, and Indian surveys have been observed with this instrument or with those nearly identical in size and construction; and though several minor additions and improvements have been made, the great theodolite is still considered as a very efficient and almost infallible instrument.



We believe that the high reputation of the great theodolite depends in a great degree on the *superstitious* care with which it has been used and preserved: it is undoubtedly a very fine, well-divided instrument, but in common hands its want of solidity and firmness would probably have been felt. It would be impossible as well as useless to give an account of the various constructions of different artists at home and abroad; but the reader who desires to see what had been done up to 1851 is referred to the Jury Report, Class X., where the surveying and levelling instruments and theodolites of the Great Exhibition are pretty fully noticed, as to their new points and from the personal observations of Mr. Glaisher. The general properties of a theodolite, that it should be firm, well balanced, &c., will be easily recognised by a person who knows how to make good use of the instrument, and we shall advert in the course of this article to some of the qualities which are, and to others which are not, essential.

We have given on the preceding page a sketch of the theodolite in its simplest form, such as would be proper for the secondary triangulation of a national survey, or for the most accurate private survey. The tripod which carries the instrument rests with three foot-screws in brass notches let into the top of a wooden stand. The legs of the stand are not fully represented, but the two parts of which each is composed end below in a strong and sharply-pointed metal socket. The circle is fixed, and the upper works, telescope, verniers, levels, &c., turn on a centre, which may be seen just under the cross of the telescope. The adjustments are very simple. The wooden stand is first set down with a good opening of the legs, and the top nearly horizontal. The foot-screws are placed in their notches, the plumb-line hung from its hook, below the centre of the circle, and the telescope turned round till one level is parallel to the line joining two foot-screws, while the other level is in a line from the third foot-screw to the centre. Bring the bubble of the first-mentioned level into the middle by raising one of the two foot-screws and depressing the other, and then adjust the cross-level by raising or depressing the third foot-screw alone. Now turn the telescope round 180°, and if the bubbles are not in the middle, bring them half way there by touching the foot-screws, and the other half by screws which adjust the levels themselves. When this has been nicely done, the bubbles will remain in the middle in every position of the telescope. If the objects to be observed lay all in the horizon, or in a plane parallel to it, the above adjustment would be sufficient; but when the objects are out of the horizontal plane they must be referred to it by a perpendicular, that is, the plane described by the telescope must be a great circle, and must also pass through the zenith. There are generally two wires at least in the focus of the telescope, one horizontal and the other vertical. Place the eye-piece to give sharp vision of the wires, and turn the milled screw, seen towards the object-glass, until the objects you are going to observe are distinct. Place the vertical wire on any well-defined object, making the bisection near the crossing of the wire; raise or depress the telescope until the object is nearly at the bottom or top of the field; if it is still bisected, the wire is rightly placed, but if not, twist the tube carrying the eye-piece so as to effect a bisection. To make the telescope describe a *great* circle, select some well-defined object near the horizon, and bisect it: now take the telescope *very carefully* out of its Y's, reverse it, and look again at the object. If it is still bisected, there is no error; but if not, the bisection is to be effected half by the tangent-screw of the instrument and half by the screws which carry the wire-plate, screwing up one and releasing the other. Restoring the telescope to its first position, it will be seen whether the adjustment is correct, and if not, the process must be repeated until the bisection is the same in both positions of the telescope, the clamp and tangent-screw remaining fixed. For the adjustment of the axis of the telescope a level would be convenient, but in this instrument the axis is supposed to have been correctly placed by the maker, and the only mode of correcting any error is by filing the Y's. It may be ascertained whether the axis is tolerably correct as follows:—Bisect an object as far above or below the horizon as the motion of the telescope will allow. Reverse the telescope, and if the object is still bisected, the pivots of the telescope are the same size: if not, the observer must deduce the difference of the pivots from the altitude and the error observed, which is not difficult. When this has been satisfactorily executed, bisect, as in the last instance, an object as far as possible from the horizon, and read off the verniers. Turn the instrument round 180°, return the telescope *end for end,* bisect the object again, and read off the verniers. If the mean readings differ exactly 180°, the axis is horizontal; but if they do not, the observer will have sufficient data from this, and the altitude or depression, for determining the quantity and direction of the error, which he may correct by the file or by calculation, according to his pleasure. There is a much easier method of examining the position of the axis by observing an object directly and as seen by reflexion from a fluid, as mercury, oil, or water. The axis is truly horizontal when the vertical wire bisects the object and its reflected image without moving the tangent-screw. It must be recollected that the adjustments of the horizontal circle already described must be previously and very scrupulously performed before attempting the examination or adjustment of the cross-axis.

As the objects in a survey are at very different distances, an adjustment is required for forming the image exactly on the wires. The use of the milled screw, seen towards the object-end of the telescope for this purpose, has already been mentioned.

In use, this theodolite should be placed on a repeating table or tripod, such as is to be found figured and described in REPEATING CIRCLE, and the repeating-tripod upon the stand. This was not done in the present plan for the sake of clearness. To adjust the repeating tripod, place the levels as described in the first adjustment, and clamp the theodolite. Bring the foot-screws of the theodolite over the foot-screws of the repeating-tripod by the motion of the tripod, and then by touching the foot-screws of the tripod or theodolite set the level-bubbles in the middle. Turn the upper plate of the tripod half-round, and again bring the bubbles into the middle, half by the tripod foot-screws, half by those of the instrument, and repeat the operation until the revolution of the repeating-table does not alter the position of the level-bubbles. The repeating-stand is now clamped, and the instrument itself is to be adjusted exactly as we have described above.

The course of observation after the instrument is adjusted is very simple. The problem is to measure the horizontal angle between two objects. Turn the telescope two or three times round in the direction in which you intend to observe, then bisect one of the objects, read off the verniers, and take a mean; bisect the second object, read the verniers, and take a mean. The difference between the two means is the angle required. This is all that can be done by the instrument as usually mounted; but with a repeating-table the operation is continued, thus:—Bring the telescope back on the first object, by the motion of the repeating-table, using its clamp and tangent-screw, and by the motion of the instrument bring the telescope on the second object. It is clear the motion of the repeating-table has merely restored the telescope to its original direction, without altering the readings of the circle; and that if the telescope be turned on the second object by its motion alone, without disturbing the circle, the difference between the mean of these new readings and the preceding mean will also be the angle required. By continuing the process, the angle may be measured as often as the observer pleases. It is evident that all readings-off, except the first and last, are superfluous, save as checks, or as giving the means of estimating the accuracy of the final result. The series should terminate after a whole number of revolutions as nearly as possible, when the excentricity of the repeating-table will be eliminated, a matter of possible importance if the objects are near and the repeating-table carelessly made, or, if the objects are pretty distant and this caution superfluous, when the verniers are nearly at the divisions at which you set out, which gets rid of or at least diminishes any errors of division. The latter condition is however rather a speculative than a practical one. As the error of division is divided by the number of observations, and the casual error of observation only by the square-root of the same number, it is evident that a moderate number of repetitions in our excellently-divided circles will reduce the error arising from mal-division to a much smaller quantity than that which belongs to the class of casual error of observation.

The essential condition of repetition is, that the motion of the theodolite shall not disturb the repeating-table. The motion of the latter therefore should be as heavy as will admit of nicety in the tangent-screw, while the motion of the parts which move with the telescope should be as light and free as is consistent with firmness. There is, we believe, no difficulty whatever in effecting both these points; but lest any error should arise from repetition, we should recommend a careful observer to determine his angles by two series,—one by always moving the telescope and its tangent-screw forward, and the repeating-stand and its screw backwards; and another, by reversing the process. If the two results agree, as they should do within the limits of casual observation, the mean is probably free from all other error; and if they do not, the observation should be repeated and varied until the quantity and probable law of the error is ascertained. We should then be able to say decidedly where, when, and under what precautions, repeating was a safe as well as a convenient and economical process, which at present is rather a *vexata quæstio,* unless the decision be supposed to be against all repetition, to which we do not bow.

The foregoing description has been confined to a form of theodolite which is not in ordinary use, though from its simplicity and power it is well adapted to the purpose of explanation. The common theodolite is generally carried by a pair of parallel plates, fixed on a three-legged staff. The lower of these circular plates is screwed upon the staff, and has an aperture above the screw. The upper plate has a strong descending shank which passes loosely through this aperture. A button of a spherical form is fixed on the end of the shank, the curvature uppermost, and rubs against the under surface of the lower plate, which is dome-shaped to fit it. Four strong screws pass through the upper plate and abut with their lower ends against the lower plate. When the screws are turned the plates are separated until the button and the spherical surface on which it rubs are brought into squeezing contact. To level the theodolite, set the levels each parallel to a diagonal pair of screws of the parallel plates. Then screw one pair until you come to a bearing, and by releasing one screw and screwing up the other, but not very tight, set the corresponding level horizontal; leaving this pair and taking hold of the other pair set the second level also right, and if the first level is deranged, as it probably will be a little, restore its position by screwing up the proper screw. Turn the telescope half round and correct the error, half by the parallel plate-screws, and the other half by the level-adjustments themselves. It is desirable that, when the final adjustment is made, the screws should bite pretty hard, otherwise there is a great chance that the upper plate will turn a little during the observation. This objection would seem fatal to the use of parallel plates where great nicety is required; they are however very convenient and of very ready use, and perhaps if the screws are strong and the observer is careful to give the telescope three or four turns round in the direction he means to observe, before starting, and always to move the telescope the same way, serious error may be avoided. The first object observed should always be observed at the end of the service, in order to see whether there has been any change in the original position. If one of the screws rest in a notch, perhaps the tendency to twist may be wholly overcome.

Another contrivance which is to be found in almost all theodolites is much more objectionable. The surveyor wishes to save himself addition or subtraction, and requires an adjustment by which he can turn the whole circle about and bring the telescope upon the first object, the verniers being previously set to zero. There is, therefore, a motion with a clamp and tangent-screw for this purpose, which, as the clamp has usually a very short bearing, is particularly liable to yield, and so to destroy all accuracy. To remedy this unnecessary evil, a second or *watch* telescope, as it is called, is attached to this part of the instrument, and brought to bear upon a well-defined object. Any motion or wriggling of the zero-clamp is betrayed by the watch-telescope, and when an angle is taken it must be first ascertained whether the watch-telescope keeps its position, and the position if disturbed must be restored to the zero-tangent screw, before the observation is finally made. In some theodolites made for the Indian survey, under the direction of Colonel Everest, the zero and slow-motion clamp take the form of a repeating-table, and may be so applied. It would be safer to have this motion made considerably heavier than in the patterns we have seen, and if the instrument is likely to fall into clumsy hands the watch-telescope might easily be added for greater caution. Such a theodolite would, so far as we can judge, have no limit to its accuracy, except that depending on the diminutive telescope.

For many purposes of surveying it is desirable that the telescope should allow of being considerably elevated or depressed, and that means should be given for measuring this angle with considerable accuracy. A circle, or portion of a circle, is then fixed upon the telescope axis, and the necessary verniers and level may be secured by a tail-piece or otherwise to the support. If the vertical angles are to be measured as accurately as the horizontal angles, the instrument becomes an altitude and azimuth circle. [CIRCLE.] But such instruments are rarely applied to the measurement of terrestrial angles. The direction of the meridian was determined in the Ordnance Survey by observing Polaris at its greatest elongations E. and W., and taking the middle of the two readings for the direction of the north. Hence, the telescope required all the transit adjustments except that for azimuth [TRANSIT], and was considerably elevated above the circle. Though the results were upon the whole satisfactory, yet we greatly doubt the prudence of ascertaining this fundamental and delicate point from such an instrument, or of risking the steadiness of the telescope supports by raising them so much above the body of the instrument. It would have been better, we conceive, to have determined the direction of the meridian by a series of careful transit observations, using more optical power with greater steadiness, and to have kept the theodolite to its proper office, that of measuring horizontal angles, greatly reducing the height of the telescope supports. The great theodolite had originally a semicircle fixed to the axis of the telescope, for measuring altitudes and depressions. This has since, very properly, been removed, and a whole circle substituted.

Where a theodolite is merely used for surveying, the telescope requires only a moderate vertical range. Mr. Troughton fixed a portion of a circle (which may be more properly called a *slice* than a sector) to one or two of his 12-inch theodolites, and this construction is often found in other makers. The telescope is thus kept lower, the instrument is firmer, and the larger radius gives the portion of the circle a seeming advantage over the entire circle of smaller radius. There is, however, something very unsatisfactory in a portion of a circle, and we should prefer a sort of compromise, giving the supports such an elevation as would allow a vertical circle of about half the dimensions of the horizontal circle. If the direction of the meridian is to be determined by this instrument, the supports must be at least so high as to see 2° or 3° above the latitude of the place, and the vertical circle may be increased accordingly.

It is perhaps requisite to give some description of the mode of adjusting the vertical circle. Where the supports are high enough to allow the telescope to pass when turned round in a vertical plane, all the adjustments are the same as in the altitude and azimuth circle. [CIRCLE.] When the telescope is too long for this, the circle must be lifted out of its Y's, in order to bring the line of sight again upon the object to be bisected, and then set down again. The operation is, in fact, the same, whatever be the nature of the vertical arch, and the adjustment is to be effected either by altering the level or the horizontal wire until the reading is the same in both positions of the telescope. If the observer has a Y level, or collimator, he can set the cross of his level-wires horizontal, and this being bisected by the telescope of the theodolite, the vernier must be made to read zero, and the bubble of the level be brought to the middle by its proper screws. Or if the observer possess two stands (and there is a great convenience in having more stands than one in surveying), he may place the stands at a considerable distance from each other, and, fixing the instrument on one stand, and a mark of exactly the same height as the telescope-axis on the other, observe the mark, noting its elevation or depression. Now, exchanging the instrument and mark, he must re-observe the depression or elevation exactly as before. On drawing the figure, it will be seen that if light move in a straight line, 90°−elevation at lower station = 90−depression at higher station + the angle between perpendiculars to the earth's surface at each station, which last quantity is known from the distance between the stations, and may be easily calculated, that is, depression − elevation = a known angle. But if the zero is wrong, depressions will be increased while elevations are diminished, and *vice versâ*, so that depression observed − elevation observed − the known angle, instead of being = 0, will be ± 2 error of the vernier, which may be corrected accordingly either by the adjustment of the level or of the horizontal wire. Or, lastly, if the telescope has so much motion as that a star can be observed directly and by reflexion from mercury or any other fluid, the index-error of the vertical circle may be most accurately determined thus:—Take any star in the meridian, and having observed it directly, observe it immediately after by reflexion. If great nicety is required, the observations should be repeated alternately several times, and the partial results reduced to the meridian. The mean reading between the meridian altitude and meridian depression is the reading which corresponds to the horizon, and the difference of this from 0, or 90°, acording as the circle reads altitudes or zenith distances, is the error of the instrument, which may either be corrected or allowed for. This method, though very accurate, requires some knowledge of the time, and is rather restricted by the choice of stars. It is nearly as safe to observe a star not far from the east or west point, first directly, then by reflexion, and lastly, directly, making the contacts at following whole minutes, or at even or odd minutes if the interval of a minute is not sufficient. As the stars rise nearly uniformly in this part of the heavens, the mean of the first and third observations should give an altitude equal to the depression observed midway. The discrepancy between these results will be the double index-error as before, which may be corrected or allowed for. By some of these methods the index-error of the vertical circle or sector is to be found.

In some of the older theodolites the telescope rides in Y's at the top of the vertical arch, and is reversible as a level. The horizontal position of the telescope Y's can therefore be found as in any other level, and the verniers of the vertical circle set to zero when the telescope is horizontal. The vertical angles measured by these instruments are not, however, to be greatly depended on. They are usually greatly out of balance in all positions of the telescope, except the horizontal position, and therefore they make better levels than altitude instruments. This error may be partially got rid of by having a second level fixed to the instrument which is parallel to the plane of the vertical circle, and adjusted to the telescope-level when that is horizontal. If this supplementary level is pretty well graduated, it will show the tilt which is given the plane of the instrument by want of balance, and so give the correction required.

It may be as well to mention here that the principal adjustment being that of setting the plane of the theodolite horizontal, or, more correctly speaking, the principal axis vertical, any horizontal level anywhere placed is sufficient for the purpose, though the cross-levels are a little handier. A box-level is convenient, if a stand and repeating-table are used, to bring the planes nearly horizontal, and to make both ends of the bubbles visible at first.

Many surveyors give themselves and the instrument-maker a great deal of unnecessary trouble by being very difficult on the chapter of excentricity, which they confound with error of division. The English dividing-engines, up to the present time, do not divide the circles upon their centres; and therefore it frequently happens that the point round which the circle turns is not the point round which it is divided. When this error is not absolutely monstrous, the only effect is that one vernier gains what another loses, and that the mean of two opposite, or of three, four, or more equidistant readings, is precisely the same as if there were no excentricity. The advantage of a *little* excentricity is, that it gives you the benefit of an unbiassed reading at every vernier as well as the first: again, if all the verniers are recorded, it is a check on the dishonest observer, who might read one vernier and set down the rest. The instrument-maker must please his ignorant customer, and so either hammer his circle after it is divided, which may deform his work, or have an adjustment, which injures its solidity.

In Ramsden's great theodolite, and several others which have been made, the circle is read off by micrometer microscopes. Sometimes the microscopes revolve with the telescope (as the verniers do in our figure); sometimes the microscopes are fixed, and the circle revolves with the telescopes, as in Ramsden's theodolite.

Ertel of Münich has made several *astronomical* theodolites in which the rays entering into the telescope are reflected along the horizontal axis by a prism. The observer therefore looks in at the end of the horizontal axis, whatever the position of the star may be. The eye and body of the observer are more satisfactorily placed, and the supports are kept close and snug to the horizontal circle. The instrument is well adapted to one of its principal objects, observing stars at their passage over the prime vertical [TRANSIT]; but there is some trouble in finding an object when you have no better direction to look for it than your eye affords. Excellent latitudes have been determined by instruments of this class used in the prime vertical, and even the small vertical circle seems from some accounts to possess more power than from its dimensions we should have thought probable. As a general rule, the greater the number of readings, the less the effect of bad division, but beyond a limited number, the trouble and difficulty of reading-off is found in practice to counterbalance the advantage. Two opposite readings annul the effect of excentricity; three or four equidistant readings destroy such an error as would arise from the circles becoming elliptic after it was divided, or any error which follows the same law. In small stoutly-made theodolites we think two the most convenient number, and they can be much more conveniently read off than a larger number. When the circle is so much as 8 inches in diameter and the telescope good, we should prefer three or four readings. The vertical circle or sector may have two opposite readings. For many matters connected with surveying on the most extensive and accurate scale, see the memoirs published of the English, Scotch, and Irish Trigonometrical Survey; and the 'Base Métrique,' or account of the French measurement of an arc of the meridian, although that survey was conducted by a different instrument. Similar operations have been carried on in many countries during the last seventy or eighty years, and the memoirs which relate to these surveys contain the best information which can be had on the subject.

It should be mentioned that Mr. Simms has introduced a *Transit Theodolite*, or portable altitude and azimuth instrument, for the use of the scientific traveller and engineer. The ordinary vertical arc of the theodolite is extended to a complete circle, and is read by two opposite verniers. The range of the telescope is unlimited, and by means of a diagonal eye-piece observations can be made in the zenith. The axis is perforated for illumination of the field of view. The instrument is 8 inches in diameter.

THEODOSIAN CODE. In the year A.D. 429 Theodosius II. appointed a commission of eight persons, at the head of whom was Antiochus, to form a code out of all the constitutions and other laws which had been promulgated since the time of Constantine the Great. The code was to be formed on the model of the private compilations respectively called the Codex Gregorianus and the Codex Hermogenianus. Either nothing was done by this commission, or, for some reason, a renewal of it was thought necessary, and this renewed commission received its instructions in the year 435. This second commission consisted of sixteen members, with the same Antiochus at its head. In remodelling their materials the commission was empowered to omit the superfluous, insert the necessary, change the ambiguous, and reconcile the incongruous.

The code was completed and promulgated as law in the Eastern empire in the year 438; and it was declared that the laws enacted since the time of Constantine should only be in force so far as they were incorporated into this code. The code was forwarded in the year 438 by Theodosius to his son-in-law Valentinian III., who confirmed it and laid it before the Roman senate, by whom it was received. In the year 448 Theodosius forwarded to Valentinian other constitutions which he had made since the completion of the code, as circumstances had arisen; and these new constitutions were promulgated in the Western empire in the same year. The new constitutions were called Novellae, and all such new constitutions which were interchanged between the East and West, and had reference to the code of Theodosius, were called by the name Novellae. This interchange subsisted as long as the empire of the West continued: the last constitution of the kind that we know is one of Anthemius, who was contemporary with Leo I. in the Eastern empire: it belongs to the year 468, and relates to Bona Vacantia.

This code consists of sixteen books, which are divided into titles, and the titles are subdivided into sections. The arrangement of the matter differs from that in the subsequent compilation of Justinian, also called the Code. The code of Theodosius treats of Jus Privatum in the first part, and especially in the second and fourth books, both included, and in the beginning of the fifth: the following books treat chiefly of Jus Publicum. The first book treats of offices, and the sixteenth book treats of matters pertaining to the Christian church. The code of Theodosius was the first great compilation of the kind, and it was much used in the compilation of the code of Justinian. It also forms the basis of the code of the Ostrogoths, called the Edictum Theoderici; it was incorporated into the code of Alaric II., commonly called the Breviarium, in an abridged form, accompanied by a continual interpretation or explanation; and it was used in the compilation of the Lex Romana of the Burgundians, which is often incorrectly called Papiani Liber Responsorum.

The greater part of the Theodosian code and of the Novellae Constitutiones exist in their genuine state: the first five books of the code and the beginning of the sixth are chiefly found only in the Breviarium. The excellent edition of J. Gothofredus (6 vols. fol., Lyon, 1665, re-edited by J. D. Ritter, fol., Leipzig, 1736-1745), and also the edition of the Jus Civile Antejustinianeum, Berlin, 1815, have followed the text of the Breviarium for the first five books and the beginning of the sixth. But Clossius and Peyron have subsequently made additions to the first five books, and particularly to the first; the former from a Milan MS. of the Breviarium, and the latter from a Turin palimpsest of the Theodosian Code. ('Theodos. Cod. Genuina Fragmenta,' &c., W. F. Clossius, Tüb., 1824, 8vo.; 'Cod. Theodos. Fragment. inedd.,' &c., Amad. Peyron, 1823, 4to.) Hänel has also added to the later books.

THEOLOGY (θεολογία), the science which relates to God.

1. *Definition of Terms.*—All that men know of the nature of God, considered absolutely, of the relations between God on the one hand and themselves and other beings on the other, together with the consequences resulting from those relations, and the duties arising out of those relations:—all this knowledge is described by the word *religion*. [RELIGION.] To reduce this knowledge to a systematic form, is the province of the science of *theology*; and the truths of religion, when arranged in a scientific form, constitute *a system of theology*. Theology stands to religion in the same relation as that in which every other science stands to its subject; for instance, natural philosophy to matter, metaphysics to the mind, philology to language. By many writers the words *theology* and *religion* are used as synonymous terms; but such a usage of them is incorrect.

The above definition applies to the word as it has been understood for some centuries; but its earlier use was somewhat different from this. The θεολογία of the ancient Greeks was φιλοσοφία περὶ τῶν θείων, the philosophy of divine existences; and it included all questions relating to the origin, the nature, and the service of the gods. As relating to the origin and mode of existence of the gods, Aristotle uses the verb θεολογέω ('Metaphys.,' i. 3); and Cicero the noun *theologus* ('De Nat. Deor.,' iii. 21). In a wider signification the word is used by Varro (Augustin., 'De Civitat. Dei,' vi. 5; compare Eusebius, 'Præparat. Evang.,' iv., 130), who distinguishes three different kinds of theology: (1) μυθικόν, or *fabulosum*, mythical or legendary; (2) φυσικόν, or *naturale*, physical, or relating to the nature of the gods; (3) πολιτικόν, or *civile*, political or popular. Of these, the first is the theology of poets, the second that of philosophers, the third that of the people.

In the New Testament the word is not used. (The title of the Apocalypse, in which the word θεόλογος is applied to the author, is much later than the book itself.) [APOCALYPSE.] The simpler terms *knowledge* (γνῶσις) and *faith* (πίστις) are those which approach most nearly to the meaning of the word *theology*; but the fact being that theology, as a system, is not taught in the New Testament, there is nothing surprising in the absence of the word.

Lastly, the modern usage of the word, as expressed in the above definition, was first adopted by Peter Abailard (ob. 1142), who drew up a system of scholastic divinity, to which he gave the title of 'Theologia Christiana.' It should be remarked that instead of the Greek word *theology*, the Latin word *divinity* is often used to describe the science of religion.

2. *Divisions of the Science.*—With reference to its foundation, theology is divided, as explained in the preceding paragraph, into *Natural* and *Revealed*, or *positive*. The latter word is used to indicate that the foundations of revealed theology are the *expressed will* of God; just as we speak of positive laws. The term *positive theology* is also used to describe any system of theology which rests upon authority, as, for example, the system embodied in the formularies of a particular church.

According to the method of treating the subject, theology is divided into *popular* or *biblical*, and *systematic* or *scholastic* theology.

According to the part of the subject which is treated of, it is divided into *theoretical* and *practical* theology. Of these, the former includes—(1) the knowledge of the documents which contain the revelation, the proof of their authority, and the explanation of their meaning, that is, *Exegetical Theology*; (2) the investigation, arrangement, and discussion of the truths so revealed, that is, *Systematic Theology*; (3) the workings and changes of religion among those who have professed it, or *Historical Theology*. *Practical Theology* has for its subjects the duties of practical religion, and the various modes of enforcing them on men; and with reference to the latter, it is divided into—(1) *Homiletics*, or preaching; (2) *Catechetics*, or teaching; (3) *Liturgics*, or worship and the administration of the sacraments; and (4) *Pastoral Theology*, or the care and government of a church.

3. *Dogmatic Theology*, or *Dogmatics*, means more than the term *systematic theology*. The province of the latter is simply to give to the scattered truths of revelation the scientific form of a connected system, in whatever manner may seem most convenient to the framer of the system; but *dogmatic theology* aims at forming a system which shall be accepted as binding by a large body of religionists, and then views all religious truth in the light of that system. It is *systematic theology*, with the idea of *authority* superadded.

Out of *Dogmatic Theology* springs *Controversial Theology*, or that mode of treating the subject of religion in which some particular system of dogmatics is defended, or some other system attacked.

See, further, the articles CANON; MIRACLE; RATIONALISM; and REVELATION; in which many of the subjects of dogmatic controversy are discussed.

THEORBO, a musical instrument of the lute kind, which has long fallen into disuse. This instrument has been called the *Cithara Bijuga*, its two heads having been erroneously considered as two necks; and it was commonly known under the name of Arch-lute, on account of its magnitude. The upper and middle strings were attached to the lower head or nut; the lower, or base strings, to an upper or additional one. According to *Maister Mace* (1676), the Theorbo was the old English lute very much enlarged, and used chiefly, if not only, as an accompaniment to the voice.

THEOREM (θεώρημα) means properly a thing to be looked at or seen; and is used in mathematics to signify any proposition which states its conclusion or makes any affirmation or negation; as distinguished from a PROBLEM, which demands or requires a conclusion to be arrived at, without so much as stating whether that conclusion is even possible. Thus: "Required to draw a tangent to a circle at a given point," is a problem; but "If a straight line be drawn at right angles to a diameter from its extremity, that straight line is a tangent to the circle," is a theorem. The problem asks discovery both of method and demonstration; the theorem asks demonstration only.

This distinction, as noticed in detail in PROBLEM, was not made by the older Greek geometers. Theodosius is the first, so far as we know, who uses the word theorem, but none of his propositions are problems. Pappus is the first who uses both terms in the distinctive sense.

THEORY, THEORY AND PRACTICE. If articles upon the mere meaning of words be admissible, it is the consequence of the manner in which the words are used. Of all the fallacies which infest society, the most common is that of applying to one sense of a word ideas or associations derived from another; and of all the words in use, there are few which are more often subjected to such process than those which stand at the head of this article.

By theory, properly speaking, is meant the mode of making seen and known the dependence of truths upon one another: a theory is a connected body of such truths belonging to one or more common principles. The use of this word has enlarged with the boundaries of the sciences. For example, before the discovery of universal gravitation, all that was known of any one planet was the empirical formulæ for one or two of its inequalities. This constituted the theory of the planet (then so called): thus the theory of the moon, so far as peculiar, consisted in the statement of the laws of the inequalities called the equation of the centre, the evection, &c. In our day the point of view is changed; it is no longer the mere exhibition of these inequalities which constitutes the theory, but the deduction of them, as necessary consequences, from the principle of gravitation. The theoretical astronomer now starts from this principle, and, taking only one position and velocity for his numerical data, finds out every inequality of the planetary motions, those which were previously known from observation and more, and shows how to form them into tables. The practical astronomer makes these tables, computes places from them for the current year, compares these places with the results of observation, and returning the comparison into the hands of the theorist, enables him, if need be, to correct the original numerical data to which he applied his methods, or to detect new inequalities. The process is now deductive; but before the time of Newton it was the other way. The observer had the first task; the inequalities were to be collected from comparison of observations, and their laws, reduced to the simplest form, were the data for future tables.

Again, before the introduction of the undulatory hypothesis, the theory of light consisted in the exhibition of the laws of reflexion and refraction, with a certain extent of explanation from the emanatory hypothesis of Newton. Since that time the theory of light has become, though at a distance, a resemblance of the theory of gravitation in its character: prediction has commenced, that is to say, the phenomena which would appear under certain new circumstances have been announced before any experiments were made to discover them; and correctly announced. This is the end to which theory ought to be constantly tending; namely, the discovery of laws of action in so complete a manner that the necessary consequences of those laws never fail to make their appearance, so that everything which is seen is found to be a consequence of the laws when examined, and every consequence of the laws is seen in phenomena when looked for. Whatever fulfils these conditions may be called a perfect theory, or a perfect *mathematical* theory.

The next step in the chain of discovery is one which may in most cases be incapable of attainment. For example, nothing is more certain than that the assumption of every particle of matter attracting every other particle, according to the Newtonian law, leads to the complete deduction of the celestial motions, and gives the complete power of prediction just alluded to. But whether this ATTRACTION does actually take place, or whether any intermediate agent is employed, though it matters nothing *at present* to the mathematical theory, is the next object of inquiry. Could this point be ascertained, it is more than probable that the knowledge of the constitution of matter to which it would lead, would open hundreds of important consequences even in the application of science to the arts. [CAUSE; HYPOTHESIS.]

Before coming to the distinction between theory and practice, we must observe that theories may be divided into two classes, the more perfect and the less perfect. We cannot say that any theory is absolutely perfect; but there are some of which the defects are hardly perceptible, and others in which the contrary is the case. For example, the theory of the statics and dynamics of *rigid* bodies is tolerably perfect; but that of bodies composed of particles acted on by molecular forces is in its infancy. We know a great deal more of the connection of the planetary worlds with each other than we do of the particles which, when connected together, form a bar of iron or of oak. We know that the bar is not perfectly rigid; that it bends and breaks: and the degree of bending which a given force will cause, and the amount of pressure necessary to produce fracture, must be sought for in experiments, from which, imperfect as they are, the laws which would follow from a good theory, if we had one, are to be deduced. In such a subject our theory, instead of being an all-sufficient *guide*, is only a *help*, the services of which are to be used to an extent which discrimination derived from practice and experience must point out. Many a person who thinks he is proceeding upon experience only is really making use of a mixture in which there is theory, though his own knowledge of the process he uses, and of its history, may not be sufficient to inform him of it.

A person who uses an imperfect theory with the confidence due only to a perfect one will naturally fall into abundance of mistakes; his predictions will be crossed by disturbing circumstances of which his theory is not able to take account, and his credit will be lowered by the failure. And inasmuch as more theories are imperfect than are perfect, and of those who attend to anything, those who acquire very sound habits of judging are few compared with those who do not get so far, it must have happened, as it has happened, that a great quantity of mistake has been made by those who do not understand the true use of an *imperfect* theory. Hence much discredit has been brought upon theory in general; and the schism of theoretical and practical men has arisen. Fortunately there are many of the former who attend properly to the improvement of imperfect theory by practice; and many calling themselves practical who seize with avidity all that theory can do for them, and who know that step by step theory has been making her way with giant strides into the territory of practice for the last century and a half.

By practice, as distinguished from theory, is meant (not by us, but by those who contend for the distinction) the application of that knowledge which comes from experience only, and is not sufficiently connected with any general principles to be entitled to the name of a theory. The distinction of labourers in the field of science or art into theoretical and practical is not strictly a just one, for there is no theorist whose knowledge is all theory, and there is no practical man whose skill is all derived from experience. But the terms will do well enough to distinguish two classes whose peculiarities it might be difficult to define exactly.

The practical man, when he is really nothing more, is one who can just do what he has been taught to do, and who has acquired skill and judgment in a small range of occupations. All who pride themselves upon the title would be displeased at this definition, and we readily admit that many of them are entitled to a higher character; but only because the title by which they delight to describe themselves is a wrong one. They desire, under the name of a workman, to claim the qualities of a master. The term *theoretical* serves, as one of contempt, to designate any thing of which they disapprove; and as there never is any fallacy which is not carried to a fool's-cap extent by the lower order of users, it would not be difficult to make a most amusing selection of instances of the manner in which the distinction has been worked by the large number who are at the bottom of the class, and in whose heads it runs that their own *ignorance* is practical and others' *knowledge* theoretical. Our attention was called to this class in early youth by hearing an educated person state that he was a "practical man," by way of declining a question which involved knowledge of *fractions*; it was then extracted from him, to the delight of bystanders, that all above *integers* is *theory*. And from that time whenever we wish, in a delicate way, to find out how much a person knows of his subject, we manage to ascertain to what extent he considers it *practically useful*. And we have thus discovered that what happens to ourselves happens to others, namely, that all knowledge which *is* possessed is practically useful, and all which *is not* possessed is not. It is very often noticed that men are unduly given to puff and vaunt their own professions; whereby they provoke the retort of "nothing like leather," being the words the currier used when he was asked what the city walls should be made of. The sarcasm is often unjust. The exaggerator is frequently giving a true account of the effects of *knowledge*: his mistake lies only in restricting those effects to the knowledge of things in his own line, the only knowledge he has ever sufficiently cultivated.

We say nothing about those to whom *theory* is but a name under which they may safely sneer at *knowledge*, except this: two small commercial companies sometimes prolong their existence by amalgamating, as they call it; would it not be desirable that they should join those who use the word *infidelity* instead of *theory*? We give a passing word to the many who blind themselves to the difference between truth and falsehood by disguising the latter under the name of practice. It chanced to us long ago to advise a very worthy man of business, now dead, upon the terms of an advertisement. On one of our alterations he remarked "Don't you think that, practically, it would read better my way?"—"It would," said we, "the objection is, that it would not be true." Our friend stared as if a light had broken in upon him, and said, "Well, Sir, there *is* something in that." We remember seeing a theorist, as he was called, endeavour to make the managers of a certain undertaking comprehend that their profits could not exceed the excess of the gross returns over the outlay, after they had been trying to *cheat the equation* by inventing names for what they would have liked to have, but which the theorist assured them they would not get, for the preceding reason. The answer was, "That is very true *theoretically*, but now let us look at it *practically*." We shall say no more of the gross abuse of the terms, except to remark that were it worth while really to make a contest between theory and practice, it would be difficult to say on which side the balance of absurdity would incline; or whether the man who is too confident in his theory, or too confident in his experience, has done most mischief for the time being.

Coming now to the higher class of practical men, and speaking as of the balance between two methods the value of both of which is admitted, we observe there are obvious faults to which both parties are subject, both in conduct, and in argument respecting their pursuits. Great care is necessary to secure the theorist from pushing an imperfect theory too far, and neglecting causes of disturbance; but at least as much is necessary to prevent the practical man from generalising into theory from imperfect experience, or from restraining inquiry by a notion formed from practice. This is his besetting sin, to such an extent that we should almost be inclined to say that the fault of a practical man is a tendency to form false theory, as that of the theorist is to make false applications. We have often been surprised at the boldness with which the former assert generalities, upon evidence which would only make a pure theorist look for further information. Analogies are of all things the most deceptive. Much and frequent attention to men's arguments has left us with a feeling which, whenever we hear a person begin with "I am a practical man," makes us say to ourselves, "Now for a smack of false theory."

In argument there is one mode which is common to both parties, and which is exceedingly detrimental. It is the selection of instances from the very highest minds of the two orders, to illustrate the effects of theory or practice upon the general mass of understandings: minds the superior calibre of which, and their power of adapting themselves to circumstances, and making the most of what they have, render them exceptions to all rules, and no proper examples of the most advantageous course of training. Every one likes, no doubt, to draw consequences about and concerning his own self from a contemplation of the minds and methods of the Newtons or the Galileos of a higher sphere of intellectual existence, or the Arkwrights or Telfords of a better state of power of adaptation. "What is your theory good for?" says the tongue attached to some head which holds about the same weight of conceit that Telford's did of sagacity; "Telford knew nothing of it, and I may do without it too." The answer is—*Telford*. The opinion of Bacon was, that "the root of *all the mischief* in the sciences is, that, falsely magnifying and admiring the powers of the mind, we seek not its real helps," a maxim full of meaning, and a lesson to him who rates theory too highly, and also to one who thinks that the only use of his mind is to arrange the results of experience, his own or others. What are the majority of men, that they should look down upon any course of training, theoretical or practical?

Another fault of argument, but almost peculiar to the practical world, who have the force of numbers on their own side, is the habit of claiming all who are successful in application as instances of their own method and knights of their own order. Suppose that one individual should discover a mine, work it with his own hand, purify the ore, and beat the metal into a horse-shoe; which is he, a geologist, miner, furnace-man, or blacksmith? He has done the work of all, but the community of blacksmiths would hardly be allowed to claim him as peculiarly belonging to themselves. When a person who has mastered the difficulties of theory has also successfully applied them, he is free of both corporations; but those who attend only to application, never fail to appropriate his merits. WATT is a striking instance; he was a highly accomplished theorist on every point on which he worked: and yet his name has been frequently cited as a proof that theory could be dispensed with. And his career, when compared with that of Telford, will illustrate theory applied to practice, as distinguished from practice alone, however acute. It is impossible to contemplate the career of Telford without a feeling of high interest, created by the comparison of his apparently inadequate education with his startling successes. Looking at the individual himself, there is everything for his age to admire; and so long as his structures last, each of them is the *monumentum*, but not *ære perennius*. The time will come when his name shall be like that of the builder of the old London bridge, who was no doubt the Telford of the day, a stimulus to his contemporaries, useful and honoured, but not the remembered of succeeding ages. On the other hand, the discoveries of Watt, though equally startling in what is called the practical point of view, have the mind of the discoverer impressed upon them, and have been, and must be, the guide of his successors, not merely to repetitions of what he did himself, but to enlargement of ideas, and to the conversion of principles into forms useful in art. Take away the honourable qualities which enabled the two men to outstrip their contemporaries, each in his line, qualities which are the properties of the individual minds, and consider what is left, namely, their modes of proceeding: consider the effect of these two modes upon men in general, and there is nothing in that of Telford which would raise the workman above a workman, while in that of Watt there is the vital principle to which we owe all the mechanical triumphs of civilisation and all the theoretical successes of physical philosophy.

This country has been long and happily distinguished for the great attention which has been paid to application; but it is a mistake to suppose, as some do, that our supremacy in practical matters has been co-ordinate with, still less owing to, neglect of theory. It would be easy to show that though the comparative neglect of theory alone, *as a pursuit*, added to its diligent cultivation on the Continent, under the encouragement of government, had given to foreign countries a decided preponderance, now very much on the wane, of theoretical inquirers and writers, yet that there has been no country in Europe in which a competent knowledge of the mathematics and their applications has been spread over so large a mass, or raised to so high an average. At any time since the beginning of the 17th century the total amount of theory in Britain has been larger than in any other European country, on account of the numbers who have possessed a useful amount of knowledge: the diffusion of education in Germany may have altered our position, but of this we are not sure. For ourselves we are perfectly satisfied, however little those most concerned may know it, that this greater diffusion of theory has been the original moving cause of the practical excellence to which we have alluded. If those who have become known for splendid achievements in the former are few, the same may also be said of the latter; but a country owes its excellence in either department, not to one or two of the highest, but to the mass of those who have competent knowledge, producing good habits of thought and action. It is a new thing to hear one branch set against the other, and would make our writers of a century back think that posterity had lost its senses. The only addition wanted has been some means of systematically nurturing the growth of theory, so that, well as we have done with what we have, we may do better with more. The efforts which are making on every side to extend education will, it may be hoped, do what is wanted in this particular; they will at least have the effect of making it clear that, whatever the force of genius may do for an isolated exception, the mass of mankind must place their best hope of progress in the union of theory and practice.

There is also a mode of viewing what we may call the action of theory, which is absolutely necessary to a true conception of the value of their labours who employ their time in its advancement. Watch the arguments of a person who calls himself, distinctively, a practical man, and it will be always found that a well-established theory, fifty years old, is practical knowledge, so called. To this there cannot be the slightest objection in the non-distinctive sense: a well-established theory, which has been shown to be sufficient, is highly practical, as opposed to one of which the investigation is more recent, and the completeness not so well ascertained. But when the question is theory, as theory, against practice, as practice, the advocates of the latter frequently find it convenient to assume, for their own share of the matters in contest, all the best theories *plus* the most recent practical knowledge, leaving to the other side the onus of supporting theory upon the most imperfect part of the mass of doctrines which it contains, being that part which is not yet off the anvil. Suppose a merchant going into the bail court to prove his being worth a certain sum: he is asked whether his business, all debts and risks allowed for, would produce that sum: he replies, that his ventures must be beyond record unsuccessful, if it would not be so, over and over again. "So then," he is further questioned, "you cannot positively swear that your business will make you worth the sum in question." "I cannot," he replies, "positively swear any such thing; but I have enough not employed in business, in land and mortgages, and in the funds, to pay twenty shillings in the pound five times over upon every risk which I am liable to." What would be thought of counsel who should retort, "That is nothing to us; you are described as a merchant, and your solvency must be tried by the state of that part of your property which is now undergoing the fluctuations of trade?" Such is and always must be the state of theory; the amount which is actually realised is enormously greater than the floating balance which is being worked out. Those who are engaged in producing fixed capital from the latter, have a right to the credit which arises from the interest of the former: their labours for the time being are not to produce their return at the instant.

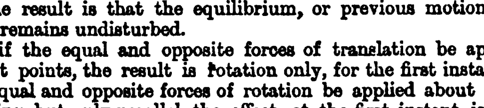
We have, in compliance with common notions, not adverted to the consequences of theory upon the mind and thoughts of men, but have treated it as if its sole object were to advance the mechanical arts and better the physical condition of society. But this is under protest that even if it could not be proved that rational investigation of nature had added one single atom to the physical comfort of life, there would remain such an enormous mass of social ameliorations which can be traced to that source as would outweigh even the triumphs of steam. This is often forgotten by the highest men of the highest and most valuable practice, meaning the best application of the truest theory. They confound practice with application to *matter* as opposed to *mind*. On this point we quote something we have printed elsewhere. "There is a strong impression in the world of physical inquiry that a mathematician is almost bound, whatever his pursuit may be, to make his science the means of investigating or registering some facts connected with the material world. A *teacher* of mathematics for example, whose business it is to study the mind and its discipline, that he may make his teaching permanently useful to those who will not, in nineteen cases out of twenty, ever have any need to apply it professionally, would be thought quite in the right way if he should take to investigating the force of steam, or the strength of beams, or the orbits of binary stars: they would call him a *practical man.* I should give him quite another name if he took up steam or star for anything beyond relaxation, supposing his taste to turn that way. The disposition to hold material application to be *always* practical is one of the consequences of the want of psychological thought, and will vanish before sound logical training, with other myopisms." ('Cambr. Phil. Trans.,' vol. x. p. 1.)

In conclusion, the word practice as opposed to *theory* takes an advantage from its meaning as opposed to *profession.* There are many persons who have so hazy a view of the two meanings as to imagine that the two antitheses are one and the same.

THEORY OF COUPLES. The two motions of which any rigid system is susceptible are those of TRANSLATION and of ROTATION. Each of these has this peculiarity, namely, that one particular case of its application yields the other kind of motion. Every motion of a system can, for any one instant, be resolved, at most, into a motion of translation of the whole system, combined with a motion of rotation about an axis; and every application of a system of forces to any rigid body, produces, generally speaking, this compound of translation and rotation. Also, if equal and opposite forces, such as would produce simple translation, be applied at the same point, or if equal and opposite forces, such as would produce rotation, be applied about the same axis, the result is that the equilibrium, or previous motion, of the system remains undisturbed.

But if the equal and opposite forces of translation be applied at different points, the result is rotation only, for the first instant; and if the equal and opposite forces of rotation be applied about axes not coinciding, but only parallel, the effect, at the first instant, is translation only. And though the doctrine of motion is now properly excluded from statics, yet the preceding theorems, together with others mentioned in ROTATION, should be well understood, and viewed in connection with the science of equilibrium, which is always illustrated, though it may not be demonstrated, by such considerations.

It was for a long time a curious but barren exception, that though any two forces acting in the same plane may, generally speaking, have their joint effect supplied by one single third force, yet if the two forces be equal in magnitude, and opposite in direction, no such single third force will do. If indeed they be applied in the same line, as O P and Q R in the first figure, they equilibrate each other; but if not in



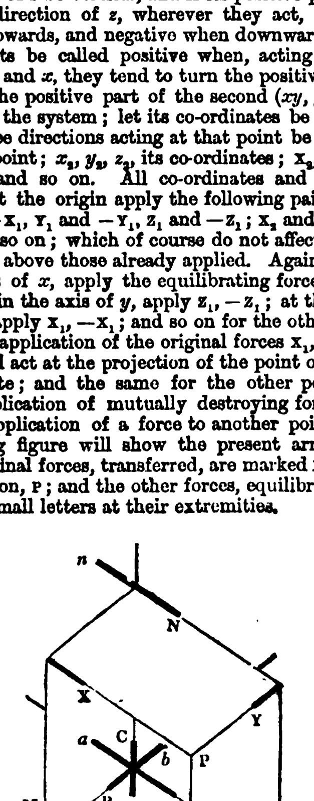
the same line, as O P and Q R in the second figure, no one single force can be found which will either equilibrate them, or produce their effect. Some years ago, M. Poinsot, already mentioned for his beautiful theory of ROTATION, applied a remarkable theorem connected with such pairs of forces to the establishment of the theory of the statics of rigid bodies, in a manner which has made his system rapidly take its place among the fundamental bases of the science. We shall in this article point out the manner in which this can be done, without much demonstration, with a view to draw the attention of those who have learned the doctrine of equilibrium in the old way: we cannot make it intelligible (without too great length) except to those who have learned the principles of analytical statics.

M. Poinsot called a pair of equal and opposite forces, not equilibrating each other, by the name of a *couple*—too general a term perhaps: by it is to be understood a couple which cannot be made anything but a couple, or cannot be replaced by one force: an *incomposible* couple. The *plane* of the couple is the plane drawn through the parallel forces; the *arm* of the couple is any line drawn perpendicular to the forces from the direction of one to that of the other; the *axis* of the couple is any straight line perpendicular to its plane. And if we consider any axis, it will be apparent that the moment or leverage of the couple [LEVER] to turn the system about that axis is represented by the product of one of the forces and the arm. For if, with reference to the axis, x be the arm of one of the forces, $x \pm a$ is that of the other, a being the arm of the couple. Hence if P be one of the forces, the united leverage is $P(x \pm a) - Px$ or $\pm Pa$. This product Pa is called the *moment* of the couple.

The last-mentioned property will give a high probability of itself to the following theorems, which are the basis of the theory of couples, and can be proved, the first by aid of the composition of forces only, the second by the principle of the lever. Any couple may have the direction of its arm changed, and consequently of its forces, in any manner whatsoever, either in its own plane, or in any plane parallel to it, provided only that the direction in which it tends to turn the system remains unaltered. Secondly, any couple may be replaced by another which has the same moment, the plane and direction of turning remaining unaltered; that is, the arm may be shortened or lengthened in any manner, provided the forces be increased or diminished in the same proportion. If the system were in equilibrium before, it will remain in equilibrium, however its couples may be altered, in any manner described in the above theorems. Hence it follows that a couple is entirely given when there are given:—1. Its axis or any line perpendicular to its plane, which is also perpendicular to any of the planes into which it may be removed. 2. The moment of the couple; specific forces or arms are unnecessary for its description, so long as their product is given. 3. The direction in which it tends to turn the system. The easiest way of describing a couple is then as follows; suppose, for example, a horizontal one:—Take any vertical line for the axis of the couple; on that axis lay down a line proportional to its moment, and agree that vertical lines drawn upwards shall represent moments tending to turn the system from west to east; and downwards, those tending to turn the system from east to west. But a sign must also be agreed upon; positive moment must consist in tendency to turn in one direction, and negative in the other.

The composition and resolution of couples is easily shown to be done in a manner which perfectly resembles that of ROTATIONS. When the couples can have a common axis (act in the same plane or parallel planes), the moment of the resultant is, in sign and magnitude, the sum of the moments of the components, with their proper signs. To find the resultant of two couples which cannot have a common axis, take axes to them which pass through the same point, and on these axes lay down lines representing the moments of the couples in their proper direction. On those lines complete a parallelogram; the direction of the diagonal is the axis of the resulting couple, and its length represents the moment of that couple. Care must be taken to lay down the directions of the moments properly on the axes; the best isolated rule (when reference is not made to distinct co-ordinate planes) is as follows: Let the parts of the plane of the axes which lie in the angle made by the lines representing moments be turned by the two couples in opposite directions. To the student to whom such a direction would be useful, we should say, appeal in all cases to the perceptions derived from ROTATION.

To apply the preceding theorems to the statics of a rigid body, we first take the following conventions:—Assume an origin and three rectangular axes of co-ordinates, as usual. Let the forces which act at each point of the system be decomposed into three, parallel to the axes of x, y, and z. Let each force be called positive, when it acts towards the positive part of the axis to which it is parallel; if, for instance, the axis of z be vertical, and if its positive part tend upwards, all forces in the direction of z, wherever they act, are called positive while they act upwards, and negative when downwards. As to couples, let their moments be called positive when, acting in the planes of x and y, y and z, z and x, they tend to turn the positive part of the first-named towards the positive part of the second (xy, yz, zx). Let P_1 be the first point of the system; let its co-ordinates be x_1, y_1, z_1; let the forces in the three directions acting at that point be X_1, Y_1, Z_1. Let P_2 be the second point; x_2, y_2, z_2, its co-ordinates; X_2, Y_2, Z_2, the forces there applied; and so on. All co-ordinates and forces have their proper signs. At the origin apply the following pairs of equilibrating forces: X_1 and $-X_1$, Y_1 and $-Y_1$, Z_1 and $-Z_1$; X_2 and $-X_2$, Y_2 and $-Y_2$, Z_2 and $-Z_2$, and so on; which of course do not affect the equilibrium, and are over and above those already applied. Again, at the extremity of x_1, in the axis of x, apply the equilibrating forces $Y_1, -Y_1$; at the extremity of y_1, in the axis of y, apply $Z_1, -Z_1$; at the extremity of z_1, in the axis of z, apply $X_1, -X_1$; and so on for the other points. Lastly, let the points of application of the original forces X_1, Y_1, Z_1, be changed so that each shall act at the projection of the point of application made by its co-ordinate; and the same for the other points. Nothing is done but the application of mutually destroying forces, or the change of the point of application of a force to another point in its direction, and the following figure will show the present arrangement for one point. The original forces, transferred, are marked X, Y, Z; the original point of application, P; and the other forces, equilibrating two and two, have great and small letters at their extremities.



We now see that the forces X, Y, Z, are equivalent to—

1. The forces X, Y, Z (marked A, B, C) applied at the origin.

2. A pair of couples to the axis of z (L, b) (X, n), the first positive with the moment Yx, the second negative with the moment Xy. These two are equivalent to one couple with the moment $Yx - Xy$.

3. A pair of couples to the axis of x (M, c) (Y, l), the total moment of which is $zy-\text{Y}z$.

4. A pair of couples to the axis of y (N, a) (Z, m), the total moment of which is $\text{X}z-\text{Z}x$.

Apply this to every point in the system, and let ΣX stand for X_1+X_2+, &c., and so on: hence it appears that the whole of the forces are equivalent to forces ΣX, ΣY, ΣZ, applied at the origin in the directions of x, y, and z, together with couples in the planes of xy, yz, zx, of which the moments are—

$$\Sigma(\text{Y}x-\text{X}y),\ \Sigma(\text{Z}y-\text{Y}z),\ \Sigma(\text{X}z-\text{Z}x).$$

$$\text{Let } \text{A}=\Sigma\text{X},\ \text{L}=\Sigma(\text{Z}y-\text{Y}z)$$
$$\text{B}=\Sigma\text{Y},\ \text{M}=\Sigma(\text{X}z-\text{Z}x)$$
$$\text{C}=\Sigma\text{Z},\ \text{N}=\Sigma(\text{Y}x-\text{X}y)$$
$$\text{V}=\sqrt{(\text{A}^2+\text{B}^2+\text{C}^2)},\ \text{W}=\sqrt{(\text{L}^2+\text{M}^2+\text{N}^2)}$$

Then it appears that all the forces can be reduced to one force, V, acting at the origin, making angles with the axes whose cosines are A : V, B : V, C : V; and one couple having a moment W, and whose axis makes with the axes of co-ordinates angles whose cosines are L : W, M : W, N : W. But when there is equilibrium, both the force and the moment of the couple must vanish, for the single force cannot equilibrate a couple. Consequently the conditions of equilibrium are V = 0, W = 0, which give A = 0, B = 0, C = 0, L = 0, M = 0, N = 0, the six well-known conditions of equilibrium.

The forces will have a single resultant when V falls in the plane of the couple whose moment is W; that is, when the direction of V is at right angles to the axis of the couple. This takes place when AL + BM + CN = 0, a well-known condition.

(For further information, we may refer to Poinsot's *Elémens de Statique*; or, in English, to Pratt's *Mathematical Principles of Natural Philosophy*; or Pritchard's *Theory of Couples*.)

THEORY OF EQUATIONS. Under this term is expressed all that part of algebra which treats of the properties of rational and integral functions of a single variable, such as $ax+b$, ax^2+bx+c, ax^3+bx^2+cx+e, and so on; a, b, c, &c., being any algebraical quantities, positive or negative, whole or fractional, real or imaginary. Unless however the contrary be specified, it is usual to suppose these co-efficients real, not imaginary.

The great question of the earlier algebraists was the finding of a value for the variable which should make the expression equal to a given number or fraction: as what must x be so that $3x^2+2x$ may be 11, or x^3-x^2+6x may be 40, and so on. In modern form it would be asked what value of x will make $3x^2+2x-11=0$, or $x^3-x^2+6x-40=0$, and so on. To find values of a variable which should make an expression vanish, or become equal to nothing, was then the first desideratum; and these values are now called *roots* of the expressions. Later algebraists made the finding of these roots subservient to the discovery of other properties of the expressions.

The Hindu algebraists communicated to the Arabs, and through them to the Italians, the complete solution of equations of the first and second degrees. The Italians added the solution of equations of the third degree, and of the fourth imperfectly. These last two degrees have been completed in more recent times, so that it may be now said that the equations of the first four degrees have been completely conquered: that is to say, having given the equation $ax^4+bx^3+cx^2+ex+f=0$, an algebraical expression can be found, having four values, and four values only, and being a function of a, b, c, e, f, which being substituted for x on the first side of the equation, shall make that first side vanish. But the student would look in vain through the books of algebra to see this expression: it is both complicated and useless, and it is more desirable to indicate how it is to be found, than to find it.

The equation of the fifth degree was attempted in all quarters, without success: means were found of approximating to the arithmetical value of one or another root in any one given equation; but never a definite function of the co-efficients which would apply in all cases. A proof was given by Abel, in Crelle's Journal (reprinted in his works), that such an expression was impossible, but this proof was not generally received: it was admitted by Sir W. Hamilton, who illustrated the argument at great length in the 'Transactions' of the Royal Irish Academy, vol. xviii., part ii.; but the singular complexity of the reasoning will probably prevent most persons from attending to the subject. We do not mean in this article to enter into the history of the theory of equations, but only to place its general state before the reader by an exhibition of the principal theorems, without proof. For works on the subject we may refer as follows:—Hutton, 'Tracts,' vol. ii., tract 33, which contains a full account of the earlier algebraists; Peacock, "Report on certain Parts of Analysis," in the 'Report of the Third Meeting of the British Association;' or the recent works of Murphy, Young, or Hymers; all of which are good, and written on such different plans that any one who makes a particular study of the subject will find it advantageous to consult them all. In French the standard works are those of Budan, Lagrange, and Fourier, which however all treat of particular topics: the algebraical treatises of Bourdon and Lefebvre de Fourcy treat it more generally.

The particular points relative to equations of the first four degrees are as follows:—

1. The expression of the first degree can be reduced to the form $ax+b$; it vanishes when $x=-b:a$, and has only this one root. And $ax+b$ is of the same sign as a or not, according as x is greater or less than the root.

2. The expression of the second degree is more important. It can always be reduced to the form ax^2+bx+c, and its properties are best developed by transforming the preceding into

$$\frac{(2ax+b)^2+4ac-b^2}{4a}$$

There are three distinct cases, according as b^2 is greater than, equal to, or less than, $4ac$.

When $b^2>4ac$, the expression ax^2+bx+c has two real and differing roots, contained in the formula*

$$\frac{-b\pm\sqrt{(b^2-4ac)}}{2a}$$

and has always the same sign as a, except when x lies between those roots. Every change of signs in passing from a to b and from b to c indicates a positive root, and every continuation a negative root: and when one root is positive and one root negative, the positive or negative root is numerically the greater, according as (a, b) shows a change or continuation. When $x=-b:2a$, the expression is at its numerical maximum between the two roots, its then value being $(4ac-b^2):4a$.

When $b^2=4ac$, the expression ax^2+bx+c is a perfect square with respect to x, and absolutely so if a be a square. The two roots become equal, and each equal to $-b:2a$. The expression now never differs in sign from a.

When $b^2<4ac$, the two roots become imaginary, the expression always has the sign of a, and is numerically least when $x=-b:2a$, being then $(4ac-b^2):4a$.

3. The equation of the third degree (or cubic) has been separately considered in the article IRREDUCIBLE CASE.

4. Nothing belongs particularly to the equation of the fourth degree (or biquadratic) except the recital of the various modes in which the solution is reduced to that of a cubic. The various modes are distinguished by the names of their inventors.

Ferrari. Let $x^4+ax^2+b+c=0$. This can be transformed into

$$(x^2+v)^2=(2v-a)x^2-bx+v^2-c:$$

make the second side a perfect square; that is, find the value of v from $b^2=4(v^2-c)(2v-a)$, or

$$8v^3-4av^2-8cv+4ac-b^2=0;$$

the extraction of the square root then reduces the biquadratic to a couple of quadratics.

Des Cartes. Let $x^4+ax^2+bx+c=(x^2+\sqrt{p}\,.\,x+f)(x^2-\sqrt{p}\,.\,x+g)$, which gives

$$g+f-p=a,\ (g-f)\sqrt{p}=b,\ fg=c, \text{ or}$$
$$p^3+2ap^2+(a^2-4c)\,p-b^2=0:$$

find a positive root of this equation (it certainly has *one*), and from it find g and f; then the roots of $x^2+\sqrt{p}.x+f=0$, and $x^2-\sqrt{p}.x+g=0$, are those of the given equation.

Thomas Simpson gave a modification of Ferrari's method, and Euler one of that of Des Cartes. (Murphy's Theory of Equations ('Library of Useful Knowledge'), pp. 54, 55.)

The theory of equations of all degrees is to be divided into two distinct parts; the numerical solution, and the general properties of the roots and the expressions themselves. The *numerical solution* must be carefully distinguished from the *general solution*; the former term applying to any mode of approximating to a single root, the latter to any mode of exhibiting a general expression for the roots. We shall begin by the general properties of the roots: the expression in question being ϕx, or

$$a_0x^n+a_1x^{n-1}+a_2x^{n-2}+\ldots\ldots+a_{n-1}x+a_n.$$

1. If r be a root of ϕx, or if $\phi r=0$, then ϕx is divisible by $x-r$, and the quotient is another such expression of the $(n-1)$th degree, every root of which is also a root of ϕx, and every number which is not a root (r excepted) is not a root of ϕx. Hence ϕx cannot have more roots than it has dimensions, or cannot have more than n roots.

2. When the expression ϕx is divisible by $(x-r)^m$, it is said to have m roots each equal to r; and when this is the case, the substitution of $r+y$ for x would give an expression in which y^m is the lowest power of y.

3. Every expression has as many roots as it has dimensions. This

* This formula should be committed to memory, and quadratic equations always solved by it. Nothing is more amusing than the vitality of the old method of completing the square and extracting the root in every particular case. No doubt a student should have some training in this last-mentioned process; but his ultimate method should be that of remembering, once for all, the formula in the text.

proposition is of complex proof, but it begins to occupy its proper place in elementary works, especially on the continent.

4. We may now refer to STURM'S THEOREM, to Fourier's theorem (given in the article just cited), to Des Cartes' theorem, a very limited particular case of Fourier's, and to Horner's adaptation of, and addition to, the old method of numerical solution by Vieta (an account of the history of this last problem is given in the 'Companion to the Almanac' for 1839). [INVOLUTION AND EVOLUTION.] We have then, since the beginning of this century, a complete theoretical mode of determining the number of roots, real or imaginary, between any given limits; both exceedingly difficult in the complication of the operations which they require. Also, a mode of easy application, though not theoretically perfect, of determining the limits between which the real roots lie; and a process for the numerical solution which places that question upon the same footing as the common extraction of square, cube, &c., roots; making those extractions themselves, except only in the case of the square root, much easier than before. In Cauchy's theorem, now beginning to be generally known, and which was given in the 'Penny Cyclopædia,' we have a theoretical mode of determining the imaginary roots. And Horner's method has been extended to their computation. But it seldom happens that the actual determination of imaginary roots is required.

5. The Newtonian method of approximation is in the following theorem. If a be nearly a root of $\phi x=0$, and if $\phi a : \phi' a$ be small, then

$$a-\frac{\phi a}{\phi' a}$$

is more nearly a root. See APPROXIMATION for the use of this, and TAYLOR'S THEOREM, for a more extensive result. But the use of Horner's method is very much more easy than that of Newton: the former, in fact, includes and systematises the latter. But this remark applies only to algebraical equations: for all others Newton's form just given remains practically unamended.

6. We refer to the article ROOT for the solution of $x \pm 1 = 0$. The following equation, $x^{2n} \pm 2 \cos\theta \,.\, x^n + 1 = 0$, admits of complete solution on the same principles.

7. If ϕa and ϕb have different signs, one or some other odd number of roots of ϕx lies between a and b: but if they have the same signs, either no one or an even number of roots lies between a and b. Every equation of an odd degree has at least one real root, negative or positive, according as the first and last terms have like or unlike signs. Every equation of an even degree having the first and last terms of unlike signs has at least two real roots, one positive and one negative.

8. If all the coefficients of ϕx be real, and one of the two, $a \pm b\sqrt{-1}$, be a root, so is the other: and if all the coefficients be rational, and one of the two, $a \pm \sqrt{b}$, a and b being rational, be a root, so is the other. If there be a rational fractional root, its denominator must be a divisor of the first coefficient, and its numerator of the last, as soon as the equation $\phi x = 0$ is cleared of fractions. N.B. Among the divisors of a number we reckon 1 and itself.

9. In the equation $a_0 x^n + a_1 x^{n-1} + a_2 x^{n-2} + \ldots + a_{n-1} x + a_n = 0$, the sum of all the roots is $-a_1 : a_0$, the sum of the products of every two is $a_2 : a_0$, that of the products of every three is $-a_3 : a_0$, and so on. Finally the product of all the roots is $\pm a_n : a_0$, according as n is even or odd. And if $r_1, r_2, \ldots r_n$ be the roots, then $a_0 x^n + \ldots$ is the same as $a_0 (x-r_1)(x-r_2)\ldots\ldots(x-r_n)$.

10. If the preceding expression be called ϕx, and $n a_0 x^{n-1} + (n-1) a_1 x^{n-1} + \ldots$, its derived function, be called $\phi' x$, we have

$$\frac{\phi' x}{\phi x} = \frac{1}{x-r_1} + \frac{1}{x-r_2} + \ldots\ldots + \frac{1}{x-r_n};$$

and if ψx be any rational or integral algebraical function of x, the sum $\psi r_1 + \psi r_2 + \ldots\ldots + \psi r_n$ is the coefficient of the highest power of x in the remainder of the division of $\phi' x \times \psi x$ by ϕx.

11. If s_n in all cases stand for the sum of the nth powers of the roots of the equation, we have

$$s_0 = n,\ a_0 s_1 + a_1 = 0,\ a_0 s_2 + a_1 s_1 + 2a_2 = 0,\ a_0 s_3 + a_1 s_2 + a_2 s_1 + 3a_3 = 0,$$

and so on up to

$$a_0 s_n + a_1 s_{n-1} + a_2 s_{n-2} + \ldots\ldots + n a_n = 0,$$

after which, in all cases,

$$a_0 s_{n+k} + a_1 s_{n+k-1} + \ldots\ldots \quad + a_n s_k = 0.$$

Hence also the coefficients of the expression may be found in terms of $s_1\ s_2 \ldots\ s_n$, as soon as a_0 is given.

12. All rational symmetrical functions of the roots may be easily expressed in terms $S_1\ S_2$, &c., and thence in terms of the coefficients of the expression.

13. If it be required to find a function ψy the roots of which shall be given functions of those of ϕx, so that in all cases $y = Fx$, proceed as in finding the highest common divisor of ϕx and $Fx - y$, and take for ψy the final remainder. But if this final remainder should be of a higher dimension than, from the known number of its roots, it ought to be, it will be a sign that some of the factors introduced in the process have affected the remainder, and these must be examined and removed. The treatment of this case belongs to the general question of elimination, but the following particular cases are almost all that are necessary.

14. To decrease all the roots of ϕx by a given quantity, or to make $y = x - a$, or $x = y + a$, observe that the resulting equation must be

$$\phi a + \phi' a \,.\, y + \frac{\phi'' a}{2} y^2 + \ldots\ldots + \frac{\phi^{(n)} a}{2\,.\,3 \ldots n} y^n = 0;$$

where the coefficients ϕa, $\phi' a$, $\frac{1}{2}\phi'' a$, &c., may be the most readily found by the process described in INVOLUTION. The same process may be applied, by using $-a$ instead of a, to increase all the roots of ϕx by a given quantity. It is by this process that the second term of an equation is taken away; thus, the equation being $a_0 x^n + a_1 x^{n-1} + \ldots 0$, assume

$$y = x + \frac{1}{n}\,\frac{a_1}{a_0}$$

the sum of the roots of the equation in x being $-a_1 : a_0$, that of the equation in y will be 0.

15. To multiply all the roots of an equation by m, multiply its successive terms, beginning from the highest, by $1, m, m^2, m^3$, &c. And to divide all the roots of an equation by m, multiply all the terms by the same, beginning from the lowest. N.B. Terms apparently missing in an equation must never be neglected. Thus $x^7 - 2x^4 + 3x - 1 = 0$ ought to be written

$$x^7 + 0x^6 + 0x^5 - 2x^4 + 0x^3 + 0x^2 + 3x - 1 = 0.$$

This caution is of the utmost importance: in fact no process ought to be applied to any equation without a moment's thought as to whether all the terms be formally written down, and if not, whether the process about to be applied will not require it.

16. To change the signs of all the roots of an equation, change the signs of the coefficients of all the odd powers, or of all the even powers, as most convenient.

17. To change an equation into another whose roots shall be reciprocals of the former roots, for every power of x write its complement to the highest dimension. Thus in an equation of the seventh degree, for x^0 write x^7, for x write x^6, for x^2 write x^5, and so on: lastly, for x^7 write x^0. N.B. Consider the independent term of the equation as affected by x^0. From the reciprocal equation can be found the sums of the negative powers of the roots of the original.

18. The old methods of finding limits to the magnitude of the positive and negative roots of an equation are so rapid that they can hardly be said to be superseded by those of Sturm or Fourier. In enunciating them we speak of coefficients absolutely, without their signs, when mentioning any increase or decrease they are to receive.

If A be the greatest of all the quotients made by dividing the coefficients by the first co-efficient, no root, positive or negative, is numerically so great as $A + 1$. And if B be the greatest of all the quotients made by dividing the co-efficients by the last co-efficient, no root, positive or negative, is numerically so small as $1 : (B+1)$. Better thus: if L be the first co-efficient, M the greatest, and N the last, signs not considered, then all the roots, numerically speaking, lie between

$$\frac{M+L}{L} \text{ and } \frac{N}{M+N}.$$

19. If L be the first co-efficient, and M the greatest co-efficient which has a different sign from that of L, no positive root is so great as $(M+L) : L$. And if L be the last co-efficient and M the greatest which has a different sign, no positive root is so small as $L : (M+L)$. And to apply this to the negative roots, change the signs of all the roots of the original (§ 16), and find limits to the positive roots of the new one.

20. If L be the first co-efficient, M the *greatest* which has a different sign, and if the *first* which has a different sign be in the mth place from the first term exclusive, or belong to the $(m+1)$th term; then no positive root is so great as

$$1 + \sqrt[m]{\left(\frac{M}{L}\right)}$$

If k be the number of terms which elapse at the beginning before a change of sign, L the least of their co-efficients, and M the greatest co-efficient of a different sign, any value of x which, being > 1, makes

$$x^{n-k+1}(Lx^k - L - M) + M$$

positive, is greater than the greatest root: for instance,

$$x = \sqrt[k]{\frac{L+M}{L}}.$$

The following method is very convenient when the number of terms is large. Divide the whole expression into successive positive and negative lots, $A_p - B_q + C_r - D_s + \ldots p, q, r, s$, &c., representing the last exponent of x in each lot. Divide $A_p - B_q$ by x^q, and ascertain a value of x, say λ, which makes $A_p - B_q$ positive and equal to l. Do the same with $lx^q + C_r - D_s$, which, for $x = \mu$ (perhaps no greater than λ) becomes m. Repeat the process with $mx^s + E_t - F_u$, and so on to the end. The last value of x used is greater than any root of the equation: and the first value of x, λ, is very often the last also.

21. If each co-efficient which differs in sign from the first term, be divided by the sum of all which precede and agree with the first term (the first term itself included), the greatest resulting fraction, increased by unity, is greater than any positive root of the equation.

22. Newton's method of finding a limit greater than the greatest positive root of any equation now merges in Fourier's theorem. It consists in finding a by inspection and trial, so that $\phi a, \phi' a, \phi'' a$, &c., shall all be positive.

23. Any mode of ascertaining a limit greater than the greatest positive root of an equation may be thus treated. Apply it to the reciprocal equation (§ 17), and the reciprocal of the result attained is less than the least positive root of the original. Apply both to the equation of roots with signs changed, and the results give limits for the negative roots of the original.

24. A celebrated mode of examining the roots of equations, but too complicated for ordinary use, consists in forming the equation whose roots are the squares of the differences of the roots of the original. Any quantity being found less than the least positive root of this new equation, its square root is less than the difference of any two roots of the original. If such a quantity could be readily found, the theoretical imperfection of Fourier's theorem would be greatly diminished, and, practically speaking, much advantage would be gained in numerical solution. What is wanted to add to both Fourier's and Horner's method, is a ready mode of finding out when two roots are nearly equal.

25. Lagrange's mode of approximation is as follows:—Having found that a root of an equation lies between the integers a and $a+1$, diminish all the roots of that equation by a, and take the reciprocal equation to the result. Find a root of the last lying between the integers b and $b+1$, diminish all the roots by b, and take the reciprocal equation of the result. Find a root of this last between c and $c+1$, and proceed in the same way. Then the continued fraction

$$\frac{1}{a+}\ \frac{1}{b+}\ \frac{1}{c+},\ \text{\&c.}$$

is a root of the original. The details of the work are much abridged by use of Horner's process.

26. When an equation has equal roots, those roots can be found by an equation depending entirely on the different sets of equal roots. If ϕx have m roots equal to a, $\phi' x$ has $m-1$ of them, $\phi'' x$ has $m-2$ of them, and so on; finally, $\phi^{(m-1)}x$ has one of them. If then ϕx and $\phi' x$ be found to have a common measure, every root of that common measure enters in ϕx one time more than in the common measure itself.

27. When an equation has an integer root, which must be one of the divisors of the last co-efficient, it may be discovered by successive trial, as follows:—Suppose $a_0 x^4 + a_1 x^3 + a_2 x^2 + a_3 x + a_4 = 0$, a_0, &c., being integers. Let k be a divisor of a_4, and let $a_4 : k = l$, an integer. Then if k be a root, we have $a_0 k^3 + a_1 k^2 + a_2 k + a_3 + l = 0$, and $a_3 + l$ is divisible by k, giving m, an integer. Hence $a_0 k^2 + a_1 k + a_2 + m = 0$, and $a_2 + m$ divided by k gives an integer, say n. Hence $a_0 k + a_1 + n = 0$, and $a_1 + n$ divided by k gives $-a_0$. If all these conditions be fulfilled, k is a root. All the divisors of a_4 being tried in this manner, settle the question of the integer roots entirely.

28. If the co-efficients of an equation read backwards and forwards be the same, both in sign and magnitude, every root has its reciprocal also among the roots. By reducing it to the form

$$p + q\left(x + \frac{1}{x}\right) + r\left(x^2 + \frac{1}{x^2}\right) + \ldots = 0$$

which can always be done by division, when the dimension is even, and assuming $y = x + x^{-1}$, an equation of the $2n$th degree can be reduced to one of the nth and n quadratics. But when the dimension is odd, either -1 or $+1$ must be a root, and the equation can be depressed to an even degree by division by $x+1$ or $x-1$.

The student who is acquainted with the preceding results, namely, such as are either stated or referred to in this article, will find no difficulty either in reading on the history of this subject, or in its application. It is peculiarly a subject on which selection should be made for the beginner.

THERIACA (θηριακά) was the name given orginally by the ancients to all those medicines which were intended as antidotes to the bite of venomous animals (θήρια), as those which counteracted poisonous drugs were called ἀλεξιφάρμακα (Galen, 'Comment. in Hippocr.' 'De Alim.,' lib. iii., cap. 7, tom. xv., p. 279, ed. Kühn; id., 'Comment. in Hippocr.' 'De Morb. Vulgar. VI.,' lib. vi., cap. 5, tom. xvii., pt. ii., p. 337); afterwards, however, the word seems to have been somewhat restricted in its signification, or at least θηριακή (in the singular number) is applied to one particular compound, while at the same time this one drug was considered to be a safeguard not only against the bites of venomous animals, but also against poisonous drugs and unwholesome food. (Galen, 'De Antid.,' lib. i., c. 1, tom. xiv., p. 1.) Many of these old preparations are preserved in the writings of the ancient physicians, but of these it will be enough to mention here the two most famous, namely the *Mithridatium* (Μιθριδάτειον, or Ἀντίδοτος Μιθριδάτειος) and the *Theriaca Andromachi.*

The Mithridatium received its name from the great Mithridates, king of Pontus, who had a strange affectation of superior skill in the powers of simples. He tried the effects of these upon condemned malefactors, and, finding that different drugs counteracted different poisons, he thought that, by putting all of them together, he should be able to make a compound that would render him secure against any poison that could be given him. (Galen, 'De Antid.,' p. 2.) Accordingly he is commonly said to have so fortified his own body by the constant use of this antidote, that he afterwards tried in vain to put an end to his life; but this, if true, "was probably," as Dr. Heberden says ('Antither.,' p. 10), "less owing to the strength of his antidote than to the weakness of his poison."

Andromachus the Elder (who was physician to the emperor Nero, and the first person who is known to have received the title of *Archiater*) made considerable alterations in the Mithridatium by omitting some of the ingredients, adding others (especially the dried flesh of vipers), and by increasing the proportion of opium. His receipt was embodied in a Greek elegiac poem, in order that it might be the more easily preserved without alteration; and this has been inserted by Galen in two of his works ('De Antid.,' lib. i., cap. vi., et 'De Ther. ad Pison.,' c. 6), and has been frequently published in a separate form. Andromachus likewise changed the name of the Mithridatium thus reformed to γαλήνη; but in Trajan's time it obtained that of 'Theriaca,' either from the vipers in it, or from its good effects in curing the bites of venomous animals. (Galen, 'De Antid.,' lib. i., cap. 6; 'De Ther. ad Pison.,' cap. 5., tom. xiv., pp. 32, 232.) The formula for the Theriaca of Andromachus, as well as for others, is to be found in Geiger's 'Pharmac. Universalis. Pars. Posterior,' p. 281.

It is much to be regretted that the word 'Theriaca' is applied to the uncrystallisable juice which flows from sugar in the process of refining; for distinction's sake this should always be termed "Faex Sacchari," or "Syrupus Empyreumaticus," anglicé, "Molasses," as in the Dublin 'Pharmacopœia.' The uses of molasses (or melasses) are well known.

THERMÆ. [BATHS.]

THERMOCHROSIS. [RADIATION OF HEAT.]

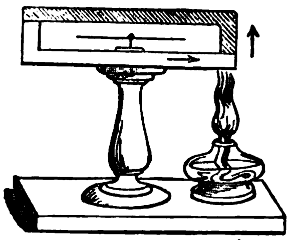
THERMO-ELECTRICITY. It has been shown, under GALVANISM, that any obstruction to the passage of an electric current produces heat in the conductor; so conversely it has been found that any obstruction to the equal propagation of heat in a conducting circuit produces a currrent of electricity. The discovery of this principle was made in 1822, by Dr. Seebeck of Berlin, while engaged in researches concerning electro-magnetism, which but two years before had been discovered by Professor Oersted of Copenhagen; and the name thermo-electricity was given to the fluid by the latter philosopher in order to distinguish it from that which is produced by the usual galvanic apparatus, which he proposed to call *hydro*-electricity.

Some of the most simple experiments by which the effects of thermo-electricity may be illustrated are those which, soon after the discovery, were made by Professor Moll of Utrecht. ('Edinburgh Philosophical Journal,' No. xvii.) A slip of copper bent in the form of a semicircle was attached (in close contact), at its extremities, to the ends of a bar of antimony about 15 inches long; and the bar being laid in the direction of the magnetic meridian with the wire above it, a small compass needle was suspended, or supported on a pivot between them. On heating the northern extremity of the bar by the flame of a lamp, the north end of the needle was observed to deviate towards the west. Again, when a slip of zinc and one of copper were bent so that, on the extremities being applied together, there was formed a parallelogram having the junctions of the slips in the middle of the shorter sides, and a compass needle was suspended within the circuit, on placing the apparatus in a plane coinciding with the magnetic meridian, with the longer sides parallel to the horizon (the copper slip being uppermost) and heating the northern point of junction, the needle deviated towards the west: the apparatus being inverted so that the zinc slip was uppermost, on heating the northern junction as before, the needle deviated towards the east. It follows from these experiments that the fluid current, if such it be, which affects the magnetism of the needle, circulates about the copper slip in such a manner that when the latter is in a horizontal position its direction is from west to east, passing above the slip, in a plane perpendicular to its length: this effect is similar to that which takes place, though in a contrary direction, when a magnetised needle is brought near a conducting wire joining the poles of an ordinary galvanic apparatus; for if the conducting wire be placed in a horizontal position in the direction of the magnetic meridian, with the copper, or the negative end of the apparatus towards the north, and the needle be below the wire, the north end of the needle deviates towards the east; if above the wire, towards the west.

Effects similar to those which result from the application of heat take place when one extremity of the bar of antimony, or one of the junctions of the zinc and copper, is made colder than the other by means of ice.

When both ends of the bar were heated, no deviation was produced in the needle; and after deviation had taken place by heating one end only of the bar, in proportion as the heat tended to a uniform diffusion, the needle gradually returned to the direction of the magnetic meridian.

The following figure shows the general arrangement of these experiments. A rectangle is composed of antimony (shaded) and bismuth.



On heating one of the junctions a thermo-electric current will set in in the direction of the arrows and the needle will be deflected.

Thermo-electric circuits may be formed in a ring consisting of two curved bars of different metals, as bismuth and copper, each being in the form of a semicircle, and the two being attached together in the direction of a diameter; or they may be produced in a rectangle made by placing in close contact four bars of metal, of two different kinds, following one another alternately. M. Oersted formed a hexagonal circuit with six pieces, three of bismuth and three of antimony, which were disposed in alternate order: on heating, by means of a spirit-lamp, one of the places of junction in the ring, or in the rectangle of four pieces, a compass-needle placed within or below the plane of circuit was found to deviate; and it deviated still more when the opposite angles of the rectangle were heated. In the experiment with the hexagonal circuit the deviation was greater in proportion to the number of alternate joints which were heated. Similar effects were produced when the alternate joints were artificially cooled; but the deviation was the greatest when the alternate joints were heated and the others were cooled.

By doubling the lengths of the bars in a rectangle composed of four, the deviation was less than that which was produced by the smaller rectangle; but when the larger rectangle was composed of eight pieces, the deviation was greater.

In this country the subject of thermo-electricity was pursued by Professor Cumming of Cambridge, who appears to have entered upon it without any other knowledge of the discovery of Seebeck than the simple fact that electro-magnetical action was produced by heating one end of a bar of antimony, to the extremities of which were made fast those of a brass wire. The details of his researches are published in the 'Cambridge Philosophical Transactions,' for 1823. From these it appears that all perfect conductors of electricity, on being heated or cooled in any part, exhibit in general magnetical phenomena; but the intensity of the action, which is indicated by the amount of the deviations produced in a magnetised needle, is not the same in all substances, and with some the direction of the current is contrary to that which is produced in others. When a single bar, of symmetrical form, is heated in the middle, it produces no effect on the needle, probably because the opposing currents counteract each other; and in a ring formed of two metals, when heated at one of the points of junction, the fluid seems to pass from one metal to the other; so that one loses positive electricity, or becomes negative, while the other becomes positive. If, however, the ends of a sensitive galvanometer be united by means of a platinum wire, no current will be perceived on heating the wire until a portion of it be twisted into a loop; the molecular tension thus produced will interfere with the conducting power of the wire, and a current will flow through the apparatus from right to left when heat is applied close to the loop and to the right of it. Or if the wire be formed into two flat spirals, and one be heated to redness, and brought into contact with the cold spiral, a current will flow from the hotter to the colder portion. Or if portions of a metallic wire be stretched by weights while other portions are free, a current will flow from the former to the latter on applying heat to the junctions. These last-named facts are due to Professor W. Thomson.

Professor Cumming having ascertained from experiments on bars of bismuth, which were made alternately hot and cold, and were placed in contact with each other (each pair of the hot and cold parts, and also the two extremities of the whole compound bar, being connected together by wires), that the action of the whole bar on a needle was greater than that of any two portions, one hot and the other cold, was led to the discovery that electro-magnetism may be exhibited by the mere juxtaposition of an indefinite number of small plates. He was also enabled to determine the thermo-electric relations of different metals by merely placing in contact with each other a small portion of each of the two kinds of metal to be examined, and touching first one of them, and then the other, with one end of a silver or copper wire which was connected with the heated bar. When the metals were bismuth and antimony, the former, on being touched, caused the compass-needle to deviate so as to indicate positive electricity, and the latter so as to indicate negative electricity; and in the memoir above quoted there is given a table of the electrical relations of metals in several different combinations. In the same memoir there is also an account of several curious anomalies which were observed in the magnetic action: one of these is, that when iron wire is used to touch the metals examined, of which one is iron, the needle deviates a certain number of degrees in the positive direction; then, as the heat of the wire is increased, the deviation in that direction gradually diminishes till it becomes zero; after which the deviation takes place in a negative direction, and it becomes a maximum in this direction when the wire acquires a red heat.

Metals with a marked crystalline structure, and an inferior power for conducting electricity, display thermo-electric effects most perfectly. Thus bismuth and antimony are favourable metals, and even the warmth of the hand applied to one of the junctions of a pair will deflect the galvanometer needle. Indeed for small differences in temperature, no instrument is so sensitive as a thermo-electric pile or thermo-multiplier. An instrument of this kind was invented by Cumming, and improved by Nobili, who introduced the astatic needle into it.

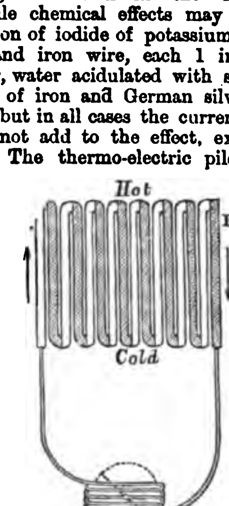
If a thermo-electric pair have one of its junctions kept at 32°, whilst the other junction is gradually raised in temperature, the current will gradually increase in intensity up to a certain point, then decline, and become reversed. If, for example, the metals be zinc and silver, the current will decline at 248°, then cease, and set in, in the opposite direction as the temperature continues to rise. This probably arises from the effect of heat on the crystalline structure of zinc. Iron and antimony produce the same effect to a less extent. The thermo-electric order of the metals is quite different from their voltaic order. It is for a few of the principal metals as follows:—

Bismuth.	Copper and Silver.
Platinum.	Zinc.
Lead.	Iron.
Tin.	Antimony.

but for further details, see Matthiessen, 'Phil. Trans.', 1858.

Thermo-electric circuits have been formed between non-metallic bodies. Thus the point of a heated cone of porcelain clay, brought into contact with a cold cylinder of the same material, and connected with the galvanometer by means of moistened cotton, caused a deflection of the needle. This effect has been ascribed to the mutual re-action of two portions of water of different temperatures.

Thermo-multiplier.—Bars of antimony and bismuth A and B may be arranged into a thermo-multiplier or thermo-electric pile, so that a high temperature may be applied to one series of junctions and a low one to the other. The current is then measured by its effect on the galvanometer needle, as shown in the figure. By means of a thermo-electric pile chemical effects may be produced, such as decomposing a solution of iodide of potassium, and with one hundred pairs of platinum and iron wire, each 1 inch long and $\frac{1}{100}$th of an inch in diameter, water acidulated with sulphuric acid has been decomposed. Wires of iron and German silver make a very good thermo-electric pile, but in all cases the current is feeble, and the size of the elements do not add to the effect, except by increasing the conducting power. The thermo-electric pile used by Nobili and



Melloni formed a very delicate measure of temperature. It consisted of thirty-six pairs of bars of bismuth and antimony packed into a small space, connected with a delicate astatic galvanometer. When the alternate junctions of the bars at each end of the pile were covered with lamp-black the pile was so sensitive to radiant heat as to be affected by the warmth of the hand at a distance of 30 feet. Even the amount of heat radiated by insects could be estimated by means of this apparatus. Mr. Joule placed the instrument in vacuum, with a steel magnet near it to diminish the action of the earth's magnetism, and so far increased its sensibility, as to indicate by means of a single pair of bismuth and antimony, a change of temperature amounting to only the $\frac{1}{1000}$th part of a centigrade degree. By means of this instrument Melloni was able to prove the instantaneous transmission of heat through glass and other bodies, and the thermo-transparency of rock-salt. By its means Forbes was able to show the polarisation of heat. The fineness of the wires used for the junction, together with its great sensibility, allow the use of this instrument, where a common thermometer could not be applied, as in measuring the temperature of the muscles of the human body. It has also been employed by Mr. Joule in confirming the deductions of Professor Thomson's theory of the thermal effects of stretching solid bodies already alluded to. Mr. Joule has found that if a strip of vulcanised india-rubber is stretched by a weight which doubles its length, an elevation of its temperature by 50° C. shortens it by as much as $\frac{1}{10}$th of its whole length; and Peltier has discovered that a cooling effect is produced by an electric current in flowing from bismuth to antimony across a surface of contact. This result has been applied by Professor Thomson to the establishment of a "Mechanical Theory of Thermo-electric Currents" ('Transactions of Royal Society of Edinburgh,' 1851).

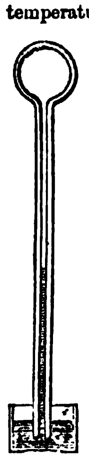
The term *pyro-electricity* is sometimes applied to the phenomena produced by heating certain minerals, such as boracite, topaz, axinite, mesotype, tourmaline, prehnite, calamine, and sphene. It was shown by Œpinus, so far back as 1757, that the two electricities are to be found on opposite sides, or ends, of the same piece of tourmaline when heated, and it was proved by Haüy that electric crystals exhibit different sets of crystalline faces on the two sides on which the contrary electric effects are observed. It is remarkable, also, as lately pointed out by Svanberg, that in bismuth and antimony, where there is one particular plane of cleavage more brilliant than the rest, when bars of the metals are placed with this plane of cleavage perpendicular to the direction of the current, such bars are more highly negative than in any other position, whilst if a less brilliant plane of cleavage be placed across the line of current, the bar is more highly positive than in any other position.

THERMO'METER (from the Greek words θερμός, *hot*, and μέτρον, *a measure*) is an instrument by which the temperatures of bodies are ascertained. It consists of a glass tube with a capillary bore containing, in general, alcohol or mercury, which expanding or contracting by variations in the temperature of the atmosphere, or on the instrument being immersed in the liquid or gas which is to be examined, the state of the atmosphere, liquid, or gas, with respect to heat, is indicated by a scale which is either applied to the tube or engraven on its exterior surface.

The end proposed by a thermometer is the measurement of the temperature of any body with relation to the temperature of some other substance, as of water at the point of freezing; but the measure so obtained must not be understood to express the absolute quantity or density of heat in any body, it being well known that different substances, though exhibiting the same apparent temperature, contain very different quantities of heat according to their *capacities* for that element. [Specific Heat; Latent Heat.]

The thermometer must have been in use in the beginning of the 17th century, but it is not known, precisely, to whom the honour of the invention is due. A physician of Padua, named Santorio, and Cornelius Drebbel, of Alkmaar in Holland, are the persons to one of whom that honour is, with most probability, ascribed; and the former, in his 'Commentaries on Avicenna' (1626), actually claims it for himself. It may, however, have happened with this, as with other scientific discoveries, that the idea of the instrument occurred to two persons or more at or about the same time.

The first thermometers were intended to indicate variations in the temperature of the atmosphere merely; and the most simple of them consisted of a hollow glass-ball at one extremity of a long tube which was open at the opposite extremity. The air within the ball and tube being rarefied by the heat of a lamp, and the tube being in a vertical position, the open end was plunged into a vessel containing a coloured spirit; as the enclosed air cooled, the pressure of the atmosphere on the liquid caused it to ascend in the tube till the expansive force of the air in the ball and the upper part of the tube became equal to the pressure. In this state, an increase of the temperature of the atmosphere caused the air in the ball to expand and press down the spirit in the tube; on the other hand, a diminution of temperature, by causing that air to contract, allowed the external pressure to raise the spirit. A scale was adapted to the tube in order to express the degree of temperature by the number of the graduation at the upper extremity of the spirit.



Original Air-Thermometer.

An effort was made to render the instrument portable by bending the lower part of the tube upwards, and terminating this branch also with a ball; and a small aperture was made in the latter in order that the external air might have access to the lower surface of the spirit. Mr. Boyle subsequently modified the air-thermometer by making the tube quite straight and open at both ends: the lower end was immersed in a small glass vessel containing both air and coloured spirit, and the vessel being formed with a neck which closely encircled the tube, it was hermetically sealed to the latter. The variations in the temperature of the atmosphere caused the air in the vessel to expand or contract, and thus to press with more or less force on the surface of the spirit; the latter was consequently made to ascend or descend in the tube.

The air-thermometer invented by Amontons (1702) consisted of a tube nearly four feet long, open at both ends, and curved upwards at bottom, where it terminated in a ball. This tube carried a column of mercury about 29¼ English inches high, so that the air in the ball was compressed by the weight of two atmospheres. A light body, in which was inserted the lower end of a wire, floated on the upper extremity of the column of mercury in the tube; and near the upper end of the wire was an index by which the number of the graduation on a scale was shown. The variations of the temperature of the air in the ball caused the mercurial column to ascend or descend in the tube; and thus were produced corresponding movements in the index. By this instrument it was proposed to measure high temperatures on a scale whose length was only half of that which was required with the simple air-thermometer.

The defects inseparable from all the above thermometers are, that the dilatations of the air are not proportional to the increments of heat; that the length of the column of spirit or mercury varies with the temperature of the atmosphere; also, that the air which is in contact with the surface of the spirit in the open vessel, in the first kind of instrument, or with the top of the column of the spirit or mercury in the others, exerts more or less pressure according to its density; and thus the indications afforded by the thermometer are rendered erroneous, or require corrections which it is difficult to apply. The air-thermometer proposed by Dubuat, and of which the following is a brief description, possesses some advantages above those which have been mentioned; but not being portable, it has never been employed.

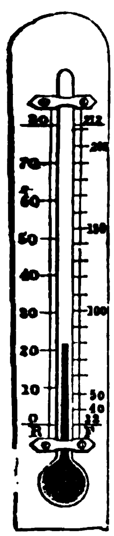
It consists of a column of mercury in a tube, like that of a barometer, hermetically sealed at the upper end, and bent below so as to form a short branch inclined at about 40° to the straight part of the tube; this branch terminating with a hollow ball. The mercury occupies the straight part of the tube to the height of about 29¼ inches above the bend; and at this bend it terminates without entering into the ball, which, by the construction, is a little above the bend. The part of the tube which is above the column of mercury is free from air, and when the bend is plunged in boiling water the tube is to be in a slightly inclined position, so that a vertical line may pass through the two extremities of the mercurial column; then, upon the ball becoming cool, and the elasticity of the air in it being diminished, the weight of the mercury will cause it to descend in the long branch and rise in the other. The mercury is to be prevented from entering the ball by making the tube decline farther from the vertical position, so that the lower extremity of the mercury may remain in the vertical line before mentioned; and the temperature of the air is to be determined by the height of the top of the column of mercury above a horizontal line passing through the lower extremity, that is, by the cosine of the declination of the tube from the vertical. Since the air in the ball preserves constantly the same volume, the elasticity communicated to it by the heat of the atmosphere, or by the fluid in which the instrument is plunged, is always in equilibrio with the pressure of the column of mercury, which is the force acting against it, and is proportional to the vertical height of that column.

About the middle of the 17th century the members of the *Accademia del Cimento* caused thermometers to be constructed in which, instead of air, alcohol or spirit of wine was employed. The fluid was introduced, as at present, into a glass tube terminating at bottom in a hollow ball, from which the air had been expelled by heat. The opposite extremity of the tube was then hermetically sealed, and a scale of equal parts was applied to the stem, by means of small beads of coloured enamel, for the purpose of expressing the temperature of the atmosphere, or of the liquid which was to be examined. Alcohol dilates and contracts considerably with the variations of temperature to which it may be subject, though not in so great a degree as air. It is also capable of measuring very low temperatures; but as it is brought to a boiling state much sooner than water, it cannot be employed to ascertain a high degree of heat. Spirit-thermometers were introduced into this country by Mr. Boyle, and they are still used for low temperatures.

Sir Isaac Newton, being dissatisfied with the smallness of the range of spirit-thermometers, employed linseed-oil in tubes for the purpose of measuring degrees of temperature. This liquid has nearly the same amount of expansibility by increments of heat as alcohol; and it is capable of bearing a considerable amount of heat and of cold without either boiling or freezing; but from its viscidity it adheres so much to the interior side of the tube as to render accurate observations quite impossible, and on this account it has not since Newton's time been employed for thermometers.

The thermometer which is now in general use is a slender tube of glass terminating in a ball containing mercury, the air having been expelled and the tube afterwards hermetically sealed. The idea of employing this fluid for the purpose of measuring degrees of heat by its expansion is supposed to have first occurred to Dr. Halley; and the reason why it was not employed by that philosopher appears to have been that the range of its expansion is much less than that of alcohol. According to Boerhaave ('Elementa Chemiæ,' 1732), the honour of having been the first to recommend a mercurial thermometer is to be ascribed to Römer, the discoverer of the motion of light, who is said to have invented it in 1709; but it was not till the year 1724 that such a thermometer was known in this country. In that year an account of a mercurial thermometer which had been invented by Fahrenheit, of Amsterdam, in 1720, was read before the Royal Society, and was published in the 'Philosophical Transactions' (vol. xxxiii.).

The advantages of mercury over alcohol and air, as a measure of temperature, are that its expansions are more nearly proportional to the increments of heat than those which take place in either of the other fluids; it is easily deprived of air, and its power to conduct heat being considerable, the changes of its volume by changes of temperature in the surrounding medium take place more rapidly than those of any other fluid except the gases.



Fahrenheit's Thermometer.

At first the scales for measuring degrees of temperature were arbitrary, and consequently no two thermometers could be compared together. The scale of the Florentine thermometer was determined by marking the place where the top of the spirit column stood in the tube when the latter was immersed in snow, and the place at which it stood at the time of the greatest heats in Florence: the interval between the points was divided into 60 parts. Subsequently, in this country, Mr. Boyle and Sir Isaac Newton formed scales for determining the expansion of the spirit or oil by making the space included in each degree of the tube equal to a certain portion of the whole volume. Thus, supposing the ball of the thermometer and part of the tube to be divided into 10,000 equal parts, and to be wholly occupied by the oil when the instrument is plunged in melted ice, Sir Isaac found that by the heat of the human body the oil expanded 256 such parts, and by that of boiling water 725 parts; then, considering the point at which the top of the column stood in the tube when the latter was placed in the ice, as the zero of the scale, he divided the interval between this point and that at which the top of the column stood when the ball of the thermometer was placed under the arm of a man, into 12 parts. Afterwards by proportion he found that the distance from the ice-point to that of boiling water was equal to 34 such parts ('Phil. Trans.,' vol. xxii.). This method, being of difficult execution, was soon abandoned.

The scale which has been in general use in this country since the year 1724, is supposed to have been invented by Fahrenheit. It is quite unknown on what ground he made choice of the fixed points on his scale, or of the number of graduations between them; but it is thought that one of the fixed points was that of boiling water, and that the other, which is the zero of the scale, was that at which the top of the column stood when the instrument was exposed to an intense cold in Iceland, in 1709. The extent of the scale between this last point and that of boiling water is divided into 212 parts, and the point of freezing water is at the thirty-second division from the zero point. See the scale on the right of the tube in the above figure.

M. Réaumur constructed a thermometer in which spirit of wine was employed, and he formed a scale in a manner nearly similar to that which had been put in practice by Sir Isaac Newton. He computed the volume of the glass ball, and graduated the tube so that the space between two divisions was equal to one-thousandth part of that volume: he then found the zero of the scale by marking the place where the top of the column stood when the thermometer was placed, in water just freezing: and afterwards, plunging the instrument in boiling water, he observed whether or not the spirit rose exactly eighty divisions. If not, he strengthened or diluted the spirit till it did so; and the point at which the top of the spirit stood became the point of boiling water. Of this instrument an account was published in the 'Mémoires' of the Academy of Sciences for 1730, but the construction has been long since abandoned; for, besides the difficulty of giving a proper degree of strength to the spirit, it is well known that the latter cannot be made to take the temperature of boiling water, so that the determination of the upper point in the scale must be very erroneous. That which is now called Réaumur's thermometer is an improvement on the former, by M. Deluc, who determined the points of freezing and boiling water by experiment, and divided the distance between them into eighty parts, the zero of the scale being at the former point. See the scale on the left of the tube in the above figure.

A third scale, called "Centigrade," has been much in use among the philosophers of the Continent within the last eighty years: it was invented by Celsius, a Swede, and it differs from that of Réaumur or Deluc, only in the distance between the points of freezing and boiling water being divided into 100 parts. The length of each degree in this thermometer, as well as in that of Réaumur, is greater than in the scale of Fahrenheit; and consequently the indications of temperature, when the top of the spirit or mercury is between the lines of division are rather uncertain, from the difficulty of estimating them accurately by the eye; also, the temperatures required to be determined being often below the point of freezing-water, the employment of negative signs is of more frequent occurrence with these thermometers than with those of Fahrenheit.

The following formulæ will serve to convert any given number of degrees on Fahrenheit's scale into the corresponding number of degrees on Réaumur's and the Centigrade scales, and *vice versâ*.

Let F, R, and C express any corresponding numbers of degrees on the three scales respectively: then—

$$(F - 32°)\ \frac{4}{9} = R, \text{ and } (F - 32°)\ \frac{5}{9} = C:$$

$$\frac{9}{4}\ R + 32 = F, \text{ and } \frac{9}{5}\ C + 32 = F:$$

$$\text{also, } \frac{4}{5}\ C = R, \text{ and } \frac{5}{4}\ R = C.$$

N.B. When F is between zero and 32°, the values of R and C are negative, and express the required number of degrees below zero on Réaumur's and the Centigrade scales. Also, when F, R, or C expresses any given number of degrees below zero on its proper scale, it must be considered as negative.

The scale invented by De l'Isle of St. Petersburg, in 1733, being still occasionally in use, it may be necessary to mention that it is formed by making the space included in each degree equal to one hundred-thousandth part of the whole volume of the mercury; the zero of the scale is at the point of boiling-water, and between this point and that of freezing-water the space is divided into 150 parts.

It may be observed that the situation of the freezing-point on the scale of a thermometer can be determined with great accuracy if the ball and part of the tube be immersed in pounded ice; for it is known that water containing ice and snow remains of the same temperature till the ice is entirely dissolved, every accession of heat to the water being employed in promoting the dissolution. But the point of boiling water is far from being so precisely known, since it varies with the density of the atmosphere at the time of making the determination. Distilled water in an open vessel, and under a given pressure of the atmosphere, boils at an invariable temperature, except as far as the nature of the vessel may make some difference; for if the heat communicated to the water be increased, the only effect produced is that of driving off a greater quantity of steam in a given time: in a vessel exhausted of the air the water will boil at a temperature expressed by about 70° of Fahrenheit's scale, while in a vessel constructed so as to prevent the steam from escaping it will remain in a liquid state at a temperature of 400° and upwards. In order therefore that the temperatures indicated by different instruments may agree together, it is recommended that this point should be found from water boiling in the open air at a time, if possible, when the height of the mercurial column in the barometer is 30 inches, and when the temperature of the air is indicated by 55° of Fahrenheit's scale.

This effect of the pressure of the atmosphere on the boiling of water was noticed by Fahrenheit in 1724, and M. Deluc, in his 'Recherches sur les Modifications de l'Atmosphère,' has investigated a formula for determining the height of the boiling-point above the freezing-point of the scale in terms of the height of the mercury in the barometer; but the English artist, Bird, was the first who applied a correction on account of the state of the barometer, for the purpose of fixing the point of boiling water on the scales of thermometers.

The Royal Society having, in 1776, appointed a committee to consider the best means of adjusting the fixed points of thermometers, the formula of Deluc was verified and reduced to English measures for the benefit of artists, in the event of their being obliged to make the instruments under different states of the atmosphere with respect to density and temperature; and the following are some of the corrections which are given by Sir George Shuckburgh for determining the true place of the boiling-point of water. The first column contains

Inches.	°
26	−7·09
27	−5·27
28	−3·48
29	−1·72
30	0
31	+1·69

the height of the barometer in inches; and the second, the correction which is to be applied with its proper sign to the number 212 on Fahrenheit's scale, in order to give the correct number of degrees at which the water will boil under the pressure expressed by the height of the mercurial column. The committee observe that in trying the heat of liquors, the quicksilver in the tube of the thermometer should be heated to the same degree as that in the ball; or if this cannot be done, a correction should be applied on that account. ('Phil. Trans.,' vol. lxvii.)

Thermometer-tubes should have their bores very slender, and, if possible, perfectly equable in the whole of their length. When there is any inequality in the transverse sections, the best artists make the graduations of the scale vary so that they may correspond to the equal divisions of a cylindrical tube; and in order to ascertain the relative dimensions of the sections, they cause a small quantity of mercury, about an inch in length, to slide along the interior of the tube, measuring its length in different places; then, since the lengths are inversely proportional to the areas of the sections, the variations of the former will immediately show the corresponding variations of the latter. The method of *calibration*, as it is called, recommended by the Kew committee, will be noticed presently. It is usual to give to the bore an oval form, with the broader side towards the front, in order that the mercury or spirit may be easily distinguished at a certain distance, as by approaching very near the instrument, the heat of the observer's person may affect the length of the column. Mr. Sheepshanks found that tubes with round bores were far more nearly true than those with flat ones. He also approves of bulbs three or four-tenths of an inch in diameter. They should not be too small, or the graduations of the scale will be close together, nor too large, or the instrument will not be sensitive on account of the large body of mercury required to be heated. The bulb should not be blown by the breath, lest moisture be introduced, but by an india-rubber bag.

It is of course essential that the extent of the thermometer-scale should be great enough to comprehend all the temperatures at which the substances generally required to be examined exist in a state of fluidity; and this extent may be obtained when mercury is employed. According to the experiments of Mr. Dalton, mercury does not boil till it has acquired a temperature equal to 660° of Fahrenheit's scale; and it does not freeze till it is subject to a degree of cold expressed by 39 divisions below the zero of that scale, (—39°) or 71° below the freezing-point of water. Pure alcohol, on the other hand, has never been frozen, though it has been exposed to a degree of cold exceeding that which is expressed by 166° below the zero of Fahrenheit; (—166°) though at that remarkably low temperature it became viscid. Hence a spirit-thermometer is to be preferred to one of mercury when it is intended to ascertain the temperature of the air in high northern or southern latitudes: but since the spirit boils in air with a degree of heat expressed by 173° of Fahrenheit, it is unfit for many of the purposes for which a thermometer is required. For instruments capable of measuring very high temperatures, see PYROMETER.

In the construction of a thermometer, the air should be carefully expelled from the tube, and even from the mercury or spirit within it: the variations in the density of the atmosphere cannot, under proper precaution, affect the instrument, since the tube is hermetically sealed. This precaution consists in not graduating the tube for some months after it has been sealed, or until the glass has accommodated itself to the altered circumstances of a vacuum within and atmospheric pressure without. The most carefully constructed thermometers will shift their fixed points if graduated too soon after filling. It must also be observed that the indications of temperature are not precisely expressed in terms of the dilatation of the mercury or spirit only, but in terms of the excess of that dilatation above the dilatation of glass. The apparent dilatation of mercury in a glass tube is equal to $\frac{1}{64·8}$ of its volume, between the temperatures of freezing and boiling water; and its true dilatation between the same limits is $\frac{1}{55·08}$ of its volume.

A perfect thermometer would be one in which the expansions of the fluid in the tube were exactly proportional to the increments of heat which it might receive from the substance whose temperature is to be determined; but it cannot be said that any of the fluids which as yet have been employed in the construction of thermometers strictly possess this property. Mercury is the fluid in which it exists in the greatest degree; but from the experiments of Deluc it has been ascertained that, between the points of freezing and boiling-water, the temperature indicated by the mercurial thermometer is lower than the true temperature, the greatest difference (which, however, is only equal to 1°·4 of Réaumur's scale, or 3°·15 Fahrenheit), being in the middle between those two points on the scale. From the same experiments it is also found that when thermometers are regulated so as to agree at the points of freezing and boiling-water, whether the liquid be oil, spirit, or water, the indications are always below those of mercury, the difference being the greatest at the middle between those points. With oil of olives the difference is 1° of Réaumur's scale (2°·25 Fahr.); with highly-rectified alcohol, 4°·9 Réaumur (11°·02 Fahr.); with half alcohol and half water, 6°·7 Réaumur (15°·07 Fahr.); and with water, 19°·5 Réaumur (43°·87 Fahr.). It must be observed that great irregularities take place in the expansion of all fluids when near their boiling state, and that mercury contracts very suddenly when at the point of its congelation. The deviations of the spirit-thermometer from the true indications of heat are known to be rather greater than those of the mercurial thermometer. It may be added, that the alcohol in a thermometer-tube loses, in time, part of its strength; and that, in consequence, the degree of expansion by a given increment of heat is not the same as when the instrument was made. The expansion of alcohol for temperatures greater than about 173° Fahr., at which the spirit boils, cannot be ascertained practically, because the spirit at that temperature passes into a state of vapour; and the comparison between the mercurial and the spirit thermometer ought not to be carried higher than that temperature; or the scales for mercury and spirit ought to be regulated so as to agree with one another at the freezing-point of water and at the temperature of 173° Fahr.; if this were attended to, the differences between the indications of the mercurial and spirit thermometers, above that point, would be less than they appear to be by the tables of Deluc.

Later measurements by Regnault of the total expansion of mercury for three progressive intervals of 180° Fahr., give the following results: Between 32° and 212° it is 1 part in 55·08; between 212° and 392° it is 1 in 54·61; and between 392° and 572° it is 1 in 54·01. In the mercurial thermometer it may be assumed, without sensible error, that between 32° and 212° equal increments of heat raise the thermometer through an equal number of degrees. The increase in the capacity of the glass bulb (especially for crown glass) almost exactly compensates for the increasing rate of the expansion of mercury, although for temperatures above 212° the compensation is not so exact. It has been found, also, that the temperature of 572° Fahr., as measured by an air thermometer, is 586° by a mercurial thermometer, on account of the increasing dilatation of mercury, with an increased temperature. Mr. Dixon, in his 'Treatise on Heat,' says: "Different glasses have different co-efficients of expansion, and also vary in the law of their dilatation at high temperatures, and as the amount of absolute dilatation of mercury is small, this variation in the expansion of the glass envelope produces irregularities of considerable magnitude in the apparent dilatation of mercury. As the real expansibility of air is much greater, its apparent expansion in glass is not affected to the same extent by these variations in the rate of expansion of the latter, and accordingly in an air-thermometer the rate of expansion of the glass may be considered as sensibly uniform. When corrected, therefore, for the expansion of its envelope, such an instrument forms the most perfect thermometer with which we are acquainted in the present state of science." An air-thermometer, corrected for the expansion of its envelope, being compared with a mercurial thermometer made with the peculiar description of glass employed by M. Regnault, the agreement between the two instruments was perfect up to 200° C.; whereas, in a mercurial thermometer made of ordinary tube, compared with one of crystal glass, although they agreed from 0° to 100° C., yet at higher temperatures the discrepancies were:—

1st Thermometer.	2nd Thermometer.	Difference.
190·51	191·66	1·15
246·68	249·36	2·68
251·87	254·57	2·70
279·08	282·50	3·42
310·69	315·28	4·59
333·72	340·07	6·35

Water, like other substances, suffers a diminution of volume by the abstraction of heat, but when it is cooled to a temperature between 39° and 40° of Fahrenheit's scale, it seems to have attained the maximum of density; and if the process of cooling be continued, it then increases in volume till it is converted into ice. Therefore, if a thermometer were made with water, and the top of the column were at 50° Fahr., it would be impossible to know whether the temperature were 50° or 30°, the expansion being nearly equal at equal distances within 10° above and below 40° of the scale. The cause is uncertain, but it is probably owing to a partial crystallisation, which may begin to take place in water when at a temperature expressed by about 8° above its freezing-point.

The mercurial and spirit thermometers formerly differed considerably at temperatures below that of freezing water. By observations made during Sir Edward Parry's second voyage, the differences between the indications of the spirit and mercurial thermometers varied from 3°·05 to 8° Fahr. between the temperatures + 58° and − 30°, the alcohol being always too low. At very low temperatures alcohol thermometers, unless very carefully prepared, differ greatly among themselves. Dr. Kane in his Arctic voyage records temperatures as low as from —60° to — 75°; but he admits that "it was not uncommon for thermometers which had given us correct and agreeing temperatures as low as —40° to show at —60° differences of from fifteen to twenty degrees." In remarkable contrast with this are the results obtained by Sir E. Belcher in his Arctic voyage with the thermometers furnished to him by Mr. Welsh of the Kew Observatory. While wintering in Northumberland Sound, 76° 52′ N., 97° W., he made a comparison of seven thermometers, marked 2, 6, 8, 20, 3, 4, 5, with a standard instrument, with the following results. The temperatures were all natural ones:—

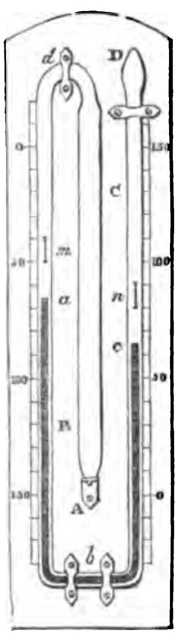
Standard.	2.	6.	8.	20.	3.	4.	5.
Fahr.	°	°	°	°	°	°	°
—20°	—21	—20	—20·6	—21·2	—20·4	—20·7	—21·1
—30°	—31	—30	—30	—31·5	—30·8	—31·2	—31·5
—40°	—40·5	—39·6	—39·8	—40·5	—40·5	—39·5	—41·3
—50°	—50	—49	—49	—51	—49	—49·3	—51·9

The lowest temperature observed was on 12th January, 1853, namely —62°·5. The indices of the minimum thermometers read next day at 8 A.M., gave —62°, —61°·6, — 66°, —63°·2. "The night was bright and calm; no sensation of cold. —63°·2 is the external exposed thermometer, but was never read excepting by its index of that graduation." Parry's coldest was —54° for 15½ hours. In Belcher's Expedition, the following temperatures were observed:—

—46° and below, for	150	continuous hours.
—50°	89	"
—52°	88	"
—55°	52	"
—58° to 62°·5	14	"

In the preparation of spirit thermometers the alcohol should be *absolute*, and the stem should be deprived of air by boiling. When the instrument is intended to mark very low temperatures, it is desirable to graduate it by means of two fixed points, namely, the freezing point of water (32°) and the freezing point of mercury (−39°). Professor Miller has also proposed a third fixed point, namely, the fusion of solid carbonic acid when it shall have been determined. The very low artificial temperatures that have been recorded must not be insisted upon, as the law of contraction of alcohol (which seems to form a converging series) is not yet accurately known, and upon it the indications of the spirit thermometer must of course depend. Even the low natural temperatures which are sometimes recorded, are not always trustworthy. During the severe cold of the winter of 1860-61, some very low readings have been proved to be erroneous, in consequence of the distillation of a portion of the spirit in the minimum thermometer into the further extremity of the horizontal stem. It has been shown that such a thermometer requires to be tilted from time to time to connect this portion of alcohol with that in the stem, unless indeed the new make come into general use, in which the end of the stem is turned upwards, and the stem itself a little raised in the frame.

Register Thermometers.—It is of great importance in meteorology that the observer should be able to ascertain the highest or lowest point of a thermometer scale at which the column of mercury may have stood during his absence; and a very large number of contrivances have been made to obtain this end. Of these, one, which is not quite gone out of use, was invented by Mr. Six, whose name the instrument bears, and is described in the 'Philosophical Transactions' for 1782. We retain it in this place, as it shows the principle of construction in a very large number of register thermometers. Six's contrivance consists of a long tube bent so as to form three parallel branches, A, B, and C: the part A is an elongated bulb, and the rest of the tube has a capillary bore. The lower portion, *b*, contains mercury, which rises in B and C to certain points, as *a* and *c*, and the bulb is filled with spirit of wine, which passing over the bend at *d*, descends to the upper extremity of the mercury in B: above *c* the branch C is also filled with spirit to near the upper extremity, which is hermetically sealed.



Six's Register Thermometer.

Two small indices of steel coated with glass, which are represented at *m* and *n*, are introduced in the branches B and C: these are capable of being forced upwards by the rising of the column of mercury in either tube, and they have about them a fine wire or a bristle or a thread of glass; so that they will remain stationary where they happen to be when the heads *a* and *c* of the columns recede from them. Their lower extremities consequently indicate the points at which the ends of the columns may have stood before such recession.

It is evident that the expansion of the spirit in A by increments of heat will cause that which is in B to press down the column of mercury in that branch and force up the extremity *c*, moving the index *n* before it, while by its friction the index *m* is prevented from descending. On the other hand, the contraction of the spirit in A allows the elasticity of the air in the ball D to force the column in C downwards, the index *n* remaining at the highest point to which it had been previously raised; the mercury in B then rises up, carrying the index *m* before it, till an augmentation of temperature causes the spirit in A to expand, and again force the mercury in B downwards.

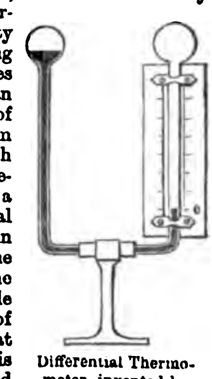
The graduations on the scale belonging to branch C are numbered upwards; while the graduations on the scale belonging to B are numbered downwards. The points *a* and *c* should always indicate the same degree on the two scales; and by means of a magnet the indices *m* and *n* may be brought down to those points: from thence afterwards the former ascends by a decrease, and the latter by an increase of temperature.

This instrument is apt to get out of order, and has given way to simpler forms. The *maximum* thermometer, as now generally made, is a mercurial thermometer with a horizontal stem. Within the bore is a small piece of steel wire, which is pushed forward by the expanding mercury, and is left stationary when the mercury begins to contract and recede, thus marking the highest temperature in the absence of the observer. The instrument can be reset for another observation, by tilting it, or by applying a magnet to the outside of the stem. The *minimum* thermometer is arranged like the maximum, only it contains coloured alcohol, the index being a small piece of enamel terminating in a bead, and resting just below the surface of the liquid column. As the liquid contracts by cold it carries the index with it by capillary adhesion, but as soon as the liquid begins to expand, it passes by the enamel, and leaves it at the lowest point to which the liquid had descended, thus marking the minimum temperature. To reset the instrument it may be tilted a little forward, or the enamel may contain a piece of iron wire, which can be acted on by a magnet on the outside. Another form of maximum thermometer, by Negretti, is to contract the tube just above the bulb, so as to allow the mercury to pass when it expands, but not to return when it contracts. The maximum temperature is thus marked, and the instrument can be reset by giving it a slight swing. The advantage of this instrument is that there is no index to get out of order, but there is some trouble in determining the corrections necessary to bring its readings into unison with a standard thermometer. Professor Phillips has a maximum thermometer, in which a portion of the mercurial column is detached from the rest by means of a small bubble of air, which detached portion remains stationary in the tube when the mercury in the bulb contracts, and thus marks the highest reading. The instrument is reset by swinging or inclining it. A good minimum thermometer may still be considered as a desideratum. Messrs. Negretti and Zambra have contrived one of very ingenious construction, in which a slender-pointed needle is brought down to the surface of the mercury in the tube, the latter being of wide bore, and in a vertical position. As the mercury contracts the needle descends with it, but on rising the mercury presses the needle to the glass, and rises up by the side of it, instead of raising it. There are difficulties in the manufacture of this instrument, and also in the method of observing it, and all we can say of it is, that it is under trial. The introduction of photographic registration [SELF-REGISTERING INSTRUMENTS] in meteorological observatories has greatly limited the necessity for mechanical registration. Even the wet and dry bulb thermometers [HYGROMETER] are now registered photographically.

The *Chromatic Thermometer* is a contrivance by Sir D. Brewster, in which a number of superposed plates of glass exert under differences of temperature a polarising action, which is estimated when the plates are held in a beam of light polarised by reflection.

Wollaston's Thermometer, for determining heights by variations in the boiling point of water, is described under BOILING OF LIQUIDS.

Differential Thermometer.—This instrument, which was invented by M. Sturmius, of Altdorf, before the year 1676, and was revived by Professor Leslie, in 1804, consists of two thermometer tubes, terminating, at one extremity of each, in a hollow glass ball, and containing coloured sulphuric acid: the opposite extremities are united by the flame of a blow-pipe, and an enlargement of the bore is made at the place of junction. The tube is then bent so as to form three sides of a rectangle, the two balls, which are of equal diameter, forming the upper extremities of two sides; and the instrument is on a stand with the branches of the tube in vertical positions. When the temperature of the air in the two balls is the same, the acid occupies one side and the base, and rises a little way up the other side of the rectangle. To the latter side is attached a graduated scale, with the zero of which the upper extremity of the acid in that branch should coincide. In the event of this adjustment being deranged, it may be restored by causing a small quantity of air to pass from one ball to the other, which is done simply by the warmth of a hand applied to that ball from whence the air is to be driven.



Differential Thermometer, invented by M. Sturmius of Altdorf.

The variations of temperature in the apartment will evidently have no effect on the instrument, since the action upon the two balls will be equal: but if one ball alone be heated, the rise of the acid in the other will immediately indicate the difference between the temperatures of the media about the two balls by the excess of the expansion of the air in one ball above the expansion in the other. The delicacy of the instrument is such that the least difference of temperature is immediately made sensible by the movement of the acid.

Radiating Thermometer, or Actinometer.—For the purpose of measuring the intensity of solar or terrestrial radiation, an instrument, called an ACTINOMETER, has been contrived, for the use of which we must refer to that head; but it may be remarked that an approximation to the measure of solar radiation may be obtained by simply exposing a register thermometer with a blackened ball to the direct action of the sun's rays. [RADIATION.] The thermometer should be placed a few inches above the ground, and be screened from currents of air; and the graduations should be made on the stem of the thermometer, in order to avoid the errors arising from the expansion or warping of the scale. The force of terrestrial radiation may be measured by the minimum temperature of a register thermometer, whose ball is placed in the focus of a concave mirror: the face of the mirror is to be turned towards the face of the sky, but away from the rays of the sun.

Since the establishment of the Kew Observatory, the construction of meteorological instruments has received the earnest attention of competent minds. Under BAROMETER will be found the method by which the Kew standard was formed by Mr. Welsh, the late superintendent. He has also given directions for the construction and comparison of thermometers; his Report, presented to the Royal Society in 1852 (and printed not in the 'Transactions' but in the 'Abstracts of the Papers,' &c.,*), being founded in great measure on the plan proposed

* See also British Association Report, 1853.

by M. Regnault. Our limits will not allow us to do more than just indicate the methods adopted. And *first*, as to the *calibration* of the tube. A short column of mercury (less than 1 inch in length) having been introduced into it, the tube is attached to the frame of Perreaux's dividing engine, and, by means of flexible tubing, is connected at both ends with india-rubber air-bags, the pressure on which is regulated by screws. The mercury is brought to that part of the tube where the graduation is to be commenced. The cutting-frame of the engine carries a small microscope with cross-wires in its focus; on turning the dividing-screw, the microscope wire is made to coincide with the first extremity of the mercury, and the screw is then turned forward until the wire reaches the second extremity; so that the length of the column is thus given in revolutions of the screw. The mercury is then made to move along the tube by pressing on one of the india-rubber bags until the first end again coincides with the microscope wire, when the length of the column is again measured, and the mercury again moved forward: this process is repeated until the column has been measured for each length of itself through the whole extent of the proposed scale. Permanent marks are made on the glass at the points of commencement and ending of calibration. If the progress of the numbers shows any considerable irregularity in the tube, and as a verification of the first set of measures, the calibration may be repeated, commencing at a point one-half the length of the column in advance of the original starting point. A series of measures interpolated from the two sets may then be adopted. In this operation the mercury should be very pure and the tubes clean. *Secondly*, with respect to the *graduation*, measured lengths of the column of mercury, in its successive steps along the tube, correspond to equal volumes, so that assuming the calibre of the tube not to vary throughout the small length of the calibrating column, it is evident that by dividing the spaces occupied successively by the mercury into an equal number of parts, the divisions will represent the same capacity, although they may be of different lengths. Before making the tube into a thermometer, the divisions of the scale may be verified by introducing a longer column of mercury, and examining whether the column occupies an equal number of divisions in different parts of the scale. Should there be any irregularity, a table of corrections is to be formed, but this is seldom required. The divisions are cut with a fine needle-point upon a coating of engraver's varnish, and are afterwards etched by means of hydro-fluoric acid. The required dimensions of the bulb may be found approximately by weighing a measured length of the mercurial column, and from the known expansion of mercury and its specific gravity, computing the capacity of the bulb. *Thirdly*, as to the determination of the scale co-efficients. The thermometer being properly filled with mercury and sealed, the divisions of the scale evidently represent equal increments of the volume of the fluid, but their value is quite arbitrary. The advantage of this plan is, that the divisions can be tested before the instrument is converted into a thermometer. The instrument is kept sufficiently long to allow of the settlement of the freezing point. The tendency of this point to shift, if the graduation take place soon after the filling, has already been noticed, but Mr. Welsh has pointed out another peculiarity in this respect: after a thermometer has been exposed for some weeks to the ordinary temperature of the air, if its freezing point be ascertained, and it be suddenly exposed for a short time to the temperature of boiling water, and again immediately placed in ice, the latter determination of the freezing point will be lower than the former, by as much as from 0°·1 to 0°·2, and the freezing point does not recover its former position for some time, probably two or three weeks. The freezing point is found by placing the thermometer in finely pounded ice, from which the water is drained off as it melts. The boiling point is taken at the temperature of steam (from distilled water) of the same elasticity as that of the atmosphere. The barometer is observed at the time, and the correction to a uniform height of 30 inches (reduced to 32°) is found from Regnault's Table. The fixed points are determined in the position in which the thermometers are to be used.

In the graduation of mercurial thermometers, it is customary to consider increments of volume as proportional to increments of temperature, a plan which cannot be adopted in the case of spirit thermometers. In testing some spirit thermometers graduated for low temperatures (namely, to —75° Fahr.) intended for the Arctic Expedition under Sir E. Belcher, Mr. Welsh proceeded to determine the rate of expansion of alcohol in glass, as compared with that of mercury. The alcohol had been carefully prepared by Prof. Miller, and its specific gravity at 60° was 0·796. A tube was calibrated and divided with an arbitrary scale, and its divisions were found upon verification to be of exactly equal capacity throughout. The tube was then furnished with a bulb of the same dimensions as those intended to be supplied to the Admiralty, and was filled with alcohol. Comparisons were then made between the readings of this instrument and those of a standard mercurial thermometer through as wide a range as was found practicable. The comparisons above the freezing point were taken in water: those below 32° were taken in freezing mixtures of ice and salt, or chloride of calcium. From these comparisons the law of expansion was deduced, but for the details we must refer to Mr. Welsh's report.

The apparatus used at Kew for comparing the indications of different thermometers consists of a cylindrical glass vessel, 15 inches deep, and 8½ inches diameter, together with a stand for supporting the thermometers, and an agitator or flat ring of tinned iron, fitting easily within the vase, for agitating the water so as to preserve an equable temperature throughout. The stand is a vertical rod supported by a small tripod, resting on the bottom of the vessel. Hooks sliding on this rod serve for suspending the thermometers. These are arranged with their bulbs at the same height in a circle of 3 inches diameter round the rod, and are kept fixed by means of elastic bands to a projecting six-rayed frame, attached to the supporting rod. In this way six thermometers can be compared at once. The whole apparatus is placed on a wooden revolving stand, and in taking the observations, the observer first agitates the water briskly for some time, then turns the revolving stand until each thermometer is brought opposite to his eye, and he reads off the scales as quickly as possible to an assistant, who takes down the numbers. The six thermometers can be read off and recorded in 20 seconds. More than one set of readings should be made for each temperature, and the order of observing the instruments should be reversed, to avoid, as much as possible, the changes which may occur during the reading off.

In graduating a thermometer for meteorological purposes, the freezing point is determined as usual with melting ice or snow, and an upper reading is fixed, by placing the thermometer in water of a certain temperature, together with a standard instrument. Instruments are now sold which have undergone comparison with the standards of the Kew Observatory, and as their price is moderate, there is no reason why the observations made by amateurs in various parts of the kingdom should not be accurate, and comparable with each other. The scales are engraved on the tubes, so that no correction is required for the scale. When the instrument is intended to record the external temperature, it should be placed in the shade away from the reflected and radiated heat of walls and buildings, and the bulb should be kept perfectly dry. Convenient thermometer stands have been contrived by Mr. Glaisher, Mr. Lawson, and Dr. Drew, for sheltering the instruments from disturbing influences. The best hours for observation are 9 a.m., 3 p.m., and 9 p.m. The readings should be taken rapidly, especially in cold weather, to prevent the warmth of the body from influencing them.

THERMO-MULTIPLIER. [Thermo-Electricity.]

THERMO-PHONE. When a bar of copper slightly curved and furnished with a wire for a handle, is heated, and its convex surface placed on a notch cut in the upper surface of a stout ring of lead resting on a sounding board, it will vibrate and evolve a variety of musical sounds resembling those of an æolian harp, and also the drone of the bagpipes, changing in the most fitful and irregular manner, and varying with the pressure applied by means of a point to the concave surface of the copper. The sounds will continue until the temperatures of the lead and the copper approach each other. Such an arrangement is called a *thermo-phone*. The experiment succeeds best with metals whose conducting powers for heat are very different, such as copper and lead, the conducting power of the former being =845, and of the latter =287 (silver =1000). The experiment, which is due to Mr. Trevelyan, was investigated by Professor Forbes ('Phil. Journal'), who showed that it could be performed with various other metals of different conducting powers, and the subject has been more recently investigated by Professor Tyndal ('Phil. Trans.')

THERMOSTAT, or *heat-governor*, is an apparatus invented and patented in 1831 by Dr. Ure, for regulating temperature in the processes of vaporisation and distillation, in heating baths and hot-houses, in adjusting the draught of stoves and furnaces, in ventilating apartments, &c. It acts upon the principle that when two thin metallic bars, of different degrees of expansibility, are riveted or soldered side by side, any change of temperature will cause a sensible flexure in the compound bar; the side consisting of the least extensible metal becoming concave, and the other convex. By this flexure of the compound bar, which takes place with considerable force, a movement is effected, which, by the intervention of levers, may be made to open or close stop-cocks, dampers, ventilators, or any description of valves, and thereby to regulate the flow of heated liquids or the admission and emission of air. The principle of the thermostat may be applied in many different ways, of which the following may serve as examples. In *fig.* 1, *a* is the compound bar, firmly fixed at *b*. To the other, or free

Fig. 1.

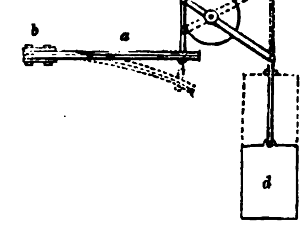


Fig. 2.

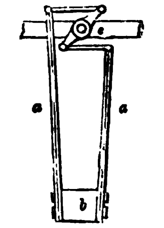

end of the compound bar, is attached, by means of a connecting rod, the short end of a lever mounted upon the axis of a circular revolving valve, or ventilator, *c*; and from the longer end of the lever is suspended a sliding valve, or damper, *d*. By increasing the temperature of the chamber or vessel in which the thermostat is placed, the compound bar will assume the curved form indicated by the dotted lines, by which means the position of the lever will be altered, the valve *c* will be turned on its axis, and the damper will be raised. *Fig.* 2 shows another arrangement, in which two compound bars, *a*, *a*, fixed at *b*, are made to open and close a valve, *c*, in a pipe through which air, water, or any other fluid is passed. By increasing the temperature of the apparatus, the upper or moveable ends of the bars would recede from each other, and, consequently, alter the position of the valve. *Fig.* 3 shows the principal part of a thermostatic apparatus in which three pairs of compound bars, *a*, *a*, *a*, are used to give motion to a sliding-rod *d*, *d*, with which any kind of valve may be connected by a rack and pinion, a chain and pulley, or otherwise. *b*, *b*, in this figure, is a straight guide-rod, which is fixed at one end by a screw-nut *c*. The

Fig. 3.

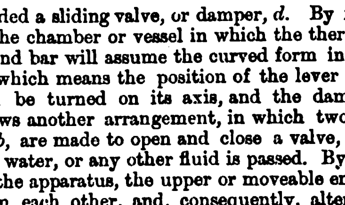

Fig. 4.

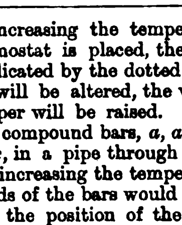


thermostatic bars are nearly or quite straight when cold, and become more or less curved by the action of heat; but in some modifications of the apparatus the bars are always curved, and the action of the apparatus depends upon the increase or decrease of the ordinary flexure. *Fig.* 4, for example, represents a thermostatic hoop, *a*, *a*, which may be immersed horizontally beneath the surface of the water-bath of a still. The hoop is fixed at *b*, and to its free ends are attached short links *c*, *c*, which impart longitudinal motion to the rod *d*. *e* is a lever-handle moved by the sliding-rod, and turning a valve on its axis *f*. The outer end of this lever carries an index, which moves against a graduated scale. *g* is a screw-nut, moveable upon the sliding-rod to adjust the apparatus before graduating the scale or arc traversed by the index. [PYROMETER.]

THESMOPHO'RIA (Θεσμοφόρια), a festival with mysteries in honour of DEMETER, to whom all the institutions of civilised life, especially of civil and religious laws, were attributed. The festival of the Thesmophoria especially referred to this part of the character of the goddess, as is clear from several of the ceremonies observed at its celebration, and from the surname of the goddess, "Thesmophoros," from which the festival derived its name. It was celebrated in various towns in Greece, and in the Greek colonies, as Sparta, Thebes, Eretria, Ephesus, Syracuse, Agrigentum, and others. But the place where it was held with the greatest solemnity, and where the particulars of its celebration are best known, was Athens. It was introduced at Athens, according to some writers, by Orpheus, and according to Herodotus (ii. 171) by the daughters of Danaus from Egypt. Its celebration was confined to women, especially married women. It commenced every year on the 11th of Pyanepsion, and lasted three days, though some writers extend it to four or even five. The discrepancy in this case, as well as in that of other Greek and Roman festivals, seems to have arisen from the circumstance that the real festival was in many instances preceded by one or more days devoted to preparations and purifications, and that some writers reckoned these days as belonging to the festival.

Previous to its celebration, the women of each demos elected from among themselves two matrons to conduct the solemnities, whose husbands, provided they had received a dowry of not less than three talents, had to pay the expenses of the festival as a liturgy. (Isæus, 'De Cironis Heredit.,' p. 208). The first day of the festival was called ἄνοδος or κάθοδος, that is, the procession; because the women went from Athens to Eleusis in a procession in which they carried on their heads certain laws (θεσμοί) written either in books or upon tablets. During the night between the first and second day the women solemnised their mysteries at Eleusis. The second day, called νηστεία, or "The Fast," was a day of mourning, on which the women were not allowed to take any other food than cakes of sesame and honey, and the greater part of it they spent sitting in mournful attitudes on the ground around the statue of the goddess. Meursius and others think that the procession to the Thesmophorion (the temple of Demeter Thesmophoros) at Athens, which is alluded to by Aristophanes ('Thesmophor.,' 276, &c.), and in which the women walked behind a waggon laden with baskets containing mystic symbols, took place in the afternoon of this day, the whole of which was a sacred day at Athens, on which neither the senate nor the people were allowed to hold their usual meetings. The third day was called καλλιγένεια, a surname of Demeter, by which she was invoked on this occasion. (Aristoph., 'Thesmophor.,' 296, with the Scholiast.) On this day the women made up for the day of mourning, and indulged in various kinds of merriment, in imitation of Iambe, who was believed to have created a smile on the face of the goddess during her grief.

THESSALONIANS, EPISTLES TO THE. Christianity was introduced among the Thessalonians in A.D. 50, by St. Paul, when he first passed over from Asia Minor into Europe to preach the gospel. St. Paul found at Thessalonica a synagogue of the Jews, "and went in unto them, and for three Sabbath days reasoned with them out of the Scriptures," endeavouring to convince them that Jesus was the Christ or Messiah expected by them. Though some of them believed, his success with the Jews does not appear to have been great; but a considerable number of the "devout Gentiles" were converted, and many women of distinction; so that the Christian church at Thessalonica was composed both of Jews and Gentiles, of whom the latter were the more numerous. The unconverted Jews stirred up a persecution against him, so that himself and his companions "were sent away by night by the brethren" to the neighbouring city of Berœa. Here, again, the Jews of Thessalonica stirred up a tumult against St. Paul, so that he was obliged to retire to Athens, leaving, however, Silas and Timothy at Berœa. At Athens he was subsequently joined by them, and being anxious about his recent converts at Thessalonica, "when he could no longer forbear" (1 Thes., iii., 1), he sent Timothy from Athens "to establish them, and to comfort them concerning the faith." St. Paul then visited Corinth, and on the return of Timothy with "good tidings of their faith and charity, and that they had a good remembrance of him always" (1 Thes., iii. 6), he wrote his first epistle to them, A.D. 52, from Corinth, and not from Athens, as the subscription of the epistle imports.

It was one of the earliest, if not the very first, of all St. Paul's epistles, the doubt lying between this epistle and that to the Corinthians, written from the same place. That to the Galatians was also probably written from Corinth before the Second Epistle to the Thessalonians. The genuineness of the first epistle has always been admitted: together with the second epistle, it is quoted and recognised as the work of St. Paul, by Irenæus, Clement of Alexandria, Tertullian, Origen, and all subsequent ecclesiastical writers. The immediate occasion of St. Paul's writing this epistle was the favourable intelligence brought by Timothy of the steadiness with which the Thessalonians adhered to Christianity, in spite of the persecution with which they were assailed by their own countrymen. Besides being exposed to direct persecution, there can be little doubt that they were also in danger of being moved by the reasonings of their religious adversaries, to which the sudden disappearance of St. Paul from Thessalonica, and his apparent desertion of them at a critical moment, might give some plausibility and apparent confirmation. To counteract the natural result of all this was one of the chief objects of Timothy's mission, and the First Epistle to the Thessalonians was written with the same design. Accordingly, in chap. i., after a short introduction, in which he couples the names of Timothy and Sylvanus (the Roman form of Silas) with his own, he expresses his thankfulness for their "work of faith and labour of love, and patience of hope in the Lord Jesus Christ," and then (v. 5–10) reminds them of the "proofs of power and of the Holy Ghost" with which the preaching of the gospel among them was accompanied, as evidences of its truth, and commends them for the constancy of their faith.

The Second Epistle to the Thessalonians was undoubtedly written soon after the first; Sylvanus and Timothy being joined with the apostle in the inscription of this Epistle as well as of the former; and as in chap. iii., ver. 2, he requests the prayers of the Thessalonians for his deliverance from wicked men, it is not improbable that he wrote it soon after the insurrection of the Jews at Corinth, when they dragged him before Gallio, and accused him of persuading men to worship God contrary to the law. This Epistle seems to have been occasioned by the information which St. Paul received on the state of the church at Thessalonica from the messenger who conveyed his first letter to the elders of the church, and his report of the effect produced by its contents. From some expressions in that Epistle (iv. 15; v. 4–6), compared with chapter ii. of the second, it would seem that a number of Thessalonians had come to the conclusion that the day of judgment was at hand, and would happen in their generation. To correct this misapprehension, and to prevent the anxiety and the neglect of secular affairs which resulted from it, appears to have been the main object and design of St. Paul in writing this Second Epistle to them.

This Second Epistle to the Thessalonians is, next to that to Philemon, the shortest of St. Paul's Epistles, but not inferior to any in style or spirit, and it is also remarkable as containing a distinct prophecy of the corruptions and delusions which were to arise in the Christian Church.

The undesigned coincidences between these Epistles and the "Acts of the Apostles" are given in Paley's "Horæ Paulinæ."

THIACETIC ACID (HS, $C_4H_3O_2S$). The product of the action of tersulphide or pentasulphide of phosphorus upon monohydrated acetic acid. It is a colourless liquid, possessing at the same time an odour of acetic acid and a sulphurous smell. It unites with bases, and may also be made to yield an anhydride—*thiacetic anhydride* ($C_4H_3O_2S+C_4H_3O_2S$).

THIACETONINE ($C_{12}H_{10}(C_2H_3)_3NS_4$). An artificial organic base produced by the simultaneous action of ammonia and sulphuretted hydrogen upon acetone.

THIALDINE ($C_{12}H_{13}NS_4$). An alkaloid produced by the action of sulphuretted hydrogen upon aldehydide of ammonium. It is volatile and crystalline, very slightly soluble in water, but readily so in alcohol and in ether. It forms crystalline salts with acids. A similar base containing selenium in the place of sulphur and termed *selenaldine*, may be prepared by an analogous process.

THIANISOL ($C_{16}H_8O_2S_2$). *Hydride of sulphanisyl.* A white pulverulent organic substance, formed by the action of hydrosulphate of ammonia upon hydride of azoanisyl.

THIN PLATES. [UNDULATORY THEORY.]

THIOFORMYLIC ACID ($C_2H_2O_2S_2$?). A crystalline body, formed by the action of dry sulphuretted hydrogen upon formiate of lead. It possesses a slightly alliaceous odour, and is insoluble in water, but freely soluble in boiling alcohol and ether. Its alcoholic solution does not redden litmus paper, and it has not yet been made to form definite salts.

THIOFURFOL ($C_{10}H_4O_2S_4$). An unimportant organic substance, formed by the action of hydrosulphate of ammonia upon solution of furfurol.

THIONAPHTHAMIC ACID. [NAPHTHALIC GROUP.]

THIONAPHTHIC ACID. [NAPHTHALIC GROUP.]

THIONESSALE. [STILBENE.]

THIONURIC ACID. [URIC ACID.]

THIOSALICOL. [SALICYLIC GROUP.]

THIOSINAMINE ($C_8H_8N_2S_2$). *Rhodalline.* A compound of ammonia with the oil of mustard, or sulphocyanide of allyl. It crystallises in brilliant white right rhombic prisms, which are inodorous and bitter. Thiosinamine is easily soluble in hot water, in alcohol, and in ether. It forms salts which are very instable and rarely crystalline. Treated with oxide of mercury it yields *sinamine*:

$$\underbrace{C_8H_8N_2S_2}_{\text{Thiosinamine.}} + HgO_2 = \underbrace{C_8H_6N_2}_{\text{Sinamine.}} + HgS_2 + 2HO.$$

Treated with ethylamine instead of ammonia, oil of mustard yields *thiosinethylamine* ($C_{12}H_{12}N_2S_2$). Whilst by treatment with oxide of mercury the latter body yields *sinethylamine* ($C_{12}H_{10}N_2$). [MUSTARD, OIL OF.]

THIOSINETHYLAMINE. [THIOSINAMINE.]

THIRD, an interval in music, classed among the imperfect concords, because liable to alteration; that is, the third part may be either *major* or *minor*. The ratio of the Major Third is 5 : 4; of the Minor Third, 6 : 5. The former comprises one major and one minor tone, as C E. The latter comprises a major tone and a semitone, as A C. Example:—

Major Third. Minor Third.

Or, according to the mode of description adopted by many writers on the subject, the Major Third comprises, inclusively, five semitones; the Minor only four. Example:

Major. Minor.

THIRLAGE, a tenure or custom formerly very common in Scotland, by which the owners or occupiers of certain lands were compelled to take their corn to a particular mill, to which the lands were said to be thirled or astricted, and to pay a certain proportion of it, varying in different cases, as a remuneration for the grinding, and for the expense of the erection and maintenance of the mill. This kind of servitude, having become in many cases exceedingly oppressive, has fallen very much into disuse.

THISTLE, ORDER OF THE, an ancient Scottish order of knighthood, sometimes called the order of St. Andrew. The claim to a high antiquity rests on no other authority than the legendary account recited in the warrant for the restitution of the order in 1687, and given most minutely by several Scottish antiquaries, attributing its formation to Achaius, king of the Scots, in commemoration of a victory obtained by himself and Hungus, king of the Picts, over Athelstan. Nicolas observes, as a fitting illustration of this legend, that Achaius died upwards of a century before the reign of Athelstan. The investigation of Sir Nicholas Harris Nicolas, in the third volume of his 'History of the Orders of Knighthood of the British Empire,' shows that the Order of the Thistle, as an organised fraternity, did not exist until the reign of James VII. of Scotland and II. of England. The warrant of James II. for the re-institution, as it is styled, of the "most ancient and honourable order of the Thistle," which is printed at full by Nicolas, and which asserts that by authentic proofs, documents, and records, the order "continued in great glory and splendour for many hundreds of years," bears date Windsor, May 29, 1687. Statutes were issued, and eight knights were nominated by James II., but the patent for the restitution of the order never passed the great seal; and on the abdication of James II., the order fell into abeyance, until it was revived by Anne in 1703. The statutes then authorised were much the same as those framed in 1687, and are still in use. The order consisted originally of the king and twelve brethren. This continued without alteration until July 16, 1821, when, in consequence of the coronation of George IV., an ordinance was issued for the appointment of four extra members, who should become regular knights as vacancies should occur; and in May, 1827, the number of knights was permanently extended to sixteen. The decorations worn by the knights consist of a collar of enamelled gold, composed of sixteen thistles, interlaced with sprigs of rue, fastened to the mantle by a white riband; a small image of St. Andrew, also of enamelled gold, suspended from the collar; a medal or badge of gold, having an image of St. Andrew within a circle containing the motto of the order, "NEMO ME IMPUNE LACESSIT" (No one provokes me with impunity), and a thistle; a green riband, to which the medal is attached, and which is thrown diagonally over the left shoulder; and a star, consisting of a St. Andrew's cross of silver in the centre of which is a thistle enamelled in its natural colours upon a field of gold, and surrounded by the motto and rays of silver. The star is worn on the left shoulder, on a mantle of green velvet, which, with other parts of the dress, are minutely described by Nicolas. The officers of the order are the dean, the secretary, the lordly king-at-arms, and the usher of the green rod, each of whom receives an annual salary, and a fee on the election of a knight. A complete list of knights of the Thistle, from the revival or creation of the order in 1687 to 1840, is given by Sir N. H. Nicolas in the work above cited.

THORINA. [THORINUM.]

THORINUM (Th). A metallic body discovered by Berzelius in an earth to which he had given the name of *thorina*. When this was converted into chloride of thorinum, and treated with potassium, after washing the mass a heavy metallic powder was left of a deep leaden-gray colour, which, when pressed in an agate mortar, acquired an iron-gray tint and a metallic lustre. It is not oxidised by water, either hot or cold, but when heated in the air it burns brilliantly, and is converted into oxide of thorium, or thorina, which is perfectly white, and devoid of any trace of fusion. Thorinum is scarcely at all acted upon by nitric acid, and slowly by the sulphuric; but hydrochloric acid dissolves it readily with the evolution of hydrogen gas. Its equivalent is 39·5.

Oxygen and Thorinum combine to form oxide of thorinum, (ThO) or thorina, by heating the metal in the air, or by decomposing the chloride by means of an alkali. When it has been strongly heated, its density is 9·402, and it is then insoluble in any acid but the sulphuric, and in that with difficulty. It is precipitated in the state of hydrate from its solutions by the alkalies, and in this state it is readily soluble in acids, and is converted into carbonate by exposure to the air. The alkaline carbonates dissolve the hydrate, carbonate, and subsalts of thorina; thorina is precipitated from solution by the ferrocyanide of potassium.

Besides combining readily with oxygen, as already mentioned, thorinum unites energetically with chlorine, sulphur, and phosphorus; but the compounds which they form have not been minutely examined.

THOROUGH-BASE, the art of playing (on keyed instruments, and according to the rules of harmony) an accompaniment from figures representing chords, such figures being placed either over or under the notes of the instrumental base staff. This is one of the many absurd terms employed in music, and its meaning is altogether arbitrary.

The figures used in *Thorough-Base* are the nine units. These represent certain intervals or sounds. Thus a 6 placed over a C in the base, points out A as an accompaniment: and that figure also implies two other notes attendant on it, namely, the 3rd and 8th, which are called the *accompaniments* of the 6th. A 6 and a 5 placed under it $\binom{6}{5}$, indicate the intervals of the 6th and 5th played together; and also, as accompanying notes, the 3rd and 8th. The figures 3, 5, and 8, singly, or together, represent the perfect or common chord. But in *Thorough-Base* a base note without any figure is supposed to carry a perfect chord. The chords are, as a general rule, assigned to the right hand of the performer, and the intervals are, in most cases, counted from an octave above the figured note. This will be more clearly understood by referring to the articles ACCOMPANIMENT, CHORD, and HARMONY.

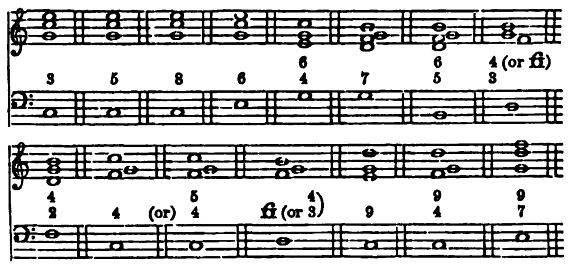
The following is a tabular view of the figures used in *Thorough-Base* to represent chords, together with those, not written, but understood, representing the accompaniments which, with the base, form the chords:—

Chords designated by figures.		Accompanying intervals.
3rd,	accompanied by a . . .	5th and 8th.
5th,	„ . . .	3rd and 8th.
8th,	„ . . .	5th and 3rd.
6th,	„ . . .	3rd and 8th.
6 4th,	„ . . .	8th.
7th,	„ . . .	3rd, 5th, and 8th.
6 5th,	„ . . .	3rd and 8th.
4 3rd,	„ . . .	major 6th.
4 2nd,	„ . . .	6th.
4th,	sometimes called the 11th, accompanied by a . .	5th and 8th,

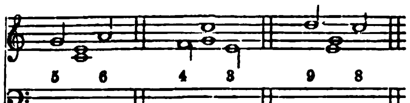
Chords designated by figures.		Accompanying intervals.
$\frac{5}{4}$th,	accompanied by an . . .	8th.
6th (sharp 6th)	,, . . .	$\{\frac{4}{3}$rd.
9th,	,, . . .	3rd and 5th.
$\frac{9}{4}$th,	,, . . .	5th,
$\frac{9}{7}$th,	,, . . .	3rd.
7 (sharp 7th)	,, . . .	5th, 4th, and 2nd.

Some other chords of an extraordinary kind are occasionally formed; but they are always clearly denoted, in *Thorough-Base*, by an ample number of figures.

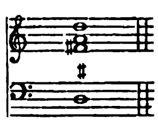
The above chords exemplified.



When two figures are placed in succession over one base note, the time of the latter is divided between them. Example :—



A sharp, or flat, or natural, placed alone over a base note, relates solely to the 3rd. Example :—



When other intervals are to be raised or lowered, the proper characters for the purpose are prefixed to them. A dash through a figure is equivalent to a sharp.

The practice of figuring a base staff, whether in a score or in the part assigned to a keyed instrument, has fallen into disuse, the harmony being now fully and clearly presented to the eye of the accompanyist in notes placed in a treble staff over the base. But a knowledge of what is yet too commonly misnamed *Thorough-base*, that is to say, harmony, is absolutely indispensable to the good musician, and very much abbreviates the labour of those who, as amateurs, only aspire to a practical skill either as vocal or instrumental performers. The rules of harmony stand in the same relation to music as those of grammar do to language.

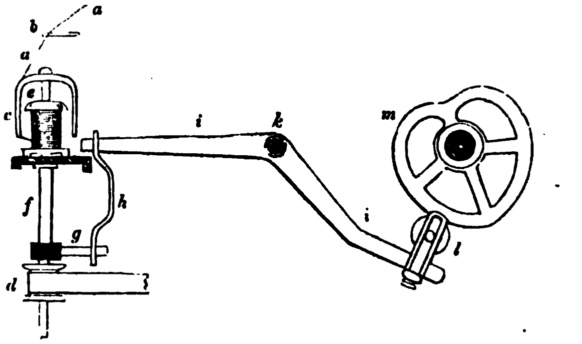
The invention of a *Figured Base* (*Basso Cifrato*, as the Italians so well denominate it) has been stated to have taken place in 1605, and is commonly attributed to Ludovico Viadana, *Maestro di Cappella* at the cathedral of Mantua. But this kind of musical abbreviation was earlier practised, and by an English composer, Richard Deering, who, in 1597, published his *Cantiones Sacræ*, at Antwerp, in which a figured base appears. And we have now before us Jacopo Peri's serious opera *Euridice*, printed at Florence in 1600, in which the base is figured throughout. Lying by us also is Caccini's *Nuove Musiche*, likewise printed at Florence, but one year later, and here we find the base regularly figured.

THREAD AND YARN. The distinction between thread and yarn is such as to render it desirable to describe them together under the present heading.

Yarn is the general name given to the threads which are woven into the various kinds of textile fabrics, whether cotton, silk, flax, hemp, wool, or worsted; the terms *twist, mule-weft, organzine, tram, abb, line*, &c., being particular names applied to particular sorts. Yarn for *cotton*-weaving is of two distinct kinds, according as it is intended for *warp* or *weft;* each kind being varied to suit different fabrics. *Water-twist* or *throstle-yarn* (the first name having been derived from the water-frame by which this kind of yarn was formerly spun, and the second from the throstle now employed) is smooth and wiry, and is usually employed for warp in heavy goods, such as fustians, corduroys, or for making sewing-thread. *Mule-yarn* (named from the mule machine by which it is spun) is of a soft and downy nature, calculated for the weft in coarse goods, and for both warp and weft in finer fabrics. The spun yarn is distinguished by certain numerals, which indicate the number of hanks contained in one pound, each hank consisting of 840 yards of yarn. The two kinds of machines are adapted for different numbers; thus, the *throstle* is not now often employed for yarns finer than No. 30 or 40, the higher numbers being generally spun by the *mule*. By successive improvements in the machinery employed, yarn is now spun to an exquisite degree of fineness, several hundred miles of yarn being spun from one pound of cotton. The excellence and cheapness of the yarn spun by modern machinery has led to very large exports. *Flax*-yarn is not estimated by No., like cotton, but by terms peculiar to that branch of spinning. Three hundred yards form a *lea* of flax-yarn; 38 leas form a *spindle;* 6 leas form a *rand;* 72 leas, or 21,600 yards, or 12 rands, form a *dozen*. There is this difference, however: in Scotland, flax yarn is designated by the number of lbs. in 48 leas; thus the same yarn is known in England as No. 48, and in Scotland as 1 lb. yarn. In the process of preparation by spinning, the flax becomes separated into two qualities, the finer obtaining the name of *line*, and the coarser that of *tow;* and the yarn spun from these two qualities is applied to different purposes. Modern improvements have led to the production of such fine qualities of line, that it is now used in combination with silk in pocket handkerchiefs and other fabrics. With regard to *hemp*, besides the yarn employed for weaving into sacking and other coarse goods, the term yarn is applied in rope-making in a different sense. The yarn in this case is a loose kind of string or cord, and it receives a No. according to the number of such strings required in making ropes three inches in circumference; thus, Nos. 18, 20, or 25 imply such thicknesses of yarn that 18, 20, or 25 of them are required in making a rope of the dimensions just stated. *Silk*-yarn has names applied to it not known in the examples just given. The silk is imported as a fine filament, or in the state of *raw* silk; it is twisted as a means of giving it greater firmness of texture, and then obtains the name of *singles;* two filaments are twisted together rather loosely, and formed into a yarn called *tram*, which commonly forms the weft or cross-threads of manufactured goods; lastly, two or more filaments are twisted separately into hard *singles*, and then twisted together in an opposite direction, forming a strong silken yarn called *organzine*, used generally for warp. Silk-yarn in the form of tram or organzine, that is, ready for the weaver, is called *thrown* silk. Yarn made from *wool* is called *woollen* or *worsted*, according as it is formed from short or from long wool, from clothing or from combing wool. The former of these is so spun that the elementary fibres shall be in a fit state for felting or fulling; while the latter has the filaments ranged more nearly parallel. The worsted yarns are further divided into the coarse and the fine, according as they are to be used for hosiery or for such goods as mousseline-de-laines, fine merinoes, &c.

Thread is a stronger kind of yarn. Whether or not it is composed of a greater number of filaments, it is twisted more closely, and has a harder and smoother surface. Most of it is used in needlework, as *sewing-thread;* but some is employed in net and lace making, and in other ways, though seldom in actual weaving. The manufacture of thread was first attempted in this country by Mrs. Millar, of Balgarran, in 1722, on having received some information and machinery from Holland. Her example was speedily followed by several families in Paisley, where the manufacture soon became of considerable importance. The first manufacturers imitated the kind called Nuns' or ounce thread, which was made up in hanks of forty threads each, reeled upon reels a yard in circumference; but when the profits of the manufacture were diminished by competition, it was injured by the surreptitious practices of some of the manufacturers. It was even deemed necessary, in 1788, to pass an act of parliament requiring all manufacturers of thread to use uniform standard reels of thirty-six inches in circumference, and to put thirty threads or rounds of the reel in each hank.

The manufacture of thread from fibres of cotton-wool, for sewing and other purposes, is one of the many important departments of British industry called into exercise by the improvements effected by Arkwright and his successors in spinning-machinery. The operation of combining yarns of cotton or linen into thread is performed by a machine called a doubling and twisting frame, somewhat resembling the throstle of the cotton-spinner. Along the centre of the machine is an elevated creel or frame-work, which supports two parallel rows of cops or bobbins of yarn. The cops are placed vertically, or nearly so, and the lower ends of their axes rest in oiled steps or hollows, while the upper ends are supported by wire eyes, so that they may revolve with facility. The number of cops is twice as great as that of the twisting spindles when the thread is to consist of two yarns, three times as great for thread formed of three yarns, &c. The yarn with which they are charged is frequently *gassed*, or passed quickly through a series of gas flames, to singe off any loose downy fibres. From the cops the yarns are conducted over horizontal glass rods, which are fixed parallel with the creel, and thence downwards into troughs filled with water or very thin starch-paste. To ensure the equal moistening of the yarns they are, while being drawn through the troughs, made to pass either under a glass rod, or through eyes. After being wetted the yarns pass over the rounded edge of the trough, which is covered with flannel for the purpose of absorbing the superfluous moisture; and thence under and partly around an iron roller, which is made to revolve with any required velocity by a train of wheel-work. Upon this roller rests another, of box-wood, which revolves solely by contact with the iron roller, its axis playing in vertical slots. In passing under the iron roller, then between it and the wooden roller, and finally over the latter, the yarns required to form the thread are brought together and slightly compressed; but although thus prepared for a more intimate union, they are not yet twisted together. In the annexed figure *a a* represents the united yarns which are to form the thread, and *b* is a fixed eylet through which they are conducted to the flyer *c*, which is mounted upon and revolves with a long vertical spindle set in motion by a whorl or pulley and strap at *d*. *e* is the bobbin upon which the finished thread is wound by the revolution of the flyer, which also gives to it any predetermined degree of twist. The spindle passes



freely through a hole in the centre of this bobbin, which rests upon a bar called the copping-rail, the transverse section of which is indicated by a tint in the cut; and the copping-rail, which extends the whole width of the machine, is supported at intervals by vertical rods, one of which is shown at *f*. To these rods, and consequently to the copping-rail and bobbins supported by them, a reciprocating vertical motion is imparted through the connecting pieces *g* and *h*, from the bent lever *i i*, which is pivoted at *k*, and receives its motion through the adjustable friction-roller *l*, from an eccentric or heart wheel *m*. Thus by the combined rotatory motion of the spindle and flyer, and the rising and falling motion of the bobbin, the thread is at once twisted and wound regularly upon the bobbins, which may be easily removed when full. By changes in the relative sizes of some of the toothed wheels by which the moving-power is distributed from the main shaft, the spindles, which always revolve much faster than the rollers, may be made to do so to any required degree, so as to impart a greater or less degree of twist to the thread.

These few illustrations will suffice to show the nature of the twisting processes, aided by details given in such articles as COTTON; LINEN; SILK; SPINNING; and WOOLLENS. We may, however, mention that the *polishing* of sewing thread is a process on which its saleable quality much depends. Mr. Adam, of Paisley, polishes sewing thread by passing it through a dressing composition, over a guide roller, through the teeth of a reed, over a metal drum, under a brush roller, again through a reed, and finally under a polishing roller covered with cloth. Mr. Brooks, of Derby, has invented a mode of producing a polish on thread, which he called *patent glacé*; and the assumption of the name *glacé thread* by Mr. Evans, of Huddersfield, led to litigation between the two inventors. The polishing of sewing thread has indeed led to more than one appeal to the law. Mr. Ewen patented a process whereby he dips a hank of thread into size, squeezes it, passes it over two rollers rapidly revolving, and applies it against a cylinder-brush, which removes all asperities. Mr. Liddell, another inventor, used two sets of rollers instead of one, and teasles instead of brushes; but in some other respects he was considered to have infringed Ewen's patent. Other appeals to the law have been made in reference to the *length* of thread wound upon a reel. A manufacturer of *Persian thread* put labels on his reels, denoting the quantities to be 100, 200, or 300 yards; whereas the real lengths were less. This was done at the request of Manchester firms which had lax notions of honesty. The manufacturer refused to continue this system; whereupon a Manchester man pirated his trade-mark, and used it for short-measure cotton thread obtained elsewhere—thus committing a double fraud.

The exports of yarn and thread have now reached an enormous quantity. In 1860 there were exported:—

	Quantity.		Declared Value.
Cotton yarn . . .	197,364,947	lbs.	£9,875,073
Cotton thread . . .	6,266,724	,,	740,876
Linen yarn . . .	31,152,026	,,	1,800,927
Linen thread . . .	3,230,377	,,	339,236
Silk, thrown . . .	435,212	,,	520,413
Silk, twist and yarn . .	456,661	,,	294,878
Woollen / Worsted } yarn . .	27,533,958	,,	3,843,396
Total	266,439,905	lbs.	£17,428,799

THREAD-GILDING. [GOLD LACE MANUFACTURE.]

THREATS AND THREATENING LETTERS. Threats of personal violence, or any other threats by which a man of ordinary firmness and prudence may be put in fear, and by means of which money or other property is extorted from him, amount in law to the crime of robbery. [ROBBERY.] And by the statute 7 Will. IV. & 1 Vict. c. 87, sect. 7, a person demanding by menaces any property of another with intent to steal the same, is declared to be guilty of felony, and is liable to imprisonment for any term not exceeding three years. It is also a misdemeanor at common law to threaten another in order to deter him from doing some lawful act, or to compel him to do an unlawful one, or to extort money or goods from him, or to obtain any other benefit to the person who makes the threat.

The offence of sending or delivering letters or writings, threatening to kill or injure the person to whom they are sent or delivered, or to burn his house, or to accuse him of some heinous crime for the purpose of extorting money, was formerly considered to be high treason (stat. 8 Hen. V. c. 6); and under the stat. 9 Geo. I. c. 22, continued for more than a century to be punishable as a capital felony. By the statutes 4 Geo. IV. c. 54, s. 3, & 10 & 11 Vict. c. 66, s. 6, a less punishment is substituted; and any person sending or delivering any writing, with or without any name or signature subscribed thereto, or with a fictitious name or signature, threatening to kill or murder any person, or to burn or destroy his house, out-house, barns, or stacks of corn or grain, hay or straw, is declared guilty of felony; this offence being now punishable with penal servitude for life, or not less than three years, or imprisonment for any term not exceeding four years. By statute 7 & 8 Geo. IV. c 29, s. 8, any person sending or delivering any letter or writing, demanding of any person with menaces, and without any reasonable or probable cause, any chattel, money, or valuable security; or accusing or threatening to accuse, or sending or delivering any letter or writing accusing or threatening to accuse, any person of any crime punishable by law with death, transportation, or pillory, or of any assault with intent to commit any rape, or of any infamous crime (the meaning of which term is defined), with a view or intent to extort or gain from such person any chattel, money, or valuable security, is declared guilty of felony; the offence being now punishable with transportation for life or not less than three years, or with imprisonment not exceeding four years, with or without whipping. Threatening to publish a libel is a misdemeanor punishable by imprisonment with or without hard labour not exceeding three years.

THREE, RULE OF, the technical name of the rule in arithmetic by which, three quantities being given, the first and second of one kind, a fourth is found such that the four are in proportion, or that the first is the same multiple part, or parts, of the second, which the third is of the fourth.

In the earliest modern treatises are found the explanatory headings of this process, from which the denomination *rule of three* has been formed by abbreviation. Almost all such abbreviations date from the time when systems of commercial arithmetic began to be written—that is, about the beginning of the 16th century. Before that time, such books as were written always contained demonstrations from full definitions; and it was not judged necessary to provide the simple case of finding a fourth proportional to three given numbers with a separate name, or to divide the rule for doing it from others. This, however, was done by traders in their daily practice, who separated the rule of three from the other parts of arithmetic, and called it the *golden rule*, an older term, probably, than *rule of three*. Bishop Tonstal, ('Ars supputandi,' 1522) begins his chapter on the "Regula de tribus notis quartum ignotum commonstrantibus" in this manner: "Præcipua omnium regula est quæ de tribus notis quartum ignotum in noticiam educentibus ab Arithmeticis traditur. Vulgus *regulam auream* vocat; quia hæc cæteris Arithmeticæ regulis velut cæteris metallis aurum præstet." Robert Recorde (1540) calls it the "feate of the rule of proportions, whiche for his excellencie is called the golden rule." Humphrey Baker (1562) uses the phrase "rule of three," and says that "the philosophers did name it the golden rule, ... but nowe in these latter daies, by us it is called the rule of three."

The immense variety of questions which are to be solved by finding a fourth proportional defies all classification; but they may all be reduced to one form, though it may in particular cases not be easy to see the mode of reduction. That form is:—A produces B; what will C produce? It may be that it is money which produces goods, or goods which produce money, or money which produces interest, or money of one country which produces money of another, or time which produces distance travelled, &c., &c., &c. The difficulty to beginners is the reduction of the question given to the above simple form, which must be done before what is (or used to be) called the *statement* of the question can be made—namely, the writing down the numbers A, B, C, in the proper order, with the marks of proportion between them:

A : B : : C : the answer required.

It is proper enough to say that this is a question of proportion when numbers only are considered, but absurd when the things represented by the numbers are used instead of the numbers. Thus, if 5 pence buy 10 apples, 7 pence will buy 14 apples, and the number 5 is to 7 as 10 is to 14, or 5 is the same fraction of 7 as 10 is of 14. But it is absurd to say that 5 pence bear the same proportion to 10 apples that

7 pence bear to 14 apples: simply because 5 pence are not any assignable fraction of 10 apples. That there is a *relation* is true; but that relation is not proportion. Thus, it is not absurd to say, in the common language of the rule, As 5 pence are to 10 apples, so are 7 pence to 14 apples; for the first does stand to the second in the same relation as the third to the fourth: 5 pence must, at all rates, do as much towards the purchase of 10 apples as 7 pence towards that of 14 apples. With this understanding, there is no objection to the common mode of statement, and the proof of the rule is as follows:—If A of the first produce B of the second, then, at the same rate of production, 1 of the first must produce $\frac{B}{A}$ of the second; whence C of the first must produce $C \times \frac{B}{A}$, or $\frac{CB}{A}$ of the second.

The importance of the rule of three induced arithmeticians to attach two other rules to it: the inverse rule of three (called by Recorde, Baker, &c., the *backer* rule); and the double rule of three. Some of the writers of Cocker's school, apparently by an abbreviation of his words, tells us that the rule of three inverse is used "when less requires more and more requires less;" meaning that the greater the third of the given numbers, the less will be the answer, and *vice versâ*. Thus, suppose that 10*l.* has been lent me for 3 months, and I want to know how long I ought to lend a given sum (other than 10*l.*) in return: evidently the more I lend, the less the time for which I ought to lend it. If the sum be 15*l.*, then 3 months is to the time required, not as 10 to 15, but in its inverse ratio, as 15 to 10, or $15 : 10 :: 3 : 3 \times 10 \div 15$, or 2; and 2 months is the answer required.

The double rule of three (at least in the class of questions which are usually considered as falling under it) is applied where time is an element in the production which the question supposes. For example: supposing it known that A men can pave B square feet in C days, it may be asked how many men can pave b square feet in c days, or how many square feet can a men pave in c days, or how many days will it take a men to pave b square feet. If we write down the data and answer in two lines, and in the following order—force employed—effect produced—time of production—thus:

$$\begin{matrix} A & B & C \\ a & b & c \end{matrix}$$

the rule is—Take such an answer as will make the extremes of each line multiplied by the mean of the other, the same in both. That is, let $AbC = aBc$, and according as a, b, or c, is to be found, the mode of working is as follows:—

$$a = \frac{AbC}{Bc}, b = \frac{aBc}{AC}, c = \frac{AbC}{aB}.$$

The proof is as follows:—*One* man in C days could pave $\frac{B}{A}$ square feet, and in *one* day $\frac{B}{AC}$ square feet. By similar reasoning one man in one day could pave $\frac{b}{ac}$ square feet. Hence

$$\frac{B}{AC} = \frac{b}{ac}; \text{ or } aBc = AbC.$$

The principal caution which a beginner requires is, not to suppose that the rule of three (or the rule of finding a fourth quantity which, which three others, shall constitute a proportion) is to be applied in all cases in which three quantities are given to find a fourth. That such a caution is necessary arises from the defect of works on arithmetic, which frequently exhibit this rule without any mention of proportion, and leave it to be inferred that there is but one way of obtaining a fourth quantity from three others.

THRESHING. The separation of the grain from the ear in corn has always been one of the most laborious operations on a farm. Where the quantity grown is merely sufficient to supply food for the cultivators of the soil, the simplest methods answer the purpose sufficiently. The corn, taken by handfuls, may be beaten on a piece of wood or a table, and by repeatedly turning the straw the whole of the grain may be readily beaten out. This mode of threshing may be still adopted in order to obtain the finest and ripest grains for seed; but then the straw is afterwards threshed over again with the *flail*.

Where the corn is threshed out immediately after harvest, to be put into a granary, as is the case in those countries where extensive tracts of rich land are sown with corn two or three times without much tillage or manuring, and then left to be recruited by several years' rest and pasture, the most common practice is to level a portion of a field, and, laying the corn in the straw in a large circle, to drive oxen and horses over it till it is all trodden out. This is the method alluded to in Scripture, and can only take place where the climate is serene and dry. Till ingenuity had produced machines to supersede the flail, this was the only instrument in use. The first idea of a machine for threshing was that of imitating the motion of the flail; but so much depends on the eye of the thresher, that no mechanism could well imitate the motion of his arms. The present improved threshing-machine is now so common that it will suffice to give the general principle of action. A rapid motion is given to a hollow cylinder round a horizontal axis; on the outer surface there are projecting ribs parallel to the axis at equal distances from each other; the width of these is from two to six inches. Around half the cylinder is a case, the inner surface of which is lined with plates of cast-iron grooved in the direction of the axis. The ribs or beaters come quite close to these grooves, so that an ear of wheat or other corn cannot well pass between them without being flattened. The sheaves of corn, having been untied, are spread on a slanting table, and in some machines are drawn in between two iron rollers, of which one is plain and the other fluted. The motion of these rollers is slow, while that of the cylinder or drum is rapid. The beaters act on the straw as it comes through, and beat out most of the corn; but what remains is carried in between the beaters and the fluted case, and when it has made half a revolution all the grain has been beaten and rubbed out. It falls on a shaker which lets the grain through, but tosses off the straw. Moveable threshing-machines are very generally in use in England. The price of threshing in this way is about half of what is usually paid for threshing with the flail; it is more rapidly done, there is less chance of pilfering, and fewer grains remain in the straw.

On very large farms it has been found economical to erect a steam-engine to work the threshing-machine, chaff-cutter, and other domestic implements. But travelling machines thresh out much the largest quantity of the corn that is grown in England. The moveable steam-engines which are used for working such machines are now made in immense numbers, and no doubt 15,000 to 20,000 horse-power is thus every year added to the forces used in agriculture.

THROMBUS is a tumour formed by blood effused from a vein after bleeding, and coagulated in the adjacent cellular tissue. It is a kind of intense ecchymosis or bruise, and usually arises from the puncture in the vein not having been made exactly opposite that in the skin, so that some of the blood, instead of flowing out, is infiltrated between the vein and the surface. It is rarely of sufficient importance to require treatment, and is usually removed like the effused blood of an ordinary bruise. Sometimes, however, inflammation ensues around the tumour, which should be treated by leeches and cold; or, if it proceed to suppuration, should be managed like a common abscess.

THRUSH or APHTHÆ is a disease to which young children are particularly liable. It is a disease of the mucous membrane of the mouth and fauces, and manifests itself in the form of small points, rings, conical or hemispherical elevations. These sometimes increase in size, and become large spots, which are covered with a membrane of milk or pearl-white colour passing into a gray or yellowish colour. This membranous matter is of a more or less soft consistence, and varies in thickness. It is at first firmly adherent to the mucous membrane, but eventually peels off, leaving the mucous membrane uninjured. These spots are found on the inner edge of the lips, on the cheek, the gums and the palate; on the upper and lower surface of the tongue, in the throat, and in the œsophagus down to the stomach.

On placing this membranous secretion under the microscope, it is found to consist of epithelial cells, a certain amount of exuded matter, and of *the filaments and spores of a fungus* known by the name of *Oidium albicans*. [ENTOPHYTA; OIDIUM, in NAT. HIST. DIV.]

The filaments of the fungus are cylindrical, elongated, straight, or curved and tubular. The interior of the tube is transparent. In the midst of these filaments are found minute bodies composed of two to four oval cells. These are the germinating spores from which originate the true spores; which lie together frequently in masses and vary in number according to the age of the fungus.

There is no doubt that thrush entirely depends on the presence of this fungus. It appears, however, that certain states of the system invite their attacks. When children are weakly or have been subject to derangement of the bowels from any cause, the fungus appears to find a fit nidus for its development. In some cases the irritation produced by the fungus engenders inflammation which ends in ulceration, and this may spread and even produce destructive effects.

Old people as well as children are subject to attacks of the same fungus when the conditions are present which invite their attacks. Such being the nature of thrush, it is very clear that it is not critical of any general state of the system.

Thrush is often confounded with various affections of the mouth, such as idiopathic inflammation with ulceration, accumulation of epithelial cells, the fur of the tongue, and the remains of food especially milk, from all of which it may be easily distinguished by the presence of the filaments and spores of the fungus.

In the treatment, the object should be to destroy the fungus by external application, and to rectify the diseased condition of the child. A dilute solution of nitrate of silver painted over the aphthous spots has been found useful as an external application. Acidity of the stomach and bowels may be corrected by the carbonates of potash, magnesia, or soda. The preparations of iron with cod-liver oil are amongst the best remedies for the constitutional state in which thrush occurs.

(Küchemeister *On Animal and Vegetable Parasites*, translated by Dr. Lankester.)

THUG (from Hindustanee *t'hagna*, to deceive) means a deceiver, and is the special appellation of secret murderers in India. Of their origin nothing can be said with any degree of certainty. The Thugs themselves refer it to the remotest antiquity, and there is no doubt that the ceremonies with which they carry on their murderous trade can be traced as far back as the Kâlika Purâna, where we find them described with the utmost accuracy. Their gangs, consisting of from ten to two or three hundred men of all races, castes, sects, and religions, yet all joining in the worship of Kâli, moved about all parts of India, sacrificing to their tutelary goddess every victim that they could seize, and sharing the plunder among themselves. Still they shed no blood, except when forced by circumstances; murder being their religion, the performance of its duties required secrecy, and the instrument of death was a rope or a handkerchief, which could excite no suspicion. They were stranglers. Every gang had its leader, the *Jemadar* or *Sirdar*; its teacher, the *Guru*, whose duty it was to initiate the novice into the secret of using the *roomal*, or handkerchief. Then came the *Bhuttotes*, that is, stranglers; and the *Sothas*, or entrappers; and at last the *Lughaees*, or gravediggers. In a country like India, the striking character of whose inhabitants is an almost incredible apathy, it was easy for them to commit the most outrageous murders without exciting the interest of the victim's relations. The immense jungles which border the roads afforded the Lughaees every facility for effectually concealing the bodies; and the prevailing custom of travelling in parties prevented the designs of the Sotha from being suspected, whenever he succeeded in offering the protection of his Jemadar to travellers whom their wealth induced him to entrap. The Thugs generally assumed the appearance of merchants, which increased the confidence of their victims, whom they despatched with the greatest celerity whenever they found a convenient place. Whilst the Bhuttotes arranged themselves in a manner to effect their purpose with facility, the Lughaees dug the hole; and at a given signal the noose was passed round the neck of the traveller, and, being taken unawares, he was strangled without being able to make any resistance. He was then thrown into the hole, and large incisions were made in the abdomen to prevent the corpse from swelling, and the whole was covered over with a layer of dry sand, another of thorns and bushes, and over all was thrown the earth which had been dug out, which they smoothed down so as not to attract the notice of travellers. After every murder they offered a sacrifice to Kâli, which they called *Tapounee*. It was performed in the following manner:—A large sheet was spread over the cleanest spot they could select, and on this was cast a pile consisting of one rupee and four anas' worth of coarse sugar; near this they placed the consecrated pickaxe (an instrument sacred to Siva and Bhâvanî), and a piece of silver as a *rûpa darsana*, or silver offering. The leader then sat down on the sheet, and the best stranglers placed themselves on each side of him with their faces to the west. They then distributed the sugar and ate it in solemn silence. But for this, as well as other ceremonies, we must refer to the works of Colonel Sleeman and Captain Meadows, as well as to an article in the 130th number of the 'Edinburgh Review.'

We have already observed that Thugs were found exercising their fearful trade in all parts of India. In the Deccan they were called Phânsigars (from Sanskrit *pâsa*, a noose) or noosers, and on them we have a very interesting paper in the 13th volume of the 'Asiatic Researches.' Their customs are the same as those of the northern Thugs; but, having fewer Mohammedans among them, they are more strict observers of the duties which their religion imposes; they kill neither women, nor old men, nor any of the subjects which the Kâlika Purâna (in the 'Rudhira Adyâya') declares to be unfit for a sacrifice to Devî. In the same volume of the 'Asiatic Researches' there is another article on them, by Mr. Shakespear: both were written in 1816.

The origin of this atrocious worship is undoubtedly Hindu. The Thugs maintain that their occupation is represented in the caves of Ellora, as well as all other trades. Moreover, the terms they use are chiefly of Sanskrit origin; and the worship of Kâli, as described in the Kâlika Purâna, corresponds so well to the religious ceremonies of the Thugs, that there can be little doubt as to their identity. ('Asiatic Researches,' vol. v.) All the ceremonies of the Thugs are fixed by Purâna, the date of which it is difficult to ascertain; but frequent allusions are made to it in the Vîra Charita, a drama of Bhâvabhûti, who lived at the court of King Bhoja in the beginning of the 8th century of our era.

Thévenot, in his 'Travels' (part iii., ch. 22), is the first to notice the Thugs: he describes them as infesting the road from Agra to Delhi, and using a long rope furnished with a noose, which they throw with great dexterity round the traveller's neck; and he relates that their Sothas were frequently women. About ten years after Thévenot, Dr. Fryer found them at Surat, where a gang of them were executed. He describes them as Thévenot does; and it appears from the description that they belonged to the *Mooltaneas*, a peculiar class of Mohammedan Thugs.

Although the whole of the ceremonial is Hindu, the Thugs themselves, whether Hindu or Mohammedan, maintain that they descend from seven Mohammedan clans, Thugs, Bhys, Bursote, Kachunee, Huttar, Ganoo, and Thundee ('Ramaseeana,' p. 11); the seven clans are admitted to be the most ancient and the original stock on which all the others have been engrafted. This circumstance may lead us to suspect that Mohammedans were indeed the first to give a sort of political system to the Thugs; and the seven clans of Ismailis, whose occupation was murder as dreadful as that of the Thugs, may, when persecuted in the last days of their political existence, have joined themselves to the Hindu Phânsigars, and, adopting their ritual, have given rise to their present institution. This point is investigated with much ingenuity in an article on the 'Secret Societies of Asia,' in the 49th vol. of 'Blackwood's Magazine.' Shah Jehan and Aurengzebe instituted criminal proceedings against them. After this we again lose sight of them until the time of Hyder Ali, who proceeded against them in a summary way. Mysore, however, seems to have been their favourite residence; for in order to suppress them, in the reign of Tippoo Sultan, many of them were apprehended and sentenced to hard labour, and others suffered mutilation. It was in Mysore also that the English government first discovered them soon after 1799; but it was not before 1810 that any measures were taken for their extermination; and a plan for their suppression, which was successful, was adopted in 1830 by the then governor-general, Lord William Bentinck.

(*Ramaseeana, or Vocabulary of the Peculiar Language used by the Thugs*, Calcutta, 1836: this work is written by Col. Sleeman; *The Confessions of a Thug*, by Captain Meadows, 1840, London.)

THUJONE. A hydrocarbon produced by the action of iodine upon the essential oil of Arbor Vitæ (*Thuja occidentalis*).

THUNDER is an explosion accompanied by a loud noise, which is heard after a discharge of lightning from the clouds. The character of the noise is variable: it sometimes resembles that which is produced when a single piece of ordnance is fired; at other times it is a rolling sound like the successive discharges of several great guns; and occasionally it may be compared to a series of sharp reports from a fire of musketry.

The identity of lightning with the electric fluid is now well known [LIGHTNING], but the physical cause of the detonation which accompanies the flash is still the subject of conjecture; in general it is considered that lightning, by its heat, creates a partial vacuum in the atmosphere, and that the sudden rushing of air into the void space produces the sound; but various reasons have been assigned for its prolongation. It was formerly supposed that the rolling noise is merely the result of several echoes caused by the sound being reflected from mountains, woods, buildings, or clouds, or from the latter alone when a thunder-storm takes place over the ocean: this opinion seems to have been founded upon the fact that the report of a fire-arm discharged in a mountainous tract is prolonged by the echoes during at least half a minute, which is about the time that the rolling of thunder continues. But though the reflections of sound are, very probably, in part, or at times, the causes of the prolongation of the report arising from the explosion, yet it must be admitted that these will not always afford a satisfactory explanation of the phenomena. It may happen, for example, that, when the sky is uniformly covered with clouds, a flash of lightning will dart from the zenith, and, after a few seconds, the crash of thunder will take place accompanied by a rolling sound: soon, a second flash may pierce the clouds in the zenith and thunder may follow, but now the crash, though loud, may not be prolonged. It is justly observed by M. Arago that this is very different from the phenomena of echoes; and the explanation which was first proposed by Dr. Hooke ('Posthumous Works,' 1705) is perhaps that which possesses the highest degree of probability. The flashes of lightning, Dr. Hooke observes, are either simple or multiple: the first occupies but one small portion of space, and gives rise to an instantaneous report; the multiple flash takes place at different parts of one long line: if these parts should be situated in a circular arc, and the observer should be in its centre, all the reports would arrive at his ear at the same time, and still one loud crash only would be heard; but if the parts were nearly in a straight line, and the observer were at one of its extremities, the reports, whether they take place at the same instant or in succession, would arrive at his ear at different times, depending wholly or partly on the distances. It may be considered therefore that the rolling arises from the circumstance that the points of explosion are at different distances from the observer; and it will follow that the duration of the noise is equal to the time in which sound travels through an interval equal to the difference between the lengths of two lines drawn from the observer to the two extremities of the flash. The flash of lightning and the report of the thunder take place in reality at the same moment; but since sound travels at the rate of 1100 feet per second, while the passage of light from the cloud to the observer may be considered as instantaneous, it follows that, on counting the number of seconds which elapse between the time of seeing the flash and hearing the report, the distance of the thunder-cloud from the observer may be ascertained if 1100 feet be multiplied by that number of seconds.

An opinion prevails that thunder has been heard when the sky was without a cloud, but the fact can scarcely be said to be satisfactorily established; for the sounds which, in countries subject to earthquakes, have been supposed to be thunder, proceed from under the ground, and may result from a different cause. Volney however relates that, being one day at Pontchartrain near Versailles, when no cloud was visible, he heard distinctly four or five claps of thunder; he adds, that about an hour afterwards the sky became overcast, and a violent hailstorm followed. On this relation M. Arago observes, that the sounds could not have been heard if they had come from clouds at a greater distance than six leagues; and if the clouds had been at, or a little within, that distance, they must have been visible, unless it be supposed that they were not more than a few yards above the ground; but the hail which followed the thunder must have proceeded from clouds having great elevation, though at the time the claps were heard they were too remote to allow any sound from them to reach the ear; and therefore he concludes that the sounds must have been produced in the air itself.

From the meteorological observations made by Dr. Scoresby, and Captains Phipps, Parry, and Ross, it appears that neither thunder nor lightning is known to take place beyond the 75th degree of north latitude; even so low as the 70th degree those phenomena are very rare: and in the tables of Captain Parry the occurrence of thunder and lightning is mentioned but once between June, 1821, and September, 1823. Captain Franklin also, in 67½° N. lat., heard thunder on one day only between September, 1825, and August, 1826.

THURSDAY. [WEEK.]

THYMENE ($C_{20}H_{16}$). A hydrocarbon isomeric with oil of turpentine, forming one of the constituents of the essential oil of thyme.

THYMINE. An organic base found in the *thymus gland* of the calf (sweetbread). It crystallises in needles, and also forms crystalline salts. Its composition has not been determined.

THYMÖIL. [THYMOLE.]

THYMOLE ($C_{20}H_{13}O, HO$). *Hydrate of thymyl.* The oxidised portion of the essential oil of thyme, forming about one-half of that essence. It crystallises in oblique rhomboidal prisms, which are nearly insoluble in water, but very soluble in alcohol and in ether. Under the influence of oxidising agents it yields a crystalline substance termed *thymöil* ($C_{24}H_{16}O_4$), which is homologous with quinone.

THYMYL-SULPHURIC ACID ($C_{20}H_{12}O, HO, S_2O_6$). An unimportant acid, obtained by the action of concentrated sulphuric acid upon *thymol.*

THYMYL-SULPHUROUS ACID. Synonymous with *Sulphocymolic acid* [CYMOLE].

TIA'RA (τιάρα or τιάρας), a high kind of hat, which was in ancient times worn by the inhabitants of Middle and Western Asia, especially by the Assyrians, Persians, Parthians, Armenians, and Phrygians. There were two kinds of tiaras: the upright tiara was only used by kings, priests, and other persons of the highest rank, and the upper part had frequently the shape of a crown; the tiara worn by other people was of a soft and flexible material, so that it hung down on one side, as in the case of the so-called Phrygian bonnet. (Hesychius and Suidas, *s. v.* τιάρα.) The tiaras of persons of high rank were of the most costly colours, such as purple, and adorned with gold and precious stones.

In modern times the term tiara is applied to the head-dress of the popes, which is worn on solemn occasions, and consists of a triple crown. The peculiar form of the papal tiara has led some archæologists to trace its origin back to pagan antiquity. Triple crowns bearing a marked resemblance to the papal tiara are worn by the Assyrian kings as represented on the slabs found at Nineveh by Botta and Layard.

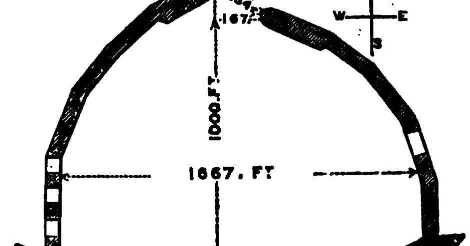
TIDAL HARBOURS. The enclosures for the protection of vessels which are situated upon the sea shore, or the portions of rivers affected by the rise of the tides, are usually known by the distinguishing name of *tidal harbours*, on account of the peculiar arrangements adopted in them in consequence of the variations of level in the waters, and of the currents which may prevail in the offing. Tidal harbours may be *floating* or *dry*, according to the rise of the tide, or the depth of water, when no artificial basins are formed; or they may be classified as *natural* or *artificial* harbours, according to the configuration of the coast, and the mode of construction adopted in them.

A natural *floating* harbour is one wherein there is at all times of the tide a sufficient depth of water to maintain a vessel afloat; a natural *dry* harbour is one which is left without water at low tides, and in which the vessels are obliged "to beach," or "to take the ground," that is to say, are left temporarily high and dry. Artificial harbours present occasionally one, or both, of these conditions; but as they are usually formed in positions where the navigation is sufficiently active to require great facilities for the commerce carried on in them, it is rare that artificial tidal harbours are constructed without the formation of floating basins in which large vessels may be kept constantly afloat. Dry tidal harbours are only of use for coasting traffic, or for vessels of small burden. The outer harbours of ports of greater importance are often in fact nothing but tidal harbours, dry at low tides; but in such cases they are accompanied by half-tide basins, and inner harbours or docks, in which the level of the water is constantly maintained at that of the high tide by means of lock gates, or pontoons. Graving docks, gridirons, scouring sluices, warehouses, and other appliances are added in such cases according to the local physical conditions of the situation, to the nature of the trade, or to the fiscal organisation of the country in which the harbours may be situated. These details have already been discussed under DOCKS; and they evidently must be the same in all import harbours, whether tidal, or otherwise; or whether the outer harbour be wet or dry.

Upon an open coast, like that of the southern counties of England, excepting between the Race of Portland and Selsea Point, the harbours must all be tidal, and dry at low water, unless they should be placed at the mouths of rivers, or at the head of deep inlets from the sea. Milford Haven and Plymouth are instances of this favourable natural configuration, and there is little necessity for the formation of closed docks in either of them. Southampton and Portsmouth present very great advantages also, and they are almost entirely devoid of the inconveniences usually attached to tidal harbours, for vessels can lie in the inclosed entrances to the floating basins of either of those ports without "touching," unless when their burden is very great indeed. In the case of ordinary tidal harbours, it therefore follows that, unless there should exist near them a good sheltered roadstead, vessels cannot safely "make" them, unless at high water; nor can they ever become really "harbours of refuge," which should be accessible at all times of the tide. Hâvre and Liverpool are instances of tidal harbours presenting tolerably favourable conditions of access in consequence of the existence of roadsteads. Cherbourg is an instance of a tidal harbour rendered safe by the creation of an artificial roadstead; for though the military port of Cherbourg has a sufficient depth of water to allow the largest vessels to enter at any time of the tide, yet the commercial port is left high and dry twice a day. Ramsgate, Dieppe, and the little harbour of refuge (so called) at Port en Bessin are instances of the true tidal harbours, with all their characteristics and all their inconveniences. They can only be entered at high tide; their jetties are so much exposed, that if a vessel should happen to miss the entrance she would almost infallibly be wrecked; and they are all liable to be silted up by the alluvial matters carried forward by the flood-tides on their shores. [TIDAL WATERS AND CURRENTS.]

Under PIERS, the modes of constructing and the principles of designing the walls which inclose the spaces intended to form harbours have been already discussed; and it may, under these circumstances, suffice to say that the area to be inclosed in a tidal harbour designed to receive ordinary coasting vessels should not be less than six acres of water surface; and that the area should increase from this minimum dimension in proportion to the depth of water and to the activity of the commercial relations of the locality. In the case of tidal harbours of refuge, the area must be proportioned to the number of vessels likely to resort to them. Thus the tidal harbour of Southampton Docks, in which there is 18 feet of water at low tides, has an area of 16 acres; the area of the tidal basin of the new port of St. Nazaire, at the mouth of the Loire, is about 22¼ acres; that of the tidal harbour of Port en Bessin, is about 27 acres; that of the outer harbour of Ramsgate is about 30¼ acres. Even in dry tidal harbours it is desirable that the extremities of the jetties should be carried out into 6 feet water at low neap tides; for the minimum depth of water at the entrance should never be less than 18 or 20 feet.

It may, perhaps, be advisable to state that tidal harbours whose entrances are exposed to be swept by a strong flood current should, generally speaking, have the jetty against which the flood strikes carried beyond the jetty on the opposite side; whereas in deep-water harbours the relative lengths of the jetties are regulated by their positions with respect to the direction of the prevailing wind. In fact the extension of the jetty on the outside of the flood may give rise to a local counter-current which would facilitate the entry into the harbour; and in some respects it may even cause the tide to "stale," as seamen say, or to remain for a short time at a constant height in the inclosed space, in consequence of the resistance offered by the great ebb-tide in the offing to the efflux of the small quantity of water in the port. The various currents which prevail in the British Channel, at the mouth of the Seine, and of the Southampton Water, may be referred to as illustrations of these peculiar conditions; and at Hâvre they occur in such a manner as to render the tidal outer harbour of nearly as great value as an ordinary floating harbour during two hours of each high tide, whilst at the same time they create a strong current setting into the tidal harbour during the flood, or precisely at the period when vessels are entering. Sometimes, however, these local currents give rise to bars or sand-banks, either across the mouth of the harbours or on the down side (to the flood) of the main channel, in consequence of the interferences they produce with the advance of the alluvions carried forward by the flood. Thus, at Dieppe, Boulogne,



Newhaven, Harwich, Harlingen, &c., bars exist at the mouths of the tidal harbours, and they are usually of a very dangerous character, although occasionally, as at the last-named harbour in the Zuyder Zee, the bars may form natural breakwaters, inclosing shallow and imperfect roadsteads. There are, in fact, very few positions in which tidal harbours are free from inconvenience, arising either from bars or from the advance of alluvial matters. The tidal harbour of refuge of Port en Bessin, in the department of the Calvados, presents in this respect some peculiarities to which it may be desirable to call attention, on account of the geological interest, quite as much as on account of the lessons in engineering, which they furnish. Port en Bessin is erected on a coast entirely open to the north, north-east, and north-west; the most dangerous storms blow from the north-east; and the flood-tide comes in from west by north. The jetty on the west side has been built with openings, for the avowed object of allowing the flood to sweep through the head of the harbour; and an opening is left in the eastern jetty to allow a fresh-water river, which rises from between the clay beds of the lower oolitic formations on the shore, to escape. This river would appear to be the continuation of the little river Drome, which loses itself about two miles in the interior, there passing between the formation known locally as the "argile du Port en Bessin" and the lower oolite itself, until it thus escapes on the sea-shore.

In consequence of the frequent occurrence of bars and banks at the mouths of tidal harbours, it is more than usually necessary that tidal signals, lighthouses, and fog-bells should be established upon them, and that the navigable channel should be carefully buoyed. These precautionary details must not, of course, be neglected in floating tidal harbours, if the latter should present any local peculiarities; but they are usually less necessary than in dry harbours; nor does there exist in the former the same necessity for the existence of a soft bottom, of mud or of sand, that exists in harbours wherein vessels are likely to take the ground. In floating or in ordinary tidal harbours which have docks for the reception of large vessels, the entrances to the docks must be placed at a position in the outer basin removed from the agitation of the open sea; and it would appear from the practical working of the docks at Hâvre, Liverpool, &c., that it is preferable to make the entrance to the floating dock from an exterior half-tide dock, rather than from the outer harbour itself. There is, in fact, a danger of the gates communicating with the outer harbour being occasionally forced open by the agitation of the latter; and at all times the half-tide basins facilitate greatly the manœuvres of a port. In some tidal harbours, as at Hâvre, Dieppe, Ostend, &c., pains are taken to break the waves which may be driven in from the open sea, by the erection of timber stockades and inclined floors of masonry; but in the majority of cases it is found that the waves become sufficiently stilled by the fact of their passing through a narrow passage at the entrance, and then widening out into a large sheltered area.

(Sir J. Rennie, *on Harbours;* Sganzin, *Cours de Construction;* Minard, *Travaux Hydrauliques à la Mer;* the Parliamentary *Reports on the Highland Roads,* &c.; Smeaton's *Reports; Life of Telford;* &c., &c. The Report of the Commission on *Tidal Harbours,* 1845, may also be consulted.)

TIDAL WATERS AND CURRENTS. The partial streams of water set in motion by the great tidal waves, which frequently flow in directions different from, or even directly opposed to, the advance of the great tide waves themselves, are known technically by the name of *tidal currents;* and they are of the greatest importance in all nautical, or hydraulic, engineering operations, on account of the interference they are able to produce in the conditions of access to harbours on the sea-coast, or to the embouchures of rivers. These currents are produced either by the projection of head-lands, or by the retarding influence of the sea-shore upon the advance of a portion of the tide wave, and they are therefore subject to so many modifying conditions, as to render it more easy to explain their nature by reference to some of the most remarkable currents known to exist. A few illustrations of them will therefore be given; but before so doing, it may be desirable to observe that the great oceanic currents, such as the Gulf stream, the current through the straits of Gibraltar and at the head of the Mediterranean, &c., have no connection with the class of phenomena in question; for their creation and propagation depend upon cosmical causes of a very different and of a much more complicated nature than those which produce the real tidal currents of the sea shores.

Now, the great flood tide, following the impulsion it receives from the attraction of the sun and the moon, and from the rotation of the earth, advances normally from the west towards the east; and in mid-ocean the only tidal current is precisely in this uniform direction. On approaching the shores of a large island, or of a continent, however, the tide striking the advanced headlands is diverted from its course in some cases, whilst in others, the great advancing stream may be carried in its former direction past the portion of the coast immediately behind the headland, and thus only allow the flood tide to exhibit itself by derivation from the main stream. On the shores of the Atlantic, for instance, the flood wave striking the extremities of Ireland, England, and the department of the Finisterre in France, changes its course in a remarkable manner. A portion of the flood continues to advance in its original direction through the British Channel; a second portion runs northwards along the western coast of Ireland and of Scotland, giving off in its advance a branch, or subsidiary, current running up through the St. George's Channel, and flowing in a rather north-easterly direction until it meets a smaller derived current, flowing through the Mull of Cantire, from the N.W. to the S.E.; a third portion striking Cape Finisterre turns towards the south, and runs along the coast of the Bay of Biscay. The flood tide running up the British Channel passes through the straits of Dover, and spreads itself over the North Sea, meeting a portion of the flood which had passed round the extremity of Scotland, and down the eastern coast of England, near the embouchure of the Thames; so that the united tides flow up the river, sometimes synchronously, sometimes at slight intervals. In the former case, the tide in the Thames is a simple one; in the latter it may present the peculiarity of a double rise in the level of the water; and the same phenomenon of the existence of more than one period of flood may be perceived in other rivers of the east, and even of the south, coasts of England, as well as on the northern coast of France, in consequence of the creation of subsidiary tidal currents by advancing headlands.

Thus, the Bill of Portland projects so much into the line of advance of the flood tide that the latter sweeps along in the offing at an elevation above the water in-shore, until it reaches the Needles point; in its course parting with some of its own body, by derivation, into the sheltered bay. At the Needles the flood divides, one portion flowing from the W. by S. into the Southampton Water, the other continuing up the Channel, but as it passes the Spithead Passage it gives off a branch current, which flows through that channel from S.E. to N.W. until it meets the ebbing tide from the Southampton Water already running out. The Spithead flood current drives back the Southampton ebb, and thus makes the peculiar double tide of that river; and it also superposes itself in a manner upon the ebb of the coast lying west of Calshot Point so as to create a double tide, known locally by the name of the *Gulder,* which only ceases to be felt at the Bill of Portland. Very much the same kind of action may be observed on the French coast between the rocks of the Calvados and the Cape Antifer; for the first flood tidal current in the bays at the mouths of the Orne and of the Seine, derived from the edges of the great flood tide in the offing, is maintained for a variable period, by the return of a subsidiary tidal current deflected by the projection of the cape. At Southampton, the double tide keeps the water at nearly a constant height for the space of two hours; at Havre it remains in this state for about one hour and a quarter; whilst at the mouth of the Orne, the flood tide is held up for about one hour. The advantage thus produced to the navigation of those localities by these peculiar tidal currents is enormous.

The tidal current at Havre is, moreover, accompanied by a further peculiarity. As was before said, the main flood tide in the Channel runs in the offing with a direction from W. to E. until it strikes Cape Antifer; there it divides, one portion or tidal current continuing to flow up the Channel, the other running into the bay of the Seine from E. to W., until it strikes the jetty at the entrance to the port, which deflects it a little, and causes the bulk of the current to run on until it meets the Cape du Hoc. A portion of the flood is there deflected, and turns back towards the mouth of the harbour, with a general S.E. by S. direction. A ship making this port at the flood tide, has thus to encounter no less than three tidal currents, flowing in different directions; and as all the shores swept by these currents are composed of rocks consisting of materials easily transportable by the water, there is a constant formation of shifting banks at the mouths of the Seine taking place at a short distance from the shore.

The effect of tidal currents upon the outline of a coast is one of the most important forms of their action. For instance, it will be found that all the bays exposed to the action of strongly defined floods open towards their line of advance; and it also generally is the case that the most violent storms blow in the same direction, that is to say, in the direction of the flood tide. In fact, the water is driven with the most violence upon the shores by the flood tides; and they are the great agents in removing and transporting the materials detached from the shores. In all works for coast defences it is important, therefore, to calculate all the existing, and the probable future, effects of the tidal currents, observing always that they may depend in many cases on modifications of the outline of the coast lying far away from the locality considered. The advance of the flood tide on the eastern shore of England from the north to south is, for instance, an effect of the same circumstances which cause the flood tide on the west coast of Ireland, and of Scotland, to flow from south to north; and in the British Channel from west to east. The direction of the bars at the mouths of rivers pouring into seas exposed to be crossed by tidal currents, it may be added, follow as a general rule the direction of a resultant between the lines of flow of the ebb from the river, and of the advancing flood.

The greatest amount of theoretical information on the subject of the laws of hydrodynamics affecting tidal currents, is to be found in Venturoli, 'Sur la communication latérale du mouvement dans l'eau;' in Brémontier and Emmy, 'Sur les Ondes;' in Sganzin and Minard, 'Cours de Construction;' in the 'Nautical Magazine;' in Lubbock, Whewell, Airy, &c., 'On Tides,' in the 'Philosophical Transactions;' in Rennel's 'Investigation of Currents;' Young 'On Tides,' in 'Encyclopædia Britannica,' &c., &c.

TIDE MILL. A mill driven by the water which is affected by the rise and fall of the tides is called a *tide mill,* whether the wheel be affixed to a building on the land, or to a vessel floating in the river. In the former case the water sometimes acts upon an undershot wheel in escaping from a reservoir, which has been filled during the flood tide; but the working of the mill in this case can only take place when there is a sufficient difference of level above, and below, the wheel, to produce the necessary head, and the sluices must be arranged in such a manner as to regulate the dynamical effort exercised upon the wheel during the period of working, which is usually about four hours in each ebb. At other times, the motion is given by a species of horizontal reaction wheel, made to revolve horizontally by the advancing or receding tide; in this case also the action of the wheel cannot take place continuously, for at the turn of the tide in either direction there is a period during which it neither advances nor recedes; but directly the current assumes a marked velocity, either of ebb or flow, the wheel will be set in motion, in alternate directions. As the velocity of the tidal current is always greatest about the half tides, it is necessary to provide some regulating machinery for the working parts of the mill, if they should happen to be of a nature to require uniformity of motion; this remark of course applies to both the undershot, and to the horizontal wheel.

The tidal wheels attached to boats on rivers are, in fact, vertical float wheels working in unlimited water; that is to say, the stream alone acts upon the wheel by its horizontal velocity, without being in any way confined or directed by a race or channel. These wheels rarely exceed from 12 to 17 feet in diameter, and the floats vary from 12 to 24 in number; the depth of the floats never exceeds 0·25 of the radius, but is usually only about 0·20 of that dimension, and the whole of the floats are immerged; the width of the face of these wheels varies between 8 and 18 feet. In tidal rivers, where the current alternates in its direction, the floats are placed upon the radii of the wheel; though the wheels working in unlimited water, flowing in one direction, are found to produce a greater useful effect when they are made with floats inclined to the line of flow. Boat mills of this description, it may be added, should never be tolerated on rivers capable of receiving an active navigation; and under all circumstances their action is irregular, and of very little practical value. Their working effect may be represented by the formula $\text{P}w = 20\ \text{S}\text{V}^2$: in which $\text{P}w$ = the effective power transmitted by the working shaft; S = the sectional area of the float; V = the velocity of the current. The working effect of the other descriptions of tidal wheels is to be calculated upon the ordinary principles applied to that class of machinery, when the head of water and the velocity of the current are known. [WATER WHEEL.]

TIDES. [ACCELERATION AND RETARDATION OF TIDES; WAVE.]

TILES AND PAVEMENTS. A tile is a kind of thin brick, or plate of baked clay, used chiefly for covering roofs, but occasionally for paving floors, constructing drains, &c. The English name, and those by which tiles are known in other European languages, are derived from the Latin *tegula*, which contains the same element as *tego*, to cover.

Among the Greeks and Romans roofing-tiles were originally made, like bricks, of baked clay; but later, tiles of marble were made of much larger dimensions than was practicable in clay, and consequently the effect produced by their parallel joints might be brought into harmony with the rest of the building. A still more expensive and magnificent method of roofing occasionally adopted consisted in the use of tiles made of bronze and gilt. Tiles were originally made flat, or with nothing more than the hook or nozzle underneath the upper border, which fulfilled the purpose of fixing them upon the rafters. They were subsequently formed with a raised border along each side, on the upper surface, and the sides of the tile were made to converge towards the lower end, in order that the raised sides or ledges might not prevent the successive rows of tiles from overlapping each other neatly. The lines of junction between the flat tiles were covered by small semi-cylindrical tiles, called *imbrices*, the rows of which, extending from the ridge to the gutter, divided the surface of the roof into a series of channels, along which water descended to the gutter. Both the *tegulæ* and the *imbrices* terminated at the edge of the roof in ornamental pieces. Another kind of ancient tiling, mentioned by Pliny under the name of *pavonaceum*, consisted of tiles of a semicircular form at their lower edges, which, when laid in overlapping rows, somewhat resembled the feathers in the train of a peacock.

The process of making tiles is so similar to that of brick-making [BRICK], that it will be sufficient to observe that only the best qualities of brick-earth are fit for the purpose. Since the year 1833 no excise-duty has been levied upon the manufacture of tiles. The roofing-tiles used in this country are chiefly of two sorts: namely, *plane-tiles*, which are flat, of a rectangular form, and usually about 10½ inches long, 6 inches wide, and 5-8ths of an inch thick; and *pan-tiles*, which also have a rectangular outline, but are bent in such a manner that, when laid on the roof, the greater part of their surface forms a concave channel for the descent of water, while one side forms a narrow convex ridge which overlaps the edge of the adjoining tile. These are usually 13½ or 14½ inches long, and about 9 inches wide, measured in a straight line from side to side. *Plane-tiles* are made with a hole near their upper extremity to receive a wooden peg, by which they are hung upon the laths of the roof. They are laid either with or without mortar, in such a manner that the successive rows overlap each other about 6 inches. *Pan-tiles* have no holes, but are hung upon the laths by ledges formed at their upper edges; they do not require so great an over-lap as plane-tiles. Tiles of a semi-cylindrical form, laid in mortar, are for covering ridges if the convex side be uppermost, and for covering gutters if the concave.

Paving-tiles are usually square, and of greater thickness than those for roofing. *Drain-tiles* are commonly made in the form of an arch, and are laid or bedded upon flat tiles, called *soles*. The substitution of *drain-pipes* for *drain-tiles* is noticed under DRAINAGE. Machinery is now extensively employed in the manufacture of tiles, similar in principle to the brick-making machinery noticed under BRICK.

What are called *Encaustic Tiles*, are productions midway in constitution between pottery and brick, and midway in artistic character between mosaic and plane-tiles [MOSAIC; TESSERA]. Decorative paving-tiles of baked pottery were much used in the middle ages; but their manufacture in England was almost forgotten until the late Mr. Minton revived it. The Temple Church, in London, was one of the first buildings in which the revival was exhibited; and since that period (about twenty years ago) the use of such tiles, principally for pavements, has extended largely. *Pressure* is brought to bear in their making, thereby rendering them much harder and less porous than ordinary tiles. One mode of making them is as follows: Supposing each square tile to exhibit a yellow device on a brown ground, the brown portion is formed of a suitable kind of stiff clay, pressed in a mould to a thickness of about one inch. The mould not only gives the form, but also produces depressions about a quarter of an inch deep, marking out the device. Heavy pressure is employed to harden the clay, and to give sharpness to the device. The yellow clay to fill up the depressions is mixed to the consistence of honey, and is applied chiefly by means of a kind of trowel. The clays are selected with much care, in order that they may shrink equally in drying; and they are allowed a long time to dry in the open air, before being baked. The surface is well scraped and cleaned before firing. The tiles are either left dead, or are glazed in the same manner as pottery and earthenware. If more than two colours are exhibited, the process is necessarily more complicated. To form a pavement, the tiles are usually imbedded in cement, and are roughened or in some way hollowed on the under surface to increase the hold.

Many other modes have been partially adopted for the production of ornamental paving-tiles. Mr. C. Wyatt at one time made pavements of stone inlaid in coloured cements. Other inventors substituted pieces of terra-cotta for the stone. Mr. Blashfield has tried cements coloured with metallic oxides, and bitumen coloured in like manner. Messrs. Singer and Pether have made pavements, by rolling out prepared clay into sheets, cutting it into small cubes, combining these cubes according to their colours, forming them into a slab having a defined pattern, and laying down the slab as a pavement; the cubes on this plan are usually about an inch square on each side, and are made into slabs about half a yard square. Cubes or tesseræ have since been made of exceeding hardness, by a process due to Mr. Prosser; he pulverises fire-clay and felspar, or flint, and subjects them while dry to intense pressure between two steel dies; the colour is introduced either by mixture with the powder, or by being thrown into the oven while baking. These cubes or tesseræ produce a pavement of exceeding hardness and durability.

TILLAGE, applied to arable land, is the stirring and preparing of the surface of the soil, so as to render it fit for the vegetation of the seeds committed to it: its object also is the destruction of noxious weeds.

The whole art of cultivation consists in tillage and manuring, and the profit of the husbandman depends on the perfection of the tillage and the economy of labour in producing the effect. A defect in tillage will cause a great deficiency in the crops in ordinary years. To ensure good crops, the soil should be in such a state that the rains and dews may readily be diffused through it, without giving it a wet appearance, or evaporating too rapidly. It requires great knowledge and experience to give any particular soil the exact portion of tillage which is suited to it. A fine garden-tilth, as it is called, is the most perfect for light soils which have been long cultivated and manured; when they can be brought to such a state that after continued rains the surface dries without forming a crust, and crumbles of its own accord, the tillage has been good; and the deeper this soil is stirred, the more it will produce: but where clay abounds in the soil, which in dry weather can be readily pulverised by crushing the dry clods, and be reduced to the finest powder, too much tillage may do more harm than good. The fine clay is soon converted into mud at the surface by the least rain, because it is not sufficiently porous to let the water through it; it dries into a hard crust, which effectually precludes the access of air, and consequently stops the vegetation of the seed. It is only by abundant manuring with organic matter, especially of animal origin, that this natural tendency in clays to cohere can be overcome; and until this is effected it is best to stir clay soils as deep as possible by means of subsoil-ploughs, but they should not be pulverised so that the water cannot run down between the lumps and clods, and especially the surface should be left in such a state of roughness that heavy rains cannot cover it with a coat of mud. The clods which are left on the surface imbibe the moisture more gradually, and in drying fall to pieces, by which the young plants are invigorated, and, as it were, moulded up. This is particularly the case in winter after a frost, as all clay-land farmers are well aware. It is very easily ascertained whether a soil will bear much tillage or not. It is only necessary to try some of it in a large pot or box; make the surface very fine by breaking the clods, then water it abundantly, and let it dry in the sun; if a crust is formed in drying, that soil will not bear too much harrowing and pulverising, and should be left in a moderately rough state after sowing or drilling the seed; but if, after it dries, the surface is loose and porous, then the finer the tillage the better the seed will vegetate. The whole depends on the ready admission of air or its exclusion. When grass-seeds are sown, the surface should be well pulverised; but this cannot be safely done if the soil is apt to run together when much rain falls soon after the seed is sown. Some plants, like beans, will force their way through a very hard surface; but small seeds are too weak to do so, and their growth is entirely stopped by the least crust on the surface. Besides the preparatory tillage of the soil before sowing the seed, there is a great advantage in the stirring of it as the plants are growing. On this depends all the merit of the row-culture for every kind of plant, especially those which have esculent roots or extensive foliage, and which are chiefly cultivated for the sustenance of cattle. The effect of deep tillage is here most remarkable. If rows of turnips or cabbages be sown at such a distance that a small plough or other stirring implement can be used between them, and the intervals be stirred more or less, and at different depths, it will be found that the deeper and more frequent the tillage, until the foliage covers the whole interval or the bulbs swell to a great size, the heavier and more abundant the produce will be. It was this which led Tull, the father of drill husbandry, to the conclusion that tillage was all that the soil required to maintain perpetual fertility. As tillage can be increased by mechanical contrivances where labourers are scarce, whereas the supply of manure must generally be limited, it follows that, as a general rule, the land should be well and deeply tilled, due attention being paid to the nature of the soil and its property of retaining or transmitting moisture. Very loose sands should not be much stirred until they are consolidated by the admixture of marl, clay, chalk, or well-rotten dung; but in all cases the manure should be mixed as intimately as possible with the soil, and as deep as the tillage has gone, not including the stirring of the subsoil; for the roots will always penetrate thus far and find the nourishment which they require. Those plants which throw out roots from the bottom of the stem, as wheat, barley, and oats, require the surface to be most pulverised and enriched to allow these roots to spread, and Mr. Smith of Lois Weedon has found that where land is clayey and contains the mineral food of plants, sufficient tillage between rows of wheat is all that is needed for constant cropping, or taking wheat after wheat annually from the same field. Under ordinary culture, however, of this crop a spring tillage is highly advantageous, which can only be given when the seed has been deposited in rows by drilling or in patches by dibbling. This last method is found to give much finer crops, from the circumstance that the hoe not only loosens the earth between the rows, but also between the different patches of the growing corn, by which the coronal roots are strengthened and the tillering of the stems so much encouraged, that it is not uncommon to see twenty, thirty, or more strong stems all bearing fine ears arising from one tuft of plants, the produce of one or more seeds, whose roots are matted together and send out fibres in every direction. The crowding of several plants does not prevent their growth, provided the fibres can spread around in a rich mellow soil, well pulverised, and admitting the air and moisture readily.

The old plough which acts on the principle of turning up a fresh portion of the soil, burying that which has for some time been at the surface, will probably always continue to be the chief implement of tillage; but other implements have been invented, which by means of wheels can be regulated so as to act at a greater or less depth. These have received the different names of scarifiers, grubbers, or cultivators, according to the fancy of the inventors. Many of these answer the purpose well, and save labour. They can be used in all directions so as to pulverise the soil to any degree. Heavy rollers are used when clods require breaking.

It would be endless to enumerate all the implements of tillage which are daily invented: some of the most useful have been already described. [Agricultural Implements; Arable Land; Plough.] It is however right that reference should be made to the use of steam-power in their employment.

Tillage by Steam-power.—Steam-power has long been used in driving threshing-machines and chaff-cutters, and other barn machinery. It is now coming rapidly into field use for cultivating the land. The moveable steam-engine on wheels is the source of power most generally adopted, being available for any purpose; and the higher powers of this engine, being best adapted for the laborious work of cultivation, are being made in increasing numbers. Probably in this way alone 10,000 horse-power, equal in its efficiency to at least 25,000 horses is being added annually to the force employed in agriculture in this country.

Steam-power is in the beginning cheaper than that of horses; it is continuous, while that of horses is necessarily intermittent; and it is more efficient, because a greater force can be more easily concentrated on a given point.

A horse, as used in agriculture, costs 5*d.* or 6*d.* per hour; a steam-engine, under agricultural circumstances, costs from 3*d.* to 4*d.* per horse-power per hour. A horse works in Scotland ten hours a day, in England eight or nine hours a day, in the field—it is forced to break off work for the maintenance of its strength: an engine works as many hours, with unremitting vigour, as the engineer may choose. It does, in some instances, work 24 hours per diem, and on some farms it is made to work as long as daylight lasts. Again, horses lose time in all field operations, owing to the dilatory process of turning on the headland: where steam-driven machinery is employed instead, this loss of time is greatly diminished. But the chief advantage of steam-power for cultivation arises from the ability by means of it to concentrate any quantity of force that may be desired. At Buscot Park, near Faringdon, ploughing was this spring (1861) done by steam-power in the stiff Oxford clay of that district, which could not have been done by any quantity of horses, because the power required demanded a team which would have trampled the ground into a harder state than that out of which any implement drawn after them could have got it; and there is ample experience to show that on this ground alone steam-cultivation is more efficient—resulting in better crops than those afforded by horse-cultivation. This is especially true in the case of clay lands, whose value will no doubt be materially increased by the efficient means now at length provided for working them.

There are two systems in general adoption of applying steam-power to the cultivation of the soil. In the one, which has been carried out by Mr. Smith, of Worlstone, the steam-engine stationed in one corner of a field gives motion alternately to one and the other of two windlasses detached from it, round which is coiled a portion of the wire-rope which is carried from one to the other round the piece of land that is being cultivated, and a grubber being fastened to this rope is thus dragged backwards and forwards on the largest straight side of the piece that is being worked: the anchors carrying pulleys at the ends of the working furrow and at all other corners in the course of the rope, are shifted as the extension of the work requires, and the grubber tears up or "smashes up" two or three feet in width at a time, of the land that is being cultivated. The common 7 or 8-horse power moveable steam-engine is well adapted to this work.

In Mr. Fowler's system the steam-engine is furnished with a single pulley lying horizontally beneath the boiler, and it pulls itself along the headland, while a travelling anchorage, namely, a truck on sharp discs for wheels, which cut into the land, pulls itself along the other headland. This anchor is provided with a similar pulley, and a rope travels round both pulleys, being kept tight by an arrangement on the framework of the ploughs, which is drawn by it alternately to and fro between the two. The pulleys hold this rope by a clip-groove, which hinders it from slipping, so that a single half-round holds it tight enough. The tilling implement thus drawn to and fro, consists of two sets of ploughs or grubbers facing one another; the one working when going from the engine, and the other working when travelling to the engine. The change from one to the other need not waste more than half a minute on the headland; and the furrow may be 400 yards long, or even longer. It will be easily seen what a small loss of time in the day is thus incurred, when compared with the usual experience of horse-culture. Mr. Fowler employs generally a 12-horse engine, and, with a four-furrow plough, gets over eight or ten acres a day, at a cost generally of not more than 5*s.* or 6*s.* an acre; whereas by the less efficient horse-cultivation, the process must cost at least 10*s.* or 12*s.* an acre.

There can be little doubt that the application of steam-power to the cultivation of the land will revolutionise agriculture on all clay soils. It will enable the farmer to dispense with probably nearly half his draught animals, and it will both cheapen the cost and increase the efficiency of all tillage operations.

TILT-HAMMER, is a large hammer worked by machinery, impelled either by a water-wheel or a steam-engine. Such hammers are extensively used in the manufacture of iron and steel, and the name *tilt-mill* is sometimes applied to the mechanism of which they form the principal feature. The various details given under Hammer; Iron; and Steel, will serve to illustrate the chief points in the construction and action of tilt-hammers.

TIMBER, PRESERVATION OF. [Timber.]

TIMBER AND TIMBER-TRADE. It is the purpose of this article to treat briefly of several matters relating to timber-trees, wood-working, and the timber-trade, and to refer to such portions of the subject as have been noticed in other articles.

Timber-Trees; Wood.—The botanical characteristics of timber-trees are given under the scientific names of the several trees in the Nat. Hist. Div. The economical uses of many of them are described in the present Division, under Ash, Beech, Birch, Elm, Fir, Oak, &c. But the characteristics of timber-trees, and of wood generally, may be rapidly glanced at in this place.

Wood is that part of a plant that exists between the pith and the bark. Amongst the various kinds of wood yielded by the different families, there are great differences of character depending on the mode and rapidity of its growth, the size of the fibres of which it is composed, and their relation to the medullary rays which pass through them, and also on the character of the secretions deposited in it. Endogens have no bark, and are generally hollow in the middle, and their wood does not permit of being worked into many shapes; but its cylindrical form affords great facility for constructing a variety of utensils, and for application to the simple wants of man in tropical climates. The stems of Exogens are solid, and the older the tree becomes the more solid is the wood. Hence a distinction is made between the centre of the wood of the trunk and its circumference, the one being called heart-wood, the other sap-wood. The heart-wood is the seat of the deposition of the peculiar secretion of the tree, and is frequently separated from the sap-wood by a distinct line. It is the secretion in the heart-wood that renders it darker, harder, and more durable than the sap-wood; and for practical purposes it is of importance to distinguish between the one and the other. There is much difference between the relative sizes of the ultimate woody fibres of which wood is composed; and the durability and tenacity of wood frequently depend on the fineness of its fibres. It is to the secretions deposited in the wood, probably more than to the fibres themselves, that wood is indebted for its varying degrees of density. Thus, although it has been ascertained that woody fibre itself has a specific gravity of about 1·50, water being 1, yet there are many woods whose specific gravity is lighter than water on account of the mode in which their fibres are arranged. The conducting power of wood in relation to heat is a matter of importance in the construction of buildings and other purposes. In some experiments performed by Delarive and De Candolle on prisms of different kinds of wood, to ascertain their power of conducting heat, they found that the direction of the fibres materially interfered with their conducting power. Thus it appeared that the obstruction to the passage of caloric was greater when the current was at right angles to the woody fibre than when it flowed longitudinally in the direction of the fibres. This difference also appeared to increase in proportion as the wood was a bad conductor of heat. The cooling power of these woods is another important point, and this is not at all in relation to their conducting power: thus fir-wood being 100, the cooling power of oak-wood is only 30·38, whilst that of beech-wood is 120·2; whereas, in conducting power, if fir-wood be taken at 100, then beech-wood is 83·19, and oak-wood 134·10. Another important point of inquiry with regard to the physical properties of wood, as to its value in building, &c., is its relation to moisture. The less the specific gravity of the wood the greater is its capacity for moisture: fir absorbs more and teak less than most other kinds of timber.

It is the peculiar resinous, gummy, oily, or other secretions, that give to the various woods their different colour, smell, and taste. The colouring matter is sometimes deposited in such abundance as to render it useful for dyeing, as seen in log-wood, red sanders-wood, and other woods used as dyes. Some woods have volatile oils deposited in them, which, being slowly given out, render them odoriferous; and this is the case with sandal-wood, rose-wood, the wood of cedar, fir, and other trees. Frequently bitter and other secretions are deposited in wood, giving it a peculiar taste, and rendering it useful in medicine. The wood of the quassia, as well as of the sassafras, are examples of this kind of use. The wood of trees frequently contains in small quantities the secretions which are deposited in other parts of the plant.

If wood be submitted to destructive distillation, it is decomposed, and the consequence is the production of acetic acid and an oil, which pass off, leaving a certain quantity of charcoal. Taking them one with another, the chief kinds of English timber yield, by the distillation of 1 lb. weight, about 7¼ ozs. of wood acid, 3¾ ozs. of charcoal, and 1¾ ozs. of oil.

The woods that are used by the cabinet-maker for furniture of a more delicate kind are called fancy-woods. The use of these has become much more general since the introduction of the art of veneering; and now that this is done by machinery, instead of by hand, many woods are used for furniture and other purposes which, on account of their scarcity, could have been formerly used only to a very limited extent. The most common of the fancy woods, and that which is used most by the cabinet-maker, is *mahogany*. Next in point of importance and use to mahogany is *rose-wood*. *King-wood* is a beautiful wood, used only for delicate articles. *Beef-wood* is a very heavy wood, of a pale red colour, and is brought from Australia in logs 9 feet long and 13 or 14 inches wide. *Tulip-wood* is brought into the market in very small pieces, not more than 4 feet long and 5 inches in diameter. It is clouded with red and yellow colours, and is used for bordering and making small articles, such as caddies and work-boxes. *Zebra-wood* is the production of a large tree, and is cheap enough to be made into tables, piano-fortes, &c. It is coloured brown on a white ground, and clouded with black. *Satin-wood* is of a brilliant yellow colour, with delicate glowing shades. It is found in the market in logs 2 feet wide and 7 or 8 feet long. *Sandal-wood* is of a light brown colour, with golden-coloured waves. *Ebony* and *iron-wood* are the names given to some very hard woods, mostly brought from India, although some of the species are found in Europe and America. *Canary-wood* has a deep yellow colour. *Purple-wood* has a purple colour, without veins. *Snake-wood* is of a deep red colour, with black shades. *Calamander-wood* is a handsome cheap wood, taking a high polish, and is brought from Ceylon. Other woods are called from the places they come from, as *Coromandel* wood, *Amboyna* wood, &c.

The practice of staining wood is sometimes had recourse to for the purpose of making the more common woods resemble in colour the fancy-woods. A method has been proposed of doing this by introducing into the tree during its growth various colouring agents, so that during the course of the ascent of the sap the colouring matter may be taken up and deposited in the woody tissue. Some of the woods thus treated have been made to assume very remarkable colours; but as the trees on which it can be practised are too soft and coarse for fine work, it is not likely that this method will at all supersede the use of the naturally beautiful fancy-woods.

Growing trees are exposed to the attacks of animals and of insects, in addition to their own natural causes of decay; and when they are used as timber they are still liable to the attacks of insects and of worms of a peculiar description. The mischief done by animals is of a comparatively simple and limited description; and may briefly be described as consisting in blows and wounds of the trunk, and in the violent disruption of the smaller boughs, thus rendering the formation of knots more frequent than might otherwise be the case. Birds are actually of service in woods, for the carnivorous birds do good by keeping down insect life. The woodpecker and nuthatch only attack the bark of trees when in search of the larvæ boring in them; rooks and crows destroy immense numbers of the larger beetles; and, in fact, nearly all the forest-feeding birds render the same service. Squirrels, bats, and other insect-devouring mammalia, play the same part in the economy of nature; so that our attention may almost exclusively be devoted to the consideration of the attacks of insects and of the boring worms.

There are three descriptions of insects which prey upon trees, which may be classified according to the parts they especially attack, namely, those which attack the leaves, those which attack the bark and the alburnum, and those which attack the heart-wood. The leaf-eaters are of countless varieties, some of them eating the upper, some the under surfaces, and others the substance of the leaves without touching the epidermis. Again, there are insects which only attack the flowers, some living upon the farina of the flowers, others on the fluids in the vessels of the flowers, and others on their leaves; whilst there are also other insects which injuriously affect growing timber by giving rise to galls or other analogous excrescences. The principal mischief caused by this description of insects consists in the interferences they produce in the flow of the sap, and in their interferences with the respiratory functions of the leaves; but fortunately their ravages are apparent, and their enemies are extremely numerous, both in the animal and the insect tribes. There are several varieties of the bark-feeders; some of them attacking exclusively the outer bark, some the inner bark, and some the alburnum. Their ravages, however, in all cases are exercised only superficially, so to speak, and they do not affect the quality of the timber in any serious manner. These insects may kill a tree, but the heart-wood will remain sound, whatever be their numbers. Such insects as the *Scolytus destructor* will, nevertheless, do more injury to a forest in a month than all the animals it may shade could do in a decade. The *Hylesimus fraxini*, the *Tomicus typographicus*, the *Bostrichus pinastri*, the *Sphinx apiformis*, the *Curculio abrestis*, and the *Curculio potatus* are almost equally mischievous; whilst the *Lymexylon* attacks both the alburnum and the heart-wood. Of the heart-wood devourers the most dangerous in our latitudes are the *Cossus ligniperda*, the *Cryptorhynchus lapathi*, the *Lucanidæ*, the *Cerambycidæ*, the *Sirex gigas*, the *Sirex duplex*, and the *Zengera esculens*; and of these, the *Cossus* and *Sirex* of our own latitudes, and the *Prionus giganteus* and the *Callidium giganteum* of tropical climates, together with the *Lymexylon*, attack the converted timber after it has been long removed from the forest.

Of the boring-worms the only varieties hitherto specially noticed are the *Teredo navalis* and the *Limnoria terebrans*; and their ravages seem to be the most dangerous when wood is exposed to them in decidedly salt water. The *Limnoria*, however, occasionally attacks timber in slightly brackish water, and it would seem that both these species of worms have an antipathy to water containing sulphuretted hydrogen, or some of the vegetable and mineral acids; for they do not attack timber driven into the sea-shore near the outlets of sewers, and they avoid timber which either contains, naturally, considerable proportions of pyroligneous acid, or has been artificially impregnated with creasote, sublimate of mercury, sulphate of copper, &c. The supposed immunity of the green-heart timber was long attributed to the existence of some such quality in it; and though it is now known that the boring-worms do attack that wood, they certainly do not destroy it with anything like the same rapidity that they destroy fir, beech, elm, or even oak. Notwithstanding the fearful nature of the ravages caused by the boring-worms, the habits of those creatures have not been thoroughly studied; and it is difficult to trace the conditions which tend the most decidedly to their multiplication. It would seem, however, that both the species are to be found in the greatest numbers in warm latitudes; that the *Teredo* prefers the sea-shores from which it can derive the carbonate of lime necessary for its growth; that the *Limnoria*, on the contrary, prefers the shores upon which the sands are charged with the decomposition of silicious rocks; and that the portions of the timber devoured by both these worms occur a little below and a little above the lines of high and low water: these worms, in fact, require both air and water. The works of Messrs. Forbes and Hanley ('History of British Mollusca'), Cailliaud ('Mémoire sur les Mollusques perforantes'), 'L'Instruction sur les bois de Marine,' published by the French Government, and a Report by a Commission of Dutch engineers and naturalists on the boring-worm, published in Amsterdam, 1860, should be consulted by all who are interested in the durability of hydraulic works, or in shipbuilding. Opinions seem to be divided as to the merits of the various schemes proposed for resisting the attacks of the worms upon timber. Some engineers recommend exclusively the use of copper sheeting, or of copper nails, over the whole exposed surfaces; whilst others recommend exclusively the use of creasote. In practice, it is found that the worms frequently make their way into timber in the intervals between the nails, and then devour the inner portions. Ten years' experience would also appear to show that when the creasote has been thoroughly injected into the heart of a piece of timber, the worms will not attack the latter. The injection of mineral salts, by Kyan's patent (mercury) or by Margery's patent (copper), does not seem to produce any permanently good effect; for they are all removed in course of time by the action of sea-water frequently renewed by the tide.

The system of injecting creasote seems also to provide an efficient protection against the ravages of the white ants, which are so incalculably numerous, and so destructive to timber in tropical latitudes. It also adds greatly to the durability of timber in damp confined positions; and resists the tendency of the timber to assume either the wet or the dry rot. The two last-named modes of decay are of the most serious importance to the solidity of the buildings into whose construction timber enters largely. They affect all kinds of timber, whether native grown or foreign; and though tolerably well understood by physiologists, and by practical men, it is too much the case that they are unattended to in the application of these materials.

Dry Rot has already been treated of. The *Wet Rot* proceeds from a chemical action in the wood itself, which may either arise from the decomposition of the sap retained in it, or from the decomposition of the vegetable tissue under the influence of confined moisture: for the albuminous parts of the sap, or of the wood, commence a putrefactive process directly they meet with the conditions of heat and moisture necessary for its development. It is therefore important that all timber should be cut at the season of the year when the trees contain least sap, and that the timber should be preserved in such positions as to allow the sap to pass away, for some considerable time before it is used in a building; this precaution is technically called *seasoning.* It is therefore the custom to fell timber during the winter and early spring months, because at those seasons the sap circulates with the least activity; or the time of the year for carrying on this description of work may be said to range between October and April. In addition however to this precaution, and to a careful seasoning, it is essential to remove all the alburnum of a tree, if it should be required for use in confined situations, for the fluids it retains ferment quite as dangerously to the durability of the timber as does the sap itself. The architect and the shipbuilder cannot be too particular in excluding sappy timber from positions where there would not exist a free circulation of air, and where there is any moisture. Sappy wood, moreover, is soft, and of a feeble power of resistance. The decomposition which takes place in timber affected by druxy, or by dead knots, is of the same character as the ordinary wet rot; that is to say, it proceeds from a chemical action in the wood.

A mode of rendering timber less combustible has been described under Fire-proofing.

Working in Wood.—The cutting up of timber into beams and planks is described under Saw, Saw-Mill; and into thin layers under Veneering. The use of timber in building-work is illustrated in such articles as Carpentry, House, Roof, &c.; and the use of fine woods in Carving and Marquetry. We proceed to a few manufacturing processes not hitherto described: first noticing, however, that Mr. Holtzapffel, for practical purposes, classifies woods under eighteen groups, according as they are used for ship-building, hydraulic engineering, house carpentry, machinery frame-work, rollers, teeth of wheels, foundry patterns, common turnery toys, best Tunbridge toys, hard-wood turning, common furniture, best furniture, ornamental work, elastic work, inelastic work, carving, colour and dye-woods, and scent-woods.

Timber-bending has recently occupied considerable attention. Various plans have been introduced by Meadows, Hookey, and other inventors, for this purpose, chiefly by the application of steam and pressure; but the most effective seems to be that of Mr. Blanchard, of Boston. He has established a manufactory for bending timber of various kinds and sizes, and rendering it applicable for the making of chair-backs, gig-shafts, sofa-frames, horse-hames, plough-handles, wheel-felloes, arch-pieces, staircase-rails, curved mouldings, ship-timbers, &c. Oak-timber 14 feet long and 16 inches square can be bent to a curve in one hour, and timber of 9 inches square in twenty minutes. A piece 12 feet long, 12½ inches wide, and 7 inches thick, can be bent into a perfect and permanent semicircle. A trough is prepared, of the proper size and form for the curve; one side of which is rendered moveable. There is a lever, turning on a central axis, and a travelling table under the lever. The timber, after being steamed for some hours, is laid on a flexible band of metal placed on the travelling table, and is pressed and clamped down firmly to it. One end of the timber is next clamped to one end of the curved trough; the other end butts against a block, acted on by a screw. The action of the lever then drives or forces the timber into the trough; the two ends of the timber are connected by a tie or chord; the fourth side of the trough is then put in its proper place; and the timber, thus clamped and bound with a combination of forces, is left till cold. It is now found to have acquired a permanent set, without any rending, crippling, or loss of hardness and durability. The timber, in the first instance, is not put simply into a vessel full of steam; it is introduced into a hot closet, through which steam at low pressure passes in a continuous current.

Labour-saving expedients in the working of wood have been introduced in recent years nearly in as great variety as in the working of metals. The Americans, on account partly of the abundant supply of timber in that country, have been very successful in this direction. Mr. Molesworth, in a paper on this subject read before the Institute of Civil Engineers in 1857, said that the Americans have now in use no less than five different groups of wood-planing machines, exhibiting many varieties. In one group the plane has a reciprocating motion; in another there is a fixed cutter; in another a rotatory cutter; in a fourth, the cutter is on a vertical axis; and in the fifth a socket-plane is used. The angle of the cutter is made to vary with the quality of the wood operated on, the nature of the work, and the speed of movement. There are also machines for shaping irregular work; for tenoning, either with circular saws or tenoning-cutters; for copying or carving, by means of rotatory cutters advancing to and receding from an iron pattern; for dovetailing, by reciprocating chisels or by dovetailing cutters; for making boats' oars; for making railway keys; and for sawing, planing, boring, shaping, and jointing timber in various ways. One ingenious machine shapes the arms and legs of chairs; there are two vertical cutters revolving in opposite directions, at 1700 revolutions per minute; the pattern to which the wood is temporarily fastened is so pressed against the cutters as to guide the cut. As the cutters revolve in opposite directions, the work may be pressed against the one or the other, so as to suit the cut to the direction of the grain, without the trouble of reversing the position. In some districts, where wooden houses are made in large numbers for emigrants and backwoodsmen, the timber is cut up with great rapidity; one saw of a particular kind will cut into shape 10,000 shingle boards in a day; another will cut 60,000 or 70,000 laths in the same time; while another will plane 50 feet of flooring-boards per minute, tongue and groove them at the same time, and convey the chips and shavings to a fuel-house.

The inventions are little less varied, although the operations are on a much smaller scale, in England. The Enfield rifle stock is shaped entirely by machines, no less than a dozen different machines being employed in succession, some of the cutters of which revolve 6000 times per minute. A series of machines at Woolwich Arsenal make wooden scabbard-linings for cavalry swords; and so efficient are these, that by their aid two boys can make 500 scabbard-linings in a day. Rifle-bullets sometimes have a small box-wood plug inserted in the rear of each: there are machines at Woolwich which will cut and shape 300,000 of these plugs per day. Mr. Kinder, of Worcester, has invented and brought into use a complete series of machines for working in wood, by the use of which he can plane scantlings 6 or 7 inches square; work the edges of curved timbers on the square; form both regular and winding bevels; work oblique sections of irregular figures; cut tenons with shoulders of almost any pitch; make rebates and grooves of various kinds; box down or sink irregular surfaces in such a manner that the surface destroyed shall be reproduced at the required depth; and produce curved or straight beads and mouldings—all by making the wood move while the cutting instrument remains stationary. Mr. Wilson, of Banbury, has brought into use a curious series of machines for making broom and mop-handles, umbrella-sticks, brush-backs, and railway-pegs. Mr. Dickie, of Glasgow, has a series of machines for producing irregular forms in wood, such as boot-trees, shoe-lasts, gun-stocks, and shovel-handles, by a kind of differential action of several cutters. Other morticing, moulding, dovetailing, tenoning, planing, jointing, dowelling, rebating, and chamfering-machines have been invented in great variety, and introduced in various ways; but they need not be separately described.

The application of elaborate machines to the production of cheap articles is curiously illustrated in the manufacture of *fire-wood* and of *matches.* Terry's fire-wood machinery, introduced in 1857, performs all the operations of sawing, splitting, cutting, and binding. Rough blocks of wood slide down an inclined table; they are pressed by a drum against circular saws; they are sawn into pieces of a uniform length; the pieces slide down a shoot to the splitting-mill, and fall against a series of circular cutters, which cut them into flat slabs; the slabs slide down and are split into sticks, which fall into a moveable carriage, and are discharged down another shoot; they fall into a horizontal channel, where a piston, by the action of a lever and weight, presses together enough sticks to form one bundle; the piston drives them half through a circular opening; wire from a reel is made to pass round the middle of the bundle, where it is twisted and cut off; and finally, an incoming bundle pushes out the completed one. Thus the wood is not touched by hand throughout the operations. In the making of splints for congreves or lucifers, the wood is first cut into blocks by circular saws; and these are either separated into four-sided splints, by a series of lancet-points ranged equidistant, or into cylindrical splints by being forced through small perforations in a metal plate. The best pine plank, free from knots and irregularities, is alone fit for this purpose; cheap wood would injure the cutting apparatus, and thus would not be cheap in the end. A plank 12 feet long, 11 inches wide, and 3 inches thick, will cut up into 200,000 lucifer-match splints of ordinary size; and some firms thus cut up twenty of such planks in a day.

In an article by Mr. Charles Knight, in the 'Companion to the Almanac,' for 1861, an account is given of the curious wooden-ware manufactures of Buckinghamshire and one or two neighbouring counties. The beech, elm, and ash trees of those districts are brought into immediate and local manufacturing use. At Chesham are made bread-trenchers, butter-prints, cricket-bats and stumps, money bowls, washing bowls, malt shovels, sand shovels, butcher's trays, trundling-hoops, toy garden-rollers and garden-rakes, toy wheelbarrows, hat blocks, straw bonnet blocks, and wig blocks. The taste exhibited in these articles is of a humble kind, and very little machinery is employed in the production. Chair making is the chief trade in and around High Wycombe. The many thousand cheap but strong chairs made within the last few years for use in the Crystal Palace, St. Paul's, Westminster Abbey, and other public places came from the district in question. One contract of 6000 chairs for barracks, and another of 8000 for the Crystal Palace, are mentioned. "Wycombe," says Mr. Knight, "boasts of making a chair a minute all the year round: chairs which would not be unsightly in the handsomest sitting-room, and which can be sold at five shillings each. More costly chairs are here produced, as well as the commonest rush-bottom chair of the old cottage pattern. But the light caned chair, stained to imitate rosewood, or of the bright natural colour of the beech, and highly polished, finds a demand throughout the kingdom—a demand which might appear fabulous to those who have not reflected upon the extent to which a thriving industrious people create a national wealth which gives an impulse to every occupation, and fills every dwelling with comforts and elegancies of which our forefathers never dreamt. The wondrous cheapness of the Wycombe chair is produced by the division of labour in every manufactory; and by the competition amongst the manufacturers, in a trade where a small capital and careful organisation will soon reward the humblest enterprises." Some of the operations are conducted in factories of considerable size; while others are undertaken by workmen in all the villages round.

Timber Trade.—Several centuries ago the woods and forests of England were sufficient to supply all the timber required for the building of ships and houses, as well as for fuel. In the 16th century we begin to hear complaints of their exhaustion. An act was passed in 1531 requiring coopers to sell their barrels at fixed prices, and ordering that the exporters of beer should import clapboards sufficient to replace the barrels sent out of the country. Another act, passed in 1541, was designed to enforce certain restrictions respecting the felling of trees, and to prevent the conversion of woodlands into pasture or tillage. In 1558 an act was passed, entitled 'An Act that timber shall not be felled to make coles for the making of iron,' which prohibited the use of timber one foot square in iron-works within fourteen miles of the sea, or within the same distance of eight of the principal rivers of England, or any navigable stream having an outlet on the coast: but three southern counties, Kent, Sussex, and Surrey were exempt from the operations of the act. The design seems to have been to encourage the trade in timber fit for building, and to benefit those parts of the country which did not possess a sufficient supply. In 1592 the subject again attracted notice, and an act was passed, which, amongst other things, prohibited aliens exporting fish, unless they imported clapboards; and altogether prohibited the exportation of wine-casks. In the following century the scale of prices turned in favour of pit-coal.

During the decline in the internal supply of timber, it gradually became an article of extensive demand from other countries. In 1830, according to a statement of Mr. Huskisson, the fir timber used in England for building purposes was nearly all brought from abroad. The proportion of timber of native production used for similar objects is not known or even guessed at. The north of Europe, especially the countries on the Baltic, and our colonies in British North America, are the great sources of supply. The timber of the north of Europe is generally of excellent quality, and much superior to that from the colonies. The inferior colonial timber was for many years forced into use by enormous differential duties, which amounted to a bonus of 1000 per cent. in some cases: that is, the one duty was ten times as much as the other. In 1787 the duty on foreign timber was only 6*s.* 8*d.* the load of fifty cubic feet, but it was raised at different times, until, in 1804, it amounted to 25*s.* In 1810 the duty was raised to 54*s.* 8*d.*; and from 1814 to 1820 it was 64*s.* 11*d.* and 65*s.* the load. The trade in colonial timber had scarcely any existence before 1803, although until 1798 it had been admitted free of duty; and the duty imposed in that year was only 3 per cent. *ad valorem*, which was changed in 1803 to a specific duty of 2*s.* the load. In consequence of the war there was a great rise in the price of European timber, Memel fir advancing from 78*s.* to 320*s.* the load. In order therefore to encourage the supply from our own colonies, North American timber was again, in 1806, admitted duty free; and from that time it was more largely used than Baltic timber. The return to a sounder principle of taxation was very slow. In 1821 the duty on European timber was reduced from 65*s.* to 55*s.* the load, and a duty of 10*s.* was imposed on colonial timber, leaving a preferential duty of 45*s.* still in operation. In the tariff of 1842 the duty on colonial timber was reduced to a merely nominal sum, namely, 1*s.* the load, and to 2*s.* on deals, and 6*d.* on lathwood; while that on foreign timber was to be gradually reduced to 30*s.* and 35*s.* on different kinds. The mode of charging the duty was at the same time improved and rendered less complex than before. The difference of duty was from 24*s.* to 30*s.* in favour of colonial timber. This difference was reduced in 1847 to 14*s.* In 1851 the differential duties ceased altogether; the duty was established at 7*s.* 6*d.* to 10*s.* per load, without respect to country. In 1860 it was reduced to 1*s.* and 2*s.* per load, or 1*s.* and 2*s.* per ton, according to the mode of measurement. It may here be remarked that timber is sold by the load, the cubic foot, the square foot, the foot run, the ton, the lb., or the number of pieces; but the greater portion is by the *load*. A load of unhewn timber is 40 cubic feet; of squared timber, 50 cubic feet; of planks, 150 to 600 square feet, for thicknesses varying from 1 to 4 inches. Of a very usual kind of plank, 12 feet long, 11 inches wide, and 3 inches thick, 18 make one load.

The imports of timber, in the fifteen years from 1844 to 1858 inclusive, ranged from 1,500,000 loads to 2,500,000 loads annually. In 1860 the quantities and classification were as follow:—

	Loads.
Foreign, unhewn timber	692,788
„ hewn timber	768,791
Colonial, unhewn timber	580,349
„ hewn timber	760,356
Total	2,802,284

TIMBER AND TIMBER-TREES. Timber-trees are those the wood of which is used for building or repairing houses. Oak, ash, and elm, of the age of twenty years and upwards, are the trees most generally included under that denomination; but there are many other kinds of trees, such as beech, cherry, aspen, willow, thorn, holly, horsechesnut, lime, yew, walnut, &c., which are, by the custom of certain parts of England, considered as timber-trees, as being those used in building. (Cruise, 'Dig.', t. 3, c. 2, ss. 6, 7.) Most of the cases upon the question as to what trees are to be considered timber, have arisen in reference to the stat. 46 Edw. III., c. 3, whereby it was enacted that great or grosse wood of the age of twenty, thirty, or forty years, or upwards, should not be titheable, but that *sylva cædua*, or underwood, should be titheable. (2 'Inst.', 642, 643; 3 'Rep.', 12.)

The timber-trees growing upon land belong to the owner of the inheritance. A tenant for life has only a qualified interest in them, in so far as they afford him shade and shelter, and a right to take the mast and fruit. If the tenant for life fells timber-trees on the land to any amount greater than he is entitled to as estovers, that is to say, the allowance of wood necessary for the reparation of houses and fences, he becomes liable to an action of waste [WASTE]; and the trees, which by these or any other means, accidental or otherwise, have become severed from the land, may be seized by the owner of the inheritance, or an action may be brought by him for them. If, however, the estate of the tenant for life be without impeachment of waste, he has the full right to fell timber, and also the property in all timber-trees felled and blown down during his life.

In leases for lives, when timber is included, if the lessor fells the trees, the lessee may maintain an action of trespass against him, because the lessee, though he may not cut down the trees without being subject to an action of waste, has an interest in them for shade and shelter, and a right to take the mast and fruit, and may also lop them if they be not thereby injured. But where the trees are excepted in a lease, which is usually done, the lessee has no interest whatever in them, and the lessor may bring an action of trespass against him if he fells or damages them. The lessor has also a power, incident to the exception, of entering on the land in order to fell and take away the trees; though this power, for the sake of avoiding questions, is often expressly reserved.

The timber growing on copyhold estates is, by the general custom of most manors, the property of the lord, who may cut it down, provided he leaves a sufficient quantity for the repairs of the copyhold, which the copyholder is entitled to of common right. But the general right of the copyholder to have timber for the reparation of houses and for ploughbote and hedgebote may be restrained by custom, namely, that he shall not take it without assignment from the lord or his bailiff. A copyholder in fee may, by the particular custom of the manor, have a right to cut timber-trees growing on his copyhold, and sell them at his pleasure; and the same right may belong by custom to a copyholder for life, who is entitled to nominate his successor, as being a *quasi* copyholder in fee; but a custom that a copyholder for life may cut down timber is unreasonable and void, as being a destruction of the inheritance, and contrary to the nature of a life estate.

Ecclesiastical persons being considered in most respects as tenants for life of the lands held by them *jure ecclesiæ*, are not permitted to cut down timber except for repairs. The Court of Chancery will always interfere to prevent the owner of a particular estate joining with the person entitled to the inheritance for the time being to cut down the timber on the estate.

TIMBRE. [ACOUSTICS.]

TIMBREL, a musical instrument of the highest antiquity; the *tympanum leve* of the Roman poets, and, in the opinion of all writers of any authority, the same, in an almost unaltered state, as that now known in every part of Europe under the names of tabor, tambourine, *tambour de Basque*, &c.

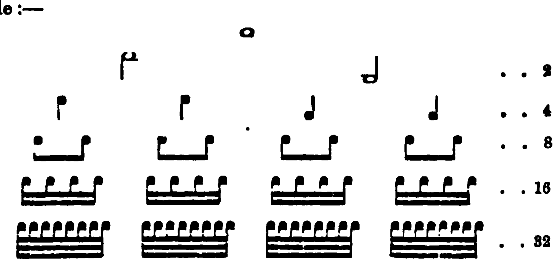
TIME (in Music) is:—

I. The measure of the duration of sound.

II. That which divides a bar into two or three equal parts, and subdivides these.

III. The movement—that is, the quickness or slowness—of a composition.

1. The degree of sound, or pitch, is shown by the place on the staff of any one of the characters called notes; but its duration is known by the particular note; that is, as minim, or crotchet, &c. The longest note, in relation to time, used in modern music, is the semibreve, which is considered the measure-note, and its average length is about four beats of a healthy man's pulse. The five other notes are proportionate parts of this. Thus the minim is in duration ½ of a semibreve; the crotchet is ¼, &c.: consequently two minims, or four crotchets, &c., are equal to one semibreve, as exhibited in the annexed table:—



2. Time is either duple or triple. The former divides every bar, or measure, into 2, or 4, &c., equal parts; the latter into 3, or 6, &c. Times are marked by the letter C,—also by this letter barred (₵), and by figures. The C, whether barred or not, indicates *Common Time;* that is, duple time, having one semibreve, or its equivalent in notes, in each bar. Figures represent the fractions of a semibreve, the upper figure the numerator, the lower the denominator. When the numerator is 2 or 4, the time is duple; when 3, it is triple; when 6 or 12, it is compound-common; and when 9, it is compound-triple. But in reality, there are only two times—binary and ternary; or duple and triple.

3. The term *Time* has hitherto had a third meaning annexed to it in musical language, by its employment in the sense of movement, a practice which has produced some confusion. The Italian word *Tempo*, signifying the same, is now growing into use. [METRONOME; RHYTHM.]

TIME. This word may be considered either with reference to our abstract idea of the thing signified by it, or to the measures of it which have been contrived for use in the business of life. Something on the first point of view will be found in the article SPACE AND TIME, to which the following may be added.

When we think of time in the usual manner, it is of a real thing external to ourselves, which we cannot help imagining to have an existence and a measure, both of which would remain though those who now speculate upon the conception were annihilated. A little more consideration shows that we are indebted for the idea to successions of observed events, or at least for the power of applying the idea to external objects. No description can be adequate; if we say that *change* necessarily implies *time*, and that the perception of that which *is* being different from that which *was*, suggests the notion of an interval, we see that we have already fully assumed the idea of time in the words *is* and *was*. But we may say that space and the objects which fill it exist independently of ourselves, and would undergo changes though we were not in existence to perceive them, and that therefore the times which those changes require would also exist; this involves the whole of the most abstruse part of metaphysics, and is much beyond the scope of our article. We shall therefore turn to the mode of measuring time; we have a thorough conviction that time is a magnitude, that is, has its *more* and *less*. We must ask ourselves in the first instance what we mean by a greater or a smaller time.

In the perception of time as a magnitude, that is, of intervals of time as containing more or less of duration, we refer in the first instance to a habit derived from continual acquaintance with those great natural successions on which the usual actions of our lives depend, with which we can constantly, though unconsciously, compare the duration of our thoughts and actions. There is no more an absolutely long or short time than there is an absolutely great or little space; these words are only comparative. If, for example, any one were to affirm that the universe was continually growing less and less, all its parts altering in the same proportion, and the dimensions of the human race with the rest, in such manner that the whole solar system would now go into a nut-shell, such as nut-shells were a thousand years ago, it would be impossible either for him to prove it, if true, or for any one else to prove the contradiction, if false. In like manner if any one were to say that the revolutions of all the heavenly bodies were continually accelerating, but that the properties of matter were also continually altering, and the speed with which ideas are formed and communicated, and muscular efforts made, continually increasing: it would be impossible to prove a contradiction. The oriental story is the best illustration of this:—A prince was ridiculing the legend of Mohammed being taken up by an angel, and holding many long conferences with his Creator, and having many views of heaven and hell to the smallest details, in so short a time, speaking with reference to things upon earth, that on his being brought back, the water had not quite flowed out of a jug which he had dropped from his hand when the angel caught him. A magician at the court of this prince checked his laughter by offering to prove the possibility of the story, if his highness would only dip his head into a basin of water. The prince consented, and the instant his head was immersed, found himself lying by the sea-shore in a strange country. After a reasonable quantity of malediction upon the magician, he found himself obliged by hunger to go to a neighbouring town, and seek the means of support. In time he became independent, married, and brought up a family, but was gradually stripped of all his substance by losses, and buried his wife and children. One day he threw himself into the sea to bathe, and on lifting his head out of the water, found that he had only lifted it out of the basin, the magician and the other courtiers standing round. On his bitterly reproaching the magician, the latter assured him, and was confirmed by all the bystanders, that he had done nothing but just dip his head into the basin and lift it out again. Of course the prince expressed no more doubts about the story of Mohammed, and however much any reader of the two tales may think that neither *is* true, a little reflection will show that either *might* be so. Perhaps the allegory might have been suggested by what is known to take place in dreams; there is evidence enough that many of the longest of these illusions really occupy no more than, if so much as, a second or two by the pendulum. [DREAMS.]

In the laws of motion it seems as if, so to speak, matter took cognisance of time; a particle of matter will continue to describe equal spaces in *equal times*, until acted on by force from without. Yet it would be possible to state this law as follows, in such a manner as to avoid the comparison of quantities of duration. If two particles acted on by no external forces, are at A and a at the same epoch of duration, and at B and b at the same subsequent epoch, then if AC be m times AB, and if ac be m times ab, the law of motion is that C and c will be respectively attained at the same instant. The mathematician will readily see that the equations of motion do not depend upon the absolute recognition of time as a measurable quantity, but that any moving particle, as A, being acted on by no force, the distance AC, described in the time t, might be introduced into all formulæ instead of the time, without any question as to whether, time being physically considered, the space AC varies as the time. It is enough that the uninfluenced motion of any other particle should be connected with that of the standard particle by the law above described. But though we can thus avoid the idea of measurement of time, we cannot get rid of its existence or of the notion of succession of epochs; grant that we can reduce dynamics to a *theory of simultaneous positions* of particles of matter, without reference to the absolute length of time employed in passing from one position to another, there is still the notion of time in the notion of simultaneous. But, nevertheless, the idea of succession thus introduced is hardly, if at all, more physical than that which comes into most of the branches of pure mathematics, a point on which it will be worth while to dwell for a moment.

When Newton, in his doctrine of fluxions, or flowing quantities, imagined length, space, solidity, and number itself, to be generated by a continual and gradual flow, as a line by the motion of a point, a surface by that of a line, and so on, it was objected that he introduced the ideas of time and motion, both of which were foreign to pure mathematics, and properly belonged to mechanics. To get rid of these intruders, the theory of limits, which the notion of fluxions immediately requires, was attached, not to flowing quantities, but to variable quantities. Let x be a variable quantity, is one of the most common phrases of the systems which have superseded that of Newton. Now variation means change; it is never pretended that a variable has two values at once. All the difference is, that by Newton the object of consideration is supposed to grow larger or smaller, while the moderns pass in thought from a larger quantity to a smaller, or *vice versâ*, taking one first and the other afterwards. If so slight a difference as this be worth a contest, the distinction of pure and mixed science must be trivial enough: the fact is, that both systems consider successive values, and *succession is time*. If two computers were to quarrel which was the purer arithmetician, the one who stood still and counted the carriages as they passed by him, or the other who walked from one to another and counted them as they stood still, they would, to us, much resemble some of the disputants for and against the principle of fluxions.

The actual measure of time depends upon our being able to secure successions of similar events which shall furnish epochs separated by equal intervals of time. We cannot do this by our thoughts, except approximately, and for short periods. The memory of a musician, aided by the sentiment or feeling of time which is part of a good ear for music, will do remarkably well for a short period: a person who could not well preserve the division of a second into eight parts at least would make a poor figure in an orchestra. As to the judgment of considerable periods of time, it is materially influenced by the manner in which it has been spent: a time which *seems* to have been long through weariness *has* been long, and the contrary, on grounds already alluded to. Thus a year of mature age is really, to the thoughts, of a different length from one of childhood. Again, when we talk of a long period of time having passed quickly or slowly, we speak not of the time, but of our mode of remembering it. A person of rapid recapitulation always says that time has passed quickly, another of a contrary habit the contrary; and this whether the rapidity be a consequence of quickness of ideas, or of having little to recall.

In all the more correct machines which have been invented to measure time, there is but one principle: a vibration is kept up by the constant application of forces only just sufficient to counteract friction and other resistances, and machinery is applied to register the number of vibrations. The remarkable law noted under ISOCHRONISM and VIBRATION makes it comparatively immaterial whether the vibrations are of precisely the same extent. But the imperfections of such instruments, or rather, our ignorance of the precise action of disturbing causes, and particularly of changes of temperature, renders them comparatively useless for measuring long periods, so that if we could not have recourse to the motion of the heavenly bodies, there would be no permanent measure of time. And even in astronomical phenomena there is no absolute recurrence at equal intervals, though nearly enough for common purposes. The value of such phenomena for the most accurate measures consists in most of their irregularities being truly distributed about a uniform mean, so that the excesses of some periods are compensated by the defects of others, giving, in the long run, power of determining that mean with as much accuracy as our modes of measurement can appreciate. The determination of time for civil reckoning may be divided into two parts: first, the mode of making the different periods derived from the sun and moon agree with each other so as to afford an easy method of reckoning co-ordinately by both [PERIODS OF REVOLUTION]; secondly, the mode of procuring true and convenient subdivisions of the natural unit consisting of a day and night. To the second of these we now turn our attention.

The actual revolution of the earth, as measured by the time elapsed between two transits of the same star over the meridian, is called a *sidereal* day. It is divided, as are all other days, into twenty-four hours of sixty minutes each, &c. The time so given is called sidereal time. If the sun were a fixed star, this sidereal time would be the common mode of reckoning. But the sun having its own slow motion in the ecliptic, in the same direction as the revolution of the earth, the interval between one meridian transit of that body and the next is [SYNODIC] longer than the simple revolution of the earth, for just the same reason that the time in which the minute-hand of a watch moves from coincidence with the hour-hand to coincidence again is longer than the hour, or simple revolution of the minute-hand. If the sun moved uniformly, and in the equator, the real solar day, which means the interval between two meridian transits of the sun, would always be of the same length, and a little longer than the sidereal day. But the sun neither does move uniformly, nor in the equator; and each of these circumstances causes a slight irregularity in the absolute length of the solar day, or, as it is called, the *real* solar day. This is the reason why the time shown by a sundial does not agree with the watch. To remedy this inconvenience, a fictitious sun is supposed to move in the ecliptic, and uniformly, while another fictitious sun moves in the equator, also uniformly. Both the fictitious bodies have the average motion of the real sun, so that the years of the three are the same; and the fictitious sun of the ecliptic is made to coincide with the real sun at the perigee and apogee, or nearest and farthest points from the earth; while the fictitious body in the equator is made to coincide with the fictitious body of the ecliptic at the equinoxes (from which it arises that there is also a coincidence at the solstices). This fictitious sun of the equator is that to which clocks are adjusted; the interval between two of its transits, which is always of the same length, is called a *mean solar day*, which is divided into twenty-four mean solar hours, &c. The difference between time as shown by the real sun and the fictitious sun in the equator, is called the equation of time.

The determination of the equation of time is a mathematical problem of some complexity: what we have here to notice is, that owing to the joint action of the two sources of difference, it presents a very irregular series of phenomena in the course of the year. If the sun moved regularly, but in the ecliptic, there would be no equation of time at the equinoxes and solstices: if the sun moved with its elliptic irregularity, but in the equator instead of the ecliptic, there would be no equation of time at the apogee and perigee. Between the two the equation of time vanishes only when the effect of one cause of irregularity is equal and opposite to that of the other; and this takes place four times a year. In this present year (1861) the state of the equation of time is as follows:—January 1, the clock is before the sundial $3^m\ 58^s$, and continues to gain upon the dial until February 11, when there is $14^m\ 32^s$ of difference. This then begins to diminish, and continues diminishing until April 15, when the two agree, and there is no equation. The dial then is before the clock until May 14, when the equation is $3^m\ 53^s$, which diminishes until June 14, when there is again no equation. The clock is now before the dial, and the equation increases till July 26, when the equation is $6^m\ 12^s$, which diminishes until the 1st of September, when there is no equation, for the third time. The dial is now again before the clock; and by November 3, the equation has become $16^m\ 18^s$, from which time it falls off until December 24, when it is nothing for the fourth and last time. The clock then gets gradually before the dial till the end of the year. The phenomena of the next year present a repetition of the same circumstances, with some trivial variations of magnitude. There are several slight disturbing causes to which we have not thought it worth while to advert in a popular explanation: in particular, the slow motion of the solar perigee [YEAR; SUN], which will in time wholly alter the phenomena. For instance, when the perigee comes to coincide with the equinox, there will be only two periods at which the equation of time vanishes, namely, when the sun is at either equinox.

The sidereal day is $23^h\ 56^m\ 4^s{\cdot}09$ of a mean solar day, and the mean solar day is $24^h\ 3^m\ 56^s{\cdot}55$ of a sidereal day. We have in this article only to do with the mode of obtaining a uniform measure of time, or of intervals of time; this being premised, the subject will be taken up again in the article YEAR.

TIME BALL. [TELEGRAPH, ELECTRIC.]

TIME BARGAIN. [STOCKS.]

TIME OF DESCENT, the technical term for the time employed by a material particle in falling down an arc of a curve under the action of gravity, the mode of obtaining which is explained in VELOCITY. When any number of curves are drawn from a given point, and another curve is so drawn as to cut off from every one of them an arc which is described by a falling particle in one given time, that curve is called *tautochronous*, or a *tautochron*. But when a curve is such as the cycloid, namely, that a particle, wherever placed, will fall to the lowest point in the same time, such a curve is also called *tautochronous* by various writers, and *isochronous* by others. Our only object in inserting this article has been to note this confusion of language.

TIN (Sn). One of the first known metals. Its early history is intimately associated with that of our own country, for three thousand years ago the Phoenicians regularly visited the southern shores of this island, and carried on smelting operations for tin.

The alchemists called tin *Jove*, or *Jupiter*, and gave it the sign ♃, indicating that they thought it to be one half silver and the other half acrimony.

The chief ore of tin is the binoxide. [TIN, in NAT. HIST. DIV.] It is roasted to peroxidise iron, and volatilise arsenic and sulphur; washed, to remove sulphate of copper and the oxide of iron; reduced to the metallic state by charcoal; and refined by fractional fusion.

The equivalent of tin is 59.

Tin has a high metallic lustre; its colour is silver-white with a tinge of yellow; in tenacity it is exceeded by several of the metals, but is very ductile, and, as *tinfoil*, is met with in plates varying from 1–250th to 1–1000th of an inch in thickness. It suffers but little change on exposure to the atmosphere, and is unaffected by moisture. Tin is inelastic but very flexible, and when bent produces a peculiar crackling noise, termed the "cry" of tin; the latter effect, as well as the heat rendered sensible during flexion, is due to the mechanical alteration in position, and consequent friction, of the particles of the metal. When rubbed, tin imparts to the fingers a peculiar and somewhat persistent odour. It is a good conductor of heat and electricity; has a specific gravity of 7·292; melts when heated to 442° Fahr., and at a higher temperature burns with a brilliant white light. Tin, like iron, remains in a passive state when plunged into very strong nitric acid; on diluting with water, however, the metal is violently acted on, much nitrous vapour is evolved, and hydrated binoxide of tin is formed. Hydrochloric acid dissolves it with evolution of hydrogen; aqua regia converts it into bichloride; cold sulphuric acid does not affect it, but when hot converts it into sulphate, sulphurous acid escaping. The fused alkalies also oxidise tin, hydrogen being given off. At ordinary temperatures tin is not brittle, but when heated to near the fusing point it may be powdered with facility: the operation is most conveniently performed by pouring the melted metal into a wooden box and well shaking for a few minutes.

Oxygen and *Tin* combine in three proportions, forming—

Protoxide of tin	SnO
Sesquioxide of tin	Sn_2O_3
Binoxide of tin	SnO_2

Protoxide of Tin (SnO) cannot be procured perfectly pure by direct action: the best method of preparing it is to evaporate a solution of protochloride of tin carefully to dryness, and then triturate it in a mortar with excess of crystallised carbonate of soda, which decomposes the chloride, and leaves the protoxide of tin. When this has been washed and dried carefully, it is of a fine bluish-black colour, is very soluble in hydrochloric acid, and when heated in the air takes fire, burns, and is converted into peroxide. The density of protoxide of tin is 6·66; it is soluble in solution of potash and soda, but not in ammonia, nor do the alkaline carbonates dissolve it. The alkaline solutions of this oxide gradually deposit metallic tin, and peroxide remains in solution. Its salts very quickly absorb oxygen from the air, and form compounds which readily yield oxygen; and it is on this account that it converts the sesquioxide of iron into protoxide, and precipitates silver, mercury, and platinum in their metallic state. With gold, a purple compound is formed, known by the name of the *purple powder of Cassius*.

Hydrated Protoxide of Tin (SnO, HO) precipitates as a white powder on adding together solutions of protochloride of tin and carbonate of soda.

Sesquioxide of Tin (Sn_2O_3) is formed by mixing fresh precipitated and moist hydrate of peroxide of iron with a solution of protochloride of tin, as free as possible from hydrochloric acid. By the mutual action of these substances a slimy gray matter is thrown down, which is generally slightly yellow, from the presence of a little peroxide of iron. It is probably a definite *stannate of protoxide of tin* (SnO, SnO_2). It is soluble in hydrochloric acid, and also in ammonia, which last property distinguishes it from the protoxide; and it is distinguished from the peroxide by giving a purple precipitate with the salts of gold.

Binoxide or Peroxide of Tin.—One variety of this results from the action of strong nitric acid upon tin. Dried in air, it contains Sn_5O_{10}, 10HO; at 212° it loses half its water ($HO, Sn_5O_{10} + 4Aq$), and by exposure to a red heat becomes anhydrous and of a straw-yellow colour. It is known in commerce as *putty powder*, and is used for polishing plate. In the hydrated state it is insoluble in hydrochloric or nitric acids, but is freely dissolved by the alkalies forming salts, which do not crystallise, but which may be obtained in a granular state: that of potash contains ($KO, Sn_5O_{10} + 4Aq$). It is distinguished from the next form of binoxide of tin by the name *metastannic acid*. When its hydrate is moistened with protochloride of tin, a beautiful golden-yellow *metastannate of tin* ($SnO, Sn_5O_{10} + 4Aq$) is formed.

When carbonate of lime or baryta is added to excess of bichloride of tin, a gelatinous binoxide is thrown down. Unlike metastannic acid, this variety is readily soluble in nitric or hydrochloric acids. It is called *stannic acid*, has the formula HO, SnO_2, and combines with the alkalies to form crystalline *stannates*. The *stannate of soda* ($NaO, SnO_2 + 4Aq$) is largely used by the dyer and calico-printer as a mordanting agent. By a heat of 284° Fahr., stannic acid is converted into metastannic acid.

Binoxide of tin renders glass semi-opaque or opalescent. It is an ingredient of most enamels.

Chlorine and Tin combine to form the protochloride and the perchloride. The *protochloride* ($SnCl + 2Aq$) is prepared by dissolving the metal in hot hydrochloric acid till the evolution of hydrogen gas ceases: the solution is colourless, and deposits crystals, which sometimes are acicular, and at others prisms of considerable size. When heated to about 212°, the water is nearly expelled; at a higher temperature, hydrochloric acid is evolved, and oxichloride of tin remains. It is soluble in a small quantity of water, but decomposed by a large quantity, oxichloride of tin being precipitated.

The protochloride of tin is used as a mordant in calico-printing, under the name of *salts of tin*, and in chemical investigations as a deoxidising agent, acting in the mode already described.

Protochloride of tin may also be obtained by distilling a mixture of equal weights of granulated tin and bichloride of mercury, or by transmitting hydrochloric acid gas over tin heated in a glass tube; in all these cases it is free from water, and is a gray solid, of a resinous lustre, which fuses below redness and sublimes at a high temperature. It is commonly known as *butter of tin*.

Perchloride or *Bichloride of Tin* ($SnCl_2$) may be prepared in several modes: first, by heating the protochloride in chlorine gas; second, by dissolving the hydrated peroxide in hydrochloric acid; third, by putting tin into the mixture of hydrochloric and nitric acid, called *aqua regia*, which yields nascent chlorine; fourth, when a mixture of 1 part of tin with 4 parts of bichloride of mercury is distilled with a gentle heat, a colourless limpid liquid is obtained, which fumes strongly in moist air; this is the bichloride of tin, formerly known by the name of the fuming liquor of Libavius. It boils at 239·5° Fahr., is rendered solid by the addition of one-third of its weight of water, and dissolves in a larger quantity. By the action of alkalies it is decomposed, hydrated peroxide of tin being precipitated.

A solution of this salt under the name of *nitromuriate of tin*, or *composition*, is extensively used in dyeing and calico-printing. It forms double salts with alkaline chlorides.

Sulphur and Tin combine in three proportions. The *protosulphide* (SnS) is prepared by adding to melted tin an equal weight of sulphur, and stirring the mixture till combination is effected; the product is to be powdered when cold, mixed with an equal weight of sulphur, and thrown in small portions into a hot crucible, and eventually heated to redness. It is of a bluish-black colour, has a metallic lustre, fuses at a red heat, and when cooled has a lamellated texture. When hydrosulphuric acid gas is passed into a solution of protochloride of tin, a similar compound is obtained. Hydrochloric acid dissolves protosulphide of tin with the evolution of hydrosulphuric acid gas, a solution of the protochloride of tin being formed.

Sesquisulphide of Tin (Sn_2S_3).—To prepare this, finely-powdered protosulphide of tin is to be mixed with a third of its weight of sulphur, and the mixture is to be heated to moderate redness until sulphur is no longer volatilised. It has a deep grayish-yellow colour, and when strongly heated is re-converted to the state of protosulphide; when heated in hydrochloric acid, hydrosulphuric gas is given out.

Bisulphide of Tin (SnS_2) may be prepared in different modes. When hydrosulphuric acid or hydrosulphate of ammonia is added to a solution of bichloride of tin, a bulky precipitate of a dirty yellow colour is obtained; this is hydrated bisulphide of tin: in the dry way it is procured by heating in a retort 12 parts of tin amalgamated with 6 parts of mercury, rubbed up with 7 parts of sulphur and 6 of chloride of ammonium; the mercury facilitates the combination of the tin and sulphur, and the ammoniacal salt, by its evaporation, appears to prevent the temperature becoming so high as to decompose the bisulphide of tin formed. This substance, formerly known to the alchemists by the name of *Aurum musivum*, or *Mosaic gold*, is in crystalline scales, and sometimes in six-sided plates, of a golden-yellow colour and metallic lustre. It is not soluble in any acid, but nascent chlorine, in the form of what is called *aqua regia*, dissolves it; it is soluble also in solution of potash and soda, forming what have been termed *sulphur salts*. It is used in the arts to give an appearance of bronze to the surface of metals.

Phosphide of Tin is readily formed by adding phosphorus to the melted metal; it is of a silvery-white colour, and soft enough to be cut with the knife. After fusion it crystallises on cooling; when thrown upon a red-hot coal, the phosphorus burns. This compound does not appear to have been accurately analysed. When phosphuretted hydrogen is made to act upon a solution of protochloride of tin, a phosphide is formed, which is readily oxidised by the action of the air.

Iodides of Tin.—To prepare the *protiodide* (SnI), 2 parts of granulated tin are to be heated with 5 parts of iodine; the resulting iodide is a red translucent substance, very fusible, soluble in water, and volatile at a high temperature.

The *Periodide of Tin* (SnI_2) is formed by dissolving the hydrated peroxide of tin, precipitated by an alkali from the solution of the bichloride, in hydriodic acid; it forms crystals of a silky lustre, which are resolved by boiling water into peroxide of tin and hydriodic acid.

Selenide of Tin.—When tin is fused with selenium, they combine with the evolution of light. The compound formed is a spongy mass, of a gray colour and metallic lustre; when heated, selenium is expelled and peroxide of tin remains.

Oxisalts of Tin.

Protonitrate of Tin is formed by dissolving either the metal or the protoxide in dilute nitric acid. A yellow uncrystallisable solution is obtained: by exposure to the air it absorbs oxygen, and peroxide of tin is precipitated.

Pernitrate of Tin.—When tin is acted upon by strong nitric acid, the peroxide formed remains entirely insoluble in the acid; to procure the pernitrate it is best to cause the hydrated peroxide to dissolve in dilute nitric acid. The solution is colourless, and yields no crystals; when diluted or heated, it is rendered turbid.

Sulphates of Tin.—By boiling excess of tin in sulphuric acid, a solution is obtained from which colourless acicular crystals of sulphate of tin (SnO, SO_3) are deposited. When, on the other hand, tin is boiled in excess of sulphuric acid, or hydrated peroxide of tin is dissolved in the acid, persulphate of tin is obtained in solution, but it cannot be made to crystallise.

Phosphates of Tin.—When phosphate of soda is added to a solution of protochloride of tin, an insoluble white precipitate of protophosphate is obtained; the perphosphate, also an insoluble colourless precipitate, may be procured by adding the phosphate of soda to a solution of perchloride of tin.

The characters of the salts of tin are as follow:—The protosalts are white, and the solutions of them are usually colourless; their taste is astringent and metallic, and highly disagreeable; when in solution, they rapidly absorb oxygen, and are converted into the corresponding persalts.

When a plate of lead or zinc is put into a solution of tin, the latter is thrown down in the metallic state. Ferrocyanide of potassium occasions a white gelatinous precipitate when dropped into these solutions, and sulphide of potassium or sodium or sulphuretted hydrogen occasions a coffee-brown precipitate in the salts of the protoxide of tin; neither gallic acid nor infusion of galls occasions any precipitate. When chloride of gold is poured into solutions of protoxide of tin, a purple-coloured precipitate falls. A solution of potash or soda throws down a white precipitate, which dissolves in excess of the alkali. If the solution be boiled, a black powder falls, which is metallic tin; while a compound of peroxide of tin and potash remains in solution. Ammonia throws down a white precipitate, not soluble in excess of the alkali.

Persalts of tin give a white precipitate with caustic alkalies, soluble in excess, the solution not being decomposed on boiling. Sulphuretted hydrogen and sulphide of ammonium give a dirty yellow precipitate, soluble in excess of the alkaline sulphide or in caustic alkalies. Before the blowpipe on charcoal, salts of tin give, in the reducing flame, a white malleable globule of metal.

Estimation of Tin.—This is usually effected in the state of binoxide, of which 78·66 per cent. is metal.

Alloys of Tin.

Most of the malleable metals are rendered brittle by alloying with tin: it combines readily with potassium and sodium, forming brilliant white alloys, which are less fusible than tin; the potassium alloy burns readily when it contains more than one-fifth of potassium. With arsenic it forms a metallic mass which is whiter, harder, and more sonorous than pure tin. With antimony tin forms a white, hard, and sonorous alloy. Bismuth forms with tin an alloy which is more fusible than either of the metals separately, a mixture of equal weights melting at 212°; this compound is hard and brittle. Copper and tin form alloys which are well known and highly useful: they are BELL-METAL and BRONZE. [See, also, BRITANNIA-METAL; PEWTER; SOLDER; and GUN-METAL.] With mercury tin readily amalgamates, and the compound is used for silvering mirrors. With iron, tin forms white compounds, which are more or less fusible according to the proportion of iron they contain. *Tin-plate* is of all the alloys of tin the most useful, and the preparation of this and of pewter are the most extensive applications of this very valuable metal.

In making tin-plate the best iron is employed, and, after being thoroughly cleansed from oxide and grease, by immersion in dilute sulphuric acid and scouring, the plates are dipped into a vessel containing melted tin, on the surface of which tallow floats. These and other similar precautions are necessary to secure the uniform adhesion, or rather alloying, of the two metals. Copper may be tinned by a somewhat similar process.

Moiré métallique is tin-plate to which a beautifully crystalline appearance has been given by moistening the warmed plate with a mixture of equal parts of nitric and hydrochloric acids diluted with its own bulk of water. [MOIRÉ.]

TIN, BUTTER OF. [TIN.]

TIN MANUFACTURE AND TRADE. Referring to other articles for notices of the mineralogical, chemical, and medical characteristics of tin, we shall here treat the metal in its manufacturing and commercial aspects.

Under MINING it is explained in what way the ores of tin are extracted from the mines of Cornwall and other places, and by what processes they are mechanically separated from some of the impurities, and broken into fragments. We shall now take up the details from that point.

Smelting and Refining.—After being reduced to a coarse powder, the ore is roasted or calcined in a reverberatory furnace, until it ceases to exhale arsenical vapours. By this, together with some subsequent processes, it is further cleansed from the admixture of foreign matter and prepared for smelting. The ores of tin raised in Cornwall and Devonshire are always smelted within those counties. The smelting works do not generally belong to the proprietors of the mines, but to other parties who purchase the ore from them. The value is determined by a kind of assay. When several bags of ore, of nearly uniform quality, are conveyed to the smelting works, a small sample is taken from each. These samples, after being blended together, are mixed with about four per cent. of ground coal, placed in an open earthen crucible, and heated in an air-furnace until the ore is reduced. The melted metal is poured into a mould, and the drossy substances which remain in the crucible are pounded in a mortar, in order to separate, and to add to the ingot, any minute granules of tin remaining among them. The ratio of good tin to crude ore determines the value.

The smelting of tin-ores is effected by two different methods. In the first and most common, the ore, previously mixed with culm, is exposed to heat upon the hearth of a reverberatory furnace, in which pit-coal is used as fuel; while in the second, which is applied merely to *stream tin* (the tin procured from stream-works), and which is followed in order to obtain tin of the finest quality, the ore is fused in a blast-furnace, in which wood-charcoal is used for fuel.

In the former process the prepared ore, called *schlich*, is mixed with from one-fifth to one-eighth of its weight of powdered anthracite, or culm, to which a little slaked lime is sometimes added as a flux. These substances are carefully blended together, and a little water is added to the mixture to facilitate the operation of charging the furnace, and to prevent the charge from being blown away by the draft at the commencement of the smelting process. From twelve to twenty-four cwt. of the mixture forms a charge. The charge is spread upon the concave hearth of the furnace; then the apertures by which it is inserted are closed and luted, and the furnace is gradually heated, and kept hot for six or eight hours, by which time the reduction of the ore is complete. When the fusion of the ore is finished, one of the apertures of the furnace is opened, and the melted mass is stirred up to complete the separation of the tin from the scoriæ. These scoriæ consist principally of masses of refuse matter from which no more tin can be profitably extracted, and which are therefore immediately thrown away; but among them are pieces which yet retain a considerable quantity of tin, and which are separated and reserved for further processes. So soon as these refuse matters are removed, a channel is opened, by which the melted tin flows from the hearth into a large vessel, where it is allowed to rest for some time, in order that the impurities may separate. When it has settled, the tin is ladled into moulds, so as to form it into large blocks or ingots. These ingots frequently contain portions of iron, copper, arsenic, tungsten, sulphurets and arseniurets, unreduced oxide of tin, and earthy matters which have not passed off with the scoriæ. To remove these the tin is exposed to the process of *refining*, which commences by placing the blocks or ingots on the hearth of a second reverberatory furnace, and applying a moderate heat. This causes the tin to melt and to flow into a basin provided for it, leaving upon the hearth a residuum consisting of a very ferruginous alloy. Fresh blocks are then placed in the furnace, without removing the unmelted remains of the former, until about five tons of tin have flowed into the basin. This part of the process is termed a *liquation*, and is followed by the actual refining, which is usually effected by plunging billets of green wood into the melted tin in the refining basin, by means of an apparatus erected near it. The heat occasions the disengagement of considerable volumes of gas from the wood, and thus a kind of ebullition is produced in the tin, which causes the lighter impurities to rise to the surface in a frothy form, and the heavier to fall to the bottom. The scum is taken off and returned into the furnace; and when the tin is sufficiently boiled, the green wood is lifted out, and the whole is allowed to settle, in doing which the purest tin rises to the top, that with a trifling admixture of foreign metals remains in the middle, while the foulest portion sinks to the bottom. When the mass becomes so cool that no further separation can take place, the tin is again ladled into moulds. The blocks formed from the lowest part of the tin are usually so impure as to need a repetition of the refining process. A similar effect is sometimes produced by an operation called *tossing;* in which, instead of the ebullition produced by the green wood, the mass of melted tin is agitated by a workman repeatedly lifting a quantity of tin in a ladle, and letting it fall into the basin from a considerable height. After continuing this agitation for some time, the surface is skimmed carefully; and if the upper part of the tin be yet too impure for the market, the refining is rendered more perfect by keeping the metal in a fused state, without agitation, until the impurities separate spontaneously. After refining, the tin is cast into blocks of about three cwt. each. The moulds used for this purpose are frequently made of granite; and the tin thus prepared is sold as *block tin.*

It has been stated that the richer portion of the scoriæ left by the process of smelting is reserved for further operations. Such as contain small grains of tin among the slag or refuse are taken to a stamping-mill, and broken and washed in a similar manner to the ore: while those which contain much tin are re-smelted without any previous preparation. From these scoriæ, which are called *prillion*, an inferior kind of tin is produced by a second smelting.

Of the average quality of tin-ore, as prepared for the smelting-furnaces, 20 parts yield from 12½ to 13 parts of metallic tin, or from 62½ to 65 per cent.; and the quantity of coal required for producing one ton of tin is about a ton and three-quarters. Respecting the time when this economical fuel was substituted for wood-charcoal in the smelting of tin-ores, authorities are at variance; but it is generally supposed to have been about the year 1680. Whatever may have been the precise time or manner of this improvement, its importance is indisputable; and such is the effect of the superior economy of this and other metallurgic operations as performed in England, that experiment has shown the possibility of bringing tin-ore from the Malay countries to this island for the purpose of smelting, and sending the tin back to the East at a lower price than it can be produced for on the spot.

The smelting or reduction of tin by the blast-furnace, with wood-charcoal, is practised on a limited scale for the production of tin of the greatest possible purity. The finest ores supplied by stream-works, and the finer tin sands, are selected for this operation; and as these are free from many of the impurities found in other ores, they do not require calcination. The works in which blast-furnaces are employed are commonly called *blowing-houses.* The furnaces used are about six feet high; the long narrow chimney, after proceeding for some distance in an oblique direction, contains a chamber in which the metallic dust carried off by the blast is deposited. The furnace is lined with a vertical cylinder of cast-iron, coated internally with loam; and it has an opening near the bottom, by which the blast is introduced, either from large bellows or from cylinders. No substance is added to the ore and charcoal, unless it be the residuary matter of a previous smelting; and the proportion of charcoal consumed is about one ton and six-tenths for every ton of tin produced. The melted tin runs from the furnace into an open basin, whence it is run off into a large vessel in which it is allowed to settle. The scoriæ which flow with the metal into the basin of reception are skimmed off, and separated into two portions, one consisting of such as retain tin oxide, and the other of such as have no oxide, but contain tin in a granulated state. The subsequent operations are much the same as with block tin prepared in a reverberatory furnace with pit-coal. In order to convert the blocks of tin produced by the blast-furnace process into the form known as *grain tin*, they are heated until they become brittle, and made to fall from a considerable height in a semi-fluid state, thus producing an agglomerated mass of elongated grains.

From a comparison of the results of the two methods of smelting above described, it appears that the reverberatory furnace with pit-coal occasions less loss of metal than the blast-furnace, and is by far the most economical. The superior quality of the tin produced by the other process is attributable partly to the greater purity of the fuel, and partly to the finer quality of the ore selected for the purpose.

Manufacture of Tin-ware.—It is unnecessary here to enumerate the various purposes to which tin is applied in the useful arts, either as an ingredient in many useful alloys, for which its ready fusibility, its cleanliness, and its beautiful appearance, render it especially valuable, or as the basis of chemical compounds used in dyeing, &c. It is rarely employed alone in our metalline manufactures owing to its softness, but when laid in a thin coat upon the surface of sheet-iron by the process of TINNING, it produces a material of extensive use in the manufacture of culinary and other articles. In this country the greater portion of the tin used in the manufacture of articles composed exclusively of that metal is that which is expanded by rolling or hammering, or by a combination of the two operations, into leaves or sheets barely one-thousandth part of an inch in thickness, under the name of *tin-foil*. [FOIL.]

The art of tin-plate working, or of forming sheets of tinned iron into vessels and utensils, depends more on the manual dexterity of the workman than upon any peculiarity in the tools he requires, which are few and simple, consisting of bench and hand-shears, mallets and hammers, steel heads and wooden blocks, soldering-irons, and swages. In the formation of a vessel the first operation is to cut the plates to the proper size and form with shears; and when the dimensions of the article require it, to join them together, which is done either by simply laying the edge of one plate over that of the other, or by folding the edges together with laps, and then soldering them. Similar joints are required when gores or other pieces are to be inserted, and also at the junction by which a cylinder is closed in. The usual method of forming laps, bends, or folds for this or other purposes is to lay the plate over the edge of the bench, and to bend it by repeated strokes with a hammer. After a tin vessel has been rounded upon a block or mandril, by striking it with a wooden mallet, and the seams finished as above described, all its exterior edges are strengthened by bending a thick iron wire into the proper form, applying it to what would otherwise be the raw edges of the metal, and dexterously folding them over it with a hammer. By this means the appearance of the articles is improved, and their durability and strength are greatly increased. A superior kind of tin-ware, commonly known as *block-tin*, is carefully finished by beating or planishing with a polished steel hammer upon a metal stake; by which means the surface, which otherwise appears somewhat wavy, is made very smooth and silvery, especially after it has been polished with dry whiting. It is principally in the production of block-tin wares that *swaging* is resorted to as a ready means of producing grooved or ridged borders or other embossed ornaments. This process consists in striking the metal between two steel dies or swages, the faces of which bear the desired pattern, and are made counterparts to each other. The mouldings round the edges of dish-covers and other similar articles are produced in this way; the swages embossing the pattern in short lengths, and the article being gradually turned round until every part of its circumference has been submitted to their action. The lower die is usually fixed in an apparatus to which moveable guides are attached to insure the correct position of the article to be operated on, and the upper is made in the form of a hammer, the handle of which is pivoted so as to insure its descent in precisely the right position. Sometimes the requisite power is applied by simply working the upper swage or swage-hammer itself; but in other cases the head of the swage-hammer is struck with a mallet. Very many ornamental articles are produced by embossing or stamping tin-plate, in the same manner as other metallic sheets, with a fly-press or other machinery. Cheap coffin-plates are manufactured at Birmingham in this way; and these and similar articles are sometimes lacquered, painted, or japanned. A very beautiful method of ornamenting tin wares by producing a crystallised appearance on the surface was much practised a few years since, under the name of *moiré métallique*. It is described under MOIRÉ.

Tin forms the principal ingredient in various kinds of pewter and other white metallic alloys, which are manufactured into domestic utensils by casting, stamping, and other processes in which much ingenuity is displayed. The *Britannia metal* manufacture was commenced on a large scale at Sheffield, where it is still carried on, about the year 1770; and the brilliancy, lightness, and cheapness of the wares, which, when well made, greatly resemble silver, have secured for them a very extensive sale in this and other countries. The tin is first melted and raised to a red heat in a cast-iron pot, and then antimony, copper, and brass are successively poured into it from the crucibles in which they have been melted; the mass being stirred during the operation, to complete the mixture. The fusion being completed by the continued application of fire under the pot, the metal is removed by ladles to cast-iron boxes or moulds, in which it is cast into slabs fifteen inches long, six inches wide, and one inch thick; or if for casting small articles, into smaller moulds to form it into convenient ingots. The thick slabs of metal are then extended by passing them between polished steel rollers until they are reduced to the required degree of tenuity. The principal consumption is for candlesticks, tea-pots, coffee-biggins, and other vessels for containing liquids. The feet of candlesticks, the bodies of tea-pots, and other articles having embossed work, are stamped between dies; and when the shape of the article will not allow it to be stamped in one piece, it is stamped in halves, which are subsequently fitted and soldered together. Articles approaching the globular form may in like manner be stamped in three or more pieces. Plaster casts are produced of the required pattern, either from original models or designs, or from manufactured articles of silver; and from these are made moulds or dies of fine hard pig-iron, which, with a very little finishing, form dies fit for stamping so tractable a metal. When very thin, it may even be stamped in dies of brass or of spoon-metal. The great facility with which this alloy may be moulded to any required form is illustrated by the operation termed *spinning*, by which the bodies of tea-pots with concentric circular swells are usually formed. [SPINNING.] Many small vessels, spoons, and other articles are cast in an alloy somewhat harder than that which is rolled into sheets. The facility with which Britannia metal may be run into any shape and cut in the lathe, as for turning measures and small vessels previously formed by casting, is a great recommendation to the manufacturer. Articles of this metal are cleaned from the oil, resin, and other impurities acquired during their formation, by boiling in water containing soap; after which they are polished, either by hand, or more commonly by the buff and brush set in motion by a steam-engine. After buffing and brushing, the articles are boiled in a solution of pearlash, and finally hand-brushed and hand-polished by an application of soft soap, a little oil, and powdered rotten-stone. This operation is usually performed by females; as it is found that no instrument can supply an effectual substitute for a soft hand, which is one of the first requisites inquired for when persons apply for work in this department.

Produce and Trade.—The history of the trade in tin commences with the very earliest records of commercial intercourse with the British islands. We shall only notice it, however, as it has existed within the last two centuries. Davenant gives some interesting information concerning it soon after the middle of the 17th century. In 1663 our exports of tin to all foreign countries amounted to 153 tons; in 1669 to 240 tons; in the three years of peace, from 1698 to 1700, on an average to 1297 tons; and in the ten years of war, from 1700 to 1710, on an average to 1094 tons. In these last ten years the annual purchases of the Dutch amounted to 300 tons, of the estimated value of 21,874*l.* But the produce of the mines more than kept pace with the increased demand; and when Davenant wrote, Queen Anne had between 4000 and 5000 tons of tin on hand, a quantity equal to four or five years' consumption. The produce of the mines went on increasing, and the accumulation to which Davenant alludes is only half a year's produce of the mines at present. From 1750 to 1785 the produce of the mines varied from 2273 tons to 3005 tons; the average price being 64*s.* 6*d.* per cwt. From 1789 to 1816 the annual average quantity was 2875 tons at 79*s.* 9*d.* per cwt. From 1817 to 1837 inclusive, the annual average was 4211 tons, and the average price paid to the tinner was 73*s.* the cwt. In 1787 Banca tin was imported into this country for the first time, and the price of Cornish tin soon fell to 58*s.* the cwt., and would have declined still further if a new market had not been opened. The purser of an Indiaman, who took some tin from the Molucca islands to China in 1787, found the speculation so profitable that the East India Company were induced to direct their attention to the trade, and the Company entered into arrangements with the Cornish tinners for an annual supply. The purchases of the company were made at low prices, but the tinners were indemnified by the artificial scarcity which raised prices in the home market. At first the Company paid only 68*l.* 13*s.* 4*d.* the ton, delivered on board in London; this gradually rose to 80*l.* The connection finally ceased in 1817, as the supply of the home market had become more profitable.

On account of the increasing consumption at home, the portion exported gradually lessened from 7-10ths to 1-5th of the whole. Most of the foreign tin imported is for re-exportation; for it can be supplied to the continent cheaper than English tin. A duty was formerly paid upon all tin raised in Cornwall, to the duchy; but as the mode of stamping the blocks, for the estimation of duty, was very inconvenient, the duty was commuted in 1838 for a perpetual annuity; the duty amounted to about 5*s.* per 120 lbs. Under the tariff of 1842, foreign tin-ore was rendered admissible on payment of a customs' duty of 50*s.* per ton. At present the duty is very light—free if unmanufactured, and 10*s.* per cent. if manufactured. The produce of the British tin mines from 1848 to 1855 varied from 6000 to 7000 tons a year. In 1857 it reached the large amount of 10,000 tons. So varying is the quality, that the price in the last-named year ranged from 18*l.* to 93*l.*; the total value was 750,000*l.*, giving an average of about 75*l.* per ton. This was the value of the ore itself. The metallic tin, after smelting and refining, ranged from 108*l.* to 146*l.* per ton. The English mines which were most productive in that year were the Great Huel Vor, Dolcoath, Carn Brea, Par Consols, and Providence; the produce ranged from 54,000*l.* down to 23,000*l.*, from these five mines.

In the last financial year (1860), there was imported 58,000 cwts. of tin, in blocks, ingots, bars, and slabs; and the exports in the same year amounted to 55,000 cwts. of unwrought tin, besides 1,500,000*l.* in value of tin-plates, in which the greater part of the weight is of iron.

TIN, MEDICAL PROPERTIES OF. It cannot be asserted that tin in a metallic state has no influence over the human system, as many respectable writers affirm that tin-filings are decidedly anthelmintic, and that this is not owing to mechanical irritation of the worms causing them to be detached from the surface of the intestines; it is stated that water in which tin has been boiled, and wine digested in a tin vessel, are also anthelmintic. Others, denying to tin any inherent power over worms, have attributed these effects to the presence of a small portion of arsenic. Be this as it may, it is a very crude method of treating worms to exhibit such a material as tin-filings. [ANTHELMINTICS.] Even oxide of tin is of doubtful efficacy, as might be expected from its extreme insolubility. Its powers may be heightened by occasionally meeting with acids in the stomach, such as the hydrochloric, and therewith forming a chloride. Two compounds of chlorine with tin are known, one the protochloride, the other the bichloride. Both of these are exceedingly soluble; the latter so much so that it can with difficulty be kept in the solid state, and more frequently occurs in the liquid state, and is then called the spiritus fumans Libavii, or butter of tin. The former is much used by dyers, among whom, when in the solid state, it is called *salt of tin*, and when liquid, *spirit of tin*. In the former condition, it has sometimes been mistaken for common salt: it has thus been the source of poisoning, though it is not very active when introduced into the stomach. A few grains of it injected into the jugular vein prove rapidly fatal to dogs. In case of any of it being swallowed, emetics or the stomach-pump, demulcent drinks, such as milk, and, if necessary, moderate venesection, may be employed, followed after a time by vital stimulants. A very weak solution of protochloride of tin in distilled water is used as a lotion in chronic cutaneous diseases. It has been thought by some to be dangerous to allow fluids containing acids, such as the weak acid wines, or cyder, or even fatty, saline, or albuminous substances, to remain long in tin-vessels, as an injurious action of these on the tin is supposed to occur. If any serious effects have ever followed from such a cause, it is most likely that these vessels were only coated superficially with tin, which being rubbed off, exposed the more potent metal beneath to the solvent power of these substances. It is, therefore, prudent to examine from time to time all copper and other vessels to see that the tinning is entire. For small dishes the German enamelled stew-pan is to be commended.

TINCAL. [BORACIC ACID.]

TINCTURES are solutions of the active principles, mostly of vegetables, sometimes of saline medicines, and more rarely of animal matters, in certain solvents. From possessing more or less of colour, they have obtained this name. They are distinguished according to the kind of solvent employed. When alcohol is used, they are termed *alcoholic* tinctures, or more generally simply *tinctures*; when sulphuric ether is used, they are denominated *etherial* tinctures. When wine is used, though differing little from pure alcohol, the term *medicated wines* is applied to them; and when the process of distillation is employed to aid the extraction, particularly of volatile oils, the result is termed a *spirit*, such as of rosemary. Ammonia is sometimes conjoined, and the proceeds termed an *ammoniated* tincture. In some cases less of the principal ingredient is taken up or dissolved when ammonia is used, than when simple alcohol is employed, as in the tinctura guaiaci ammoniata. Formerly some tinctures were called *essences*, from the term *esse*, it being thought that they contained only the purer or more refined portion, the alcohol leaving all the baser principles, such as the starch, gum, woody fibre, &c., undissolved: *quintessence* was a still higher degree of this. These terms are now disused by pharmaceutists, though retained in popular language. *Elixirs* differ only from being of a greater consistence: they are not unfrequently turbid from the extractive matter suspended in them. Tinctures are further distinguished into simple and compound. They are called *simple* when one substance only is submitted to the solvent; *compound*, when two or more are. Another important distinction among tinctures is founded upon the degree of strength of the alcohol employed. Where the active principle is nearly pure resin, a strong spirit is needed; when much gum is associated with the resin, a weaker is required. Hence some tinctures are prepared with *proof* spirit, as the greater number; a few with *spirit above proof*; and some with *rectified spirit*.

A well prepared tincture should be clear, possessing the colour of the article which is its base, and partaking in an eminent degree of its characteristic odour and taste. As a general rule, five or six parts of the liquid chosen is to be used for one part of the solid material, which is to be bruised or comminuted before being submitted to maceration. The maceration, which should be conducted in well-stopped glass vessels, is generally continued for fourteen days, during which the ingredients are to be frequently shaken, and at the end strained. The process of displacement by percolation is also good. The pure tincture is then to be preserved in a tightly-stopped bottle, which should be opaque, or sheltered from the light. From several tinctures a deposit falls down, either from some slow chemical change taking place among the ingredients, or from the evaporation of some of the spirit. This renders old tinctures not unfrequently turbid, and of variable strength. Thus tincture of opium when newly prepared contains one grain of opium in nineteen minims, but after some time one grain of opium is contained in only fourteen minims. This inconvenience may be avoided with all recent vegetables, by forming what are termed "vegetable juices." These are merely the juices of the fresh plant expressed by a powerful wooden press, and the juice allowed to stand twenty-four hours, during which a copious precipitation of feculent matter takes place, which is further promoted by adding alcohol 56° over proof, in the proportion of four fluid ounces to every sixteen fluid ounces of the juice. After standing for twenty-four hours, the juice is to be filtered through bibulous paper (prepared from wool), when it will keep unimpaired for a length of time.

These vegetable juices always retain their purity, and are of the same degree of strength at last as at first. By this means not only is the process simplified, and the time required for their preparation greatly abridged, being reduced from fourteen days to two; but their medicinal efficacy is greater than that of the ordinary tinctures, and, from containing less alcohol, they can be given in cases where the stimulating action of this principle interferes with the effect of the substance dissolved in it, or renders its exhibition improper, as in the case of young children.

In preparing the officinal *spirits*, the directions of the Pharmacopœia are rarely complied with. Most chemists content themselves with dissolving some of the essential oil of the plant in alcohol of the requisite strength, by which much expense and trouble, as well as loss of time, are avoided.

(See a pamphlet on *The Best Method of Obtaining the Most Powerful Vegetable Preparations for Medical Use*, by Edward Bentley.)

TINNING; TIN-PLATE. The art of tinning, or of coating other metals with a thin layer of tin, so as to protect them from oxidation, was known to the ancients, although it does not appear to have been very extensively practised. During many centuries, England procured tin-plate from Bohemia and Saxony, where the manufactory was established near the tin-mines of the Erzgebirge mountains, which were the most extensive in Europe after those of Cornwall. From the time of the invention of tin-plate down to the close of the 17th century, if not later, both England and the whole continent of Europe depended upon the above-named countries for their supply of tin-plate; but about the year 1665 an attempt was made to introduce the manufacture into England. The manufacture was permanently established at Pontypool in Monmouthshire about the year 1730, and soon afterwards in France. About 1740 the manufacture was brought to such perfection in England that very little was imported from foreign countries; the British manufacture was superior to the foreign in glossiness of surface, owing to the plates being drawn under a rolling-mill, instead of being hammered, as was common in those made beyond sea. The difficulty of extending iron, in what may be deemed the infancy of the manufacture, into thin uniform sheets, with a perfectly smooth and clean surface, which is essential to the adhesion of the tin in an equal film, was one of the principal obstacles to the progress of this department of the art of tinning.

The process of tinning depends upon the strong affinity which exists between tin and the metals to which it is applied. The tinning of sheet-iron, as the most important application of the process, will be first noticed. The finest English or Welsh bar-iron, prepared with charcoal instead of mineral coke, and known to the trade as *tin-iron*, is used for making tin-plates. This material is first made into flat bars, or slabs, about 30 inches long, 6 inches wide, and weighing eighty pounds. These bars are made red-hot, and extended by passing them repeatedly between rollers, until they are reduced to about 3·8ths of an inch in thickness. When cooled, the pieces are cut by shears, worked by machinery, into plates about 10 inches by 6, which are repeatedly re-heated and rolled, until they are reduced to as thin a state as the process will conveniently allow. The sheet is then doubled and again rolled until reduced in thickness one-half, after which it is doubled again, and rolled until still further diminished in thickness. When thus brought to the required tenuity, the thin sheet is cut into plates of the sizes required to suit the market (most commonly about 13 inches by 10), and then the several thicknesses or laminæ are separated. After shearing, the plates are piled in heaps, one being laid cross-wise at intervals, to separate the number required to form a *box*. This name is technically applied to 225 plates in all the subsequent processes, although it is not until they are completed that the plates are actually placed in boxes.

The next operation to be performed is the removal of every particle of oxide or other impurity from the surface of the plates. For this purpose each is steeped for a few minutes in a leaden trough containing a weak solution of muriatic acid. The plates are taken out, arranged on the floor in rows, and then removed, by means of an iron rod, to a reverberatory furnace or oven, in which they are submitted to a red heat. The heat to which the plates are exposed, combined with their previous washing in the acid, causes them to throw off a scale of rust or oxide. The plates are then flattened by beating them upon a cast-iron block, and are submitted to a second or *cold* rolling, which removes any warping acquired in the previous processes, gives a high degree of smoothness to their surfaces, and imparts elasticity to the iron. After the *cold rolling* the plates are immersed singly, in a vertical position, in an acidulous preparation consisting of water in which bran has been steeped for nine or ten days, until it has fermented and become slightly acid. In this the plates are kept for ten or twelve hours, and occasionally turned, to insure an equal exposure of every part of their surface; and from the lye-trough they are transferred to a leaden vessel containing diluted sulphuric acid. This trough and the lye-trough are slightly heated by flues, to assist the action of the acid menstrua. The plates are usually agitated in the weak sulphuric acid for about an hour, until they become bright and free from black spots. They are then removed into pure water, in which they are scoured with hemp and sand, to remove any remaining oxide; and in this bath of pure water the plates remain until wanted for tinning; because, even if left for months, they will remain perfectly free from rust.

As the sole object of these operations is to cleanse the iron plates from rust and dirt, it is evident that the details may be varied considerably; but it is not necessary to notice particularly any deviations from the usual process. The *tinning* of the plates is effected in a range of cast-iron pots heated by flues, and forming together an apparatus called the *stow.* The plates are removed one by one from the bath of pure water, and dried by rubbing with bran, after which they are immersed singly in a pot filled with melted tallow or grease, in which they are left for about an hour. The grease preserves the surface from oxidation, and appears also to increase the affinity of the iron for tin. From the grease-pot the plates are removed into the metallic bath, which contains a mixture of block and grain tin, covered with a quantity of grease sufficient to form a layer four inches deep. The mixture of block and grain tin usually contains about equal quantities of each. The tin-bath or pot is heated to such a degree as almost to inflame the fatty mixture upon the surface of the tin; and its dimensions are such that it will receive two or three hundred plates standing upright on their edges. When the plates have remained in the tin-bath about an hour and a half, they are lifted out with tongs, and placed upon an iron grating, to allow the superfluous tin to drain off; but as there still remains upon them much more than the proper quantity of tin, they are afterwards subjected to a process called *washing.* This consists in dipping them into a pot containing a quantity of pure grain-tin in a melted state, then rubbing them with a peculiar kind of brush made of hemp, plunging them again for a moment into the melted tin, and then into a pot filled with clean melted tallow. The heat of this second tin-bath melts and detaches the superfluous and coarser portions of the tin from the plates, and the drossy impurities rise to the surface; while the other portions unite with the grain-tin. The last dip serves to eradicate the marks of the brush, and to replenish the coat of tin wherever it may have been rubbed too thin; and the subsequent immersion of the plates in the grease-pot causes any superfluous metal to run off. Thick plates require the tallow to be cooler than for thin ones, because they retain more heat in themselves. So soon as the workman employed in washing has placed five plates in the grease-pot, a boy lifts the first from it into a draining-pan with a grated bottom; and when the man has placed the sixth in the tallow, the boy removes the second. Notwithstanding the apparently complicated character of the operations just described, they are performed so rapidly, that an expert wash-man will wash and brush twenty-five boxes, or five thousand six hundred and twenty-five plates, in twelve hours.

Owing to the vertical position of the plates during the preceding operations, a selvage of tin accumulates along their lower edge, which is removed by the process called *listing.* This is performed by taking the plates one by one, as soon as they are cool enough to handle, and dipping their lower edges into a pot called the *list-pot*, or *listing-pot*, which contains enough melted tin to form a layer a quarter of an inch thick. The selvage of tin being thus melted, is shaken off by a smart blow with a stick, leaving only a faint stripe, which may be discerned upon all finished tin-plates. After listing, the plates are cleaned from grease by rubbing them, while yet warm, with dry bran; after which they are packed in boxes of wood or sheet-iron.

The tinning of the inner surfaces of cooking utensils and other vessels is performed by scouring the surface until it is perfectly bright and clean; then heating the vessel, pouring in some melted tin and rolling it about, and rubbing the tin all over the surface with a piece of cloth or a handful of tow: powdered resin is used, as in soldering, to prevent the formation of oxide, which would impair the mutual affinity of the metals. Pure grain-tin should be used for this purpose, but it is frequently adulterated with lead. By this means vessels of copper, brass, and cast-iron are tinned internally, and thereby rendered fit for the most delicate culinary operations; and in a similar way any small portions of iron-plate may be coated with tin. Bridle-bits, stirrups, and many other small articles, are tinned by immersing them in fluid tin. So also are pins, as described in PIN MANUFACTURE.

Analogous in many respects to tinning are several processes which have been introduced or described within the last few years. All of these relate to the application of a thin layer of one metal to a thicker portion of another. So far as they are examples of electrotyping, they will be found described under ELECTRO-METALLURGY and PLATING; but most of them occupy a medium place between electrotyping and tinning. Messrs. Morewood and Rogers have obtained patents for coating lead with zinc, depending on the difference of melting-points between the two metals. Lead may also be coated with tin or solder by sprinkling it with sal ammoniac, heating it, and rubbing a stick of tin or solder upon it. Tinned lead may even be added to tinned iron, by sprinkling the surfaces with sal-ammoniac, heating them, placing them in contact, and pressing them between heated rollers. Methods have been devised for coating iron with copper; bearing some analogy to that for making tin-plate; and the resulting product has been recommended for use as a cheap substitute for copper in roofing, sheathing, &c. Messrs. Grissell and Redwood have devised a mode in which this coating of one metal with another has been applied widely. Iron may be coated with zinc, silver, or copper; and zinc with such metals and alloys as melt at a lower temperature. The softer material is fused; the surface is sprinkled with any one among several chlorides or sulphates; and the harder plate is dipped into the molten metal. Certain metals may be coated with silver by dipping them into a bath of mercury before that of silver. At Woolwich Arsenal, a method has been tried of coating iron nails with copper. Some schemes have been brought forward, in which an electric shock, instead of a steady galvanic current, is used to induce deposition of one metal on another.

The trade or commerce in tin-plates is noticed under TIN MANUFACTURE AND TRADE.

TINNITUS AURIUM, ringing in the ears, may arise from many different conditions. It is sometimes due to an unnatural state of the circulation in some part of the ear, the movement of the blood producing a vibration of the nerve which the mind does not distinguish from that produced by sonorous vibrations of the air. But most frequently the sensation is due to some disordered state of the auditory nerve, and is entirely subjective. It is thus perceived in some diseases of the brain, in nervous persons, and in those who are much debilitated; and is a common sign of organic disease of the auditory nerve itself. It is analogous, in these cases, to the subjective sensation of sparks and flashes of light which is perceived in cases of disease of the retina or optic nerve. It may therefore be a sign of a dangerous condition, or a prelude to complete deafness; but in the great majority of cases it is unimportant, depending on some local temporary affection of the ear, or on some disturbance of the digestive organs with which part of the brain sympathises.

TISRI, the first Jewish month in civil reckoning, is written in Hebrew תִּשְׁרִי. The name is not mentioned in the Bible, but it is found on the monuments of Palmyra. Tisri has thirty days, and it corresponds with our September or October: in the present year, 1861, it will begin on the 5th September and end on the 4th October. The first day of the month must not be either Sunday, or Wednesday, or Friday; and to prevent this from occurring, the months of Chisleu and Marchesvan may have a day added or subtracted. The great fast of Kippur [expiation], or day of atonement for the expiation of sins, is commanded for the 10th day of this month in Lev. xvi. 29, and again at xxiii. 27; and so great is the sanctity of this fast, that it is held on the Sabbath, when the case occurs, whereas all fasts but this are observed on another day in such cases. Another fast is kept on the third of the month for the murder of Gedaliah, who was made governor of the Jews by the Babylonians after the capture of Jerusalem. (Jerem. xl., xli.) The feast of Tabernacles is celebrated from the 15th to the 21st of the month, as directed in the 23rd chapter of Leviticus, as a rejoicing at the close of the harvest. A feast for the delivery of the law, and for the dedication of the Temple by Solomon, is held on the 22nd day: in the 8th chapter, 2nd verse, of the 1st book of Kings, where this is related, the month is called Ethanim. [BUL; ETHANIM.]

TITANIC ACID. [TITANIUM.]

TITANIUM (Ti). This metal does not occur in the free state in nature, but as a binoxide (titanic acid) it is not uncommon. In the latter condition, associated with protoxide of iron, it forms titaniferous iron-ore, deposits of which are found in various parts of the world. [TITANIUM, in NAT. HIST. DIV.] The variety known as ilmenite is met with in large quantity in Canada. At Bay St. Paul, on the St. Lawrence, ilmenite is found in large beds from one to three hundred feet long, and ninety feet thick. It is massive, of sp. gr. 4·6, and contains, according to an analysis by Mr. S. Hunt:—

Titanic acid	48·60
Protoxide of iron	37·06
Peroxide of iron	10·42
Magnesia	3·60
	99·68

Another kind of titaniferous iron-ore is met with in enormous quantity in New Zealand, forming, in the state of fine sand, a beach at New Plymouth several miles in extent. The following analyses of specimens taken from different parts of the deposit, will at once indicate the nature of this deposit:—

Oxide of iron	88·45
Titanic acid	11·43
	99·88

Oxides of iron	61·14
Titanic oxide	29·73
Sand	5·13
	96·00

A combination of cyanide and nitride of titanium $(TiCy, 3Ti_3N)$ in the form of reddish-brown metallic-looking cubes, is nearly always found among the slags and cinders that occur in the bottom of iron furnaces. These crystals are hard enough to scratch agate, and are attacked only by a mixture of nitric and hydrofluoric acid, or by fusion with nitre.

Titanium may be isolated by heating sodium in the vapour of bichloride of titanium. The small prisms thus obtained are soluble in hydrochloric acid with evolution of nitrogen.

The equivalent of titanium is 25.

Oxygen and *titanium* appear to form three compounds:—

Protoxide of titanium (TiO).—When titanic acid is exposed to a strong heat, a portion of it loses oxygen, and a black mass is formed, which is probably the protoxide. It has an earthy fracture, is insoluble in acids, and is difficult to reconvert to the titanic acid. It has been already mentioned in the Natural History Division of this Cyclopædia that anatase is probably the protoxide of titanium.

Sesquioxide of titanium ($Ti_2O_3 = TiO, TiO_2$).—When rutile or titanic acid is dissolved in hydrochloric acid, a piece of zinc immersed in the solution occasions the formation and precipitation of a deep purple-coloured powder, which is hydrated sesquioxide of titanium. It returns to the state of peroxide very rapidly. It is slightly soluble in hydro-chloric acid, forming a blue solution.

Peroxide of Titanium, Titanic Acid (TiO_2).—Rutile is titanic acid nearly pure; when it is reduced to fine powder and fused in a platinum crucible, with three times its weight of carbonate of potash, titanate of potash is obtained, mixed with some excess of carbonate of potash; this is to be removed by washing with water, and titanic acid is then precipitated by dilution and heat; after washing with dilute hydrochloric acid it is nearly pure. It is quite white, very infusible, and after it has been heated is soluble only in hydrofluoric acid. Its acid powers are feeble; it is insoluble in water, and does not act on vegetable blues; it combines, however, with alkalies and metallic oxides, forming salts which are termed *titanates*.

Titanic acid somewhat resembles stannic and silicic acids. It may be separated from the latter by fusion with bisulphate of potash and subsequent solution of the mass in water, silica remaining insoluble.

Bichloride of Titanium ($TiCl_2$) is formed when chlorine gas is passed over metallic titanium at a red heat. It is a colourless transparent fluid, boils at 277°, and is volatilised, and condenses unchanged. When exposed to the air it deliquesces, and when a few drops of it are mixed with an equal bulk of water, combination takes place with considerable violence and the evolution of intense heat. It absorbs dry ammoniacal gas, and forms ammonio-chloride of titanium ($2NH_3, TiCl$).

Tests for Titanium.—Tincture of galls or ferrocyanide of potassium produce, when added to a solution of titanic acid, an orange-red precipitate.

The other compounds of titanium are but little known. The metal is always estimated in the form of titanic acid.

TITANS (Τιτᾶνες, fem. Τιτανίδες) is the name by which, in the mythology of ancient Greece, a certain class of sons and daughters of Uranus and Gaea are designated. The original name of Gaea was said to have been Titæa, from which Titans was derived. (Diodorus Sic., iii. 56.) The beings generally comprised under the name of Titans were Oceanus, Cœus, Crius, Hyperion, Iapetus, Kronos, Thetys, Rhea, Themis, Mnemosyne, Phœbe, Dione, and Theia (Apollodor., 'Biblioth.,' i. 1, 3; Diodorus Sic., v. 66); but writers, as Stephanus of Byzantium (*s. v.* Ἄδανα), Pausanias (viii. 37, 3), and others, differ both in the names and numbers of the Titans. Uranus had by Gaea two other sets of children, namely, the Hecatoncheires (centimani, or beings with a hundred arms), and the Cyclops; and these two he cast into Tartarus, at which Gaea, their mother, was so indignant that she induced Kronos and the Titans to revolt against their father, Uranus, with the result already told under KRONOS. When Zeus, in his turn, made war against his father, Kronos, the latter again called the Titans to his aid. A struggle ensued, which lasted for ten years, and is celebrated in mythology as the Titanomachia, or war of the Titans. It was terminated by Zeus relieving the Cyclops from Tartarus, and by his gaining with their weapons the victory over the Titans, who were now cast into Tartarus, and were guarded there by the Hecatoncheires, while Zeus and his brothers divided the sovereignty of the world among themselves. (Apollodor., 'Biblioth.,' i. 1 and 2.)

The name Titan has also been given to those superhuman beings who were descended from the Titans, such as Prometheus, Hecate, Latona, Pyrrha, Helios, &c. It moreover occurs as a designation of a very early race of men in Crete and Egypt.

(Lobeck, *Aglaophamus*; Böttiger, *Ideen zur Kunstmythologie*; Völcker, *Mythologie des Japetischen Geschlechtes*.)

TITHES are the tenth part of the increase yearly arising and renewing from the profits of lands, the stock upon lands, and the personal industry of the inhabitants, and are offerings payable to the church, by law. Under the Jewish system, the tenth part of the yearly increase of their goods was due to the priests. (Numbers xviii. 21; Deut. xiv. 22; Levit. xxvii. 30, 32.)

In the earliest ages of the Christian church, offerings were made by its members at the altar, at collections, and in other ways; and such payments were enjoined by decrees of the church, and sanctioned by general usage. For many centuries, however, they were voluntary. But when the church had increased in power, and began to number amongst its members many who adhered to it because it was the prevailing religion, it was deemed necessary to enforce certain fixed contributions for the support of the ministers of religion. The church relied upon the example of the Jews, and claimed a tenth. Meanwhile, the conversion of temporal princes to Christianity, and their zeal in favour of their new faith, enabled the church to obtain the enactment of laws to compel the payment of tithes. In England, the first instance of a law for the offering of tithes was that of Offa, king of Mercia, towards the end of the 8th century. He first gave the church a civil right in tithes, and enabled the clergy to recover them as their legal due. The law of Offa was at a later period extended to the whole of England by King Ethelwulph. (Prideaux, 'On Tithes,' 167.)

At first, though every man was obliged to pay tithes, the particular church or monastery to which they should be paid appears to have been left to his own option. In the year 1200, however, Pope Innocent III. directed a decretal epistle to the archbishop of Canterbury, in which he enjoined the payment of tithes to the parsons of the respective parishes. This parochial appropriation of tithes has ever since been the law of England. (Coke, 2 'Inst.' 641.)

The tithes thus payable were of three kinds—*prædial, mixed*, and *personal*. *Prædial* tithes are such as arise immediately from the ground, as grain of all sorts, fruits, and herbs. *Mixed* tithes arise from things nourished by the earth, as colts, calves, pigs, lambs, chickens, milk, cheese, and eggs. *Personal* tithes are paid from the profits arising from the labour and industry of men engaged in trades or other occupations; being the tenth part of the clear gain, after deducting all charges. It is sometimes stated that personal tithes seem to have been generally commuted for the more moderate tribute of Easter Offerings; unless in fishing-towns, or other places where peculiar circumstances have caused a continuance of the primitive usages.

Tithes are further divided into *great* and *small*. The great tithes consist of corn, hay, wood, &c.; the small tithes consist of the prædial tithes of other kinds, together with mixed and personal tithes. This distinction is arbitrary, and not dependent upon the relative value of the different kinds of tithe within a particular parish. Potatoes, for instance, grown in fields, have been adjudged to be small tithes, in whatever quantities planted; while corn and hay in the smallest portions still continue to be treated as great tithes. The distinction is of material consequence, as great tithes belong, of right, to the rector of the parish, and small tithes to the vicar.

No tithes are paid for quarries or mines, because their products are not the increase, but are part of the substance of the earth. There may, however, be tithes of minerals by custom. Neither are houses, considered separately from the soil, chargeable, as having no annual increase. By the common law of England no tithe is due for wild animals such as fish, game, &c.; but there are local customs by which tithe has been paid from such things from time immemorial, and in those places such customary tithes may be exacted. Tame animals, kept for pleasure or curiosity, are also exempt from tithes.

Tithes were originally paid in kind, that is, the tenth wheat-sheaf, the tenth lamb or pig, as the case might be, belonged to the parson of the parish as his tithe. The inconvenience and vexation of such a mode of payment are obvious, but no attempt had been made in this country, till very recently, to introduce a general improvement in the mode of collection. The inconvenience of paying tithes in kind must long since have been felt, and certain modes of obviating it were occasionally practised. Sometimes the owner of land would enter into a composition with the parson or vicar, with the consent of the ordinary and the patron of the living, by which certain land should be altogether discharged from tithes, on conveying other land for the use of the church, or making compensation. In other words, the owner of the land purchased an exemption from tithes. Such arrangements between landowners and the church were recognised by law; but it was found that they were often injurious to the church by reason of an insufficient value being given for the tithes. The acts 1 Elizabeth, c. 19, and 13 Elizabeth, c. 10, were accordingly passed, which disabled archbishops, bishops, colleges, deans, chapters, hospitals, parsons, and vicars, from making any alienation of their property for a longer term than twenty-one years or three lives. In order to establish an exemption from tithes on the ground of a real composition, it is therefore necessary to show that such composition had been entered into before the statutes of Elizabeth. Since that time compositions have rarely been made, except under the authority of private acts of parliament.

Another method of avoiding the payment of tithes in kind was by a *modus decimandi*, commonly called a *modus*. This consists of any custom in a particular place, by which the ordinary mode of collecting tithes has been superseded by some special manner of tithing. In some parishes the custom has prevailed, time out of mind, of paying a certain sum of money annually for every acre of land, in lieu of tithes. In others, a smaller quantity of produce is given, and the residue is made up in labour, as every twelfth sheaf of wheat instead of the 10th, but to be housed or threshed by the tithe-payer.

A large portion of the land of England and Wales is tithe-free from various causes. Some has been exempted under real composition, as already explained, and some by prescription, which supposes a composition to have been formerly made. The most frequent ground of exemption is that the land once belonged to a religious house, and was therefore discharged in the following manner:—All abbots, priors, and other heads of religious houses, originally paid tithes from the lands belonging to them, until Pope Paschal II. exempted all spiritual persons from paying tithes of lands which were in their own hands. This general discharge continued till the time of King Henry II., when Pope Adrian IV. restrained it to the three religious orders of Cistercians, Templars, and Hospitalers, to whom Pope Innocent III. added the Præmonstratenses. These four orders, on account of their exemption, were commonly called the privileged orders. The Council of Lateran, in 1215, further restrained this exemption to lands in the occupation of those religious orders of which they were in possession before that council. Bulls were, however, obtained for discharging particular monasteries from the payment of tithes, which would not otherwise have been exempt; by which means much land has been ever since tithe-free. Another mode by which lands belonging to religious houses became not liable to the payment of tithes was that of *unity of possession;* as where the lands and the rectory belonged to the same establishment, which would not, of course, pay tithes to itself. Yet the lands were not absolutely discharged by this unity of possession, for, upon any disunion, the payment of tithes was revived; so that the union only suspended the payment. The act 31 Hen. VIII. c. 13, which dissolved several of the religious houses, continued the discharge of their lands from tithes, though in the possession of the king or any other person by grant from the crown; and, in consequence of this, the lands of many laymen which were granted by the crown are tithe-free, and the right to tithe and the property in many rectories are vested in laymen. Many monasteries had previously been dissolved by act of parliament, but as no such clause as that contained in the 31 Hen. VIII. had been introduced into other acts, the lands of the monasteries dissolved by them became chargeable with tithes.

The payment of tithes in kind has been a cause of constant dispute between clergymen and their parishioners. With the best intentions on both sides, the very nature of tithes is such, that doubts and difficulties must arise between them: and even where there is no doubt, the form and principle of payment are odious and discouraging. Commutation of the tithes has accordingly been attempted and has been found most successful. Dr. Paley, who saw so clearly the evils of tithes, himself suggested this improvement. "No measure of such extensive concern appears to me so practicable, nor any single alteration so beneficial, as the conversion of tithes into *corn-rents.* This commutation, I am convinced, might be so adjusted as to secure to the tithe-holder a complete and perpetual equivalent for his interest, and to leave to industry its full operation and entire reward." ('Moral and Political Philosophy,' chap. xii.) This principle of commutation was first proposed to be applied by the legislature to Ireland. In addition to the common evils of a tithe system, that country was labouring under another. The mass of the people, who are Roman Catholics, were paying tithes to a Protestant clergy. Resistance to the payment of tithes had become so general that a commutation was deemed absolutely necessary for the safety of the church of Ireland. It was recommended by committees of both houses of parliament in 1832, but not finally carried into effect until 1838.

The statutes for the general commutation of tithes in England are the 6 & 7 Wm. IV. c. 71, the 7 Wm. IV., and 1 Vict. c. 69, the 1 & 2 Vict. c. 64, the 2 & 3 Vict. c. 32, and the 5 & 6 Vict. c. 54. Their object is to substitute a rent-charge, payable in money, but in amount varying according to the average price of corn for seven preceding years, for all tithes, whether payable under a *modus* or composition, or not. A voluntary agreement between the owners of the land and of the tithes is first promoted, and in case of no such agreement, a compulsory commutation is effected by tithe-commissioners; provision being made for the valuation and apportionment of tithe in every parish of England and Wales. Land not exceeding 20 acres may also be given by a parish, on account of any spiritual benefice or dignity, as a commutation for tithes to ecclesiastical persons, but not to lay impropriators.

The complete and final commutation of tithes must be regarded as a most valuable measure. It is perfectly fair to all parties, and is calculated to add security and permanence to the property of the church, and to remove all grounds of discord and jealousy between the clergy and their parishioners. Nor must we omit to mention an improvement in the mode of recovering tithes, consequent upon the commutation. There were formerly various modes of recovery, in the ecclesiastical as well as in the civil courts, and before justices of the peace, all more or less leading to unseemly litigation. The present mode of recovering the rent-charge, if in arrear, is by distraining for it upon the tenant or occupier, in the same manner as a landlord recovers his rent; and if the rent-charge shall have been forty days in arrear, possession of the land may be given to the owner of the rent-charge until the arrears and costs are satisfied. Indeed, the whole principle of the Tithe Commutation Act is to strip tithes of the character of a tax, and to assimilate them as much as possible to a rent-charge upon the land. [TITHING; SHIRE.]

TITHING (*Tithinga*, from the Saxon, *Theothunge*) is an ancient municipal division of land in England under the Saxon kings. The whole country was divided into tithings and hundreds by Alfred the Great. The former was a district containing ten heads of families; the latter comprised ten tithings, or one hundred heads of families. Every tithing had its chief man annually appointed to preside over the rest, who was called the tithing-man or borsholder, and sometimes the headborough or borough's elder. Each of these little communities was bound to keep the peace within their own jurisdiction, and the members were responsible for each other. So important were these associations deemed to be, that no man was allowed to abide in England above forty days without being enrolled in some tithing. Although the institution has long ceased, the name and division are still retained in many parts of England.

TITLE. [VENDORS AND PURCHASERS.]

TITLE-DEEDS. [VENDORS AND PURCHASERS.]

TITLES OF HONOUR are words or phrases which certain persons are entitled to claim as their right, in consequence of certain dignities being inherent in them. They vary in a manner corresponding to the variety of the dignities, or, in other words, with the rank of the possessor. Thus Emperor, King, Czar, Prince, are titles of honour, and the possessors of the high dignities represented by these words are, by the common consent of the civilised world, entitled to be so denominated, and to be addressed by such terms as Your Majesty and Your Royal Highness. These are the terms used in England, and the phrases in use in other countries of Europe do not much differ from them. In fact one European nation seems to have borrowed from another, or all to have taken their titles of honour for this exalted rank from a common original; so that little of the peculiar genius of the European nations can be traced in the terms by which they show their respect for the persons of highest dignity. But it is different when we come to compare them with the Oriental nations. In those seats of ancient civilisation the most extravagant terms of compliment are in use, and a little sovereign of a wandering tribe rejoices in titles of honour numerous and inflated in the highest degree. In the series of Roman emperors, the word Cæsar, originally the name of a family, became a title of honour; Augustus was another; and Pater Patriæ a third.

The five orders of nobility in England are distinguished by the titles of honour, Duke, Marquess, Earl, Viscount, and Baron; and the persons in whom the dignity of the peerage inheres are entitled to be designated by these words, and in any legal proceedings are to be thus designated; that is, the law or the custom of the realm guarantees to them the possession of these terms of honour, as it does of the dignities to which they correspond. They are also entitled to be addressed by such phrases as My Lord, My Lord Marquess, My Lord Duke, and they have usually prefixed to their titles, properly so called, certain phrases, as High and Mighty Prince, Most Noble, Right Honourable, varying with the kind and degree of the dignity possessed by them. The other members of the families of peers have also their titles of honour. Thus the lady of a peer has rank and titles corresponding with those of the husband. All the sons and daughters of peers are Honourable, but the daughters of earls and peers of a higher dignity are entitled to the distinction of being called Lady, and the younger sons of dukes and marquesses are by custom addressed as My Lord.

The orders of nobility in other European countries differ little from our own. They have their Dukes, Marquesses, Counts, Viscounts, and Barons. We cannot enter into the nice distinctions in the dignities of foreign nations, or in the titles of honour which correspond to them.

The Baronet, which is a new dignity, not having been known before the reign of James I., has, besides its name, which is placed after the name and surname of the person spoken of, the privilege of prefixing Sir; and their wives are entitled to the prefix of Dame, and to be addressed as My Lady and Your Ladyship. The title is, like the titles of peers, hereditary.

Another dignity which brings with it the right to a title of honour is that of Knighthood, and this is not hereditary. This dignity is of ancient origin, and, in the form in which we now see it, may be traced far into the depths of the middle ages, if it be not, as some suppose, a continuation of the Equites of Rome. Persons on whom this honour is conferred take rank above the gentlemen and esquires, and are entitled to the prefix Sir to their former name and surname. Their wives are also entitled to prefix the word Dame, and to be addressed by the compellation Your Ladyship or My Lady. The knights of particular orders, as of the Garter, the Thistle, St. Patrick, the Bath, are a kind of select number of the body of the knighthood; and the name of the order to which they belong is ordinarily used by and of them, and thus becomes of the nature of a title of honour. The Bannerets of former ages were a class of knights superior to the ordinary knight-bachelor, forming in fact an order intermediate between the knight, in its ordinary sense, and the baron.

Besides these, there are the ecclesiastical dignities of Bishop and Archbishop, which bring with them the right to certain titles of honour besides the phrases by which the dignity itself is designated. And custom seems to have sanctioned the claim of the persons who possess inferior dignities in the church to certain honourable titles or compellations; and it is usual to bestow on all persons who are admitted into the clerical order the title of Reverend.

There are also academical distinctions which are of the nature of titles of honour, although they are not usually considered to fall under the denomination. Municipal offices have also titles accompanying them; and in the law there are very eminent offices the names of which become titles of honour to the possessors of them, and which bring with them the right to certain terms of distinction.

All titles of honour appear to have been originally names of office. The earl in England had in former ages substantial duties to perform in his county, as the sheriff (the Vice-Comes or Vice-Earl) has now; but the name has remained while the peculiar duties are gone, and so it is with respect to other dignities. The emperor or king, the highest dignity known in Europe, still performs the duties which originally belonged to the office, or at least the most important of them, as well as enjoys the rank, dignity, and honours; and on the Continent there are dukes and earls who have still an important political character.

Whoever wishes to study this subject in all its details, will do well to resort to two great works: one, the late 'Reports of the Lords'

Committees on the dignity of the Peerage;' the other, the large treatise on 'Titles of Honour,' by the learned Selden. The latter was first printed in 4to, 1614; again, with large additions, folio, 1631.

TOBACCO CULTURE AND TRADE. Tobacco is the common name of the plants belonging to the Monopetalous genus *Nicotiana*. Tobacco was the name used by the Caribbees for the pipe in which they smoked; but this word was transferred by the Spaniards to the herb itself. The genus *Nicotiana* contains about forty species, most of them yielding tobacco for smoking, and many of them cultivated in the gardens of Europe. The name *Nicotiana* was given to these plants after Jean Nicot, of Nismes, in Languedoc, who was an agent of the king of France in Portugal, and there procured the seeds of the tobacco from a Dutchman who had procured them in Florida. Nicot sent them to France in 1560.

The botanical characteristics of the tobacco-plant are described under NICOTIANA in the NAT. HIST. DIV.; its medical uses are discussed under NICOTIANA TABACUM in the present Division; and its chemical properties under NICOTINE. We need scarcely revert to the following points: that the common Virginian tobacco, the *Nicotiana tabacum*, is the chief kind; and that the Orinoco, Turkish, and Persian are the kinds ranking next in extent of use.

Cultivation.—The cultivation of tobacco is most extensively carried on in the United States of America. The plant requires considerable heat to come to perfection; but with care and attention, and by treating it as an exotic, it may be very successfully cultivated in much colder climates. The least frost injures it. The seeds of the tobacco-plant are sown in a prepared seed-bed, and carefully protected from frost; for which purpose straw and fern are used. When once the danger of spring frosts is over, they may be safely transplanted into ground which has been laid in narrow beds with intervals between them, dug out deep, and richly manured with sheeps' dung. These beds are two feet wide at top, and two feet six inches at bottom, with sloping sides to keep the earth up; the intervals are only six or eight inches, and serve not only as drains to keep the beds dry, but as paths from which the surface of the beds may be stirred and weeded. Two rows of plants about eight inches high are planted at equal distances along the beds; the rows are sixteen or eighteen inches apart, and the plants at the same distance from each other. In warmer climates the plants are placed three feet apart, as there they grow to a much greater size, and cover more ground. A moist day is chosen for transplanting. The plants are taken up carefully with a small spade or trowel without shaking the earth much from the roots; they are placed slanting in a shallow basket, and thus carried to the prepared beds; they have a stem six or eight inches long. They are inserted into holes made by a proper instrument, so that the fibres of the roots and the adhering earth may be completely buried up to the bottom of the stem. Four or six leaves should be on the plant; if more, the lowest are pinched off. Great attention is paid to the beds all the time the tobacco is growing; weeds are carefully eradicated, and the earth repeatedly stirred between the plants with hoes and narrow spades to accelerate the growth. When the plants acquire a certain size, the lower leaves are pinched off, to increase the bulk of the upper. A fine tobacco-plant should have from eight to twelve large succulent leaves, and a stem from three to six feet high; the top is pinched off to prevent its running and drawing the sap from the leaves, and lateral shoots are carefully pinched off as soon as they appear, to prevent branching. A few plants are left for seed, and of these the heads are allowed to shoot the full length. The seeds are so small and so numerous on a plant, that a few plants produce a sufficiency of seed for the next crop. The plantations are continually examined, and every leaf injured by insects or otherwise is pulled off. Tobacco takes about four months from the time of planting to come to perfection; that is, from May to September, when the leaves are gathered before there is any danger from frost: one single white frost would spoil the whole crop, and cause it to rot. As soon as the colour of the leaves becomes of a paler green inclined to yellow, they are fit to be gathered; they then begin to droop, and emit a stronger odour, and feel rough and somewhat brittle to the touch. When the dew is evaporated and the sun shines, the leaves may be most advantageously gathered, which is done by cutting down the plant close to the ground, or even a little under the surface. They are left on the ground to dry till the evening, taking care to turn them often, that they may dry equally and more rapidly. They are housed before the evening dew falls, which would injure them, and laid up under cover in heaps to sweat during the night, and some mats are thrown over the heaps to keep in the heat. If they are very full of juice, they are sometimes carried out again the next day to dry in the sun; but most commonly they are left to sweat for three or four days, and are then moved and hung up to dry in sheds which allow a thorough draught of air but keep out the rain. Every tobacco-plantation has such buildings, proportioned to the extent of the cultivation. In some places the leaves are now stripped off the stems and strung on packthread to dry. In others the whole plant is hung on pegs placed in rows at regular distances, and fixed on laths which run across the building. When the plants are quite dry they are removed in moist or foggy weather; for if the air is very dry the leaves would fall to dust. They are laid in heaps on hurdles and covered over, that they may sweat again, which they do but slowly. The heaps are carefully examined from time to time to see that they do not heat too much; and, according to the season and the nature of the plants, whether more or less filled with sap, they remain so a week or a fortnight. If the leaves were not stripped off at first, they are taken off now, when the proper fermentation is completed. They are sorted; those which grow on the top of the stem, in the middle, and at the bottom, are laid separately, as being of different qualities. They are tied together in bundles of ten or twelve leaves, again dried carefully, ranged in casks horizontally, and pressed in, by means of a round board, by lever or screw, as soon as a certain quantity has been laid in; the pressure is equal to that of a weight of several tons. This is essential to the safe transportation of the tobacco; and it is thus that the great bulk of it arrives from the places where its cultivation is most extensive, as in America.

The finest tobacco, however, is made into rolls, which from their shape are called *carrots*. The leaves are placed together by large handfuls, and wound very tightly round by strips of fibrous wood or strong grass, at a time when the air is somewhat moist; they partially consolidate, and require only to be rasped to make the finest and most genuine snuff.

The refuse stems of the tobacco are sometimes burned; but it is best to let them rot in the ground, where they are converted into good manure for the next crop. From the high state of cultivation of the land, it is left very rich for any other crop after the tobacco; but as this is quite a garden cultivation, the tobacco recurs very soon on the same ground; the abundant manuring and deep trenching prevent any bad effects from this frequent recurrence.

Manufacture.—Tobacco is packed in hogsheads for shipment: it is done with the greatest care, each bundle being laid separately. They are ranged side by side, and the direction of the points of the leaves is reversed with every alternate row. When the cask is about one-quarter filled, the tobacco is compressed by a powerful lever-press, which reduces the thickness of the layer from about twelve inches to three; and the pressure is continued several hours, that the tobacco may become so consolidated as not to spring up again when it is removed. In this way the cask is filled, by successive stages, until it contains a mass of tobacco-leaves so dense and compact, that a hogshead 48 inches in length, and 30 or 32 inches in diameter, will contain 1000 lbs. weight.

Upon the arrival of the tobacco in this country it is conveyed to bonding-warehouses. Those of the metropolis, which are of immense extent, are situated chiefly at the London Docks, where every cask is opened to examine its contents, and to remove any tobacco which may have been injured in the passage. This arrangement is due to the operation of the high import-duty, which renders it better for the owner to sacrifice tobacco that may have become impaired in value than to pay the duty upon it. For the purpose of examination, the head of the hogshead is knocked out, some of the staves are loosened, and the hogshead is taken completely off from the tobacco. If it be found that, from defective packing, from the action of sea-water, or from any other cause, part of the surface has become so injured as not to be worth preserving, such part is removed, with large powerful cutting instruments, by small quantities at a time. This requires considerable power, owing to the intense compression of the tobacco, especially upon the cylindrical sides of the mass, where the cutters act across the direction of the stalks and leaves. The damaged tobacco thus removed is consumed in a furnace on the premises. The remainder of the mass is accurately weighed, and then returned into the hogshead.

The manufacture of the tobacco-leaves into the numerous varieties of *tobacco* for smoking in pipes—consisting of the leaf cut up into shreds or filaments, and usully divested of the stalk; into *cigars*, which are bundles of the tobacco-leaf rolled compactly together into a convenient form for smoking; and into *snuff*, which consists partly of the stalks of the leaves, and partly of the leaves themselves, cut and ground into the state of powder—is usually conducted by three distinct classes of traders.

The first operation performed upon a hogshead of tobacco, after it has been removed to the manufactory and opened, is the digging out of the solid tobacco with iron instruments. The pieces thus detached are then sprinkled with water, which facilitates the separation of the small bundles from each other, and also of the leaves composing each bundle. If the tobacco be of the kind called hand-work,—that is to say, with the stalks remaining attached to the leaves,—it must now be stripped, unless indeed it be required for the production of a kind of tobacco called *bird's-eye*, which contains a portion of stalk as well as leaf. The removal of the stalks is usually effected in England by women or boys, who fold the leaf along the middle, and, by means of a small instrument, separate the stalks from the leaves, and lay them aside in different heaps. To prepare them for being cut into shreds or filaments, the leaves are pressed together in large numbers in the form of a cake, during which operation they are occasionally moistened, not only to enable them to cake together the more readily, but also in order to improve the subsequent flavour of the tobacco. The details of the machinery employed for compressing and cutting the tobacco vary in different establishments. Originally the cutting apparatus consisted simply of a long knife worked by hand. Hand-engines were then introduced, and such are still partially used, in which the knife is moved by a train of machinery, which also shifts the cake of tobacco between each cut, so as to make it ready for the next. This kind of cutting-engine is turned by a winch-handle, and the motion is regulated by a fly-wheel. Horses have been applied to a similar machine; and, lastly, steam-power has been brought to the aid of the manufacturer, leaving the attendance of men necessary only to place the cake in the engine, to attend to it while at work, and to remove the cut tobacco. Generally speaking, all of these machines act upon the same principle. The cake of leaves is laid upon an iron bed, which is susceptible of a slow progressive motion, and another part of the mechanism gives motion to the knife. The depth of the cake is about two inches; the thickness of the film taken off by each stroke, and consequently the fineness or coarseness of the filaments of tobacco, is regulated by alterations in a train of cog-wheels.

Many circumstances combine to account for the different qualities and appearance of the numerous varieties of tobacco used for smoking. Tobaccos raised in various places naturally present some points of difference; variations will, as already shown, appear in different parts of the same crop; and the retention or rejection of the stalk, the nature and extent of the moistening, and the degree of fineness of the fibres, occasion still further differences. A coarse variety called *shag*, which is used both for chewing and smoking, is formed of the darkest-coloured leaves, well liquored, which darkens them still more. *Pig-tail* tobacco consists of a rope or cord, about as large as the thicker end of a tobacco-pipe, and as long as the manufacturer can conveniently make it. It is produced by a process similar to spinning, and requires the simultaneous aid of a man and two boys.

The manufacture of cigars is described in another article. [CIGAR MANUFACTURE.]

Snuff is made either from stalks only, from leaves only, or from a mixture of the two. That known as *Scotch* snuff is made either wholly of stalks, or with a very small admixture of leaves. *High-dried* snuffs owe their peculiar qualities chiefly to a degree of drying which imparts a scorched flavour to them; and innumerable varieties are produced by the choice, mixture, and preparation of different tobaccos. Most of the snuff made near London is ground in mills whose machinery is impelled by the river Wandle, near Mitcham in Surrey. In these mills two kinds of grinding-machine are employed. One consists of two cylindrical stones, several feet in diameter, and one or more in thickness, set up on edge, side by side, upon a circular slab or bed. These stones have a two-fold motion imparted to them, resembling that of a carriage wheel compelled to revolve in a small circle. The effect of this peculiar motion is a grinding action upon the bed where the snuff is laid, peculiarly adapted to the required purpose. Some kinds of snuff, however, are better ground by the other sort of machine, which consists of a kind of rolling pestle, set in motion by an ingenious train of wheels and set of jointed arms or levers. Little is done at the snuff-mills beyond a preparatory drying of the tobacco and the actual grinding; but the snuff usually receives some finishing operations from the maker after it leaves the mill.

Tobacco Trade.—The discoverers of the New World learned the habit of smoking tobacco from the natives; and on their return the practice was at first introduced into Spain and Portugal, and soon spread to other parts of the Continent. The settlers who accompanied Raleigh on his expedition to colonise Virginia, which returned unsuccessful in 1586, introduced the habit into England. Before the establishment of the colony of Virginia in 1606, all the tobacco imported into this country was raised by the Spaniards in the West India Islands. King James's invectives against the use of this weed are now curious matters of history. In 1604 he took upon himself, without the consent of Parliament, to raise the duty on tobacco from 2*d.* to 6*s.* 10*d.* the lb. In 1615 the colonists of Virginia regularly betook themselves to the cultivation of the tobacco-plant, abandoning the manufacture of ashes, soap, glass, tar, and the planting of vineyards, which they had already commenced. James felt that, without abating his well-known aversion to tobacco, in the infancy of the colony this proceeding of the planters must be tolerated. In the first instance he commanded that the production of tobacco should not exceed the rate of a hundred-weight for each individual planter. The cultivation was forbidden in England, and the plants already growing were ordered to be uprooted. At the same time he confined the right of importing the commodity to such persons as he should license for the purpose. In the last year of his reign the exclusive supply of the English market was given to the English plantations in America.

Being regarded as a source of revenue, tobacco is not allowed to be grown in England. In 1786 tobacco paid an import duty of 10*d.* per lb.; it was raised to 1*s.* 3*d.* in 1787, 1*s.* 7*d.* in 1796, and by gradual steps to 4*s.* in 1815, at which it remained till 1825. In the last-named year the duty was lowered to 3*s.* if from foreign countries, and to 2*s.* 9*d.* if from British possessions. The discriminating duty was afterwards removed, the British was raised to the same rate as the foreign, and the duties settled down at these rates—3*s.* on unmanufactured tobacco, 6*s.* on snuff, and 9*s.* on cigars, plus 5 per cent. Down to 1825 an excise as well as a customs duty was levied on tobacco; but in that year the former was removed, except in so far as concerned a licenee for the traders and a supervision of the trade. Great restrictions are placed on the importation. Specified ports, about thirty in number, are alone permitted to import tobacco. The importer is not compelled to pay the duty at once; he may allow the tobacco to remain in bond, in the queen's warehouses at the several ports, for any space of time not exceeding five years, paying a rent of 4*s.* on every hogshead, cask, chest, or case. Every soldier and sailor on British service in foreign parts may purchase *duty free* to the extent of 2 lbs. of tobacco per month; but all other tobacco must pay the duty before being taken out of bond. As the price of tobacco in bond, after all the expenses of growth and freight have been paid, varies from 3*d.* to 10*d.* (perhaps averaging 6*d.*), it follows that the duty (about 3*s.* 3*d.*) is enormously heavy, and this leads both to smuggling and adulteration. It has been pertinently remarked by Mr. Cooley, that the retail sale of genuine tobacco at 3*d.* per oz. is a commercial impossibility. The tobacco *must* be adulterated, in order to pay the planter, importer, manufacturer, wholesale dealer, and retailer, and to pay also the duty; or, if genuine, then the duty must be evaded by smuggling. The government officers, as well as chemists acting unofficially, have detected sugar, treacle, molasses, malt, roasted grain, chicory, lime, sand, umber, ochre, sea-weed, and leaves or herbs of various kinds, in tobacco. Dye-drugs are often used, not to increase the weight, but to impart a tobacco-colour to adulterants.

Tobacco, as already stated, is not allowed to be grown in England. The acts prohibiting its cultivation did not apply to Ireland till about 1840. Tobacco is extensively cultivated in France, Prussia, Holland, and Belgium, also in the southern provinces of Russia, and in Turkey and Syria. It has as yet made little progress in the British West Indies, and still less in Upper Canada. The tobacco of Cuba holds the highest rank for the excellence of its flavour. Next in favour, perhaps, are the cigars of Manilla. But the cultivation of tobacco is most extensive in the United States. In 1850 the produce in eight states of the Union was estimated at 200,000,000 lbs., of which much more than half was produced in Virginia and Kentucky. About 120,000,000 lbs. of this quantity were exported, and 80,000,000 lbs. consumed at home, amounting to 3¼ lbs. per head on a population of 23,000,000. Professor Wilson, in his Report on the New York Industrial Exhibition, spoke of the so-called *Cavendish* tobacco as being now in very extensive demand in the United States. "It is known as chewing or plug tobacco, and is put up in boxes of various sizes. Those exhibited weighed 38 lbs., and were of various qualities to which different names and prices were attached. 'Ladies' Love' sold at 16 dollars per box, 'Ladies' Twist' at 13, and 'Fair America' at 10. Tobacco for chewing undergoes a process of gradual fermentation, and is then sweetened by the addition of molasses, and either done up into rolls or pressed into cakes; the former is known as *twist*, the latter as *plug*. A good chewer, I am informed, would dispose of 4 to 8 ozs. per day."

The quantity of tobacco imported into this country in 1786 was about 7,000,000 lbs.; in 1796 it rose to 10,000,000 lbs. During the first forty years of the present century it rose gradually from 11,000,000 to 18,000,000 lbs.—a ratio of increase far less than that in the population. A marked advance then took place, and from 1844 to 1860 the import was never less than 33,000,000 lbs. In 1860 the quantity was 49,670,893 lbs., of which 35,412,841 lbs. was retained for home consumption and paid duty, the rest being re-exported. This quantity is a little more than 1 lb. per head per annum for the whole population.

TOBACCO, ACTIVE PRINCIPLE OF. [NICOTINE.]

TOBACCO-PIPE MANUFACTURE. The materials of which tobacco-pipes are formed are very numerous. White and coloured earths, porcelain, metals, ivory, horn, shell, costly woods, agate, cornelian, talc, and amber, are among the substances which have been used for the purpose. The forms admit of equal variety; but perhaps the most remarkable is the oriental hookah, in which the smoke is purified by passing through water.

The tobacco-pipes most commonly used in this country are formed of a fine-grained plastic white clay, which is called, from this application, pipe-clay. It is procured chiefly from Purbeck in Dorsetshire, and is purified from all foreign substances by working it with water into a thin paste, and then either allowing it to settle in pits, or passing it through a sieve, to separate the siliceous or other stony matter. The water is subsequently evaporated until the clay becomes of a doughy consistence, when it must be well kneaded to make it uniform. It is finally formed into cubical masses of about one hundred pounds each. From one of these the workman cuts off just enough to make one pipe. Each piece is kneaded thoroughly upon a board, and rolled out to nearly the form and size of a pipe, with a projecting bulb at one end for the formation of the bowl. These pieces are laid aside for some time to dry, and when the clay is sufficiently firm, they are subjected to the curious process of *boring*. The workman takes the roll of clay in his left hand, and with his right inserts the end of an iron needle, previously oiled, in the small end of the roll, and by dexterous management thrusts the needle through the whole length of the roll without penetrating the surface. The bulb is then bent into the proper position to form the bowl, and the piece of clay, with the needle remaining in it, is pressed into a mould to complete its form.

Tobacco-pipe-moulds are formed either of copper, brass, or iron, and each consists of two precisely similar halves, with projecting pins in one half, and corresponding holes in the other, which ensure their exact union. On their inner surfaces, which are hollowed so as to fit the finished pipe, may be added any ornamental device or inscription. One half of the mould being laid flat, the pipe is placed in it, covered with the other half, and then firmly pressed. The bowl is partially hollowed by the finger, and completed by the insertion of an oiled stopper or mould. The wire is thrust backwards and forwards until it becomes visible in the bowl. The wires are now withdrawn, and the pipes are taken out of the moulds, slightly smoothed over, and laid aside to dry. After drying for a day or two, any remaining roughness is removed by means of an instrument of bone or hard wood; and then the pipes are sometimes moulded a second time, and polished with a piece of flint bored with holes, through which the stem is passed repeatedly. Hitherto the pipes are straight in the stem; but before going to the kiln they are slightly bent. It is said that a clever pipe-moulder will make three thousand five hundred in one day. They are fired in a tobacco-pipe-kiln, which consists of a large but very light cylindrical crucible or sagger, with a dome-shaped top, and a circular opening in one side for the insertion of the pipes.

At the Cheltenham Meeting of the British Association, in 1856, Mr. Strong stated that tobacco-pipes are now made more extensively at Glasgow than in any other part of the United Kingdom. There are 600 persons employed, who manufacture, finish, and pack about 2700 gross of pipes per day, or about 120 millions in a year.

A remarkable kind of pipe for smoking is described under MEERSCHAUM.

TOD, an old measure of wool, fixed at two stones, or 28 pounds avoirdupois, by a statute of the 12th of Charles II. As usual, there are several local tods.

TOGA is the name given to the principal outer garment worn by the Romans. The Romans generally wore the same kind of dress as the other Italian nations and the Greeks; the toga alone is by some writers said to have been derived from the Lydians, but this statement probably arose from the belief that the Etruscans had come from Lydia; and that at least a particular kind of toga (the *toga prætexta*) was introduced at Rome at a very early time from Etruria, is expressly stated. (Livy, i. 8; Pliny, 'Hist. Nat.,' viii. 74.) In later times the toga was the peculiar garment of the Romans, which in times of peace they wore both at home and abroad, and whenever they appeared in full dress. Hence they are called *gens togata* (Virgil, 'Æn.,' i. 282) and *togati* (Sallust, 'Jugurth.,' 21), in contradistinction from other nations. The name "toga" was, according to Varro ('De Ling. Lat.,' iv. p. 33, ed. Bipont), derived from *tegere*, "to cover," because it covered the whole body. Gellius (vii. 12) states that in early times it was the only article of dress that was worn, but afterwards we know that it was worn over other dresses. The right of wearing it was the exclusive privilege of Roman citizens of every age and sex. (Servius, 'Ad. Æn.,' i. 282.) Slaves, foreigners, and Romans sent into exile were not allowed to wear it. (Pliny, 'Epist.,' iv. 11; Horat., 'Carm.,' iii. 5, 10.) The peculiarity of the toga as a Roman dress is also indicated by the circumstance that comedies in which Romans appeared on the stage and were represented with their native costume, were called "togatæ," to distinguish them from Greek comedies. As the toga covered the whole body with the exception of the left arm, it could not be worn by a person while at work either at home or in the field. (Juvenal, iii. 171; Livy, iii. 26.)

The material of which the toga was made was woollen cloth, which differed in thickness and fineness according to circumstances and the seasons. Under the empire, persons of rank used to have their togas made of silk. The colour was usually white—probably the natural colour of the wool. Those who appeared before the people as candidates for a public office, wore a particularly white and clean toga (*candida*), whence they derived their name of candidates (*candidati*). On festive occasions, too, it was considered a matter of importance that the toga should be perfectly white. (Horat., 'Sat.,' ii. 2, 60; Cicero, 'In Vatin.,' 13.) On melancholy occasions the Romans wore the *toga pulla*, or "dark-coloured toga." (Cicero, 'In Vatin.,' 13; 'In Verr.,' iv. 24). Towards the end of the republic, and under the empire, the toga, especially that worn by the emperors, was of a purple colour, and was called *trabea*. This custom appears to have been introduced by Julius Cæsar. (Cicero, 'Philip.,' ii. 34; Servius, 'Ad Æn.,' vii. 612.) As early as the time of Augustus, many Romans had left off wearing the toga, and taken to a kind of cloak called lacerna. This induced the emperor, who was fond of restoring ancient customs, to enjoin the ædiles to see that no Roman should appear in the forum or circus without the toga. (Sueton., 'Aug.,' 40.) The toga during the empire continued to be the honourable dress which was worn by persons of rank, as senators, judges, priests, and by clients when they saluted their patrons or received the sportula (Martial, xiv. 125), and especially on all occasions where the emperor was present.

The mode or fashion of wearing the toga appears to have been variously modified in the course of time, although the general character always remained the same. A great difference seems to have existed in the quantity of cloth used for it, as some statues present a richer drapery than others. Its form appears to have been rounded, but respecting that and the manner of putting it on, nothing can be said with certainty, notwithstanding the description in Quinctilian (xi. 3, 137, &c.) and the many statues with togas still extant. (Ferrarius and Rubenius, 'De Re Vestiariâ;' Becker, 'Gallus,' ii.)

Besides the different kinds of togas we have mentioned above, the following must be noticed:—

1. *Toga prætexta* was worn by the children of the nobles, by girls until they married, and by boys until they attained the age of puberty (fourteen), when they exchanged it for the *toga virilis*, also called *pura*, *libera*, or *recta*, which was the usual white toga described above. The prætexta was also the official robe of the higher magistrates of the city and the municipia, as well as of the colonies. The name prætexta was derived from the circumstance of this toga being adorned with a broad purple border (*latus clavus*).

2. *Toga picta* was a toga ornamented with embroidery and gold according to the Etruscan fashion. It was worn by generals in their triumph, whence it was also called *toga Capitolina*. During the empire it was also worn by the consuls and prætors when they were present at the public games.

TOISE, a French measure of six French feet, particularly used in all the older French measures of the earth. [WEIGHTS AND MEASURES.]

TOLEDO, TABLES OF. The Moors brought astronomy into Spain at the beginning of the 11th century, and about the year 1080 tables were calculated for the meridian of Toledo, by Arzachel. Of these tables there was no specific account till the time of Delambre, and no printed publication of them had been made. It was usual to state that they were intended as an improvement on the tables of Albategnius, that their character never was very high, and that the Alphonsine Tables [ALONSINE TABLES] were intended as an improvement upon them. Delambre ('Hist. Astron. Moyenne,' p. 175) examined two manuscript Latin translations of the tables, which he found in the Royal Library at Paris; and his report of their contents is what might have been expected. The theory and numerical quantities employed are in almost every instance those of Ptolemy, and there is only just enough of original observation to establish the fact that the Toledine observers were very bad ones.

TOLENE. A hydrocarbon essence obtained from balsam of Tolu.

TOLL, from the Saxon "tolne;" in German, "zoll" (called in Law Latin "telonium," "theolonium," and "tolnetum," with many other variations, which may be seen in Ducange, all which Latin terms are derived apparently from τελώνιον, "collection of tribute or revenue"), is a payment in money or in kind, fixed in amount, made either under a royal grant, or under a prescriptive usage from which the existence of such a grant is implied, in consideration of some service rendered, benefit conferred, or right forborne to be exercised by the party who is entitled to such payment.

The owner of land may in general prevent others from crossing it either personally or with their cattle or goods, by bringing actions against trespassers, or distraining their cattle or goods. These remedies cannot be resorted to where the owner of the land has acquiesced in its being used as a public way; but in such case there may have been a royal grant, enabling the party to demand a reasonable compensation for the accommodation: this is toll-*traverse*.

Where a corporation, or the owner of particular lands, has immemorially repaired the streets or walls of a town, or a bridge, &c., and, in consideration of the obligation to repair, has immemorially received certain reasonable sums in respect of persons, cattle, or goods passing through the town, such sums are recoverable at law by the name of toll-*thorough*.

An ancient toll may be claimed by the owner of a port in respect of goods shipped or landed there. Such tolls are port-tolls, more commonly called port-dues. The place at which these tolls were set or assessed was anciently called the Tolsey, where, as at the modern Exchange, the merchants usually assembled, and where commercial courts were held.

Another species of toll is a reasonable fixed sum payable by royal grant or prescription to the owner of a fair or market, from the buyer of tollable articles sold there. The benefit which forms the consideration of this toll is said to be the security afforded by the attestation of the sale by the owner of the fair or market, or his officers. In some cases by ancient custom, a payment, called turn-toll, is demandable for beasts which are driven to the market and return unsold. The term toll is sometimes extended to the compensation paid for the use of the soil by those who erect stalls in the fair or market, or for the liberty of picking holes for the purpose of temporary erections; but the former payment is more properly called stallage, and the latter picage; and if the franchise of the fair or market, and the ownership of the soil on which it is held, come into different hands, the stallage and picage go to the owner of the soil, while the tolls, properly so called, are annexed to the franchise.

If tolls are wrongfully withheld, the party entitled may recover the amount by action as for debt, or upon an implied promise of payment; or he may seize and detain the whole or any part of the property in respect of which the toll is payable, by way of distress for such toll. If excessive toll be taken by the lord, or with his knowledge and consent, the franchise shall be seized; if without such consent, the officers shall pay double damages and suffer imprisonment. (Stat. 3 Edw. I. c. 31.)

Grants of tolls were formerly of very ordinary occurrence. But it seems to be very probable that many ancient payments of this description, though presumed, from their being so long acquiesced in, to have a lawful origin under a royal grant, were in fact mere encroachments. The evil was, however, practically lessened by the exertion of the royal prerogative of granting immunities and exemptions from liability to the payment of tolls, either in particular districts or throughout the realm; a prerogative exercised also by inferior lords who possessed jura regalia.

The term "toll" is used in modern acts of parliament to designate the payment directed to be made to the proprietors of canals and railways, the trustees of turnpike-roads or bridges, &c., in respect of the passage of passengers or the conveyance of cattle or goods.

The term toll is applied to the portion which an artificer is, by custom or agreement, allowed to retain out of the bulk in respect of services performed by him upon the article; as corn retained by a miller in payment of the mulcture; also to the portion of mineral which the owner of the soil is entitled, by custom or by agreement, to take, without payment, out of the quantity brought to the surface, or, as it is technically called, *to grass*, and made merchantable, by the mining adventurer. To collect these dues the duke of Cornwall, and other great landholders in the mining districts of the west, have their officers, called "tollers."

TOLLERS. [TOLL.]

TOLSEY. [TOLL.]

TOLU, ESSENTIAL OIL OF. [ESSENTIAL OILS.]

TOLU-EUGENYL. [CARYOPHYLLIC ACID.]

TOLUENE. [TOLUENIC GROUP.]

TOLUENIC GROUP. A cluster of chemical substances, each containing the hypothetical radical *toluenyl* ($C_{14}H_7$).

The chief members of this collection are six in number, namely,—

1. Toluene or hydride of toluenyl . $C_{14}H_8 = \left.\begin{matrix} C_{14}H_7 \\ H \end{matrix}\right\}$

2. Hydrate of toluenyl . . . $C_{14}H_8O_2 = \left.\begin{matrix} C_{14}H_7 \\ H \end{matrix}\right\} O_2$

3. Toluenyl-sulphurous acid . . . $C_{14}H_8S_2O_6 = \left.\begin{matrix} C_{14}H_7 \\ H \end{matrix}\right\} O_2, S_2O_4$

4. Chloride of toluenyl . . . $C_{14}H_7Cl = \left.\begin{matrix} C_{14}H_7 \\ Cl \end{matrix}\right\}$

5. Toluidine . . . . . $C_{14}H_9N = N\left\{\begin{matrix} C_{14}H_7 \\ H \\ H \end{matrix}\right.$

6. Acetate of toluenyl . . . $C_{18}H_{10}O_4 = \left.\begin{matrix} C_{14}H_7 \\ C_4H_3O_2 \end{matrix}\right\} O_2$

1. *Toluene* ($C_{14}H_7$, H). *Toluol. Retinaphtha. Benzoene. Dracyl.* A colourless, limpid oil, first obtained on submitting balsam of tolu to distillation. It has subsequently been found among the products of the destructive distillation of resin, tar, and wood; and is also formed when TOLUIC ACID is heated with lime. It may be obtained pure by fractional rectification. The specific gravity of toluene is 0·87; vapour density, 3·260; and boiling point, 237° Fahr. Its odour resembles that of benzole. It is insoluble in water, slightly soluble in alcohol, and more so in ether; with fuming sulphuric acid it forms toluenyl-sulphurous acid, and nitric acid converts it into *nitrotoluene* ($C_{14}H_7$, NO_4). The latter body, called also *nitrobenzoene*, is precipitated on adding water to the mixture of toluene, and forming nitric acid. It is a liquid, has an odour resembling that of oil of bitter almonds; boiling point, 437° Fahr.; and specific gravity, 1·18; a mixture of nitric and sulphuric acids converts it into acicular crystals of *binitrotoluene* ($C_{14}H_6$, $2NO_4$). Several chlorine derivatives of toluene are known.

2. *Hydrate of toluenyl* ($C_{14}H_7O$, HO). The source, composition, and properties of this substance have already been referred to under its synonyme, BENZOIC ALCOHOL.

3. *Toluenyl-sulphurous acid; sulphotoluenic* or *sulphobenzoenic acid* ($C_{14}H_8S_2O_6 + 2$ Aq.). The lead salt of this acid is formed on adding excess of carbonate of lead to the solution of toluene in fuming sulphuric acid. The acid itself is set free on passing sulphuretted hydrogen through the aqueous solution of the lead salt. By evaporation of its solution in vacuo, small deliquescent penniform crystals are obtained.

4. *Chloride of toluenyl* ($C_{14}H_7$, Cl). A heavy liquid resulting from the action of hydrochloric acid gas upon hydrate of toluenyl. Boiling point about 360° Fahr.

5. *Toluidine* ($N(C_{14}H_7)H_2$), or *toluyl-ammonia* is produced by the reducing action of sulphuretted hydrogen upon nitrotoluene. Sulphur having been separated and the solution evaporated, the residue is distilled with potash; toluidine then passes over and condenses to a liquid, which subsequently solidifies.

Toluidine is very soluble in ether, alcohol, and oil. It is but little dissolved by water, but may be obtained in large crystals from its alcoholic solution. It has an aromatic odour, much resembling aniline, and a burning taste. It slightly blues red litmus paper; is heavier than water; is volatile at common temperatures; melts at 104° Fahr., and boils at 388°·4 Fahr. It has the same composition as methyl-aniline, but does not give that beautiful blue colour with chloride of lime that compounds of aniline do.

Toluidine gives stable and crystalline salts with most of the acids. They mostly are soluble in water. The *sulphate of toluidine* contains ($2C_{14}H_9N$, S_2O_6, 2HO); the acid *oxalate* ($C_{14}H_9N$, C_4O_6, 2HO). The *chloroplatinate* ($C_{14}H_9N$, HCl, $PtCl_2$) occurs as a beautiful orange crystalline precipitate.

Nitrotoluidine forms in yellow needles when binitrotoluene is acted on by an alcoholic solution of sulphide of ammonium.

Cyanotoluidine ($2C_{14}H_9N$, Cy_2?) is a body somewhat resembling cyaniline. It is produced on passing cyanogen into an alcoholic solution of toluidine. *Cyanide of toluenyl*, or *cyanonitrile*, is formed on boiling chloride of toluenyl with cyanide of potassium.

Two equivalents of hydrogen in toluidine may, as in the case of other organic bases, be substituted by alcohol radicals. Thus are obtained,—

Ethyl-toluidine . . . . . $N\left\{\begin{matrix} C_{14}H_7 \\ C_4H_5 \\ H \end{matrix}\right.$

Diethyl-toluidine . . . . . $N\left\{\begin{matrix} C_{14}H_7 \\ C_4H_5 \\ C_4H_5 \end{matrix}\right.$

Hydrate of triethyl-toluenyl-ammonium . $N(C_4H_5)_3C_{14}H_7$, O, HO

6. *Acetate of toluenyl* ($C_{14}H_7O$, $C_4H_3O_3$). A colourless, heavy oil, of agreeable aromatic odour resembling that of certain pears. It is formed on adding sulphuric acid to solution of hydrate of toluenyl in acetic acid.

TOLUENYL. [TOLUENIC GROUP.]

TOLUENYL-SULPHUROUS ACID. [TOLUENIC GROUP.]

TOLUIC ACID (HO, $C_{16}H_7O_3$). A volatile solid, produced when cymene [CYMOLE or CAMPHOGEN] is heated with diluted nitric acid. It occurs in white acicular crystals, very soluble in boiling water, in alcohol, ether, or wood spirit. It is inodorous and tasteless. With strong nitric acid it gives *nitrotoluic acid* ($C_{16}H_7(NO_4)O_4$).

Both toluic and nitrotoluic acids are monobasic and form salts, of which many are crystalline. *Toluate of baryta* contains ($C_{16}H_7BaO_4$), and *nitrotoluate* ($C_{16}H_6Ba(NO_4)O_4$). *Toluic ether* boils at 442° Fahr., and has the composition ($C_{16}H_7(C_4H_5)O_4$). *Nitrotoluic ether* has the composition ($C_{16}H_6(C_4H_5)$ $(NO_4)O_4$).

TOLUIDINE. [TOLUENIC GROUP.]

TOLUOLE. [TOLUENIC GROUP.]

TOLUONITRYLE. [TOLUENIC GROUP.]

TOLUYL-AMMONIA. [TOLUENIC GROUP.]

TOMB (in Greek, τύμβος; Latin, *Tumba*; Italian, *Tomba*; French, *Tombe* and *Tombeau*) signifies, in its strict meaning, a mass of masonry or stone-work raised immediately over a grave or vault used for interment; but it is often applied, in a wider sense, to any sepulchral structure. Of primitive sepulchres there are two classes, one of which may be distinguished by the general term *Hypogæan*, that is, subterraneous and excavated; the other, by that of *Hypergæan*, that is, *above-ground*, or raised mounds or tumuli heaped over the dead. Monuments of the first kind are very numerous in Egypt, where they occur in every variety, from the simple rock-hewn tomb to the extensive royal sepulchres consisting of numerous galleries and chambers. The other class presents itself in the Pyramids, which, though far more artificial in form and construction, had no doubt a common origin with the tumulus [TUMULUS], which occurs under various designations in every part of the globe.

The extraordinary labour bestowed in excavating or constructing these ancient sepulchres is perhaps not so surprising as the lavishness with which the ancients embellished the subterraneous abodes of the dead, not only adorning them with polychromy and paintings, but depositing in them costly and exquisitely-wrought articles. In this respect there was a striking similarity between the practice of the Egyptians and that of the Etrurians; nor is the coincidence less remarkable from such practice being contrary to that of the comparatively modern Greeks and Romans, whose tombs and sepulchres were chiefly architectural erections intended for external display. Of Egyptian architecture and art, some of the most astonishing memorials are entombed within the earth. Among these are what are called the "Tombs of the Egyptian Kings," at Bibân el Molouk, in one of which Belzoni discovered the sarcophagus, or tomb, properly so termed, which is now in the Soane Museum. [EGYPTIAN ARCHITECTURE.] In these tombs the entrance passages are narrow, and the first chambers are smaller than those to which they lead. The numerous paintings found in these tombs describe with minuteness the social life and manners of the people, their banquets, their festivals, their amusements, their costume, their furniture, their arts, and the various utensils and implements employed in them. These records prove not only the perfection the mechanic arts had attained, but also the luxurious refinement of those remote ages. The same remark applies to the paintings and frescoes in the subterraneous tombs and sepulchral chambers discovered since 1827 at Corneto, on the site of the ancient Tarquinii, at Vulci, Toscanella, Bomarzo, Cere, Val d'Asso, Orchia, and other places in the ancient Etruria. A brief description of these will be found under ETRUSCAN ARCHITECTURE.

Many of the tombs found in Lycia and other parts of Asia Minor have columns and entablatures to their façades wrought out of the solid rock. Some of the Lycian tombs, however, are upright insulated structures, either plain or decorated with pilasters and other ornaments, with roofs whose section is a pointed arch, after the fashion of some of the Indian monuments, owing to which they present a striking combination of Oriental and Grecian forms. Of sepulchres with temple-shaped façades there are two examples at Orchia, one of them a tetrastyle, the other a distyle in antis. Both partake of the Grecian Doric character, yet deviate from it greatly in two particulars: first, in the great height of the pediment; secondly, in the great width of the intercolumns. What now remains of the columns themselves is only sufficient to show their number and situation; yet that they were hewn out of the rock, like the entablature and pediment, scarcely admits of question. Of the magnificent sepulchre of Mausolus erected by Greek architects at Halicarnassus, an account is given under MAUSOLEUM.

Vitruvius says nothing on the subject of sepulchres and tombs, either Grecian or Roman; yet sepulchral edifices are still very numerous throughout Latium and Magna Græcia, and many of them must originally have been very conspicuous objects, and not a little remarkable on account of the studied architectural decoration bestowed on them externally: for besides subterraneous sepulchral chambers or vaults (which were usually very carefully finished internally, and not unfrequently ornamented with painting and stucco-work, and with marble or mosaic pavements), there is another and quite distinct class, consisting of structures raised above ground, insulated, and apparently solid. These may be described as generally of nearly cubical form, though some are of much loftier proportions. There are, besides, varieties of this class, in which either a conical or cylindrical superstructure is raised upon the square portion, which then becomes a basement; or else the superstructure is also square, but is distinguished from the lower part by pilasters, panels with inscriptions, and other architectural decorations: some of these have an upper sepulchral chamber, others a subterraneous one also, or one below the level of the ground.

What is called the "Sepolcro di Nerone," near Ponte Molle, may be taken as a specimen of the usual character of Roman tombs partaking of the cubic form. Like the generality of them, this is somewhat more than a perfect cube, the dimensions being 20 feet by 24 in height, or, including its covering, 27 feet. At each angle is a large acroterium presenting two quadrant-shaped surfaces, meeting at right angles at the external edge of two adjoining sides—a species of ornament almost peculiar to ancient altars and tombs. Of larger tombs of this class, there is one in the Via Portuensis, a double cube in height, the measurements being respectively 44 and 80 feet. In the example previously mentioned, the upper part is rather less in height than the basement, but here it is about a third more, and is also decorated with four pilasters on each front, with a small pediment, not supporting, but placed *between* the large acroteria at the angles. Of circular tombs we have a well-known example in that of Manutius Plancus at Gaeta, —a low circular tower (nearly solid within), about 60 feet in diameter, and 10 feet more in height; therefore, owing to its size, it is rather a mausoleum than a mere tomb. The same may be said of that of Cæcilia Metella at Rome; which structure, otherwise called Il Capo di Bove, from the ornaments in its Doric frieze, exceeds the one just mentioned in size, it being 90 feet in diameter, and its entire height about 130 feet. It does not, however, partake so much of the character of a mere tower as the tomb at Gaeta, because it consists of two nearly equal masses, namely, a square one with a cylindrical superstructure, and is therefore an example of that compound-form class which we have above pointed out. Among the tombs at Pompeii there is one which is circular in the upper part of its exterior, and internally has a dome of very peculiar shape, which does not show itself on the outside, but is cut out of the solid mass. Other sepulchral structures at Pompeii are very numerous, forming what is called the "Street of Tombs." Instead of cemeteries, or public burying-grounds, it was the custom in ancient Italy to erect tombs on each side of the principal roads leading from a city, as was the case with the Via Appia and others in the immediate vicinity of Rome.

The tombs of the middle ages are within buildings, churches, chantries, cloisters, &c., and exhibit almost every variety of form and enrichment, from the primitive stone coffin or Christian sarcophagus, to those lavishly decorated *catafalco* monuments which are so many piles of architecture and sculpture. Those of the first-mentioned kind are, for the most part, very little raised above the floor, and their upper surface is *en dos d'âne*, or forms a ridge-shaped lid. The next class consists of *Altar* or *Table Tombs*, comparatively plain, although with panelling or other architectural decoration on their sides. The next in order is the *Effigy Tomb*, first introduced in the 13th century, with a recumbent figure of the deceased upon it, extended, with the hands slightly raised, and joined as if in the attitude of prayer. Examples of this kind are very numerous, and highly interesting, both on account of their execution as works of sculpture and the information they afford in regard to the costume of the period.

Altar and effigy tombs were usually placed between the piers of an arch, or within a recess in a wall; and in either case the whole tomb was frequently covered by an arch forming a sort of canopy over it, of which kind is that of Aymer de Valence in Westminster Abbey (1334). In course of time this mode of architectural decoration came to be greatly extended. Instead of a single arch, three or more small arches were introduced, which, with the columns either supporting or placed between them, inclosed the figure on the tomb, giving the whole the appearance of a *shrine* or *screen*. Many of the French monuments of the period of the Renaissance are in this style of design, large and lofty insulated architectural masses, with a profusion of highly-enriched pilasters and arches, and numerous allegorical figures, beside other statutes and bas-reliefs, so that the *deposito*, or actual tomb, is the least portion of the entire composition.

In Italy there are many examples of what may be called *Façade* monuments, which are extensive architectural compositions, consisting of two or more orders of columns, with pediments, niches, statues, panels, and various other architectural decorations. Of such "*macchine colossali*," as Cicognara terms them, the monument of the doge Valier by Tirali, and that of the doge Pesaro by Longhena, may be quoted as instances. In both of them the figures are merely accompaniments to the architecture, and that which should be the principal is almost the most insignificant among them. In the Catafalc tomb, even when equally extravagant in point of accumulated embellishment, there is at least a certain degree of character that stamps it at first sight for what it is, whereas in those of the kind just referred to there is nothing to indicate a sepulchral monument. This last remark applies very forcibly to those two celebrated works of Michel Angelo, the tombs of Giuliano and Lorenzo de' Medici, each of which has, besides the figures of those personages, two naked semi-recumbent figures, a male and female, intended, or supposed to be intended, to express day and night (or sleep), and morning and evening. More becoming in feeling and in taste are many other Italian tombs of about the same period, which consist of little more than a simple *deposito*, or sarcophagus, with either a recumbent or semi-recumbent figure of the deceased upon it; such, for instance, as those of Giov. Andr. Boccaccio in the cloister of Santa Maria della Pace, and of Angelo Marzi in the church of the Annunziata at Florence. Although they have abandoned the architectural *caricatura* formerly in vogue for such purposes, instead of returning to the simple and natural expression of Christian monumental works, later sculptors have frequently given us allegorical compositions and groups of mythological figures, and the likeness of persons intended to be recorded is shown only in a medallion. In this vicious taste are many of the monuments in St. Paul's and Westminster Abbey, while others are chiefly remarkable for the fantastic conceits into which the artists have fallen, and which render them equally unbefitting the purpose they are designed for and the place where they are erected.

TOMBS, VAULTS, TOMBSTONES, TABLETS. In previous articles [COFFIN; INTERMENT] the various modes of disposing of the dead have been discussed; it is our intention here to show what rights the subjects of this country have, 1st, to burial, and 2ndly, to a permanent commemoration of themselves by means of monuments. It must be borne in mind that we treat here only of parish churches and churchyards, or of the parish burying-grounds subsidiary to the churchyard. The cemeteries which the necessities of an increasing population have caused to be established in the neighbourhood of many of our densely inhabited towns are private property, regulated at the pleasure of the proprietors.

By the 68th Canon of 1603 it is ordered that no minister shall refuse or delay, under pain of suspension by the bishop for three months, to bury any corpse that is brought to the church or churchyard (convenient warning being given him thereof before), in such form as is prescribed by the Book of Common Prayer, unless the deceased were excommunicated *majori excommunicatione*, and no man able to testify of his repentance. The Rubric further excludes from Christian burial those who have not been baptised or who have died by their own hands; and this latter class are defined to be such as have voluntarily killed themselves, being of sound mind, of which fact a coroner's jury are considered by ecclesiastical authorities to be the fitting judges. Thus the ecclesiastical law not only gives to the clergyman the right, but imposes on him the duty to bury, with only three exceptions, all who shall be brought within the precincts of his church. Nevertheless the ecclesiastical courts have admonished a minister and churchwardens to abstain from burying strangers in the churchyard, when the practice of doing so threatened to interfere with the rights of the parishioners; for the common law gives to the people the right of being buried within the churchyard of their own parishes: "Ubi decimas persolvebat vivus, sepeliatur mortuus;" and although the freehold of the churchyard, as of the church, is in the parson, he holds it only for the benefit of his parishioners, and subject to their right of interment in it.

This right of sepulture, however, applies only to the body: the Canon and the Rubric alike talk as though studiously of the "corpse" alone, never mentioning the coffin. In former times the use of coffins was confined to the richer classes, and these were often of stone or of other durable materials [COFFIN]; but the practice and no doubt the intention was that in the great majority of cases the process of decay, and, therefore, the occupation of the earth, should not be needlessly protracted. To use the words of Lord Stowell, "A common cemetery [by which he means a churchyard or parish burying-ground] is not *res unius ætatis*, the property of one generation now departed, but is likewise the common property of the living and of generations yet unborn, and is subject only to temporary occupations." On this doctrine are based the main points of the law concerning burials.

The establishment of churchyards is attributed to Cuthbert, archbishop of Canterbury, who in the year 750 introduced into this country the custom, then existing at Rome, of devoting an enclosed space round the sacred edifice to the interment of those who had been entitled to attend or had been in the habit of attending worship within its walls. Theretofore, notwithstanding a canon which forbade it (*De non sepeliendo in Ecclesiis*), the clergy interred persons of peculiar sanctity or importance within the walls of the church, especially in the side aisles of the nave, so as to remind the faithful of their example and of the duty of praying for their souls: and hence the rule that a body should not be buried in the church without the consent of the incumbent, he being supposed to be alone able to judge whether the deceased possessed the qualities which give him a title to that distinction. The churchyard was anciently held among the *res sacræ*, and no fees were taken for the use of it: nevertheless the payment of fees to the clergyman dates, in this country at least, from the Reformation, and the non-payment of those fees is held by the ecclesiastical courts a sufficient ground for the clergyman to withhold his offices, or at all events to prevent the erection of any monument or tablet for which he had previously given his consent; that consent being supposed to imply the payment of the usual or a stipulated fee. The churchwardens are also entitled to a fee for burials in the church, since on them falls the expense of repairing the pavement. It is even maintained that an incumbent is entitled to a fee upon the burial of his parishioner who has died in his parish and is removed for interment elsewhere. Sir H. Spelman preserves a vestry constitution of 1627 containing a table of fees for burial in the chancel, the nave, and the churchyard; the interments in the churchyard being differently charged as they were "coffined" or "uncoffined." These fees are not imposed at the discretion of the parson or of the parish; they are matter of ecclesiastical jurisdiction, and if they deviate from the amounts established by custom, must be approved by the ordinary after consulting the minister and the parishioners.

A vault cannot properly be made either in the church or churchyard, without the consent of the ordinary signified by a faculty, that is, a licence or permission, for that purpose; and this he does not grant until he has given the parson and parishioners an opportunity to express their opinions. A vault may be attached by prescription to a mansion; or again, the proprietors of a mansion may have a prescriptive right to be interred and to erect a tablet or tombstone in the aisle or chapel appurtenant to that mansion. But it would seem that the right adheres to the mansion, not to the family; who if they cease to be parishioners relinquish their right to the vault, the use of which may be granted to others. The heir, however, in this and in all cases may obtain an action of trespass at the common law against any one, even the parson or ordinary, who disturbs the remains, or removes or defaces the monument of his ancestor, or the hatchment, pennon, or coat armour suspended over his grave. In some parishes the parishioners have a prescriptive right to place a stone over a grave in the churchyard upon payment of a certain fee established by custom; but nothing of height can properly be erected without the consent of the ordinary; nor can a tomb or tombstone be repaired without the leave of the churchwardens; although the granting of that leave is a mere formality incumbent on those officers.

The placing of a monument in the church or a tablet on its walls is also within the jurisdiction of the ordinary; for the fixing of it in the chancel the consent of the rector is required, yet a lay rector has not a right to erect a monument or construct a vault there without a faculty from the ordinary. To remove without the ordinary's consent a monument or tablet once erected is an offence which subjects to prosecution before the ecclesiastical courts the party committing it, even though he should have himself erected the monument, and should have the consent of the incumbent for its removal.

As the erection of a tombstone, so the inscription upon it is a matter of ecclesiastical discipline, and an epitaph is unquestionably unlawful which is contrary to the canons or constitutions of the church in force at the time when the inscription is made. Thus when in a recent case the inscription "Pray for the soul of A. B." was objected to in the Ecclesiastical Court as recognising the doctrine of purgatory, the judge (whilst he deemed that prayers for the dead are not contrary to the canons, and, therefore, that the epitaph was not unlawful) distinctly affirmed the doctrine, that any new epitaph opposed to the doctrines of the Church of England might be removed, and the inscription of such an epitaph would subject the party who inscribed it to ecclesiastical censure.

(Haggard's *Consistory Reports*, i. 14, 205; ii. 333; Curteis's *Ecclesiastical Reports*, i. 880; Burn's *Ecclesiastical Law*, article 'Burial;' and Rogers's ditto.)

TON, or TUN. In modern English spelling the *ton* is a weight (twenty hundredweight, or 2240 pounds avoirdupois) and the *tun* is a measure of wine (two pipes, or 252 gallons). Accordingly, some have supposed that the measure was derived from the weight, and in fact a *tun* of water weighs about a *ton*. But a very little consideration of the manner in which *tonna* and *tunna* were used, is enough to convince any one that the weight was derived from the measure. These words are not classical, but they occur frequently in middle Latin (see Ducange, *in verb.*), and always as signifying a large cask. The hollow empty sound made by striking a large cask may have given rise to the name: we have often heard them say *ton* as plain as a cask can speak. The diminutive is *tonnella*, which was often used, but not much in England. The Commissioners of Weights and Measures found it only in Cardiganshire, standing for sixteen bushels of lime. The modern use of the word tunnel is now familiar enough. The old taxes of tonnage and poundage are enough to create a suspicion that the ton was originally a measure. This phrase would be tautology if tonnage meant a tax upon weight: we must understand tonnage and poundage to be a tax on measure and a tax on weight.

There are many local tons of weight which have sprung up in modern times.

TONE (in Music). The technical use of this word may be seen in SCALE, TETRACHORD, &c., in which it signifies a *musical interval*. In common language it refers to the *quality* of a musical sound, as when we speak of a fine-toned instrument.

In painting, the word tone is used in a somewhat similar manner. With reference to a particular tint it expresses the degree, quality, or intensity of a colour or shade, in relation to the other colours of the picture, or to the chiaroscuro. The tone of a picture, on the other hand, has relation to the general scale of colouring: thus a painting is said to be low, or gray, or warm in tone.

TONICS. [ANALEPTICS.]

TONNAGE is the term for the capacity of burden possessed by a ship or other floating vessel. The amount of tonnage possessed by the United Kingdom is given under TRADE and SHIPPING.

TONNAGE (or TUNNAGE) AND POUNDAGE. [SUBSIDY.]

TONSILS, DISEASES OF THE. [QUINSY.]

TONSURE (from the Latin, *tondere*, "to clip") is the name given to a distinguishing mark of the clergy of the Roman Catholic church, formed by cutting off a portion of the hair from the head. Mention is made of polled or shaven crowns in connection with the clerical character in the earliest ages of the church; but it seems to be clear that this has nothing to do with the modern tonsure: the practice of shaving the head or wearing the hair too short is in fact condemned in priests by Jerome and others of the Fathers. ('Bingham's 'Origines Ecclesiasticæ,' b. vi. c. iv. s. 16.) What is now called the tonsure was probably introduced not earlier than the latter part of the 5th century. Various explanations of its mystical meaning have been proposed: one theory is, that it is a sign of adoption by the church; another, that it is intended to symbolise the clerical subjection and obedience; another, that it is a memorial of the Saviour's crown of thorns, &c. According to the existing and long-established practice, the tonsure is formed by clipping away the hair from a circular space on the back of the head. The application of the scissors by the bishop to remove the first tuft is the initiatory rite by which persons are received into the clerical order. Of course the clerical crown, as it is called, must be preserved by repeated trimming when necessary; and the practice, we believe, is to enlarge it as the wearer rises in ecclesiastical station and dignity. The present however was not the universal form of the tonsure in former times. When the missionaries who had come over to Britain from Rome encountered in the 7th century the Scottish and Irish priests, they were horrified by observing that instead of a circular tonsure on the occiput, they were distinguished by a tonsure in the shape of a crescent on the forehead. The Roman missionaries asserted that this was the sort of tonsure worn by Simon Magus and his disciples. The true form of the tonsure and the proper mode of calculating Easter were the chief subjects of theological controversy in this island in the latter part of the 7th and the beginning of the 8th centuries.

TONTINE, a species of life annuity, so called from Lorenzo Tonti, a Neapolitan, with whom the scheme originated, and who introduced it into France, where the first tontine was opened in 1653. The subscribers were divided into ten classes, according to their ages, or were allowed to appoint nominees, who were so divided, and a proportionate annuity being assigned to each class, those who lived longest had the benefit of their survivorship, by the whole annuity being divided amongst the diminished number. The terms of this tontine may be seen in the French 'Encyclopédie' ('Finance' division, vol. iii). In 1689 a second tontine was opened in France. The last survivor was a widow, who, at the period of her death, at the age of 96, enjoyed an income of 73,500 livres for her original subscription of 300 livres. The last French tontine was opened in 1759. They had been found very onerous, and in 1763 the Council of State determined that this sort of financial operation should not be again adopted. Tontines have seldom been resorted to in England as a measure of finance. The last for which the government opened subscriptions was in 1789. The terms may be seen in Hamilton's 'Hist. Public Revenue.' A few private speculations have been entered into in the United Kingdom on the plan of the tontine.

TOPOGRAPHY (from the Greek τοπογραφία, which is from τόπος, "a place," and γράφειν, "describe"). Perhaps the nearest corresponding combination of English words would be "place-description." The word topography is limited by usage to the description of cities, towns, villages, castles, churches, and other artificial structures, including notices of everything belonging to the places or connected with them; for instance, not only the site, construction of the streets, public buildings, &c., of cities and towns, but the number of inhabitants, trade, history, and so forth. The word occurs in the Greek writers. Cicero ('ad Attic.,' i. 13) uses *Topothesy* (τοποθεσία) as synonymous with topography, though topothesy should have a different meaning. In the Greek "topography" has a wider meaning than it has with us. But a description of a given place, with reference to its physical character, hardly comes within our notion of a topographical description, which is generally, at least, limited as above stated.

TOREUTIC. [SCULPTURE.]

TORMENTIL, *Tormentilla officinalis* (Smith), *erecta* (Linn.), a small perennial plant, growing in the whole of Europe and the north of Asia, in forests, bogs, and heaths. [POTENTILLA.] The root, or rather the rhizoma, is officinal. As the plant flowers in June and July, the best time to collect the rhizomata is in April and May. Those gathered in autumn, while they remain moist, are phosphorescent. The roots of the Tormentilla (Potentilla) reptans (Linn.), of the Potentilla Commarum, those of the common strawberry, of the Geum urbanum, and also of the Polygonum bistorta, are frequently confounded with those of the true tormentil—errors of no great importance as far as their medical employment is concerned, as they possess properties similar in kind, but inferior in degree. In Italy the root of the Geranium striatum is substituted for it.

The rhizomata of the genuine plant are large in proportion to the branches they bear. They lie obliquely in the earth; old ones are knotty or resemble knobs, from $1\frac{1}{2}$ to 2 inches thick; younger ones are cylindrical, irregularly branched, the branches 1 to 2 inches long, and from one-fourth to one-half inch thick, curved and twisted. The epidermis and liber are very thin, but firm. The central part presents two or more concentric circles. The colour of the interior, when fresh, is a rose-red or fleshy colour; but when dried, it inclines more to a reddish or brownish yellow; in very old specimens it becomes white. It can be easily powdered: the powder is of a bright brownish-red. The rose-odour of the fresh root is lost by drying. Taste purely and strongly astringent. Specimens which are dark externally, and woody and white within, are to be rejected.

Water distilled from the fresh root has an agreeable rose-like odour. This plant contains more tannin than any other, except catechu and galls. Tormentil is the most powerful of our indigenous astringents, and more easily assimilated than oak-bark or galls. Though improper in active hæmorrhages, in passive discharges it is very useful, and may be given with aromatics, or opiates, or chalk, as in the compound powder of chalk. Few medicines are more efficacious for drying up the slimy mucus in which worms nestle in the intestines of children, than the compound powder of chalk. Infusion made with cold water is preferable to the decoction. The extract made in the common way soon spoils. But valuable as this substance is in medicine, it is of still greater utility in the arts and in agriculture. It may be most beneficially employed to tan leather, both where the oak grows and where it is absent, since one pound and a half of powdered tormentil is equal in strength to seven pounds of tan. It is used in Lapland and the Orkney Isles, both to tan and to dye leather, and in the latter parts to dye worsted yarn. By long boiling the tannin is converted into gum, and in times of scarcity the poor may collect and obtain much nourishment from the root. But the great service this plant renders in husbandry is its chief merit. Where it grows abundantly in wet pastures, the rot in the sheep is unknown. Where the heather has been burned on the Highland hills, this plant springs up spontaneously with the tender grass. [ANTHELMINTICS.]

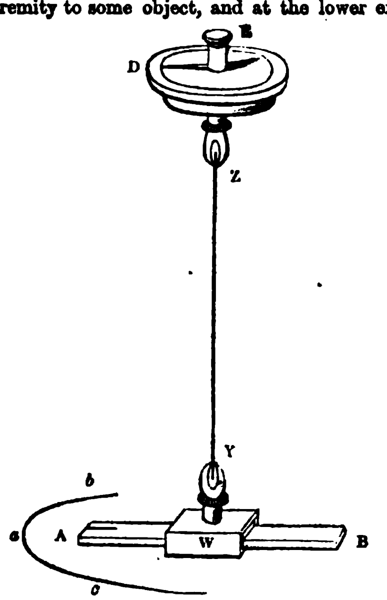
TORNADO. [WHIRLWIND.]

TORRICELLIAN VACUUM. [BAROMETER.]

TORRICELLI'S THEOREM. [HYDRODYNAMICS.]

TORRID ZONE. [ZONE.]

TORSION is that force with which a thread or wire returns to a state of rest when it has been twisted by being turned round on its axis: the thread or wire, which is suspended vertically, is attached at the upper extremity to some object, and at the lower extremity is a



weight with a horizontal index, or a stirrup, which is to carry a needle or bar in a horizontal position.

Let Z Y be the wire, W the weight or stirrup, and A B an index or needle, and let *b a c* be part of a graduated ring on the same level as the needle; then, on turning the object W round till a mark on the extremity A of the index is brought to any point, *b*, on the ring, the wire becomes twisted; and when the power by which W is turned is removed, the elasticity of the wire causes the point at A to oscillate within the ring through an arc, as *b a c*, which continually diminishes till the index rests in its original position.

Under ELASTICITY is given an investigation from which it is proved that, while the force of torsion is moderate, its intensity is directly proportional to the angle or arc through which the extremity A of the index is moved in twisting the wire. It is also proved that T, the time of a complete oscillation, is constant, or that the vibrations are isochronous, like those of a pendulum which is acted upon by gravity; and further, that when a body, as W, is suspended, the squares of the times of vibration vary directly as the momentum of the body's inertia, and inversely as the force of torsion: consequently when the forms and weights of suspended bodies are the same, the force of torsion varies inversely with the square of the time. With respect to the effects which a variation in the length of the wire will cause in the force of torsion, it may be observed that in proportion as the lengths of the wires are increased, points at the lower extremities must be turned, about the axis, through greater arcs, in order to produce equal degrees of torsion at equal distances from the points of suspension; and hence, if the number of revolutions be equal, the force of torsion will be inversely proportional to the length of the wire: it follows therefore that the time of a vibration varies directly with the square-root of the length of the wire.

These deductions from theory are confirmed by their agreement with the results of the numerous experiments made by M. Coulomb with an apparatus similar to that which is represented above; the times in which a certain number of isochronous vibrations were made with wires of different lengths, and carrying at their lower extremities cylinders of different weights, being observed. By comparisons also of experiments on wires of the same length and of different diameters, consequently of different weights, Coulomb found that the times of vibration were inversely proportional to the weights, or to the squares of the diameters of the wires; and since the force of torsion varies inversely with the squares of the times, it follows that when the wires are of the like material and of equal lengths, the force of torsion varies directly with the fourth power of the diameter. M. Poisson, in a memoir on the equilibrium and movement of elastic bodies ('Mémoires de l'Académie des Sciences,' tom. viii.), has deduced the same law from purely theoretical considerations.

It may be convenient to compare the force of torsion with that of gravity, and for this purpose it will be necessary to observe merely that the time in which a pendulum, whose length is l, makes a complete oscillation in a very small arc is expressed by $\pi\left(\frac{l}{g}\right)^{\frac{1}{2}}$ [PENDULUM], where g represents the force of gravity: then the time in which the torsion wire vibrates once on its axis being made equal to the time in which a simple pendulum vibrates, we have (using the formula in ELASTICITY), $\frac{K^2M}{n}=\frac{l}{g}$; therefore, as the momentum of inertia for a torsion wire suspending a body of a given form can be computed, and as l may be found from the observed time of a vibration, the value of n (the coefficient of the force of torsion) can be ascertained from this equation.

The torsion of slender wires was first employed by Coulomb for the purpose of determining the intensities of forces in nature and the laws of their action in circumstances which render direct methods inapplicable: his experiments were performed with an instrument which he invented, and which he designated a *torsion balance*. Under ELECTROMETER is given a description of the instrument and of the method of employing it in finding the laws of electric attractions and repulsions; and it will, therefore, be sufficient in this place to explain its application in determining those of magnetic action. For this purpose Coulomb adapted to the suspending wire, which was of copper, a small stirrup, as W, also of copper, in which could be placed a magnetised needle of steel. Before this was done, however, a copper needle, equal in weight to the magnetised needle which was to be used in the experiment, was placed in the stirrup, and the plate D at the top of the glass case was turned round till one extremity of the copper needle, which turned with the plate, was brought to the zero of the graduations on the horizontal circle *b a c* in the case, the suspending wire being in an untwisted state: the whole case was afterwards turned round till the needle, still pointing to zero, was in the direction of the magnetic meridian, which had been previously determined. The copper needle was then taken away, and the magnetised needle put in the stirrup; and as soon as it was at rest in the magnetic meridian, the suspending wire was twisted by turning the stem E, to which it is attached at the upper extremity of the case, till the index there had passed over some given number of degrees, which in one experiment was 360°. The suspended needle was thus made to deviate from its previous position $10\frac{1}{2}$ degrees, in which state the horizontal force of terrestrial magnetism was in equilibrio with the force of torsion; and the angle of torsion was then equal to $349\frac{1}{2}°$ ($=360°-10\frac{1}{2}°$). On turning the index at E through two revolutions, the needle was observed to rest between the opposing forces, at $21\frac{1}{2}°$ from its original place, when consequently the angle of torsion was 698¾° (=720°—21¼°). Obtaining in like manner several other angles of torsion with the corresponding deviations of the magnetic needle, and comparing them together, Coulomb found that the forces of torsion are constantly proportional to the sines of the deviations of the needle.

In order to discover the law of magnetic action with respect to the distances between the attracting or repelling bodies, Coulomb placed a magnetised needle in the stirrup of the balance, and after twisting the wire by turning the micrometer stem at E on its axis through a certain number of degrees, he observed where the needle rested between the opposing forces of torsion and the horizontal component of terrestrial magnetism: assuming then that the deviations of the needle were proportional to the forces of torsion, he found that, in order to make the needle deviate one degree, it was necessary to employ a force of torsion expressed by 35°. The wire being then untwisted, and the magnetised needle placed in the magnetic meridian, Coulomb introduced in the glass case, in a vertical position, and also in the plane of the magnetic meridian, a magnetised needle of the same dimensions as the other, so that if the two needles could have approached each other they would have been in contact at about an inch from the extremity of each; but the poles of the same denomination in the two needles being presented to each other, a repulsion took place, and the suspended needle came to a state of rest between the opposing forces of torsion and of magnetic repulsion. When the micrometer at E was allowed to remain in its actual position, the suspended needle was repelled 24 degrees, and consequently it was prevented from returning to the zero point by a force of torsion expressed by the sum of 24 degrees and of the horizontal force of terrestrial attraction ($=24\times 35°$, or 840°); thus the whole force of magnetic repulsion was expressed by 864°. In a second experiment, the wire being twisted by making the stem at E perform three revolutions (= 1080°) in a direction contrary to that of the 24° before mentioned, the needle rested at 17° from zero: the force of magnetic repulsion was then expressed by the sum of 1097 degrees and the value of terrestrial attraction ($=17\times 35°$, or 595°), that is, in all, 1692 degrees. On comparing together several experiments of the same nature, and also several similar experiments in which the poles of a contrary denomination were presented to each other, Coloumb found, neglecting small differences which may be supposed to have arisen from the extent and configuration of the needles, that the forces of magnetic repulsion and attraction vary inversely as the squares of the distances.

The "bifilar magnetometer" which was invented by M. Gauss, is a species of torsion balance: it is described briefly in the article TERRESTRIAL MAGNETISM, and at length in Taylor's 'Scientific Memoirs,' vol. ii. The apparatus with which, by the oscillations of two balls of lead at the extremities of a lever suspended horizontally by a string, Mr. Cavendish determined the average density of the earth, was also a balance acting on the same principle. [EARTH, MEAN DENSITY OF THE.] The bifilar suspension has also been claimed, apparently with justice, by Sir W. Snow Harris. See 'Rudimentary Magnetism,' parts i. and ii., p. 120, in which work, and also in the 'Rudimentary Electricity' of the same author, the various torsion instruments used in these branches of science are fully and satisfactorily described and illustrated.

For the strength of torsion in machinery, see MATERIALS, STRENGTH OF.

TORTOISE-SHELL. This beautiful substance, or at least the best kind of the material which goes under the name, is procured from a marine tortoise called the Hawk's-bill turtle, or *Testudo imbricata;* the Latin name being derived from the mode in which the scales upon the back are arranged, overlapping one another like the tiles upon the roof of a house, one kind of which were called by the Romans *imbrices.* In most other tortoises the several scales of which their covering is composed adhere to one another by their edges, like inlaid work. Each animal furnishes thirteen principal plates, five along the centre of the back, and four on each side; and twenty-five smaller scales or plates, which constitute the margin of the shell. The size and thickness of the plates depend on the magnitude and age of the animal, a fresh layer being produced every year; and at the margin of the large plates may be seen distinctly the edges of the layers as they thin off in succession. The horny plates are separated from the bony foundation by the application of heat; the whole shell being commonly placed over a fire until the plates begin to start from the bone, and the separation being completed by the aid of a slender knife. The shell varies much in value, being frequently injured by barnacles, limpets, and other shell-fish adhering to the turtles while alive, and interfering with the growth of the shell where they attach themselves. Occasionally plates of a uniform yellow colour are met with; and such are in great request among the Spanish ladies, who will give at least twice as much for a comb of plain tortoiseshell as for a mottled one. The belly-plates of the tortoise are yellow, and are sometimes found sufficiently clear for use.

Before working, the shell needs to be softened or *tempered,* which is usually done by dipping it for three or four minutes, or longer if it be very thick and brittle, in boiling water. Some manufacturers flatten and temper the shells with hot flat irons, similar to those used by laundresses; the tortoise-shell being, in the course of the operation, frequently dipped in cold water to prevent scorching. Generally, however, the less the shell is heated and pulled about the better, because from its apparent want of grain or fibre it is apt to become very brittle. Being also less fusible than horn, tortoise-shell cannot be made soft enough to be moulded without some injury to the colour; and accordingly the manufacturers, at least in England, never attempt to produce tortoise-shell combs with ornamental open work by means of dies. Such work is produced by pasting a piece of paper over the tortoise-shell, drawing the pattern upon it, cutting it out with drills and fine saws, and, after the paper has been removed by steeping in cold water, finishing the ornaments with the graver. The cutting or *parting* teeth of combs by machinery is described under COMB MANUFACTURE; but we may here notice another mode which is occasionally followed, and which illustrates the convenience arising from the flexibility of the material when warmed. A piece of tortoise-shell, large enough to make two combs, is bent or bowed in the direction of the length of the teeth, to such a degree of convexity that they may be cut with a straight bow-saw without cutting through either of the edges of the pieces of shell, which are required to form the top or back portions of the combs. The shell is then flattened and the ends or points of the teeth are separated with a narrow chisel or *pricker,* after which the combs are finished with files and scrapers, and bent to any required curvature upon wooden moulds. The frames for tortoise-shell eye-glasses are usually formed out of narrow slips of shell in which slits are cut with a saw, the slits being subsequently, while the shell is warm, *strained* or *pulled* open, until they form circular or oval apertures, by the insertion of tapering triblets of the required shape. The same yielding or flexible property is made use of in the manufacture of boxes; a round flat disc of shell being gradually forced by means of moulds into the form of a circular box with upright sides. The union of two or more pieces of shell may be effected by carefully scraping the parts that are to overlap, so as to render them perfectly free from grease, even such as might arise from being touched by the hand, softening them in hot water, pressing them together with hot flat tongs, and then plunging the joint into cold water.

In veneering with tortoise-shell, by which very beautiful work may be produced, it is usual to apply fish-glue, mixed with lamp-black, vermilion, green, chrome, white, or other colouring matter, at the back of the shell, both to heighten its effect and to conceal the glue or cement by which it is secured to the wooden foundation. In making knife-handles and some other ornamental work, metallic foils are put beneath the tortoise-shell veneer with excellent effect.

The qualities of tortoise-shell as brought to market are thus distinguished: Manilla, fine and large; Singapore, nearly as good as Manilla; West India, large and heavy, but red; Honduras, darker, but with large dark red spots; Calcutta, dark, heavy, and badly coloured; Bombay, the worst quality. Sometimes plates are obtained as large as 13 inches by 8 inches, and a quarter of an inch thick in the middle. The price of the best tortoise-shell is generally about 60*s.* per lb. A small import duty, formerly imposed, was repealed in 1846.

TORTURE, which in a legal sense means the application of bodily pain in order to force discoveries from witnesses, or confessions from persons accused of crimes, has been recognised by the laws of most civilised nations as an instrument for obtaining judicial truth. A learned civilian terms it "Mos antiquissimus, omnium ferè bene institutorum populorum communis: ut non immeritó pro lege ac jure quodam gentium habeatur." (Wesenbechii, 'Paratitla ad Dig. de Quæstionibus,' num. 3.) Torture was applied to slaves at Athens (Demosthen., 'Orat. adv. Pantænet.'); and Cicero states that the Athenian and Rhodian laws allowed it to be applied even to citizens and freemen ('Oratoriæ Partit.,' 34); but there is some doubt as to the accuracy of this statement with respect to Athenian freemen. It has been questioned whether torture was used by the Romans during the republican period; but Cicero frequently speaks of it as an ancient practice, and attributes it to the customs and institutions of an earlier age ("moribus majorum"). ('Oratio pro Rege Deiotarô,' c. 1; 'Pro Milone,' c. 22; 'Orat. Partit.,' 34.) Tacitus also ascribes a modification of the practice to an ancient Senatus-consultum ('Ann.,' lib. ii., c. 30). However this may have been, it is beyond all doubt that the use of torture in judicial inquiries had become fully established in the time of the early emperors. Regularly the Roman law admitted the torture only in the case of slaves when examined either as witnesses or offenders; but under the emperors—even under Augustus, but more frequently under Tiberius and Caligula—instances occur in which freemen and citizens were interrogated by torture: most of these instances, however, are to be considered as irregular acts of power, not sanctioned by law. Rules regulating the mode of applying torture, and limiting the occasions of its application, were early established in the Roman law. One of the most important of these is that which Cicero in the passages above cited refers to ancient usage, namely, that a slave should not be tortured to give evidence against his master, except in the cases of incest and conspiracy. Tacitus says that in order to evade the operation of what he calls an ancient decree, prohibiting the "quæstio servi in caput domini," Tiberius, "novi juris repertor," invented the scheme of making over the slave from the accused to a public functionary, and then putting him to the torture against his former master. This device is however ascribed by other historians to Augustus. (Dion., lib. lv.) In judicial inquiries or public trials for crimes, the "quæstio" was applied at the instance of the accuser in the presence of the prætor and judices, and the statements made under torture were reduced into writing (in tabulas relata), and signed by the prætor (Heineccius, 'Ant. Rom.,' lib. iv., c. 18, sect. 25); but private persons also were permitted "in foro domestico" to extract evidence from their slaves by torture. (Cicero, 'Orat. pro Cluentio,' cc. 63, 66; Quintilian, 'Declam.,' 328, 338, 353.) At a later period of the Roman empire, many new regulations appeared, and the earlier restrictions upon this practice were wholly removed or greatly modified. Several exceptions to the rule, which prohibited "quæstiones in caput domini," were introduced, and even freemen were subjected to torture, when there was positive evidence of the "corpus delicti," and probable or presumptive evidence that the accused was the guilty person. Moreover, when the offence was of a grave character, and affected the head of the state immediately, personal exemptions from torture were not admitted. "Omnes omninó," says the 'Digest' (lib. xlviii., tit. 18; 'De Quæstionibus,' sect. 10), "in majestatis crimine, quod ad personas Principum attinet, cum res exiget, torquentur." (Wasserschleben, 'Historia Quæstionum per Tormenta apud Romanos,' Berol., 1836.)

It is remarkable, considering the extent to which the practice of torture was eventually carried by the Inquisition, that, according to the principles and early practice of the Canon law all severities of criminal justice were prohibited; and by the ancient decretals of the church, every ecclesiastical person who took part in them was liable to censure. Previous to the 13th century no trace of the use or permission of torture is to be found in the canon law, either in the process of accusation, which was founded entirely on the model of the Roman law, or in the inquiry. In the 13th century the severe rules of the Roman law respecting the torture of witnesses and accused persons "in crimine majestatis," began to be applied by the ecclesiastical law in the case of heresy, which was then considered and termed "crimen læsæ majestatis divinæ." Nevertheless, the earlier councils relating to the Inquisition, though violent in their denunciations against heretics, are silent respecting the use of torture; and the first trace of any ecclesiastical sanction of this mode of proceeding, even in the case of heresy or apostacy, is found in a decree of Innocent IV. in 1252, which, however, does not authorise the inquisitors to use it, but calls upon the civil magistrates to press offenders to confession against themselves and others by means of torture. At a subsequent period the necessity for secrecy in the proceedings of the Inquisition induced the use of torture by the inquisitors themselves, and the extent to which it was afterwards used is notorious. (Biener's 'Geschichte des Inquisitions-Processes.') An instance of the application of torture under the ecclesiastical law occurred in England, under remarkable circumstances, about sixty years after the first sanction of the practice by the Church of Rome. In the great contest between Clement V. and the Templars in 1310, inquisitors were appointed by the pope to examine the prisoners who were charged (among other offences) with apostacy and heresy. The Archbishop of York, who was one of the inquisitors, propounded to certain monasteries and divines several difficulties which had occurred to him respecting the mode of conducting the examinations. Among other questions he asked, whether they might make use of torture:—"Licet hoc in regno Angliæ nunquam visum fuerit vel auditum? Et si torquendi sunt, utrum per clericos vel laicos? Et dato, quód nullus omnino tortor inveniri valeat in Angliâ, utrúm pro tortoribus mittendum sit ad partes transmarinas?" (Hemingford, p. 256.) In consequence of the doubts of the archbishop, Edward II. refused to allow the inquisitors to torture the accused. Upon this Clement wrote a letter of remonstrance to the king, who referred the matter to the council; and upon their recommendation it was resolved that the Templars should in the first place be separately confined and examined singly; and if upon this mode of proceeding they refused to confess more than they had previously done, "quòd extunc *quæstionarentur*, ita quód quæstiones illæ illatæ fierent absque mutilatione et debilitatione perpetuâ alicujus membri, et sine violentâ sanguinis effusione." (Raynouard, 'Monumens Historiques relatifs à la Condamnation des Chevaliers du Temple.') In accordance with this resolution, a special commission from the king authorised the inquisitors "to dispose and deal with the bodies of the Templars in *quæstionibus* et aliis ad hoc convenientibus," as might seem fit to them to be done according to ecclesiastical law; and a precept was issued to the sheriffs of London, in whose custody the accused were, to suffer the inquisitors to examine them and put them to the torture. (Rymer's 'Fœdera,' tom. iii., pp. 228, 232.)

Judicial torture formed a part of all the legal systems of Europe which adopted the Roman law. In Germany it was gradually introduced as the use of the Roman law increased, and displaced the ancient Teutonic and feudal proceedings by ordeal and battle. Indeed, while these judicia dei continued in use, there is no notice of the existence of torture. In most German cities judicial torture was unknown until the end of the 14th century; although it appears in the statutes of the Italian municipalities at a much earlier period. (Mittermaier's 'Deutsche Strafverfahren,' theil i.) A species of torture was, indeed, employed in Germany to a very great extent during the middle ages, of which there are traces and traditions connected with the torture-chambers and instruments still exhibited in Nürnberg, Salzburg, Ratisbon, and other ancient cities and castles; but these were in general not used for legal or judicial torture, but for the proceedings of those secret religious tribunals, or 'Fehmgerichte,' which abounded at that period. The regular torture, however, as derived from the Roman law, continued in many European states until the middle of the last century, when more enlightened views on the subject of jurisprudence led to a prevailing conviction of the inefficacy and injustice of this mode of ascertaining truth. In France the "question préparatoire" was discontinued in 1780 by a remarkable decree, which is to be found in Merlin's 'Répertoire,' vol. x.; and torture in general was abolished throughout the French dominions at the revolution in 1789. In Russia its abolition, though recommended by the Empress Catherine in 1763, was not effected until 1801. In Austria, Prussia, and Saxony it was suspended soon after the middle of the last century; but although so seldom used as to be practically extinct, torture continued to form part of the laws of Bavaria, Hanover, and some of the smaller states of Germany within the last sixty years. (Mittermaier's 'Deutsche Strafverfahren,' theil i.) In Scotland, where the law is almost wholly founded upon the civil law, the use of torture prevailed until the reign of Queen Anne, when it was declared by the act for improving the union of the two kingdoms (7 Anne, c. 21, s. 5), that in future "no person accused of any crime in Scotland shall be subject or liable to any torture."

The history of the use of torture in England is curious. From the hesitation to apply it to the Templars in the reign of Edward II. (1310), as above mentioned, as well as from the express statement of Walter de Hemingford, it appears to have been at that time unknown in England, either as an act of prerogative, or as an instrument of criminal inquiry warranted by law. Nevertheless, Holinshed relates that, in 1468, Sir Thomas Coke, the lord mayor of London, was convicted of misprision of treason upon the evidence of one Hawkins, given under torture; and that Hawkins himself was convicted of treason by his own confession on the rack, and executed. From this period until the Commonwealth the practice of torture was frequent and uninterrupted, the particular instances being recorded in the council-books, and the torture-warrants in many cases being still in existence. The last instance on record occurred in 1640, when one Archer, a glover, who was supposed to have been concerned in the riotous attack upon Archbishop Laud's palace at Lambeth, "was racked in the Tower," as a contemporary letter states, "to make him confess his companions." A copy of the warrant under the privy seal, authorising the torture in this case, is extant at the State-Paper Office. With this instance the practice of torture in England ceased, no trace of its continuance being discernible during the Commonwealth or after the Restoration. But although the practice continued during the two centuries immediately before the Commonwealth without intermission, it was condemned as contrary to the law of England, and even declared to be unknown in this country by judges and legal writers of the highest character who flourished within that period. Thus Fortescue, who was chief-justice of the court of King's Bench, and wrote his book, 'De Laudibus Legum Angliæ,' in the reign of Henry VI., and who notices a case of false accusation under torture (which was probably the case of Sir Thomas Coke above mentioned), condemns the practice in the strongest terms, though he does not expressly deny its existence in England. (Fortescue, cap. 22.) Again, Sir Thomas Smith, a very eminent lawyer, statesman, and scholar, who wrote in the early part of Elizabeth's reign, says that "torment or question, which is used by the order of the civil law and custom of other countries, is not used in England. It is taken for servile." (Smith's 'Commonwealth of England,' book ii., cap. 27.) And Sir Edward Coke, who wrote in the reign of James I., says "there is no law to warrant tortures in this land; and there is no one opinion in our books, or judicial record, for the maintenance of them." (3 'Inst.,' 35.) Notwithstanding this explicit denunciation of the practice as against law, both Smith and Coke repeatedly acted as commissioners for interrogating prisoners by torture (Jardine's 'Reading on the use of Torture in England'); and the latter, in a passage which occurs in the same book, and only a few pages before the words just cited (p. 25), impliedly admits that torture was used at examinations taken before trial, though it was not applied at the arraignment or before the judge. There is also a direct judicial opinion against the lawfulness of torture in England. In 1628, the judges unanimously resolved, in answer to a question propounded to them by the king in the case of Felton, who had stabbed the Duke of Buckingham, "that he ought not to be tortured by the rack, for no such punishment is known or allowed by our law." (Rushworth's 'Collections,' vol. i., p. 638.) And yet several of the judges who joined in this resolution had themselves executed the warrants for torture when they held ministerial offices under the crown. Possibly the explanation of this inconsistency between the opinions of lawyers and the practice may be found in a distinction between prerogative and law, which was better understood two centuries ago than it is at the present day. It was true, as the above authorities declared, that torture was not part of the common law; it was not used in judicature, as it was by the Roman law and the legal systems derived from it in Germany, Italy, and Spain; and, therefore, in England no judge could by law direct the torture to be applied, and no party or prosecutor could demand it as a right. But that which was not lawful in the ordinary course of justice was often lawful for the prerogative of the crown, which authorised this mode of enforcing the discovery of crimes affecting the state, such as treason or sedition, and sometimes of offences of a grave character not political,—acting in this respect independently of, and even paramount to, the common law, in accordance with the doctrine asserted so early as the reign of Edward I., "quod Rex pro communi utilitate per prerogativam suam in multis casibus est suprà leges et consuetudines in regno suo usitatas." ('Rolls of Parliament,' 20 Edw. I., A.D. 1292, vol. i.) This view of the subject is confirmed by the circumstance that in all instances of the application of torture in England, the warrants were issued immediately by the king, or by the privy council. Objectionable as the use of torture was in all countries and under all circumstances, it was in no country so unjust and dangerous an instrument of power as in England. In other countries, where it formed part of the law of the land, it was subject to specific rules and restrictions, fixed and determined by the same law which authorised the use of such an instrument, and those who transgressed them were liable to severe punishment. But in England there were no rules, no responsibility, no law beyond the will of the king. "The rack," says Selden, "is nowhere used as in England. In other countries it is used in judicature when there is *semiplena probatio*—a half-proof against a man; then, to see if they can make it full, they rack him if he will not confess. But here in England they take a man and rack him—I do not know why nor when—not in time of judicature, but when somebody bids." ('Table-Talk,'—Trial.)

The particular modes of applying torture were as various as the ingenuity of man is fertile in devising the means of inflicting bodily pain. Cicero and other Roman writers speak of the *equuleus*, or *eculeus*, and the *fidiculæ*, as common instruments of torture; but it is extremely doubtful what they were. Much discussion respecting them, and a reference to the various authors who have mentioned them, will be found in a treatise entitled 'Hieronymi Magii Anglarensis de Equuleo Liber Posthumus,' Amsterdam, 1664. The rack, which was common throughout Europe, was a large frame, in shape somewhat resembling a mangle, upon which the examinant was stretched and bound; cords were then attached to his extremities, and, by a lever, gradually strained, till, when carried to its utmost severity, the operation dislocated the joints of the wrists and ankles. This engine is said to have been brought into the Tower by the Duke of Exeter in the reign of Henry VI., and was thence called the Duke of Exeter's daughter. (3 'Inst.,' 35.) Besides the rack there were endless varieties of what were termed the "lesser tortures," such as thumb-screws, pincers, and manacles. In England, one of the most dreaded engines of this kind was the scavenger's daughter, so called by a popular corruption from Skevington's daughter, being invented by Sir William Skevington, a lieutenant in the Tower in the reign of Henry VIII. (Tanner's 'Societas Europæa.') In Scotland the instruments were the boots, called in France "le brodequin" (in which the torture was applied by driving in wedges with a hammer between the flesh and iron rings drawn tightly upon the legs); the thummikins; the pinniewinks, or pilliewinks; the caspitaws, or caspicaws; and the tosots. (Maclaurin's 'Introduction to Criminal Trials,' sect. 9.) The particular construction of these barbarous instruments it would be difficult at the present day to ascertain, but several of them were in practical use in Scotland within twenty years from the final abolition of torture in that country in 1708. (Howell's 'State Trials,' vol. vi.)

It is remarkable that although the use of torture in judicature has prevailed in most civilised countries, it has been almost universally denounced by enlightened jurists of all ages. Cicero repeatedly condemns it as unjust and inefficacious; and even the civil law, which sanctioned the practice in Europe for many centuries, speaks of it as "a deceitful and dangerous instrument, which very often fails to extract the truth." ('Dig.,' lib. xlviii., tit. 18.) The opinions of eminent lawyers in England have been already cited; and the juridical writers of the Continent, in more recent times, have unanimously taken the same view of the subject. (Mittermaier's 'Deutsche Strafverfahren, theil i.) On the other hand, a curious defence of torture will be found in Wiseman's 'Law of Laws, or the Excellence of the Civil Law.'

TORUS. [MOULDINGS.]

TORY. This name has now, for about two hundred years, served to designate one of two principal political parties in this country. It is not to be expected that for so long a time the name has been always associated with one uniform set of political principles, or that any formula could be devised which would accurately describe Toryism at every period of its history. Extending, like the name of the other principal political party, from the legislature through every class of the community, it would naturally, where the number of persons to be brought to concur in any change is so large, preserve any meaning which it has once acquired for a length of time, and throughout perhaps a general consistency of meaning; but on the other hand, engaged as the Whig and Tory parties of the legislature have been without intermission in a struggle for power, which power is attended by profit, they have been always exposed to the temptation, from whose insensible workings even the best disposed men are not secure, of altering and adapting opinions so as to facilitate the gaining what they fight for, or the keeping what they have gained; and the far more numerous members of the party who are without the legislature would generally follow those whom they look upon as their leaders, and by whose success every adherent of the party has some hope of being benefited.

The name Tory, as well as the name Whig, and the existence of two parties in the state corresponding to those which have now been known for a long time as Whig and Tory parties, date from the reign of Charles II. "It was in the year 1679," says Mr. Hallam, "that the words Whig and Tory were first heard in their application to English factions; and though as senseless as any cant terms that could be devised, they became instantly as familiar in use as they have since continued. There were then indeed questions in agitation which rendered the distinction more broad and intelligible than it has generally been in later times. One of these, and the most important, was the Bill of Exclusion, in which, as it was usually debated, the republican principle, that all positive institutions of society are in order to the general good, came into collision with that of monarchy, which rests on the maintenance of a royal line, as either the end or at least the necessary means of lawful government. But as the exclusion was confessedly among those extraordinary measures to which men of Tory principles are sometimes compelled to resort in great emergencies, and which no rational Whig espouses at any other time, we shall better perhaps discern the formation of these grand political sects in the petition for the sitting of parliament, and in the counter addresses of the opposite party." ('Constitutional History of England,' vol. ii. p. 592.) The first Tories opposed the Exclusion Bill and supported Charles II. in his endeavour to prevent a renewal of the attack upon his brother, by successive prorogations of the parliament. The origin of the name is referred by Roger North, a very hot Tory, in a curious passage, to the connection of the party with the Duke of York and his popish allies. "The Exclusioners," he says, "observing that the Duke favoured Irishmen, all his friends, or those accounted such by appearing against the Exclusion, were straight become Irish; thence Bogtrotters, and in the *copia* of the factious language the word Tory was entertained, which signified the most despicable savages among the wild Irish; and being a vocal clear-sounding word, readily pronounced, it kept its hold, and took possession of the foul mouths of the faction, and everywhere as these men passed we could observe them breathe little else but Tory." ('Examen,' p. 321.) Thus Dr. Johnson's first interpretation of *Tory* in his Dictionary is, "A cant term, derived, I suppose, from an Irish word signifying a savage;" and Mr. Moore, in his 'Memoirs of Captain Rock,' sarcastically refers the history of the Tory party to a general 'History of the Irish Rogues and Rapparees.' Dr. Johnson proceeds to give an explanation of the word *Tory*, which is perhaps as good a short general description of the principles of Toryism as is to be given:—"One who adheres to the ancient constitution of the state, and the apostolical hierarchy of the Church of England." In other words, the maintenance of things as they have been, or, when some great change has taken place against the will of this party, things as they are, has from the beginning been the prime characteristic of Toryism. The term, as indicating an existing party, is now nearly obsolete; no party, and few individuals, would choose to designate itself or themselves as Tory.

The history of the Tory party, rising and falling in the state, may be traced in a series of articles in Knight's 'Companion to the Newspaper' for 1834, 1835, and 1836, entitled 'Changes of Administration and History of Parties;' or in Mr. G. W. Cooke's 'History of Party,' 3 vols. 8vo, which is on the whole a useful publication, though its accuracy is not to be implicitly depended on.

TOURBINE. [TURBINE.]

TOURN. [LEET.]

TOURNAMENT, or TOURNEY, is from the French *tournoi*, formerly *tournoiement*, for which the Latin writers of the middle ages use *torneamentum*, *tornamentum*, or *turneimentum*, and sometimes also *torna*, *torne*, *tornatio*, *tornerium*, or *torneta*. The Byzantine annalists have transferred the word into *ternementum* (Τερνεμεντον). There can be little doubt, though other etymologies have been suggested, that *tournoiement* means merely a turning or wheeling about, from the common French verb *tourner*, to turn. This will agree with other tourns. We have in England the sheriff's turn or tourn. Other barbarous Latin words of the same connection are *tornare*, to turn about in fight, and also to call out or challenge to combat (in which last sense there is also the old French lui tourner (or torner), par gage de bataille); *torneare*, *torniare*, *turneare* (in French *tournoier*), *torniamentare*, and *torneizare*, to take part in a tournament; *torniator*, a performer in a tournament. (Du Cange, 'Glossarium ad Scriptores Med. et Inf. Latinit.,' vi.; Carpentier, 'Glossarium Novum,' iii.; H. Spelman, 'Glossarium Archaiologicum;' Fr. Junii, 'Etymologicum Anglicanum,' ad vv. *Tourneying* and *Tournoy*.)

A tournament may be defined to have been a species of combat in which the parties engaged for the purpose of exercising and exhibiting their courage, prowess, and skill in arms, and not either out of enmity (as in ordinary warfare), or even (as in the modern duel) for the mere purpose of wiping off some dishonourable imputation (a purpose which was served rather by the ancient ordeal or wager of battle than by the tournament). It is obvious, however, that although the primary and professed design of the tournament was nothing more than to furnish an exciting show, and to give valour and military talent an opportunity of acquiring distinction, other passions would be very apt to intermingle in the heat of contest with the mere ambition of superiority, and sometimes even to disguise themselves under that pretext.

The origin of the tournament has been carried back at least to the Roman times. Virgil's description of the game of Troy (*ludus Trojæ*, Æn. v. 545-602) is, in some passages, not unlike what the name would lead us to suppose the tournament may have originally been. The tournament, like the other customs of chivalry, must be properly considered to have taken its rise after the establishment of the feudal system. Some writers attribute the invention of the tournament to the Emperor Henry, surnamed the Fowler, who died in 936; and another common account, given on the authority of the Chronicle of Tours, and the Chronicle of St. Martin of Tours, is that its inventor was Geoffrey of Preuilly, ancestor of the counts of Anjou, who died in 1066; but Du Cange, in his Dissertations 'De l'Origine et de l'Usage des Tournois,' at the end of his edition of Joinville, quotes various notices of tournaments held before the age of either of these personages: among others, one which took place at the celebrated interview between Louis of Germany and Charles the Bald of France, at Strasburg, in 841, as mentioned by the contemporary chronicler Nithard. Geoffrey of Preuilly perhaps introduced the tournament into Western France. From the French it appears to have passed to the English and the Germans, and, in a later age, to the Italians and the Greeks. Tournaments are said to have been first practised by the English in the time of Stephen; but they were forbidden by Henry II., as they had already been by the church; and it was not till the reign of Richard Cœur-de-Lion that they were properly established in this country. The flourishing era of the tournament, here as well as in France and elsewhere, was in the 13th and 14th centuries; but it continued in frequent use down to the middle of the 16th, and was not altogether abandoned till a considerably later date, although the few tournaments that were held in the latter part of that century were rather such mere shows or spectacles as have been sometimes exhibited under the same name even in our own day, than the real combats which were so called in an earlier age. The accident of Henry II. of France meeting his death at a tournament in 1559 almost at once occasioned the cessation of the practice everywhere as well as in France; but the spirit by which it was formerly kept up had long before this been decaying under the influence of the various circumstances which, at least from the middle of the preceding century, had been operating a general change in the social condition of Europe. Among the physical causes in question the chief may be considered to have been the introduction of fire-arms into war; among the moral, the extension of the commercial spirit, and the rise everywhere of a new literature, together bringing with them other habits, other tastes, another civilisation. The Church of Rome, however, it may be observed, which had set its face very stoutly against tournaments from about the middle of the 12th to the middle of the 13th century, prohibiting persons from engaging in them by some of its decrees on pain of excommunication, and denying Christian burial to such as lost their lives in these contests, had long been reconciled to them, and for some ages had rather cherished and encouraged the practice than otherwise.

Tournaments were usually held on the invitation of some prince, which was proclaimed by his heralds throughout his own dominions, and at all the foreign courts or other places whence it was expected or desired that parties might come to take part in the martial competition. A detail of the forms and ceremonies that were observed in fixing the lists (or boundaries within which the fighting was to take place), in offering and accepting the challenges, in declaring the issue of each encounter, and in assigning and bestowing the prizes (which last office was often performed by female hands), cannot be attempted here. All these particulars, together with the usual laws or regulations of the combat, and the mode of fighting (which was commonly with lances and swords, and in the first instance always on horseback, although parties who were dismounted frequently continued the contest on foot), may be most conveniently learned from the many accounts of tournaments in Froissart and other old chroniclers, or even from such fictitious narratives as the 'Knight's Tale of Palamon and Arcite,' in Chaucer (or Dryden's paraphrase of it), or that of the tournament at Ashby in Scott's 'Ivanhoe,' or from Scott in his 'Essay on Chivalry' ('Miscellaneous Prose Works').

The distinction between a tournament and a joust, or just, is not very clear. Du Cange makes the joust to be properly a single combat or duel, whereas in a tournament a considerable number of combatants were commonly engaged on each side. But this distinction is certainly not generally observed in the use of the two words; and our English archæologist, Spelman, who defines *torniare*, "gladiis concutere, *justas facere*, hastitudium exercere," does not appear to have been aware of it. The term jouste or joust has been derived, improbably enough, from the Latin *juxta*, "near to," because, say the etymologists, the combatants here fought hand to hand. It is, no doubt, connected with the verb to justle, or jostle (in French, *jouster*), though possibly the original word may be best preserved in the Italian form *giostra*, which the Byzantine writers have imitated in their τζουστρα and τζουστρια. There was also the species of single combat termed a *pas d'armes*, or passage of arms: it was at a *pas d'armes* that Henry II. was killed. On this subject, besides the works quoted above, the reader may consult the 'Traité des Tournois, Joustes, Carrousels, et autres spectacles publics' (par Claude François Menestrier), 4to, Lyon, 1669; and 'Mémoires sur l'ancienne Chevalerie, considérée comme un Etablissement politique et militaire,' par J. B. de la Curne de St. Palaye, 3 tom. 12mo, Paris, 1759–1781.

TOURNIQUET is a peculiar kind of bandage applied to a limb for the purpose of arresting the current of blood through its main artery. It is employed for this purpose in several cases, but especially in amputations of parts of the limbs, where large arteries have to be suddenly cut across. Before the invention of the tourniquet, surgeons used to constrict the limb with a simple tight bandage; but although this plan may well be resorted to in an emergency, it not only produces excessive pain, but, by obstructing the current through the veins more than that through tho arteries, produces an extreme engorgement of the limb, and in amputation permits severe hæmorrhage. A slight improvement in this plan was that of twisting pieces of wood under the band, and so gradually tightening it; but the first instrument formed on the principles of the tourniquet was invented by Jean Louis Petit in 1718. Since that time various changes have been introduced, but at present the construction of all tourniquets is nearly similar. They consist of a very tough band, about an inch and a half wide, upon which there is a moveable leather pad, to be placed immediately over the artery on which it is desirable that the chief pressure should be applied. For this purpose, also, the surface of the pad must be directed towards the bone of the limb, that the artery may be pressed firmly against it. The rest of the band is passed round the limb, and is fastened by a buckle. It is tightened and loosened by means of a bridge of brass, which is capable of being elevated or let down by a screw passing through it, and at the ends of which there are two small rollers, around each of which the band is made to take a half turn. In use, the bridge and screw are placed on the opposite side of the limb to the pad.

The tourniquet is now not so generally used as formerly. Many surgeons prefer to have the artery compressed during an amputation by an assistant, because the tourniquet is not free from the objection of compressing the veins as well as the artery, and is liable to accidents which cannot be instantly repaired. An instrument of a superior character has also been invented by Signor Signoroni, a surgeon at Milan. It is composed of two arches of steel, connected by a hinge at one end, and each bearing at the other end a pad. By an Archimedes screw ingeniously placed at the hinge, the pads can be approximated and separated like the ends of the blades of a pair of callippers, and can be immoveably fixed in any position. In use, one pad is put over the artery, and the other on the opposite part of the limb, and the screw is worked till, in their tendency to approximate, the pads have sufficiently compressed the artery, upon which alone the pressure is thus made to fall.

As already said, in an emergency, such as that of a wound of any of the large arteries of a limb, when medical aid is not near, the old-fashioned tourniquet should be instantly applied. A piece of strong tape or cord should be tied in a double knot round the limb above the wound; a piece of wood, or anything firm, should be then passed under it, and twisted, just as packers tighten the cords round bales and boxes, till the flow of blood has ceased. For hæmorrhage from large veins or small arteries, this tourniquet should not be employed, but simple pressure with the finger or the hand.

TOWN, in its popular sense, is a large assemblage of adjoining or nearly adjoining houses, to which a market is usually incident. Formerly a wall seems to have been considered necessary to constitute a town; and the derivation of the word, in its Anglo-Saxon form "tun," is usually referred to the verb "tinan," to shut or enclose. In legal language "town" corresponds with the Norman "vill," by which latter term it is frequently spoken of in order to distinguish it from the word town in its popular sense. A vill or town is a subdivision of a county, as a parish is part or subdivision of a diocese; the vill, the civil district, being usually co-extensive with the parish, the ecclesiastical district, and, *primâ facie*, every parish is a vill, and every vill a parish. Many towns however, not only in the popular, but in the legal sense of the term, contain several parishes, and many parishes, particularly in the north of England, where the parishes are exceedingly large, contain several vills, which vills are usually called tithings or townships. As until the contrary is shown the law presumes towns (or vills) and parishes to be co-extensive, Lord Coke goes so far as to say that it cannot be in law a vill unless it hath, or in times past hath had, a church, and celebration of divine service, sacraments, and burials. But this, for which no authority is given, appears to confound parish and vill, and to be inconsistent with the cases in which it has been held that a parish may consist of several vills. (1 Lord Raymond, 22.) The test proposed by Lord Holt is, that a vill must have a constable, and that otherwise the place is only a hamlet, an assemblage of houses having no specific legal character. Hence a vill is sometimes called a *constablewick*. Towns are divided into cities, boroughs, and upland towns, or (as we should now call them) country towns. Towns belonging to the last of these classes have been described as places which, though enclosed, are not governed, as cities and boroughs are, by their own elected officers. The Anglo-Saxon "tun" terminates the names of an immense number of places in England; and in the southern counties the farm *enclosure* in which the homestead stands is usually called the barton (barn-*town*), in Law Latin, bertona.

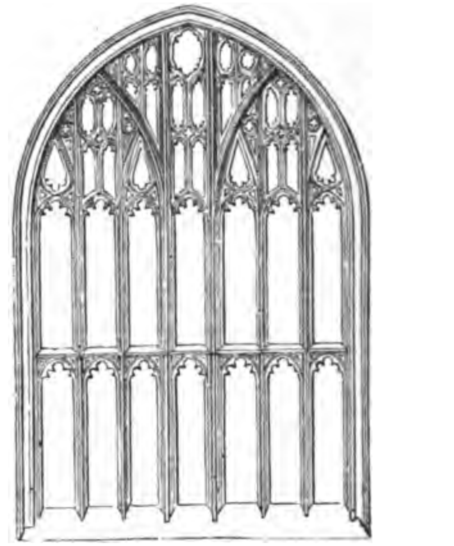
TOWNLEY MARBLES, the name of an assemblage of Greek and Roman sculpture which now forms a portion of the extensive collection of antiquities in the British Museum. It received its appellation from Charles Townley, Esq., of Townley in Lancashire, who began forming this collection whilst residing in Rome between 1765 and 1772, a period when excavations on the sites of ancient edifices were eagerly prosecuted. Mr. Townley was a Roman Catholic, educated on the

Continent, and, being well connected, was in friendly relations with the papal authorities, and was at the same time in intimate association with Winckelmann, Gavin Hamilton, and other distinguished artists and archæologists then resident in Rome, and who readily afforded their advice and assistance in his purchases. Thus aided, he succeeded whilst at Rome in bringing together a very choice collection of ancient marbles, bronzes, terra-cottas, gems, &c.; and after his return to England he continued to add to it by means of agents at Rome, who kept him apprised of any really valuable works which were brought to light and open to purchase, as well as by the purchase of the collection previously formed by Nollekens, the sculptor, and any desirable specimens offered for sale in this country. After Mr. Townley's death, in January, 1805, his executors, in accordance with the terms of his will, offered his collection of terra-cottas and marbles to the nation. The government accepted the offer, and a vote of 20,000*l.* was obtained for the purchase. The bronzes, coins, and gems were subsequently (1814) purchased for 8200*l.* The purchase of the Townley marbles rendered necessary the erection of a suite of rooms to contain these and the previously acquired works of ancient art, and led to the creation of a new department under the title of the Department of Antiquities. The collection was opened to the public in 1807, and was called the Townley Gallery; but since the rooms originally built for the collection have been swept away to make room for the present structure, the Townley marbles have been incorporated with the general collection of Græco-Roman remains, or "works discovered in Italy, but owing their origin and character, either directly or mediately, to the Greek schools of sculpture." Of these works which fill the Græco-Roman galleries in the British Museum, the Townley collection forms the most important portion, both as regards extent and character. It would be out of place to particularise here the specimens of a collection which is now incorporated in the national collection, but we may mention that among the statues belonging to it are the exquisite Aphrodite, or Dione (given in this work under DIONE); the Discobolus (the finest of its kind extant, engraved under DISCOBOLUS); the well-known Drunken Faun; a fine bronze Heracles [HERACLES], a Fortune, and several more of a very high character: that among the rilievi are, Achilles; the Muses; the singularly graceful Bacchante, and various Dionysiac groups, given under DIONYSIA; and that the busts include some of the noblest character, including an early Heracles; the Hera, given under that name; others of Athene, Zeus, Apollo, and other of the Olympian deities; the terminal Pan; the very beautiful female head rising from the petals of a water-lily or lotus, known as the Clytae; the majestic Homer; with others of the finest of the Græco-Roman period, and many of Roman date. There are besides some very fine sculptured vases, sepulchral urns, cippi, altars, &c., in the Græco-Roman rooms, as well as the terra-cottas which formed a part of the original Townley collection. A full account of the Townley Marbles will be found in the two volumes published under that title in the 'Library of Entertaining Knowledge.'

TOWNSHIP. This term is sometimes used to denote the inhabitants of a town in their collective capacity. In legal signification it is a vill forming part of a parish in cases where a parish has been divided for secular purposes into several vills or townships.

TRACERY, in architecture, a term of uncertain origin, and almost peculiar to our own architectural vocabulary, there being no corresponding term in any other language to denote with equal brevity and clearness that species of pattern-work formed or *traced* in the head of a Gothic window by the mullions [MULLION] being there continued, but diverging into arches, curves, and flowing lines, enriched with foliations. The term is also applied to ornamental design of the same character, whether for doors, panelling, or ceilings; the only difference being that in windows the pattern or tracery is perforated, and in other cases closed, that is, is a mere pattern carved on the surface of a solid part; except in particular instances, where the tracery on parapets, battlements, turrets, spires, &c., is pierced, and then it is described as *open-work*. The latter term necessarily implies tracery of some kind or other, though "tracery" does not imply "open-work," the latter being merely an exception from the usual mode.

Much both of the beauty and character of the Gothic or Pointed style depends upon windows and their tracery; and it is one great and peculiar merit of the style, that such indispensable apertures for the admission of light are made to constitute some of its most striking features, and to exhibit very forcibly the pervading principle of the entire system. On referring to GOTHIC ARCHITECTURE, col. 440, it will be seen that tracery does not occur in the First Pointed or Early English style, for there the windows consist merely of so many single apertures, placed side by side, and united only by their external mouldings, instead of being included within a larger arch. The first principle followed was therefore rather of *addition* than of *combination*; but as soon as the latter idea was adopted, it necessarily led to the continuation of the window by perforating the *tympanum*, or space between the smaller arches and the larger one over them. At first this was usually done by filling up the *head* of the window with a single circle cut into foils, and with the open spandrels or smaller triangular spaces so produced. Of such windows an example from Westminster Abbey is shown in the column above referred to, and in the following columns are other instances where tracery of the same character becomes more elaborate and complicated, either by the circle being repeated, as in the example from York, or subdivided into smaller ornamental compartments, as in that from Exeter. This species of tracery has been very inappropriately distinguished by the name of *Geometrical*, while that which succeeded it is termed *Flowing* from its being composed throughout of curved lines interwoven with each other, after the manner of the example from Kirton, which is shown along with the others above mentioned. In Third Pointed or Perpendicular tracery, on the contrary, the lines of the mullions are continued in the head of the window, and divide it into panels, which are in turn subdivided into smaller ones. The annexed is a specimen of such window, from St. Mary's Church, Oxford.



What is called *Flamboyant* tracery is a species of the *Flowing* tracery peculiar to French Gothic, and is remarkable not only for its richness and intricacy, but for its irregularity, the pattern of the separate compartments not being perfectly symmetrical, although one half of the window corresponds with the other. To the above-mentioned varieties may be added another peculiar to Germany, but not very common there; this has obtained the name of *Stump tracery*, in consequence of some of the mouldings appearing to be broken off, and leaving only short ends or stumps where they intersect other lines.

TRACHEOTOMY is the operation of cutting into the trachea. It is sometimes also called Bronchotomy; and a similar operation on the lower part of the larynx is named Laryngotomy. The anatomy of the parts principally concerned in these operations will be found in the articles LARYNX and RESPIRATION, in NAT. HIST. DIV.

Tracheotomy may be performed for several purposes; as, to form an aperture either for the admission of air into the lungs, when the larynx, fauces, or upper parts of the air-passages are obstructed, or for the extraction of foreign bodies from the adjacent parts of the air-passages, or for the facility of inflating the lungs in suspended animation. In the first view it may be necessary in many diseases; such as croup, acute laryngitis, œdema of the glottis, severe cases of quinsy, tumours, and other growths in the larynx or pressing on it, and diphtheria; in all of which the aperture through the glottis is frequently closed, not merely by the swelling of the membranes around it, or the enlargement of the adjacent parts, but by the spasmodic and fixed contraction of the muscles whose office it is to approximate the vocal ligaments. The relief afforded by the operation is often instantaneous, and, for a time, complete; but its ultimate results are less certain, for though it may be sufficient to prevent the impending suffocation, it has no influence in arresting the original disease. On the contrary, the operation itself is not without danger; and that, both from the accidents that may occur in its performance, and from its subsequent effects; and therefore, although no general rule can be laid down, its performance should not be undertaken unadvisedly, nor in any cases in which it is not absolutely and almost immediately necessary for the preservation of life.

In its performance a vertical incision is first made in the median line of the throat, either below the thyroid gland, or more or less above it, according to the circumstances of the case and the object to be accomplished. The dissection must then be continued carefully onwards in the same direction, pushing aside the sterno-hyoid muscles, and whatever vessels lie in or near the middle line, till the trachea is completely exposed. When the hemorrhage has ceased, or is but slight, the trachea must be opened, first by a vertical incision, and then by removing portions of one or more of its rings, according to the size of the aperture that is required. Through the opening a short silver canula must be introduced, and, as often as is rendered necessary by mucus accumulating in it, must be removed, cleaned, and again introduced. The means to be subsequently adopted must vary with the circumstances of each case: if the obstruction is removed, the wound in the trachea may be healed, but if not, the canula must be worn for the rest of life. If the operation were performed for the removal of a foreign body, or for the inflation of the lungs, no canula need be introduced, but the wound should be closed as soon as the main object is attained.

TRACTION, in Mechanics, is the act of drawing a body along a plane, usually by the power of men, animals, or steam; as when a vessel is towed on the surface of water or a carriage moved upon a road. The power exerted in order to produce the effect is called the force of traction.

Numerous experiments have been made for the purpose of ascertaining the value of a force so exerted; and when men are employed to draw laden boats on canals, it is found that if the work be continued for several days successively, of eight hours each, the force of traction is equivalent to a weight of $31\frac{1}{2}$ lbs., moved at the rate of two feet per second, or $1\frac{1}{3}$ mile per hour (it being understood that such weight is imagined to be raised vertically by means of a rope passing over a pulley, and drawn in a horizontal direction). The force of traction exerted when, without moving from his place, a man pulls horizontally against a weight so suspended, is estimated at 70 lbs. The action of a horse in drawing a vessel on a canal is said to be equivalent to a weight of 180 lbs. raised vertically, as above supposed, with a velocity of $3\frac{2}{3}$ feet per second, or $2\frac{1}{2}$ miles per hour; but this estimate has been considered too high; and from experiments which have been made on the power of horses in waggons, carts, and coaches, on level ground, it is found that the force of traction exerted by a stout horse is equivalent to 80 lbs. raised at the rate of $4\frac{2}{5}$ feet per second, or 3 miles per hour. Mr. Tredgold considers that a horse exerts a force of traction expressed by 125 lbs. raised at the rate of $3\frac{2}{3}$ feet per second, or $2\frac{1}{2}$ miles per hour. A man or a horse can however double his power of traction for a few minutes without being injured by the exertion; and when the carriage is in motion, so that the friction on the ground is alone to be overcome, a horse can draw, during a short time, on a level road, a weight exceeding 1500 lbs.

The force of traction is found to vary nearly with the term $(w-v)^2$, where w is the greatest walking velocity of a man or horse when unresisted (6 feet per second, or 4 miles per hour, for a man; and 10 feet per second, or $6\frac{3}{4}$ miles per hour, for a horse), and v is the velocity with which the vessel or carriage is moved. From theoretical considerations it has been determined that the greatest effect is produced when the velocity of the object moved is one-third of that with which the man or animal can walk when unresisted.

If a wheel-carriage were situated on a level plane which opposed no resistance, it is evident that, whatever were the diameter of the wheels, the smallest conceivable power of traction applied to the axle would suffice to put the carriage in motion. But when a wheel in moving meets with an obstacle on the ground, that obstacle is pressed at the point of contact by a force acting in the direction of a line drawn to it from the centre of the wheel, and arising from that part of the weight which is supported by the wheel, together with the force of traction; therefore by the "resolution of forces," the ratio between the resistance which is to be overcome by the moving-power and the weight on the wheel will become less as the diameter of the wheel is increased: also the most advantageous direction in which the force of traction can be exerted is perpendicular to the line of pressure drawn from the centre of the wheel to the obstacle. But the height of the wheels cannot exceed certain limits depending on the use to which the carriage is applied; and when the latter has four wheels, the height of those which are in front must be such only as will allow it to be turned round within a given space; also, when a horse is employed to move a carriage, attention must be paid to the conditions under which his power may be advantageously exerted.

It was first observed by M. Deparcieux, and published in the 'Mémoires de l'Académie des Sciences,' 1760, that horses draw heavy loads rather by their weight than by their muscular force. Dr. (Sir David) Brewster has also remarked that when the resistance is great a horse lifts both its fore-feet from the ground; then, using his hinder-feet as a fulcrum, he allows his body to descend by its weight, and thus overcomes the obstacle: and it may be added that when this action takes place with a two-wheeled carriage, if the loading is disposed so that some portion of it may press on the horse's back, the effect of the animal's weight will thereby be increased. Now if the traces, or the shafts of the carriage, were attached to the horse's collar near his centre of gravity, a line imagined to be drawn from the latter point to his hinder-feet may represent his weight, and a line drawn perpendicularly from his feet upon a plane passing through the traces or shafts may represent the lever of resistance: but while the former line remains the same, this lever becomes less as the plane of traction (that of the traces or shafts) inclines more upwards from the wheel; and therefore, in order that the power of the horse may be advantageously applied, the diameter of the wheel should be as small as is consistent with other circumstances.

Experiments have shown that when the angle of traction, as it is called, that is, the angle which the plane of the traces makes with the road on which the carriage is moving, is 15 or 16 degrees, a horse pulls with good effect; and the height of the points at which the traces are attached to a horse's collar being about 4 feet 6 inches from the ground, it follows that, in order to obtain this inclination, the lower extremities of the traces or shafts should be 2 feet 3 inches from the ground. In general however, in two-wheeled carriages, the height of these extremities is about 3 feet.

As an example of the force of traction exerted by steam, it may be stated that on a level line of railway, an engine with an 11-inch cylinder, and having an effective pressure of 50 lbs. per square inch in the boiler, drew 50 tons at the rate of 30 miles per hour, working 10 hours daily; and that the same engine, with an equal pressure in the boiler, drew 160 tons at the rate of $15\frac{1}{4}$ miles per hour. (Pambour 'On Locomotive Engines.') The resistances to be overcome, or, in other words, the efforts of traction required upon the various systems of intercommunication, may be stated as follows:—

	Ratio of Traction to weight.
Ordinary macadamised roads in good state, horse walking at useful velocity	1 to 20, or 25
Ordinary macadamised roads in good state, horse trotting	1 to 14
Ordinary macadamised roads, paved, horse walking . .	1 to 50
Wooden road „ .	1 to 70
Tramway, of granite blocks, horse walking . . .	1 to 180
Railways, velocity 20 miles per hour	1 to 200
„ „ 30 miles per hour	1 to 100
Canal of small section, small velocity, 2 miles per hour .	1 to 600
„ „ „ 4 miles „ .	1 to 150
„ „ „ 8 miles „ .	1 to 37
Canal of large section, 2 miles per hour	1 to 1000
„ „ 4 miles per hour	1 to 250
„ „ 8 miles per hour	1 to 62

TRACTRIX, or TRACTORY, the name given to a curve described by a heavy point attached to a string, the other end of which is moved along a given straight line or curve. For some account of this curve, which is of no interest except as a mathematical exercise, see Peacock's Examples, page 174.

TRADE, BOARD OF. The department of the English government popularly known under this title is a committee of the Privy Council, and its proper designation, which correctly defines its principal functions, is—"The Lords of the Committee appointed for the consideration of all matters relating to Trade and Foreign Plantations." This department is practically under the direction of a president and vice-president; the other members of the Board or Committee are,—the Lord Chancellor, the Archbishop of Canterbury, the First Lord of the Treasury, the principal Secretaries of State, the Chancellor of the Exchequer, the Speaker of the House of Commons, the Chancellor of the Duchy of Lancaster, the Paymaster of the Forces, the Treasurer of the Navy, the Master of the Mint, and such officers of state in Ireland as are privy councillors in England; but those functionaries do not ordinarily interfere with or assist at the deliberations of the president and vice-president. The clerks of the council are, *ex officio*, secretaries of the Board of Trade, but that duty is performed by two joint assistant-secretaries.

The president and vice-president of the Board of Trade exercise, in effect, the duties which in other countries are performed by the minister of commerce. Their office is not indeed executive, but rather consultative, the orders rendered necessary by their decisions being given by the Lords of the Treasury or by the secretary of state, as the case may require. The functions of this board have been of late years considerably extended, its duties being some of them of a ministerial, and others of a judicial character. It has the general superintendence of matters relating to merchant ships and seamen, and the carrying into execution of the statutes in force relating to them. For that purpose it has to require and receive various kinds of returns as to trade and navigation, and originate and consider reports made to it by its inspectors and other officers. It has also a partial control over local marine boards, and may lay down rules as to the conduct of examinations, and as to the qualification of applicants for the posts of masters and mates of foreign-going as well as of home-trade passenger-ships. [SHIPS.] It grants licences to persons to engage or supply seamen or apprentices for merchant ships in the United Kingdom, adjudicates on claims for wages, and investigates cases of alleged incompetency and misconduct (17 & 18 Vict. c. 104). The Board also appoints officers to report on the condition of steam-vessels and their machinery (14 & 15 Vict. c. 79).

The Board of Trade exercises a supervision over railways and railway companies, not only with respect to their original formation, but also as to their subsequent working. Railways were first placed under this control by the statute 3 & 4 Vict. c. 97. A few years afterwards the powers of the Board in this respect were transferred to a Board of Commissioners of Railways; but in 1851 all the powers of this latter board were transferred to the Board of Trade (14 & 15 Vict. c. 64). Notices of application for Railway Acts, accompanied by plans, must be deposited with the Board, before any bill can be introduced into Parliament; and before a line can be opened for traffic, notice must be given to the Board, and its permission obtained, on the report of an inspector, appointed by the Board for those and other general purposes. So, when accidents occur, notice must be given to the Board, and an inspector is generally sent to inquire into the circumstances, and on his report the Board may cause alterations to be made for the greater safety of the public.

The Board of Trade, through the medium of its registrar, is also charged with the registration of all Joint-Stock Companies (19 & 20 Vict. c. 47). By the statute giving a copyright in designs, their registration is effected by the Registrar of the Board of Trade (5 & 6 Vict. c. 100; 6 & 7 Vict. c. 65; 13 & 14 Vict. c. 104; 14 & 15 Vict. c. 8; 15 & 16 Vict. c. 6). The Board also controls the proceedings of the Commissioners for regulating the employment of coal-whippers and the discharge of coal-laden vessels in the port of London (6 & 7 Vict. c. ci. (local and personal); 9 & 10 Vict. c. xxxvi.; 14 & 15 Vict. c. lxxviii.). A department of the Board of Trade has the immediate control of the Government schools and museums of science and art, as explained under SCIENCE AND ART, DEPARTMENT OF. Lastly, another department of the Board of Trade is charged with the collection and publication of tables, containing information with respect to the revenue, trade, commerce, wealth, population, and other statistics of the United Kingdom and its dependencies, as well as of foreign countries. The officers of another department collect and prepare the tables of the prices of corn, which formerly, and before the abolition of the corn-laws, regulated the amount of duty, and still govern the rent-charge in lieu of tithe under the Tithe Commutation Act (Blackst. 'Comm.,' Mr. Kerr's edit.).

TRADE AND SHIPPING. The foreign trade of England is coeval with its earliest history. It must not, however, be supposed that the commercial dealings of those early days bore much resemblance to those of more modern times. The visits of foreigners to our shores (for England was an exporting country before its inhabitants were become ship-owners or navigators) were then confined to procuring tin from Cornwall. We may be certain that those by whom this earliest British trade was conducted did not obtain the metal without leaving in exchange that which was considered more valuable by the miners. Of what those importations consisted we are not precisely informed. "Salt, earthenwares, implements made of copper, of ivory, and of amber," are said to have formed the principal merchandise at that time imported into Britain; but no mention is made of wool, which afterwards, and at a comparatively remote period of our annals, became a principal article of export from this country. We learn from Madox's 'History of the Exchequer' that in the reign of Richard I. Gervase de Aldermanbury accounted, as chamberlain of London, for money received as fines from merchants for leave to export wool. In 1275, according to Rymer (tom ii., p. 50), wool was allowed to be exported upon payment to the king of 10*s.* per sack. Within the next twenty years the custom of wool was raised to 20*s.* the sack, and in 1296 was further raised at the will of the king to 40*s.* the sack. This export duty has been justified on the ground of its being a tax upon the foreign manufacturers or consumers, to whom English wool was an article of necessity; but the duty acted as a burden upon the grower, not only in respect of his surplus quantity which was necessarily exported, but also because the price of the remainder was as necessarily governed by the net value that could be obtained for that surplus. Accordingly we find that this imposition of customs upon the export of wool was a frequent cause of ill feeling between the commons and the crown.

In a statement of the trade of England, said to have been found upon record in the Exchequer, and quoted in a tract called the 'Circle of Commerce,' published in 1623 by Edward Misselden, the list of our exports comprised only wool, coarse woollen cloths, and a small quantity of leather, amounting in value to 294,184*l.*, including the export-duty; while the imports included fine woollen cloths, wax, wine, linen cloth, mercery, and grocery wares, to the amount of 38,970*l.* The shilling at that time contained 213 grains of silver. Taking into account the different value of money then and at present, these values are equivalent to 728,606*l.* and 96,518*l.* of the present coin respectively. This statement of imports and exports does not appear entitled in all respects to be considered accurate; but it is remarkable that this circumstance was brought forward and commented upon as the proof of "an extraordinary balance of trade in favour of the nation," a strange conclusion from such premises. It is now generally acknowledged that the commerce of a country to be successful must include in the value of its imports the whole value of its exports, together with the gain which forms the sole inducement of the merchants by whom it is prosecuted.

Still, however, the trade and commerce increased, and from the beginning of the present century has continued to increase till it has attained a most colossal importance. This has arisen in a great degree from a juster perception of the true principles of political economy, and also from the vast improvement in mechanical contrivances for the diminution of mere manual labour, of which the application of the powers of steam by the invention of Watt, may be deemed the chief. It is due also to the memory of Pitt to say, that he early perceived the truth of the principles propounded by Adam Smith, and in the commencement of his career endeavoured, though circumstances rendered his efforts ineffective, to establish a more liberal, if not an entirely free trade. Old prejudices and the war with France combined to prevent the adoption of those principles, and the first quarter of the century showed little permanent increase. Thus the official value of imports in 1802 amounted to 29,826,210*l.*, and the declared value of exports to 45,102,330*l.*; while, with considerable fluctuations in the interval, in 1825 the imports only reached 44,137,482*l.*, and the exports 38,877,388*l.*, the latter year including Ireland, which the former does not, but the amount of Irish trade was not great. The official valuation is, however, deceptive, as the price fixed does not represent the real value. This commerce was carried in 1802 inwards by 7806 British ships, registered at 1,333,005 tons, and 3728 foreign ships with a total of 480,251 tons, and outwards in 1802 by 7471 British ships, registered at 1,177,224 tons, and 3332 foreign vessels with 457,580 tons. In 1836, the official value of imports had increased to 57,023,867*l.*, and the declared value of exports to 53,368,571*l.*, and the number of British ships inwards to 14,347, of an aggregate burden of 2,505,473 tons, and outwards to 14,207, of a burden of 2,531,577 tons, and the foreign ships inwards to 7131, of a burden of 988,899 tons, and outwards to 7048 ships, and a burden of 1,035,120 tons. In 1846, the tariff was materially reformed, and successive improvements have been since introduced; and in 1854, the real value of the total imports into the United Kingdom was 152,389,053*l.*; in 1855 it was 143,542,850*l.*, and in 1856 it was 172,544,154*l.* These values are computed from the average prices fixed for the articles, which are chiefly entered by quantities at the Custom House. The value of the exports is obtained from the declared value set on the articles, except in the case of foreign and colonial produce, of which the price is computed in the same way as with the imports. In 1854 the total value of exports amounted to 115,821,092*l.*, of which 97,184,726*l.* were for the produce or manufacture of the United Kingdom, the remainder being for foreign or colonial produce. In 1855 the total value was 116,691,300*l.*, of which 95,688,085*l.* were for the produce or manufactures of the United Kingdom; and in 1856 the total value amounted to 139,220,353*l.*, of which 115,826,948*l.* were for home productions; the official values of the exports show a singular contrast to the real values; they are for the three years respectively, 29,808,044*l.*, 31,494,391*l.*, and 33,423,724*l.* The official values of the imports for the three years show less discrepancy; they were 124,136,018*l.*, 117,284,881*l.*, and 131,937,763*l.*

The remissions or reductions of duties on imports during the succeeding years contributed to the continued increase of trade and commerce; for the year ending December 31, 1860, the amount of the principal articles imported was 169,131,063*l.*, and this does not include a variety of other importations, of which many are of large amount, as, for instance, animals, living, of which in the year there were imported 77,010 oxen, bulls, and cows, 27,559 calves, 320,219 sheep, and 24,452 swine and hogs; pearl and potashes, of which there were imported 141,087 cwts.; bark, 418,069 cwts.; brimstone, 1,007,503 cwts.; bristles, 2,584,217 lbs.; caoutchouc, 43,039 cwts.; clocks and watches, 497,386 in number; nor eggs, in number 167,695,200, with a few other items.

The principal articles imported, in addition to those above mentioned, were—in articles used for diet—coffee to the value of 2,543,211*l.*, of which 1,813,213*l.* was from Ceylon; 387,226*l.* from other British possessions, and the remainder from foreign countries. Corn to the value of 16,554,083*l.*, of which 4,323,808*l.* was from the United States; 3,551,907*l.* from Russia; 3,410,161*l.* from Prussia; 1,610,762*l.* from France; and the rest from Egypt, Moldavia, Wallachia, and other countries. Barley, oats, peas, beans, and Indian corn to the value of 10,558,162*l.* Wheat-meal and flour to the value of 4,320,558*l.*, of which the United States supplied to the value of 1,826,582*l.*; France, 1,594,030*l.*; and the rest from the Hanse towns and other countries. Currants and raisins to the value of 1,253,670*l.* Bacon, 870,286*l.* Butter, 4,078,017*l.* Cheese, 1,597,569*l.* Eggs, 478,658*l.* Rice, not in the husk, 1,023,108*l.* Spirits—rum, brandy, and Geneva, to the value of 1,918,839*l.*; and wine to that of 4,201,434*l.*, of which 1,734,613*l.* was contributed by Spain; 1,036,620*l.* by France (almost twice as much as in 1859); 898,336*l.* by Portugal, and the rest by various countries. Sugar of all kinds, including sugar-candy and molasses, to the value of 12,106,069*l.*, of which, of the raw sugar of all kinds 7,110,203*l.* came from British possessions, and 4,727,658*l.* from foreign countries. Tea, 6,944,042*l.*, an increase of 1,132,497*l.* over 1859. Tobacco, to an aggregate of 1,777,632*l.* Of articles used in manufactures, we imported cotton to the value of 35,756,889*l.*, the United States supplying it to the amount of 30,069,319*l.*; the British East Indies, 3,373,614*l.*; Egypt, 1,480,895*l.*; Brazil, 561,949*l.*; and only 271,112*l.* from all other countries. The total quantity imported was 1,390,938,752 lbs. Flax to the value of 3,836,770*l.* was imported, three-fourths being from Russia and Prussia; and hemp valued at 1,199,018*l.*, of which 907,442*l.* was from Russia, the rest from various countries, with jute and other substances used as substitutes for hemp to the value of 665,764*l.* Hides, dry, wet, and tanned, or dressed, to the value of 3,296,512*l.* Indigo, to the value of 2,528,888*l.* Of metals—copper to the amount of 2,213,141*l.*, Chili and Cuba furnishing the largest amount, though Australia sent ore to the amount of 173,061*l.*; iron, 659,620*l.*; lead, 468,435*l.*; spelter, 499,636*l.*; tin, 387,307*l.* Oils—train, spermaceti, palm, and olive—to the value of 3,923,235*l.* Saltpetre and cubic nitre to the value of 1,165,815*l.* Silk, raw and thrown, to the value of 10,323,837*l.*, of which raw silk to the value of 6,829,496*l.* were supplied by the British East Indies and Egypt, 2,185,742*l.* by China, while the whole of the thrown silk only amounted to 336,991*l.*, of which 172,357*l.* came from France. Tallow, to the value of 4,014,280*l.*, of which 3,040,997*l.* was supplied by Russia, only 33,830*l.* by Australia, and the rest by South America and other countries. Timber, to the aggregate value of 9,206,092*l.*, of which British North America contributed 4,309,235*l.*; Sweden and Norway, 2,169,545*l.*; Prussia, 1,093,412*l.*; Russia, 783,388*l.*; and the remainder by various countries. Wool, to the value of 10,704,922*l.*, of which 5,387,078*l.* was furnished by Australia; 1,187,748*l.*, by British possessions in South Africa; 699,861*l.*, by the British East Indies; and the rest from various places, chiefly through the Hanse towns; together with alpaca and llama wool to the value of 326,557*l.*, and woollen manufactures not made up, to that of 918,927*l.* For agricultural purposes, we imported guano to the value of 1,563,145*l.*; oil-seed cakes to that of 910,840*l.*, and flaxseed and linseed to the amount of 3,391,938*l.*; but of this a large portion was for manufacture into oil. The total imports amounted to 210,648,643*l.* The customs duties for the year amounted to 23,032,895*l.*, a decrease of 1,862,184*l.* on those of the preceding year.

The declared value of British and Irish produce and manufactures exported during the same year (1860) was 135,842,817*l.* This does not include the foreign and colonial articles re-exported, which amounted in declared value to 5,136,652*l.* The chief articles were—apparel and slops, to South Africa, Australia, other British possessions, and to foreign countries, 2,156,348*l.* Beer and ale, of which the East Indies, Australia, and the United States were the chief consumers, 1,863,998*l.* Printed books, 494,915*l.* Butter, 633,280*l.* Cheese, 118,859*l.* Coals and culm, 3,321,539*l.*, of which France took 566,109*l.* Cotton (woven), 40,342,819*l.*, of which the Hanse towns took 1,191,703*l.*; Turkey, 2,789,954*l.*; Egypt, 1,045,988*l.*; the United States, 3,848,750*l.*; foreign West Indies, 1,062,965*l.*; Brazil, 2,300,101*l.*; China, 3,157,359*l.*; Java, 1,057,617*l.*; British North America, the West Indies, and South Africa, 1,528,106*l.*; the East Indies, 10,518,094*l.*, no other country reaching to a million; while other cotton manufactures, such as lace, net, stockings, counterpanes, and small wares, and sewing thread, were exported to the value of 1,795,593*l.*, and cotton yarn to the amount of 9,875,073*l.* Earthenware and porcelain, 1,440,998*l.* Glass—flint, window, bottles, and plate, 653,224*l.* Haberdashery and millinery, 4,011,277*l.* Hardware and cutlery, 3,772,035*l.* Leather, tanned and manufactured, 2,129,094*l.* Linens (woven), 4,432,823*l.*, with thread lace, thread and tapes, 369,380*l.*, and linen yarn, 1,800,927*l.* Machinery, including steam-engines, 3,825,361*l.* Metals:—iron, including pig, bar, railway, wire, cast, wrought of all kinds, and steel, 12,158,355*l.*; copper, of all sorts, including brass, 3,001,992*l.*; lead, of all sorts, 699,648*l.*; tin and tin plates, 1,862,150*l.*, of which the United States took 1,018,056*l.* Oils, from seeds, 1,132,324*l.* Silk, manufactured, 1,577,001*l.*; with thrown silk and silk twist and yarn, 822,291*l.* Soap, 249,876*l.* Soda, 982,906*l.* Spirits, British, 286,651*l.* Stationery, 720,721*l.* Sugar, refined, 239,762*l.* Telegraphic wire and apparatus, 250,655*l.* Wool, 868,781*l.* Woollen cloths and other manufactures, 12,192,861*l.*, for which the United States were the largest customers, though the dispersion is pretty general; and woollen and worsted yarn, 3,843,396*l.*

Shipping.—This enormous trade requires a corresponding amount of shipping. In 1860, there were entered inwards with cargoes 20,104 British ships, of an aggregate burden of 5,762,464 tons, an average of 286 tons each; and 18,270 foreign vessels of 4,292,823 tons, an average of 235 tons; an increase of both British and foreign over the years 1858 and 1859: and there were cleared outward with cargoes 23,713 British ships, of an aggregate burden of 6,359,108 tons, an average of 260 tons each; and 20,777 foreign ships of 4,425,433 tons, an average of only 205 tons. The greatest number of foreign ships was that of the Danes, 2957 entered inward, and 3362 cleared outwards; the Norwegians sent 2862 vessels, and cleared out 1746; but the shallow waters of the Baltic necessitate the use of small ships, so that the tonnage of the two inwards was only 929,483, outwards 677,605 tons, an average of only 140 tons each. The largest amount of tonnage is by the United States, who entered 1,361,021 tons in 1417 ships; and cleared out 1,367,988 tons, in 1456 ships, an average of 945 tons each. Inwards Russia sent 435 ships of 125,612 tons; Sweden, 1119 ships of 181,755 tons; Prussia, 1795 ships of 425,436 tons; Mecklenburg and Oldenburg, 722 ships of 144,088 tons; Hanover, 970 ships of 81,196 tons, an average of only 84 tons; the Hanse Towns, 580 ships of 212,006 tons; Holland, 1501 ships of 185,098 tons; Belgium, 257 ships of 54,166 tons; France, 2187 ships of 186,524 tons; Spain, 244 ships of 67,048 tons; Portugal, 147 ships of 33,638 tons; Sardinia and Sicily, 493 ships of 118,914 tons; Austria, 467 ships of 152,058 tons; Greece, 59 ships of 16,125 tons; other European countries, 38 ships of 12,280 tons; and other countries in America, Asia, and Africa, 20 ships of 6355 tons. Outwards there were cleared, in addition to those mentioned above, from Russia, 396 ships of 116,991 tons; Sweden, 1163 ships of 185,192 tons; Prussia, 1595 ships of 350,088 tons; Mecklenburg and Oldenburg, 905 ships of 100,222 tons; Hanover, 1666 ships of 134,919 tons; Hanse Towns, 867 ships of 290,788 tons; Holland, 1756 ships of 260,050 tons; Belgium, 262 ships of 59,102 tons; France, 4068 ships of 430,440 tons, a remarkable difference from those entered inwards; Spain, 221 ships of 61,383 tons; Portugal, 143 ships of 31,021 tons; Sardinia and Sicily, 553 ships of 139,301 tons; Austria, 501 ships of 163,091 tons; Greece, 44 ships of 15,684 tons; other European countries, 44 ships of 15,684 tons; and other countries in America, Asia, and Africa, 19 ships of 6081 tons.

The coasting-trade, including that between Great Britain and Ireland, is even larger in amount of tonnage; but as the return gives the repeated voyages when entered or cleared with cargoes, the number of ships employed is not shown, but only the number of voyages made. These, in 1860, were, inwards, 153,782, and the aggregate burden was 17,003,411 tons, of which only 102,223 tons came in 666 foreign bottoms. Outwards there were cleared 157,419 ships of 17,014,899 tons, of which 644 foreign vessels carried 100,056 tons.

The total number of registered ships in 1860, not including river steamers, was 20,019, of an aggregate burden of 4,251,739 tons; of these 929 were steamers of 399,494 tons burden. The number of men employed in these vessels was 171,592, exclusive of masters. The total number of vessels built and registered in the year was 1016 of 211,968 tons burden, of which 198 were steamers of 53,796 tons burden.

TRADE WINDS. [WINDS.]

TRADER. [BANKRUPT.]

TRADITION (from the Latin *tradere*) comprises, in the widest sense of the word, all that has been handed down (quæ tradita sunt) to us concerning the events of the past, and in this sense all history is tradition. In the early ages of mankind and of every nation, when the art of writing was unknown or little used, all history was handed down by oral communication from generation to generation without written records. Afterwards, when the accounts thus propagated were written down and assumed a definite shape, or many shapes, according to the information, the opinions, or the judgment possessed by the person or persons who wrote them down, such accounts were found to differ materially from accounts written by eye-witnesses at or soon after the times when events happened. Historical criticism distinguishes the two kinds of history by calling the former *tradition*, in a narrower sense of the word, and the latter *history*. Those who know how, even in our days, reports are changed and embellished, how some features are omitted and others added during the process of passing from mouth to mouth, and how in the end they frequently assume a totally different aspect from what they originally had, will readily admit that such traditions cannot be received with the same faith as contemporary history. We may add that the more important the occurrence handed down by tradition is, and the more it affects the feelings and passions of men, the greater will be the changes and corruptions which it experiences in its progress. The desire, moreover, of seeing things clear and complete is inherent in the human mind; and hence we find that in innumerable instances where a tradition or a series of traditions was deficient, unclear, or incomplete, man's imagination and ingenuity have been at work, to make up an apparently complete account, either by filling up the gaps in the original account with pure fictions, or by transferring and combining events which belong to different times and countries. Such accounts require to be examined with more caution on the part of the historian the more skilfully they are made up, and the more their apparent consistency resembles real history. It is the business of the historian who feels the want of a positive conviction, and is not satisfied with discovering that a tradition is obscure, inconsistent, or incredible, to find out its historical groundwork, by comparing the traditions about one and the same subject, by analogies, and by separating such additions and embellishments which have been made with a view to satisfy man's curiosity, or his feelings, either religious or political. The historian who undertakes this task has to guard against two dangerous rocks: the one is the desire to construct out of a tradition a history according to a preconceived notion or theory, the very thing which in many cases was the cause of the adulterated tradition itself; and the other is the so-called rationalistic mode of dealing with tradition, which consists in stripping it of everything poetical or marvellous, and leaving nothing but a skeleton, which is considered as history merely because it presents nothing that might not happen every day and within our own experience.

In the history of Christianity the term tradition has been applied to the so-called unwritten word of God; that is, to the doctrines said to have been communicated by Christ to his apostles, which were not written down by them, but were handed down by their oral instruction to their successors. This tradition is preserved in the writings of the ecclesiastical fathers; and the Church of Rome regards them, next to the Bible, as a source of knowledge which ought to regulate the life and religious observances of Christians. She claims for tradition the same unconditional faith in regard to its divine authority as for the doctrines of the New Testament. The substance of the tradition thus revered by the Church of Rome, however, affects rather the forms of religion than its essence; and some of these forms, such as the baptism of infants, the celebration of certain festivals, and the like, are retained and observed by the majority of Protestants, while on the whole they reject tradition, and do not consider it binding.

TRAGACANTH, familiarly termed *Gum-dragon*, is the produce of several species of the genus *Astragalus*. [ASTRAGALUS, in NAT. HIST. DIV.] The *A. verus* (Olivier,) a native of the north of Persia, Armenia, and Asia Minor, yields the greater part of what is used in Europe. Persia supplies it likewise to India, Baghdad, and Basrah. *A. gummifer* (Labill.) yields some of the white tragacanth. *A. creticus*, Lamarck (*Tragacantha Cretica incana*, Tournefort), yields it sparingly; while, according to Sibthorp ('Prod. Fl. Græcæ,' ii. 90), the tragacanth which is used in Italy is obtained in Greece from the *A. aristatus* (Villars), and which, according to Sibthorp, yields the tragacanth of Dioscorides. The *A. tragacantha* (var. a. Linn.), the *A. Massiliensis* (Lamarck et Dec.), long reputed to be the source of tragacanth, yields no concrete gum, but merely a gummy juice, which is used in confectionary. The *A. Dicksonii* (a name substituted by Dr. Royle for *A. strobiliferus* of Lindley) yields the reddish-coloured tragacanth. In the hot months of July and August, particularly after a dewy or a cloudy night, the branches of *A. verus* are found encrusted with tragacanth. It is not procured by artificial incisions, but exudes spontaneously from natural clefts in the bark, or from punctures made by insects, or more probably by a subepidermal fungus, like the *nemaspora crocea*, as the shrubs from which the juice exudes are always in an unhealthy state, or ready to perish. (Decandolle, 'Phys. Veg.,' i. p. 174.)

In commerce tragacanth occurs in two forms, termed vermiform, and flake or cake tragacanth. The former, called also *Morea tragacanth*, is not frequent in this country. It is mostly in small twisted thread-like pieces, seldom in flat or bandlike portions, of a variable size, of a whitish colour. The larger irregular pieces often run together, and are of a yellow or yellowish-brown colour. White worm-like pieces are selected and sold as vermicelli. Flake or Smyrna tragacanth occurs in tolerably large, broad, thin pieces, with concentric elevations or lines, seldom of a filiform shape: colour whitish. Both sorts are hard, yet somewhat soft and even flexible before breaking; fracture dull and splintery. It is with difficulty reduced to powder, except in winter, or in a heated mortar. It is devoid of taste and smell. It swells in the mouth, and is lubricous. Fine tragacanth is not rendered blue by iodine, but the *Morea tragacanth* is affected by it, as well as an artificial substance prepared by boiling starch, which last article, called tragacantin, does not swell in water. Kutera gum, the produce of a species of cochlospermum and sterculia, which is sometimes mixed with or substituted for genuine tragacanth, is not affected by tincture of iodine. It always occurs in stalactite-like pieces, and consisting almost entirely of bassorin, is scarcely soluble in water. [GUM.]

Tragacanth approximates more to starch than common gum, than which it is more nourishing, but less digestible. Tragacanth is to be preferred to gum-arabic to form a mucilage, as one part will inspissate fifty parts of water. It is better to allow pieces of tragacanth slowly to dissolve in cold water than to use the powder with boiling water. Both the mucilage and powder are used to suspend heavy powders in water; also to make lozenges and pills. For electuaries it is improper, as it renders them slimy on keeping. As a demulcent, or means of sheathing the fauces and intestines, it is preferable to gum-arabic, its insolubility rendering it a more efficient protection to the mucous membrane against either acrid poisons or unhealthy secretions. Thus in India, tragacanth boiled in rice-water is advantageously administered in dysentery and bloody fluxes. Externally, a thick mucilage of tragacanth is a good application to burns, to exclude the air.

TRAJECTORY, the technical name which was formerly given to a curve, that is, to a curve required to be found by means of given conditions; most frequently used for the required path of a particle acted on by given forces. The term is now seldom used.

TRAMMELS, the name of the ELLIPTIC COMPASSES, described in that article, in which a bar carrying a pencil is guided by two pins which move in grooves.

TRAMWAY. A track laid down on the surface of a common road, for the purpose of diminishing the effort of traction required in moving wheeled vehicles; and for this purpose it is necessary that the material of the tramway should be practically incompressible, and as smooth as possible. Iron, wood, marble, and granite are used in the formation of tramways, as in the cases of Train's Street Railways, the forest roads in wood countries, in the Italian cities, and in the Commercial Road, London Docks. See RAILWAYS; TRACTION.

TRANSCENDENTAL, a mathematical term of description, the meaning of which is not very uniform. When any particular formula is incapable of being expressed by any particular range of algebraical symbols, it is, with respect to those symbols, transcendental—that is, it transcends or climbs beyond the power of those symbols. The word was perhaps first used by Leibnitz ('Leipzig Acts,' 1686), who says, "placet hoc loco, ut magis profutura dicamus, *fontem aperire transcendentium quantitatum*, cur nimirum quædam problemata neque sint plana, neque solida, neque sursolida, aut ullius certi gradus, sed omnem æquationem algebraicam transcendant." Here, then, is the first meaning of the word; a transcendental problem is one the equation of which is infinitely high, or contains an infinite series of powers of an unknown quantity, so that its highest degree transcends every degree.

To form an idea of what is now most commonly meant by transcendental, it will be desirable to recapitulate the steps by which algebra has arrived at its present state of expression,—or, rather, mathematical analysis, as those would say who do not like to call the differential calculus by the name of algebra.

And first we have the state which preceded the time of Vieta, in which formulæ were mostly described in words, and the adoption of arbitrary symbols of quantity was only of casual occurrence.

Next, we have the introduction of arbitrary symbols of quantity by Vieta, but not to the extent of using arbitrary numbers of multiplications, or algebraical exponents. Here what we now call a^n was transcendental; Vieta could have described a^6 by *a* cubo-cubum, or a^7 by *a* quadrato-quadrato-cubum, but a^n had neither name nor symbol.

Thirdly, we have the stage which began with Harriot and Descartes, and which brought ordinary algebra into substantially its present form. During these periods, however, geometry and arithmetic, without help from algebra, had brought into use sines, cosines, &c., and logarithms, which were then properly transcendental. The words which described a particular mode of drawing lines in a circle, or the result of many interpositions of geometrical means between two given numbers, did not place those lines or means among the objects of algebra, and gave no clue to any algebraical properties.

Fourthly, we have the short but interesting period in which, before the formal invention of fluxions or the differential calculus, infinite series began to be employed, and the transcendentals last alluded to ceased to be absolutely incapable of expression. This was the state in which Leibnitz found the science when he first proposed to distinguish between algebraical and transcendental problems.

Fifthly, we have the period succeeding the invention of the differential calculus, in which the areas and lengths, &c., of curves could be expressed, whether they could be reduced into older language or not, by the new signs for fluents or integrals.

Sixthly, we have an alteration which it might have been supposed should have come long before, namely, the expression of the old transcendentals as recognised functions, and the writing of them accordingly, as $\log x$, $\sin x$, $\cos x$, &c. Strange as it may appear, this was never done till the time of Euler. And it is only in our own day that the system has been completed by the recognition of the number whose logarithm is x, the angle whose sine is x, &c., as functions of x, and the adoption of the appropriate symbols $\log^{-1} x$, $\sin^{-1} x$, &c.

Seventhly, a most important addition has been coming into use in the present century,—namely, the employment of definite integrals as modes of expression, not merely of functions of the variable of integration, but of other quantities which only enter as constants, or which, if they vary, vary independently of the variable used in integration. So powerful is this mode of expression, that it may almost be suspected to be final; and the word transcendental is rapidly acquiring a new meaning. We predict that it will settle into the following: a transcendental result will be one which is incapable of expression except by a definite integral, or by an infinite series which cannot be otherwise expressed than by a definite integral.

In the meanwhile there are two senses in which the word is used. The first is that just explained; the second has reference to the old distinction of algebraical and transcendental. A function of x is algebraical when it is finite in form, and x is never seen, nor any function of it, in an exponent, nor under the symbols of a sine, cosine, &c., or a logarithm. No operation then enters with x unless it be one of the four great operations of arithmetic, or else involution or evolution with a definite exponent. Thus, in this sense of the word, $\log x$ and $\sin x$ are both transcendentals. But in the modern sense in which transcendental is not opposed to algebraical, but to that which is expressible by ordinary means, $\log x$ and $\sin x$ are not transcendental, being among the most common of the present modes of expression, and being, in fact, connected with algebra in a way which, had it been understood when these symbols were first used, would probably have always saved them from the distinctive term.

The roots of equations of the fifth and higher degrees are, properly speaking, transcendental: there is no mode of expression except by infinite series. And, generally speaking, and with the exception of a few cases in which modes of expression have been invented and studied, INVERSE functions are transcendental. And a result of such inversions, even though, from our ignorance of its real properties, it may be expressible by ordinary means, is transcendental so long as that ignorance lasts. And it is useful to observe that forms of the most different kind may be connected together by such a relation as this, that both are cases contained under the same transcendental.

To exhibit the arrival of one of these transcendentals of inversion, as they might be called, let us take the equation $\phi x \,.\, \phi' x = \phi(\phi x)$, where $\phi' x$ means the differential coefficient of ϕx. A large class of solutions may be obtained as follows:—The equation $y \log y = 0$ has an infinite number of roots, two at most being real, and all the rest of the form $a + \beta\sqrt{-1}$. Let a, b, c, &c., be any of these roots, and let ψx be a function of x formed as follows:—

$$\psi x = \text{A}a^x + \text{B}b^x + \ldots .$$

where one, two, or any number of roots may be taken at pleasure: and A, B, &c. are any quantities independent of x. Let $\psi^{-1} x$ be the inverse function of ψx, so that $\psi(\psi^{-1} x)$ is x; then $\psi(\psi^{-1} x - 1)$ is a solution of the original equation, or $\phi x = \psi(\psi^{-1} x - 1)$ gives $\phi x \,.\, \phi' x = \phi(\phi x)$. Now $\psi^{-1} x$ is, when more than one root is used, inexpressible except by infinite series: that is, not merely inexpressible in common algebraical terms, but even with the assistance of logarithms and trigonometrical functions. Nevertheless, as particular cases of this solution, both ax and $\sqrt{(b^2 - x^2)}$ are found.

As science advances, quantities which are now called transcendental will lose the name, and be received among the ordinary modes of expression of analysis. One of the first of these will be the well-known function of n, which is generally designated by Γn, and is sometimes called the *gamma*-function, sometimes the factorial function. Its expression is $\int \varepsilon^{-x} x^{n-1} dx$ taken from $x = 0$ to $x = \infty$; and when n is an integer it is simply $2 \times 1 \times 3 \times \ldots . \times n$. But when n is a fraction it can only be calculated by series. Nevertheless, as tables are now formed of its values, and as many properties and consequences of it are known, it stands in as favourable a position for use as ordinary logarithms at the end of the 17th century.

TRANSCENDENTAL, a technical term in philosophy, derived from the Latin *transcendere*, to go beyond a certain boundary. In philosophy transcendental signifies anything which lies beyond the bounds of our experience, or which does not come within the reach of our senses. It is thus opposed to empirical, which may be applied to all things which lie within our experience. All philosophy, therefore, which carries its investigations beyond the sphere of things that fall under our senses is transcendental, and the term is thus synonymous with metaphysical. Transcendental philosophy may begin with experience, and thence proceed beyond it; or it may start from ideas *à priori* which are in our mind: in the latter case philosophy is purely transcendental; while in the former it is of a mixed character. [METAPHYSICS.]

TRANSFORMATION, a general term of mathematics, indicating a change made in the object of a problem or the shape of a formula, in such manner that the orginal problem or formula is more easily solved, calculated, or used after the transformation. Thus it frequently happens that the solution of an equation is facilitated by reducing it to another equation having roots which bear a simple relation to the roots of the former: as an instance, we may refer to the solution of the cubic equation in the article IRREDUCIBLE CASE.

All the process of algebra consists in transformation, from and after the point at which the problem to be solved is reduced to an equation: so that to write on this subject in detail would require an article on algebra. A few remarks on the leading points which present themselves in transformations are all we can here undertake to give.

It frequently happens that transformation points out the nature of a consequence in a manner by which the direct reasoning of algebra is strongly confirmed and illustrated. For instance, when we assert that a quantity has two square roots, one positive and one negative, our assertion is easily verified in its positive part: but it does not follow by the same reasoning that a quantity has *only* two square roots. We may say that $x^2=4$ is satisfied by $x=2$, or $x=-2$, because $2\times 2=4$, and $-2\times -2=4$; but how are we to say that there are no other values which satisfy this equation? When we transform the equation $x^2=4$ into $(x-2)(x+2)=0$, with which it is identical, we then see that this product can only vanish when $x-2$ or $x+2$ vanishes; that is, when x is $+2$ or -2.

Transformations frequently leave a point unsettled which can only be determined by a subsequent species of experimental test; or, lest the word experimental as applied to mathematical reasoning should give alarm, by a process of detection which is to choose between alternatives which the process of transformation leaves undecided. This frequently happens when the nature of the transformation is ascertained by means not of the expression to be transformed, but of one of its particular properties. For instance, when we expand a^x into a series of powers of x, supposing we proceed upon the property $a^x \times a^y = a^{x+y}$, we find that there is no series fit to fulfil this condition except

$$1 + \text{A}x + \frac{\text{A}^2x^2}{2} + \frac{\text{A}^3x^3}{2.3} + \dots$$

but we also find that this series is equally fit to fulfil the condition, whatever may be the value of A. So far then our transformation is effected: we see that one among the series formed by giving values to A must be the series we want, if there be any such series. If we make $x=1$, we then immediately detect the condition which is to give the value of A, namely, that A must be so taken as to make

$$a = 1 + \text{A} + \frac{\text{A}^2}{2} + \frac{\text{A}^3}{2.3} + \dots$$

This brings us to the mention of a defect of reasoning which has frequently vitiated mathematical works, namely, the assumption of the species of a transformation, and the supposition that only the character of the details remains to be settled, or the individual of the species to be picked out. In the preceding case, for example, it is often stated as follows: "Required the expansion of a^x in a series of powers of x." The form of the series is then assumed, say $p+qx+rx^2+\dots$, and by the use of the property above alluded to, it is found that the series must be of the form $1+\text{A}x+\frac{1}{2}\text{A}^2x^2+\dots$ But all that is here proved is, that if a^x be capable of expansion in integer powers of x, the expansion must be of the form $1+\text{A}x+\dots$ It is true that, looking at what we see in algebra, that science might be strongly suspected to have a peculiar power of rejecting false suppositions, or of indicating their falsehood by refusing to furnish rational results: thus it certainly does generally happen that when we attempt to select from among series of integer powers the one belonging to an expression which really has no such series, we find infinite coefficients, or some other warning. But it is too much to ask of a beginner that he should take it for granted that algebra has so peculiar a property; nor, in fact, is it true that such a property is quite universal. It is necessary, therefore, to watch all transformations narrowly, both in their general as well as their specific form: first, because there can be no sound reasoning without such caution; next, because, though it be true that in many parts of algebra the science will refuse to acknowledge and obey a false assumption of form, yet it is almost impossible to draw the line at which this refusal ends, and the idea that such a power is universal in algebra will lead the student into many a serious difficulty in the higher branches of mathematics.

TRANSFORMATION OF CO-ORDINATES. We intend this article purely for reference; that is, supposing the subject already known, we mean only to put together the formulæ in such a manner that any one can be used at once.

Rectilinear co-ordinates are the only ones which are usually transformed; such a thing rarely, if ever, happens with polar co-ordinates, except in investigations each of which has its peculiar method. And, first, we shall consider rectilinear co-ordinates in one plane, and afterwards in space. What is usually wanted is to express the co-ordinates of a first system in terms of those of a second, and subsequently given, system.

And, first, as to co-ordinates in one given plane.

1. *Both systems oblique.* Let x and y be the old co-ordinates of a point, x' and y' the new ones. Let μ and ν be the old co-ordinates of the new origin; θ the angle made by the old co-ordinates; ϕ the angle made by the axis of x' with x; ψ the angle made by y' with x. Angles are to be measured as explained in the article SIGN; thus the angle made by x' with x means the amount of revolution which would bring the positive part of x into the direction of the positive part of x', the revolution being made in the positive direction.

$$x-\mu = \frac{\sin(\theta-\phi)}{\sin\theta}\,x' + \frac{\sin(\theta-\psi)}{\sin\theta}\,y'$$

$$y-\nu = \frac{\sin\phi}{\sin\theta}\,x' + \frac{\sin\psi}{\sin\theta}\,y'.$$

2. *The old system oblique, the new one rectangular.* Here $\psi-\phi$ is a right angle, and

$$x-\mu = \frac{\sin(\theta-\phi)}{\sin\theta}\,x' - \frac{\cos(\theta-\phi)}{\sin\theta}\,y'$$

$$y-\nu = \frac{\sin\phi}{\sin\theta}\,x' + \frac{\cos\phi}{\sin\theta}\,y'.$$

3. *The old system rectangular, the new one oblique.* Here, in (1), θ must be a right angle.

$$x-\mu = \cos\phi\,.\,x' + \cos\psi\,.\,y'$$
$$y-\nu = \sin\phi\,.\,x' + \sin\psi\,.\,y'.$$

4. *Both systems rectangular.* Here θ and $\psi-\phi$ are both right angles.

$$x-\mu = \cos\phi\,.\,x' - \sin\phi\,.\,y'$$
$$y-\nu = \sin\phi\,.\,x' + \cos\phi\,.\,y'$$

5. *The co-ordinates of the new system parallel to those of the old one.* Here

$$x-\mu = x',\quad y-\nu = y'.$$

In any of the preceding cases, if the new and old origin coincide, we have only to make $\mu=0$, $\nu=0$, and use the formulæ accordingly.

Next, when the co-ordinates are those of points of space. The only two cases which are particularly useful are when both systems are rectangular, and when the new one only is oblique. Let x, y, z be the old co-ordinates, and x_1, y_1, z_1 the new ones. Let λ, μ, ν be the old co-ordinates of the new origin, and let the angle made by x_1 and y_1 be ζ, that of y_1 and z_1 be ξ, and that of z_1 and x_1 be η, which we may thus denote:—

$$\widehat{x_1y_1} = \zeta,\ \widehat{y_1z_1} = \xi,\ \widehat{z_1x_1} = \eta.$$

Then we have the following formulæ:—

$$x-\lambda = \alpha x_1 + \beta y_1 + \gamma z_1.$$
$$y-\mu = \alpha' x_1 + \beta' y_1 + \gamma' z_1$$
$$z-\nu = \alpha'' x_1 + \beta'' y_1 + \gamma'' z_1;$$

Where the meanings of α, β, &c., and the connection of those meanings with the places of the letters in the formulæ, will be easily caught from the following:—

$$\alpha = \cos\widehat{x\,x_1},\quad \beta = \cos\widehat{x\,y_1},\quad \gamma = \cos\widehat{x\,z_1}$$
$$\alpha' = \cos\widehat{y\,x_1},\quad \beta' = \cos\widehat{y\,y_1}\quad \gamma' = \cos\widehat{y\,z_1}$$
$$\alpha'' = \cos\widehat{z\,x_1},\quad \beta'' = \cos\widehat{z\,y_1}\quad \gamma'' = \cos\widehat{z\,z_1}.$$

And α, α', &c., are subject to the following six conditions:—

$$\alpha^2 + \alpha'^2 + \alpha''^2 = 1 \qquad \beta\gamma + \beta'\gamma' + \beta''\gamma'' = \cos\xi$$
$$\beta^2 + \beta'^2 + \beta''^2 = 1 \qquad \gamma\alpha + \gamma'\alpha' + \gamma''\alpha'' = \cos\eta$$
$$\gamma^2 + \gamma'^2 + \gamma''^2 = 1 \qquad \alpha\beta + \alpha'\beta' + \alpha''\beta'' = \cos\zeta$$

This case is not much required. The following, in which both systems are rectangular, is of the highest importance. When we speak of the angle made by two axes, we mean, as before, the angle made by the positive side of one with that of the other; but, since only cosines are used, the direction of revolution is immaterial. If both systems be rectangular, and if they have the same origin, we have two sets of equations, each of which follows from the other, one set being in each column; the meanings of α, α', &c. being as before,

$$\begin{array}{l|l}
x = \alpha x_1 + \beta y_1 + \gamma z_1 & x_1 = \alpha x + \alpha' y + \alpha'' z \\
y = \alpha' x_1 + \beta' y_1 + \gamma' z_1 & y_1 = \beta x + \beta' y + \beta'' z \\
z = \alpha'' x_1 + \beta'' y_1 + \gamma'' z_1 & z_1 = \gamma x + \gamma' y + \gamma'' z \\
\alpha^2 + \alpha'^2 + \alpha''^2 = 1 & \alpha^2 + \beta^2 + \gamma^2 = 1 \\
\beta^2 + \beta'^2 + \beta''^2 = 1 & \alpha'^2 + \beta'^2 + \gamma'^2 = 1 \\
\gamma^2 + \gamma'^2 + \gamma''^2 = 1 & \alpha''^2 + \beta''^2 + \gamma''^2 = 1 \\
\beta\gamma + \beta'\gamma' + \beta''\gamma'' = 0 & \alpha'\alpha'' + \beta'\beta'' + \gamma'\gamma'' = 0 \\
\gamma\alpha + \gamma'\alpha' + \gamma''\alpha'' = 0 & \alpha''\alpha + \beta''\beta + \gamma''\gamma = 0 \\
\alpha\beta + \alpha'\beta' + \alpha''\beta'' = 0 & \alpha\alpha' + \beta\beta' + \gamma\gamma' = 0
\end{array}$$

Besides which, each of the quantities α, α', &c. may be expressed in terms of the others, as follows:—

$$\begin{array}{lll}
\alpha = \beta'\gamma'' - \gamma'\beta'' & \beta = \gamma'\alpha'' - \alpha'\gamma'' & \gamma = \alpha'\beta'' - \beta'\alpha'' \\
\alpha' = \beta''\gamma - \gamma''\beta, & \beta' = \gamma''\alpha - \alpha''\gamma. & \gamma' = \alpha''\beta - \beta''\alpha \\
\alpha'' = \beta\gamma' - \gamma\beta', & \beta'' = \gamma\alpha' - \alpha\gamma' & \gamma'' = \alpha\beta' - \beta\alpha'.
\end{array}$$

For the mode in which these nine quantities are made to depend upon three, we must refer to works on mechanics, in which such reduction is particularly useful. We avoid giving it here, because trifling differences exist in the manner of taking the quantities to functions of which all the rest are to be reduced, so that no set of equations can be given which can be called universal. So far as we have gone, the expressions of all writers are the same, though the letters used are not always alike.

TRANSFUSION OF BLOOD is the operation of transferring the blood of one animal into the blood-vessels of another, and is sometimes beneficially employed for reviving those who are nearly dying after severe hæmorrhage. The operation had long been used as a means of experiment, and in the vain hope that by injecting the blood of a healthy man or animal into the vessels of a diseased one, the health of the latter would be restored; but it had rarely been employed for its only useful purpose till Dr. Blundell, after a long series of well-conducted experiments on animals, proved that it might be safely and advantageously employed in men. His observations are published in his 'Physiological and Pathological Researches;' and since his revival of the operation, the lives of many persons have been saved who were, in all probability, dying from the loss of blood during or after surgical operations, during gestation, and in other circumstances. The operation has, indeed, often failed; it has often been unnecessarily performed; and its performance is not unaccompanied by danger to the patient; but still there is sufficient evidence of its high utility in cases which, without it, would have been quite or nearly hopeless, to warrant its being resorted to under the guidance of a sound judgment.

The chief instruments employed in the operation are a syringe, with double pipes, a basin of appropriate form, and a fine tube fixed on one of the pipes of the syringe. One of the veins of the arm of the patient being opened just sufficiently to admit the point of the tube, and fixed by a probe, blood must be drawn through a free opening in the vein of some healthy person, and as it flows into the basin must be slowly sucked up, without any mixture of air, by the syringe. When the syringe is filled and carefully cleared from all air by forcing blood up to the very point of the tube, the latter must be introduced into the patient's vein, and the blood steadily and slowly injected. Four or five ounces are often sufficient to revive a patient, and if they produce head-ache, flushings of the face, tendency to fainting, and other unpleasant symptoms, the transfusion should be arrested; but if not, the injection should be continued till it produces some good effect, or till a pint of blood has been transfused. Beyond this it is not safe to carry the operation, nor is it likely to be beneficial. A second or a third injection may be employed when the state of the patient seems to render it necessary.

The experiments of transfusing the blood of various animals into the vessels of man proved only mischievous; and those of transferring the blood of an animal of one species to the blood of another species are of too little interest and have produced too few general results to be worth recording here. The injection of various medicinal substances into the veins has been tried, but its effects are not sufficiently different from those produced by the ordinary mode of taking medicine, to render it advisable to submit to an operation which is itself dangerous. All the important facts relating to the subject may be read in an article on Transfusion, by Dr. Kay, in the 'Cyclopædia of Practical Medicine,' and in the works from which he quotes.

TRANSIT, or TRANSIT INSTRUMENT (*Instrument des Passages*), was invented by Römer about the year 1690. The description is to be found at page 47 of the 'Basis Astronomiæ,' by his pupil, Horrebow, Havniæ, 1735; and we recommend the perusal of this book, which contains an account of Römer's inventions and methods, to all those who, reading Latin with moderate ease, feel a desire to learn the origin of modern practical astronomy.

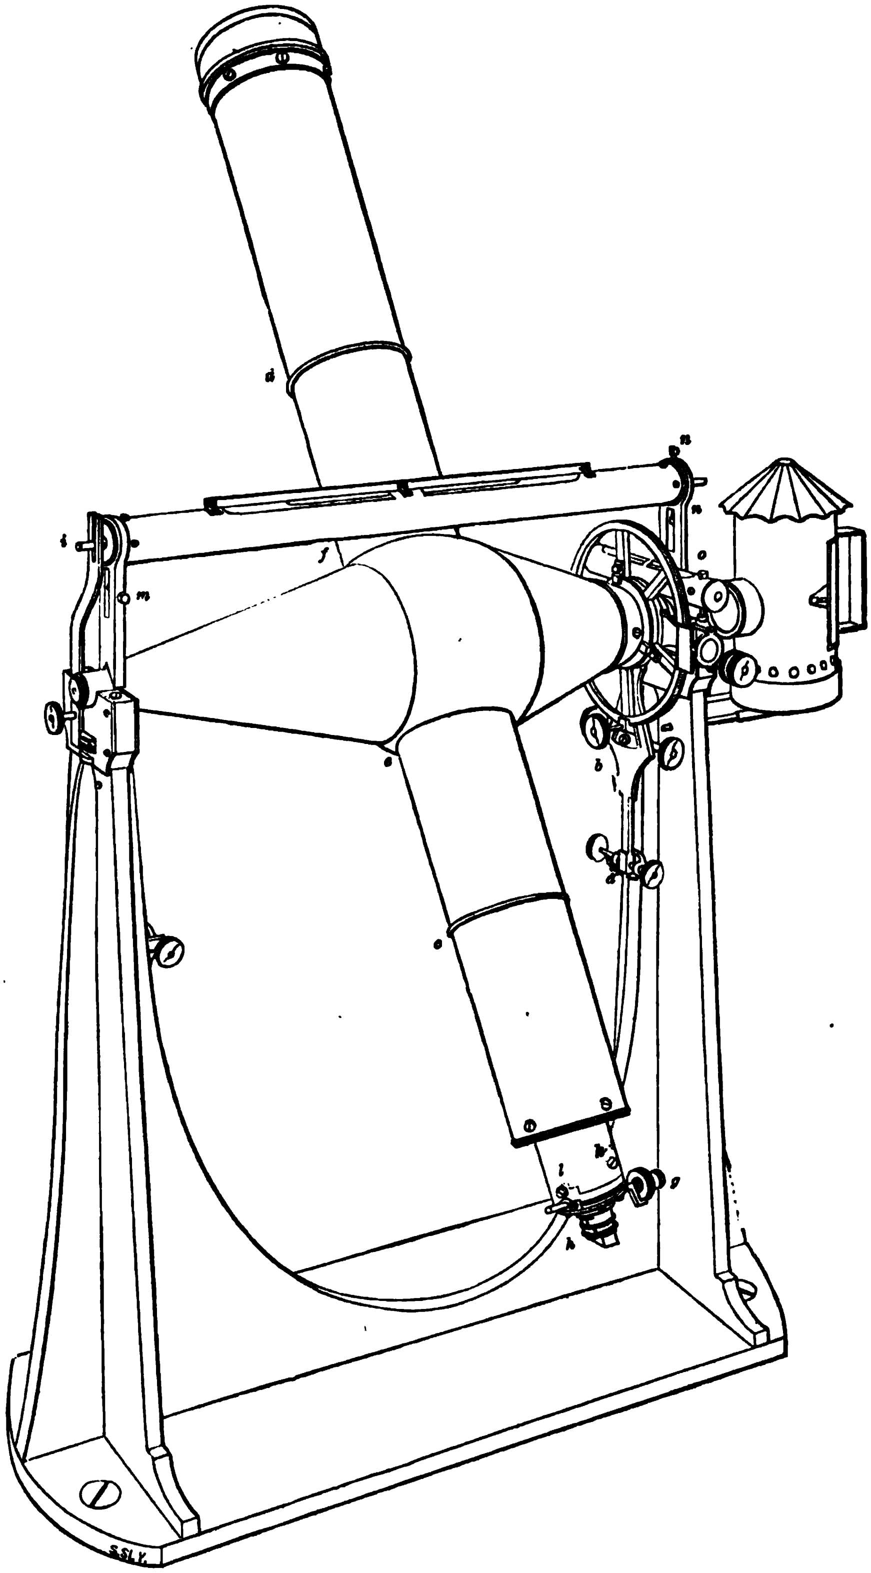
The object of the present article is to give such an account of the transit as will enable any one to use it with tolerable success. Those who wish for more perfect information must consult the introductions to the Greenwich, Königsburg, Dorpat, Cambridge, Edinburgh, &c., 'Observations.' Our type will be the *portable* transit-instrument, leaving the reader to accommodate what is here said to the powers of his own instrument, or to the practice of the Observatory which he adopts for a model.

There are three principal parts expressed in the cut. The iron stand, carrying the Y's with their adjustments; the telescope, inserted at right angles through an axis with a small vertical circle for finding or verifying stars; and the cross level. The stand is made of cast-iron, and should be of great strength, though perhaps that which is here figured would be found inconveniently heavy if the instrument is often moved. The Y's are contained in brass pieces, strongly united to the tops of the two uprights. The left hand Y has a motion up and down, which is given by a milled screw partially seen immediately under the pivot. The right hand Y is moved in azimuth by a screw, the milled head of which is seen projected upon the lantern. In portable instruments it is very convenient to have this lateral or azimuthal adjustment made by screwing against a spring, as it is in this instrument. In fixed observatories the adjustment is made by two antagonist drawing screws, one of which is tightened and the other loosened; and indeed this is the general construction of instruments of every size, and is the most solid fixture. But it is so convenient to be able to move the instrument at pleasure in azimuth while actually looking through the telescope, that we should strongly recommend the adoption of the counter-spring whenever the instrument is small, and is either to be frequently shifted, or is not furnished with a meridian mark. The spring must press pretty strongly against the screw, and there should be a clamping button in each adjustment, to keep all secure.

The axis is made of two strong brass cones soldered on the central sphere. The sphere is cast hollow with two shoulders, over which the cones slip. As this is the most important part of the instrument, great care should be taken of the fitting before the axis is finally put together, and the symmetry of the parts as to the centre should be perfect. If the instrument is weak here, it is utterly worthless. In the older English instruments the centre was a cube, and that form is frequently adopted at present by continental artists. The transit at Bruxelles, by Gambey, one of the largest and finest instruments in the world, is so constructed. The essential requisite, however, is *symmetrical strength*, and any shape is good which fulfils this condition. The pivots are soldered into the extremities of the cones, and are turned after the whole is fixed. One of them is pierced to admit light into the axis. In large instruments the pivots have an outer surface of steel, which is less affected by wear. Greater care is required to guard steel pivots from rust,* and the turning must be performed with a diamond cutter, as the hard knots to which steel is subject resist and jar the ordinary cutter out of its place. The pivots should be turned pretty nearly to the same diameter: the marks of the tool are ground off afterwards by collars which are made to fit closely on the pivots, and are changed and reversed from time to time. When the surface is perfectly formed, the grinding should be discontinued, as a small difference of size in the pivots is of little consequence, while an alteration of the cylindrical form of the pivots, or of the direction of their axes, ruins the instrument. The perforated or *illuminated* end of the axis is on the right hand pier in this figure. The light of the lantern shines through this, and lights up an annular plate in the centre, which makes an angle of 45° with the axis and with the telescope, and thus light enough is thrown down to the eye-end to illuminate the field very vividly, while the opening allows the rays from the object-end to pass without impediment. The quantity of light may be regulated by a contrivance for diminishing the aperture of the lantern, or by a shade passing between the lantern and the pivot. In some transits there is a contrivance for altering the angle of the central reflector in the body of the instrument; but this, although very handy, is objectionable, as affecting the symmetry of the instrument. In a thirty-inch transit the lantern is within reach, and may be twisted a little, so as to reduce the light at pleasure. The setting circle, with its level and clamp, are towards the illuminated end of the axis. The tail-piece, which is attached to the verniers and level, is held between the rounded ends of the two screws at *a*. By screwing one and loosening the other, the bubble of the level is brought to the middle, when the vernier points out the reading of the circle. There is a lens and reflector, for lighting and reading off the circle. The instrument here figured has a vernier which reads single minutes; but the vernier is inconveniently long for a fixed lens, and we should prefer reading to every 2′, which is more than sufficiently near for finding or identifying stars. If the small circle is carefully looked at, two out of three small screws are seen which fix the circle to the axis. When these are released, the circle will turn freely round. This contrivance will save some trouble when an instrument is used for a long time in the same place without reversing, but is scarcely worth being applied to one which is frequently shifted or reversed. The clamp for fixing the telescope in

* When the instrument is small and frequently out of use, it should be removed from the Y's, and the pivots protected by caps which slip closely over them.

altitude and the slow-motion screw are seen at *b*. There is a caution to be given here. The tail-piece should never be tightly nipped, unless the instrument is used for observing declinations, and it and the tangent screw must be released when the observer uses the azimuth screw for bisecting any object, such as a mark or a star at a given moment. In large transits there are generally two small circles fixed on each side of the transit towards the eye-end. They are here more convenient for setting, and it is easy to pass rapidly from one star to



Transit Instrument.

another, when both the circles are previously set. There is great diversity in the graduation of the setting circles. In large instruments which are used for some time in the same position, it is best to make the verniers read polar distance or declination, re-adjusting the circles whenever the transit is reversed. With a portable transit, which is or ought to be very frequently reversed, a graduation to altitudes one way, which becomes zenith distances when reversed, is perhaps as convenient as any, though a slight computation for each star is required to form a working catalogue. The telescope in this instrument is not inserted in the ordinary manner. The central portion, from *c* to *d*, is in one tube, pierced on the right side to allow the light to pass, and soldered at *e* and *f* to the central sphere. The reflecting plate is fixed in this telescope, and can be turned to throw the light up or down. The object-end and eye-end are screwed on at *c* and *d*, and are interchangeable. The telescopes are usually in two pieces, which are screwed into the central sphere at *e* and *f*. The advantage expected from the present construction is, that there is firmer screw-hold and less leverage for any blow or rough handling; and that by interchanging the object and eye-end, fresh portions of the pivots are brought into action, thus diminishing wear, and equalising minute errors of form or flexure. The object-glass of the telescope should be carefully selected, and of as large an aperture as will show a good image. The superiority of a large instrument over a small one is wholly in the increased optical power. In all other respects it is probably inferior, that is, if the support of the smaller instrument be as solid as that of the larger. There are seven fixed vertical wires at equal spaces, and two horizontal wires, between which the star is observed. The head of the micrometer is shown at *g*. A small prism for observing stars near the zenith is slipped on the eye-piece when required, as at *h*.

The level *rides* on the pivots with its Y's. There is a pin at each end, which drops into a fork at *i*, to hold the level safely and upright. This is completely seen at the left pier. At this end is the adjustment for setting the level tube parallel with the axis. At the other end is an adjustment for raising or depressing that extremity of the level. The level should be very sensible and of the same curvature throughout. The graduation we have found most convenient is to have the principal divisions to 15" and the subdivision to 1"·5, numbered as units and tenths, which, though erroneously, is briefly described by calling the units seconds of time. If this scale should be too fine for the level, a principal division to 30", and subdivisions to 3", but still numbered as units and tenths, will be found equally convenient. The riding level is generally applied to the instruments which are so large, and consequently the piers so high, that a man cannot apply the level safely while standing on the floor, and also to small instruments, of necessity, when they are clamped, as this is, to the pier. For a transit between stone piers which does not exceed five or six feet, we prefer a swinging level, which may be applied and read while standing on the floor.

When Troughton undertook, much against his will, to construct a ten-foot transit for the Royal Observatory, he adopted a very ingenious mode of uniting the cones and the telescope with the central sphere. The description will be found in the 'Phil. Trans.' for 1826, p. 423: that part which treats of the construction of the instrument is from Troughton's own pen. He also added four braces, to connect the telescope with the axis. We are not disposed to attach much value to this mode of connecting the axis and telescope, which, moreover, requires very accurate fittings. The braces are positively injurious, unless they are exactly and at the same moment exposed to the same temperature. It is said, indeed, in the memoir just mentioned, that when the antagonist braces were exposed to very different temperatures, the instrument continued to preserve its form. If so, the experiments simply show the centre-work to have been so strong that the braces could not disturb it, in which case they are merely useless. At Cambridge the braces were found to derange the instrument, and were consequently removed, to the great improvement of its steadiness.

There is no great difference of construction between different transits, except what we have already mentioned. It is desirable even for the smallest instruments that the supports should be of stone when they are not perpetually shifted about. The Y's then are separate pieces fixed by screws to plugs let into the stone. For small transits the stone may be in one or three pieces, according to the size. When practicable, the piers should be high enough and wide enough apart to let the observer stand or lie down between them. This saves perpetual meddling with the eye-piece, and the eye is less strained. We have already remarked that the performance of a well-made transit depends rather on the permanence of its fixing than anything else. It is to the greater care bestowed on the foundations of large instruments that much of their superior performance is to be attributed.

The principal use of a transit instrument is that of determining the exact moment when a celestial body passes the meridian of the place of observation. Now the meridian is a *great* circle which passes through the *zenith* and the *pole*, and the instrument is *adjusted* when the line of sight* is a portion of the meridian during the whole rotation of the telescope.

As in all other instruments, the telescope is first to be adjusted for distinct vision. Put on a tolerably high power, and slide the eye-piece out and in till you see the wires sharply without straining the eye. Then direct the telescope to a bright star or a double star; and if the image of it is distinct, the telescope is in focus. If not, release the screws at *k*, and draw the tube out or push it in until the image is as perfect as you can make it. There is another opposite screw to *k*, and the exterior holes allow a little play. Some trouble and guesswork may be saved by making two slight scratches on the eye-piece where the sight of the wires and of the star are respectively most perfect, and drawing the principal tube out or pushing it in this quantity. The operation has succeeded, if, in viewing a slow-moving star, like Polaris, there is no shifting between the star and the wire which bisects it, while the observer moves his head laterally. This adjustment is generally best made by the instrument-maker, and as it is not liable to alter, we should prefer to have the telescope tube cut the proper length upon his responsibility, so that the position of the wire is permanent. When this adjustment is completed, the telescope must be turned on some tolerably distinct object, which is to be bisected by the middle wire near the upper part of the field. If, on raising the telescope, it is also bisected at the lower part of the field, the wire is perpendicular to the axis; but if not, the tube is to be twisted without altering the focal length until the object comes half-way to bisection. The bisection is completed by the azimuth-screw, when the object ought to be seen bisected at the top of the field when the telescope is depressed. One or two trials will suffice for this purpose, and then the screws at *k* must be tightened.

* We shall speak at present as if there were only one fixed wire in the telescope, namely, the middle vertical wire. The subsequent modification will cause no difficulty.

The first of the principal adjustments is that of setting the line of sight at right angles to the cross-axis, when it necessarily describes a great circle. A distinct object must be selected not far from the horizon, and bisected by the middle wire, using the azimuth-screw. The axis is then carefully lifted out of its Y's, and returned end for end, or *reversed*, and the object viewed again. It is now to be bisected as before, half by moving the azimuth-screw, and half by the screw at *l* and its antagonist, each of which *draws* the plate on which the wires are fixed. The operation must be repeated until no difference can be seen in the bisection, whichever be the position of the axis. When there is a micrometer, the operation is somewhat easier. The micrometer wire is brought first on one side and then on the other of the centre wire, so as just to shut out the light between them, and the mean of these two readings is the reading of the zero point, that which corresponds to the exact superposition of the wires. The distinct object is bisected by the micrometer wire; and we will suppose that the screw has to be turned three revolutions for this purpose from its zero position. Now reverse the axis, and suppose the micrometer has only to be moved two revolutions from its zero to bisection. The half-way, or two revolutions and a half, is the distance which should be shown. Carry the micrometer wire two revolutions and a half back from its last position, and that is the position which the centre wire should occupy. If the joint thicknesses of the two wires (previously determined) equal ten parts, carry the micrometer five parts still farther back, and bring up the middle wire to touch it by the screws at *l* as before. The error of collimation is now corrected, as will be found by repeating the observation. The collimating screws have generally a capstan-head, which is awkward, and indeed dangerous so near the eye; and we think the square head, which is turned by a key, is more manageable. The screws should be drawn tight, but not forced. We have here followed the usual rule of directing the observer to select a well-defined object near the horizon. If the pivots of the axis are equal, the mark may be considerably elevated or depressed without introducing any error; and an object which is not very distant may be seen sharply defined when the aperture of the object-glass is diminished. In fixed observatories there is usually either a meridian mark north and south at a considerable distance, or two near marks, which are made distinct by interposing lenses. At Greenwich and Cambridge a south meridian mark is combined with a supplementary transit in the north slit; at Oxford two near marks are made visible by lenses fixed in the observatory slits. By using north and south marks at the same time, you are warned of any alteration in the Y's during the reversal, which, when the instrument is heavy, is always to be feared. Such shifting would cause the error of collimation to appear different according as it is taken from one or the other mark. In standard observatories the error of collimation is not actually corrected unless it is large, but measured by the micrometer, as we have described, and the effect thus allowed for by calculation.

When the illuminated end is west, and the telescope pointing south, let the middle wire *appear* to be 3·263 Revolutions to the right-hand of the collimating mark: as the telescope reverses, this means that the transit points 3·263 R. to the left of the mark, or to the *east*. Now reverse the telescope, the illuminated end is east, and suppose the middle wire still to appear to the right of the mark, but only 3·187 R. These observations are best made on a calm cloudy day; often, after rain, the mark, if distant, is seen sharply and steadily. If there were no error of collimation, the micrometer should give the same quantity at both observations, or ½ (3·263 R. + 3·187 R.), that is, 3·225 R. The error in collimation, therefore, is 0·038 R., and the instrument points to the east that quantity when the illuminated end is west. The scale of the micrometer screw is known. Let one revolution correspond to the space an equatorial star would move over in 3^s of time; then 0·038 R. is the space which an equatorial star would move over in 0^s·114, which is set down as the error to be employed in calculation. Now the effect of an error of collimation is to make the instrument describe a parallel to a great circle, and distant from it by the collimation error. If the instrument points to the east of the south, it also points the same quantity to the east of the north, and a star above pole will pass the *apparent* before the *true* meridian. The correction, therefore, to be applied to the observed transit is +, and when the instrument is reversed will be −. The time which a star takes to pass between the two circles, or the *correction*, is equal to the $\frac{\text{error of collimation}}{\text{cos. declin. of star}}$, or, in the supposition we have made, is—

* $+ 0^s{\cdot}114$ sec. declin. Ill. end West.
$- 0^s{\cdot}114$ sec. declin. Ill. end east.

The sign changes for stars *sub polo*.

Recently a method has been devised for recording transits, founded upon the principles of electro-magnetism. The sidereal clock is made to break the electric circuit at regular intervals of one second, and by a process similar to that employed in Morse's telegraph, the effect is impressed on a recording apparatus in connection with the clock. The observer is also enabled to break the circuit at any instant between two successive beats of the clock, and to record the fact in its proper place upon the registering paper. Hence in determining the transit of a star, the observer breaks the circuit at the instant of the star's passing each successive wire, and the results are imprinted in their proper place upon the recording apparatus. The distance between one of such recorded results and the nearest second as imprinted by the regular break-circuit apparatus of the clock, will indicate the fractional part of a second corresponding to the instant of the star's passage of the wire. In this method the eye and the sense of touch are called into operation instead of the eye and ear, as in the usual method. It originated in the United States of America, where it has been practised since the year 1849. It has been subsequently adopted at the Royal Observatory, Greenwich, and also at Altona, on the Continent. The differences depending on personal equation are almost annihilated by this method, which is well adapted for recording the transits of a great number of stars within a short compass of time.

The next adjustment is to make the axis horizontal. If the poles of motion are in the horizon, the great circle which the instrument, freed from collimation, describes, must pass through the zenith. Put on the level, and bring the bubble into the middle. Now rock it a little to and from the observer, and see whether the bubble still remains in the same place. If, in pushing the level from you, the bubble runs towards the left hand, this shows that the level tube itself is set askew upon its support, and that the left end, being nearest the observer, is elevated by that motion above the right end. Screw the small screw seen at *m*, and release its antagonist (these are *pushing* screws) until a considerable rocking motion scarcely moves the bubble at all. There is generally a cross level, to show when the principal level is upright; and this should be brought to have its bubble in the middle, when the principal level has been adjusted as above. The fork in the present example serves the same purpose when the level itself has been carefully adjusted. To level the *axis*, bring the bubble of the level to the same reading at each end (the numeration of the division is supposed to begin from the centre) by the elevating screw at the left hand Y. Reverse the level and bring the ends again to the same reading, half by the elevating screw of the Y, and half by the two screws seen at *n*, which raise or depress the level tube in its supports. On returning the level to its first position, the bubble should still be in the centre; but if not, it must be brought there, half by the Y elevating screw and half by its peculiar screws; and the operation must be repeated till this is effected, that is, if the observer cannot or will not calculate the effect of a small error, which may easily be measured. If he can (and there are few observers at present who cannot), the process is pretty much as follows; the graduation being supposed to be units each equal to 15″:—

Illuminated end West. Telescope South. Altitude 45°.
Observer North.
Level.
East end of bubble, $4^s{\cdot}76$. West end, $5^s{\cdot}84$.

The level is now reversed end for end, and the two ends again read off:—

East end . $5^s{\cdot}24$	West end $5^s{\cdot}34$
Mean, East $5^s{\cdot}00$	West . $5^s{\cdot}59$

which is the reading which the level would show in both positions if *it* were in adjustment. Hence the west end is higher than the east by half † the difference, or $0^s{\cdot}295$. The level should be applied in reversed positions several times, and a mean taken.

Now let the telescope itself be reversed, and suppose the following entries of observations to be made:—

Illuminated end East. Telescope North. Altitude 45°.
Observer North.

East $4^s{\cdot}93$	West $5^s{\cdot}66$
$5{\cdot}42$	$5{\cdot}19$
Mean East $5{\cdot}175$	Mean West $5{\cdot}425$

* The rotation of the earth requires the *apparent* place of a star to be increased by $0^s{\cdot}0206$. cos. latitude × sec. of *'s declination. This comes to the same thing as subtracting $0^s{\cdot}0206$ × cos. latitude from the collimation correction. In lat. 51° 30′ this $=0^s{\cdot}013$. The corrections for collimation become

$+0^s{\cdot}101 \times$ sec. dec. * Ill. end West.
$-0^s{\cdot}127 \times$ sec. dec. * Ill. end East.

† If the unit were 30″, the west end would be higher by the whole difference.

The difference is now $0^s{\cdot}25$, and the west end is consequently too high by half the difference, or by $0^s{\cdot}125$, a result which differs from the former (Illuminated end West) by $0^s{\cdot}17$. If the partial observations have been pretty accordant (we suppose $0^s{\cdot}17$ to be the mean result of a considerable number of observations), this difference between the values of the inclination, according to the position of the illuminated end, must be supposed to be owing to a difference in the pivots; and if so, a little consideration will show that to obtain the true inclination of the axis in the two positions, ¼ of $0^s{\cdot}17$ must be subtracted from the level error Ill. end West, and must be added to the error Ill. end East. The true level errors therefore are—

Ill. West, $+0^s{\cdot}295-0^s{\cdot}042$, or $+0^s{\cdot}253$;
Ill. East, $+0^s{\cdot}125+0^s{\cdot}042$, or $+0^s{\cdot}167$.

By the mean of a great many careful observations made when the temperature is steady * and the sky overcast, the difference of the pivots, if it exists, is to be ascertained, and the correction due to that cause is to be applied to the indication of the level.

The error of inclination in the axis being measured, the corresponding correction which is to be applied to the observations is thus computed: If the west end of the transit axis be raised, it is clear that the circle perpendicular to that axis will continue to cut the horizon at the north and south points, but will pass to the east of the zenith, from which it will be removed by an arc equal to the inclination of the transit axis. All the stars above the pole will therefore appear to pass too early, and those below the pole will pass too late; and if the inclination be 15″, the effect in *time* upon any star will be

$$\frac{\text{cos zenith distance}}{\text{cos declination}} \times 1^s.$$

Now the level graduated as we have described gives the inclination in parts of which 15″ is the unity; hence the corrections to be *added* to the observed times of passage of stars will be, using the previous example—

$$\text{Ill. end West} \quad +0{\cdot}253^s \times \frac{\text{cos. zen. dist.}}{\text{cos. declin.}} \text{ of star;}$$

$$\text{Ill. end East} \quad +0{\cdot}167^s \times \frac{\text{cos. zen. dist.}}{\text{cos. declin.}} \text{ of star.}$$

The above corrections, for errors of collimation and inclination, are purely instrumental, and, as the reader will perceive, do not require any celestial observation. Before proceeding to the third adjustment, that by which the great vertical circle now described by the telescope is made to pass through the pole, it will be proper to mention how transit observations are actually made, and then describe how this error is corrected or computed. The instrument is in or very near the meridian; a star on entering the field is placed between the two horizontal wires. It will then gradually travel through the field, describing a parallel to the horizontal wires, and passing over the vertical wires in succession. The observer looks at his clock a little before the star comes to the first vertical wire, and counting the beats steadily forward by ear, determines as well as he can the second and decimal of a second at which the star is immediately under the wire. He writes this down, counting all the time, and goes through the same process at each of the seven wires with which his instrument is furnished. When the star has passed all the wires, he looks again at the clock to see that his count is right, and then sets down the hour and minute corresponding to the last wire. The habit of mentally counting on to sixty while writing down the observation is easily acquired. The estimation of the decimal of a second at which the star is covered by the wire is a matter of more difficulty, and, with some persons, requires considerable practice.† The observer is to attempt to fix in his mind the places of the star with respect to the wire at the preceding and succeeding beat, and to divide the second in proportion to the two spaces. Thus if at 16^s the star is rather nearer the wire, before passing, than it is at 17^s, after passing, he sets down $16^s{\cdot}4$: if he judges the proportion to be less than one to two, he sets down $16^s{\cdot}3$; and so on. Finally, the mean of the observations over the seven wires is to be taken, which is to be used as the actual time of transit. It would be desirable that an observer should begin by learning to note the observation with considerable exactness, and if it may be, under the care of a practised guide; but the observation is so simple, that every one acquires the power who has the will to try; and we believe that, with a little experience, one observer is nearly as good as another.

* By adding the two readings together, you have the length of the bubble, which, if the temperature is steady, will continue to be of the same value during the series, but will grow shorter by heat. The level should be exposed some time before it is used. The coherence in the values of the length is a proof of the goodness of the observations. If the bubble continue to be of the same length when the zero is changed it is probable that the curvature is uniform. After the level has taken the temperature of the air, about a minute should be given for it to settle after each application, but not more than two. The observer should learn to read the level rapidly and boldly, as the zero changes if a light is held near to it for many seconds.

† Success will depend a good deal on the definition and magnifying power of the telescope, and also on the sharpness of the wires and the beat of the clock. The advantage of a distinct audible beat is very often entirely overlooked by clock-makers who are not observers.

Before applying the transit instrument to actual observation, the adjustment of the level of the vertical circle must be examined, which we will suppose to read altitudes when the illuminated end is west, and zenith distances when the axis is reversed. Having levelled the axis approximately, bring the bubble of the small level to the middle by the screws at *a* which hold the tail-piece, fix these firmly, and then direct the telescope on some point, which is to be placed exactly on the horizontal wire if there is but one, or between the wires if there are two. Read off the vernier, which we will suppose to give an altitude of 4°. Reverse the axis and repeat the former observation; and now read the vernier, which we will suppose to give a zenith distance of 87°. The sum of these readings is 91°, while it ought to be 90°, showing an excess of ½ a degree in each reading. Now set the vernier at 86° 30′, clamp the screw at *b*, and, by the tail-piece screws at *a* bring the object to its proper place between the wires; finally bring the bubble of the small level to the middle by the antagonist capstan-headed screws, which are seen towards the end of the level at *o*. The instrument will now show true altitudes and zenith distances within 1′ if the operation has been nicely performed. When the vernier reads polar distances, the vernier must be set to the polar distance of a known star, the telescope brought to the star, and the bubble of the small level afterwards brought to the middle. The latitude of the place may generally be supposed pretty well known: if not, direct the telescope to the pole star, or δ Ursæ Minoris, when near their upper or lower culminations, or to the sun, or to any star which the observer can identify when it is nearly south or north. The altitude or zenith distance of a known object will give a latitude near enough for finding a star from its catalogued place, or for instrumental corrections.

We will now proceed to the azimuthal correction. If the time is known from any other observations, the middle wire of the transit may be made to bisect a star at the time when by calculation it should pass; and if this star be Polaris or δ Ursæ Minoris, the instrument will be very nearly in the meridian; but if the observer has nothing but a transit instrument and a chronometer, he must place it as near as he can guess in the meridian,* and level the axis pretty carefully. A moderate knowledge of the heavens will tell what known star is likely to pass soon; and the instrument having been set to the proper altitude (or sweeping for it), the observer must wait patiently till it enters the field. The observation is then made in the manner already described. If the star is near the zenith, this alone will give an approximate clock-error. Now compute the time a star near the pole or horizon should pass, and bisect the star by the middle wire at the computed time. If the error in the position of the instrument is too large to be corrected by the azimuth screw, the stand must be shifted bodily a sufficient angle, and the instrument levelled afresh. In two or three trials it is easy to get the error within command of the azimuth-screw; and the observer, if he dislike calculation, may continue getting his clock-error by a star near the zenith, and then bisecting a star near the pole or horizon at the calculated time with the azimuth-screw, until all stars, high and low, give the same clock-error. The instrument is then in the meridian, and the clock-error is the true one. This tentative process may however be considerably abridged by a little easy calculation, which we will proceed to explain.

The errors of collimation and inclination being supposed to be annulled, either by adjustment or calculation, the line of sight describes a great circle passing through the zenith and not far from the pole. On drawing the figure, and supposing the deviation to be to the east of the south and west of the north, it will be seen that the effect of the error is to cause all stars between the south horizon and the zenith to pass too early, as well as all stars *sub polo;* while stars between the zenith and pole pass too late. The effect upon the passage of a star is proportional to $\frac{\text{sin. zenith distance}}{\text{cosin. declination}}$ of star. If x be assumed to be the amount of the deviation to the east of the south, measured in units of 15″, and the latitude of the place and the declination of the star be denoted respectively by ϕ and δ, the correction to be *added* to the observed passage of each star in respect of the error of deviation is $\frac{\sin(\phi-\delta)}{\cos\delta} \times x^s$.† Now suppose two stars, s and s', to be observed, which differ a good deal in declination, and let the values of $\sin\frac{(\phi-\delta)}{\cos\delta}$ for these stars be p and p': then $s+px$ and $s'+p'x$ are the times at which the stars would have been observed if the instrument had been in the meridian. The interval therefore between their transits thus corrected (and also corrected for the rate of the clock, if necessary) will be equal to the difference of their right ascensions, which may be taken from the 'Nautical Almanac,' if the stars are contained in its list, or must be computed from some good catalogue, if they are not.

* If a line be drawn from Polaris between the fifth and sixth stars of the Great Bear, and a point taken in this line about 1½° from Polaris, the transit directed to this point will scarcely be 1° from the meridian. With a little practice one may come nearer than this at once.

† Throughout we shall assume the latitude to be north: when the declination is south, the sign of δ is changed, and $(\phi-\delta)$ becomes $(\phi+\delta)$. North of the zenith the numerator is negative, and the correction is to be subtracted between zenith and pole. Below the pole the cos δ becomes negative (reckoned through the pole), and the correction becomes additive, as at first.

Let the right ascensions of the two stars be a and a', and we have the following equation:—

$$(s'+p'x)-(s+px)=a'-a.$$

$$\text{or } x=\frac{(a'-a)-(s'-s)}{p'-p}.^*$$

If the value of a revolution of the azimuth screw is known, it is easy to correct for this error at once with considerable accuracy. If x exceed 1^s or 2^s, it must be reduced to those limits. Should x be negative, the deviation is to the west of the south.

The accuracy of the determination of x depends, *cæteris paribus,* upon the stars which are used for the computation, that is, upon the value of the denominator of the above fraction, which should be as large as possible. The most favourable condition is, that both stars should be near the pole, one above and the other below: δ Ursæ Minoris and Cephei 51 Hevelii present this combination. It is always desirable that one of the stars should be pretty near the pole—Polaris, if possible. If the instrument is nearly in the meridian, it is better not to touch the azimuth screw, but to determine the value of x by grouping the stars together, in which $\frac{\sin(\phi-\delta)}{\cos\delta}$ is nearly of the same magnitude with the same sign. The value of x may afterwards be used to correct each star separately, and the transits thus corrected will be very nearly such as *would* have been made if the instrument had been exactly placed in the meridian.

In fixed observatories the meridian error is obtained when possible from consecutive transits of Polaris above and below pole. The observations are corrected for collimation and inclination, and for the rate of the clock. If the times of passage thus corrected differ twelve hours, there is no meridian error; but if the difference is greater or less than twelve hours, the deviation may be computed thus: Let s and s' be observed times of upper and lower culmination, corrected for collimation, inclination, and rate: let a and a' be the apparent right ascension of Polaris, taken from the 'Nautical Almanac; x^s the deviation as before; $-p$ and p' the values of $\frac{\sin(\phi-\delta)}{\cos\delta}$ for Polaris above and below pole, which have different signs. Then, exactly as before, $s-px$ and $s'+p'x$ will be the corrected times of transit, and

$$(s'+p'x)-(s-px)=a'-a,$$

$$\text{or } x=\frac{(a'-a)-(s'-s)}{p'+p}.$$

When three consecutive transits are observed, there is no need of taking any account of the rate of the clock (which is supposed to go uniformly), or the change in right ascension of Polaris in the interval; only a mean is taken of the first and third transits, which is compared with the second. The difference between these, divided by $p'+p$, gives the value of x. The sign may be made out by seeing whether the passage from upper to lower culmination is too small, and from lower to upper culmination too large, when the deviation is to the west of north, and therefore to the east of south, and the correction is to be *added*, or *versâ vice*, when it is to be subtracted.† In well-regulated observatories Polaris is always observed when it is convenient, and often when it is not; and the right ascension of the star, as well as the position of the instrument, is deduced from these double transits. When the right ascension is thus perfectly known, single transits of Polaris may be safely used in combination with other stars, to determine the azimuthal error for those times of the year when the star at one of its culminations passes altogether unseasonably. It is assumed, in this method, that the position of the instrument is the same for twenty-four hours; or that it changes uniformly.

If the reader has fully understood what precedes, he will have no difficulty in comprehending the mode of observing and reducing the observations which is followed at Greenwich and our principal observatories; but the private observer cannot always command a site which is wholly to be relied upon, and very seldom can afford the time for such an uninterrupted series of observations as is required to give full effect to the system just described. The precautions to be taken will depend mainly upon the objects he has in view, but generally speaking, the private transit observer will do wisely to take the places of the principal fixed stars from the lists furnished by Greenwich, though he may subsequently modify the values *inter se* by his own observations. Having done this, it will be easy for him to fix any other object with perfect accuracy, or to determine his time most scrupulously, although the steadiness of his transit is not beyond suspicion, and his avocations or inclination should only allow him to observe by fits and starts. We shall proceed to show how he may proceed under different hypotheses.

If he has a distant mark or a collimating telescope [see COLLIMATOR]

* Substituting for p' and p their values, the denominator of this fraction $=\frac{\sin(\phi-\delta')}{\cos\delta'}-\frac{\sin(\phi-\delta)}{\cos\delta}=\cos\phi(\tan\delta-\tan\delta')$ or $=\cos\phi\frac{\sin(\delta-\delta')}{\cos\delta\cos\delta'}$. This last is the usual form for computing the azimuth by a high and low star.

† To prevent mistake, we shall always speak of the quantity which is to be applied to the observation to make it correct.

with a micrometer to his transit, he proceeds exactly as we have described above to measure the quantity and direction of the collimation, the quantity and direction of the inclination, and then observes away, only taking care to note as many standard stars as will give him a correct clock-error, and at least some so far apart as will enable him to detect his azimuthal error. If he observe one or two stars near the pole, so much the better. Now calling ϵ the correction for the clock at the mean of the time of the observations of standard stars; s, s', s'', &c., as before the observed times of transit, corrected for collimation and level as aforesaid; p, p', p'', &c., with their proper signs, the correcting factors of the unknown azimuth x; and a, a', a'', &c., the apparent right ascensions of the standard stars, he has the following series of simple equations:—

$$s + \epsilon + p x = a$$
$$s' + \epsilon + p x' = a'$$
$$s'' + \epsilon + p x'' = a''$$
&c. &c. &c.

Group together the equations in which the coefficient of x is nearly of the same magnitude and with the same sign,* and dividing each group by the number of its component parts, so as to have ϵ with unity as a coefficient, form at least two equations in which the coefficients of x differ considerably, and subtracting one from the other, a value of x will be found with its proper sign. Substituting this value of x in each of the equations $\epsilon = a - s - p x$, you will have as many values of ϵ as you have equations; and taking the mean of those which are derived from the quick-moving stars, you have a good clock correction. Now if any other objects have been determined, the right ascension of which is required, add (speaking algebraically) the sum of all the corrections for collimation, inclination, declination, and clock-error to the observed transit, and you will have the *apparent* right ascension.

But it most frequently happens that the observer has no collimating mark and no micrometer to his instrument; nay, he may only have a view out of a window † which commands no distant or distinct object, and not be able to see even the zenith, much less the pole. This last is the greatest objection; for the accuracy of the meridian adjustment depends chiefly upon getting stars near the pole. To detect the error of collimation the observer must proceed thus:—After having carefully determined the inclination of the axis, he observes as many well-known stars as he can, especially getting them as high and as low as possible for ascertaining azimuthal error. He must then reverse the axis, repeating the measurement of the inclination, but by no means touching the elevating screw of the instrument, and make a similar set of observations. A series of equations must be formed for each position of the instrument, which will be of the following form:—supposing s, s', s'', to be the observed transits of the stars corrected for inclination *only*; q, q', q'', to be the values of the secant of declination for each star respectively; c, the unknown value of the collimation error in the first position (which becomes $-c$ when the instrument is reversed); x, the error of deviation; and ϵ the clock correction,—

$$s + \epsilon + q c + p x = a$$
$$s' + \epsilon + q' c + p' x = a'$$

and so on, for the stars first observed, and

$$s'' + \epsilon - q'' c + p'' x = a''$$
$$s''' + \epsilon - q''' c + p''' x = a'''$$

and so on, for the stars of the second set after the instrument is reversed.

The mode of treating these equations will differ according to circumstances. They might be solved by the method of least squares; but it is scarcely worth while in ordinary cases to use any such refinement. Form four groups, two in each set, those in which x has the largest, and those in which x has the smallest coefficients, dividing each group by the number of its component parts, so as to leave ϵ with unity for its coefficient. Call these equations 1, 2, 3, and 4. Subtracting (4) from (1), we shall eliminate ϵ, c will have a + coefficient exceeding 2, and x in the most difficult case, that is, when the observer can only look to the south, has a small positive coefficient. Again subtracting (3) from (2), we shall have c with a positive coefficient exceeding 2, and x with probably a small negative coefficient. From these two equations c can be determined pretty accurately. Substitute this value in equations (1) (2) (3) and (4), group (1) and (3) together, and (2) and (4) together, and we have a pair of equations in which x has coefficients considerably unequal; and by subtracting one from the other, ϵ is eliminated and x determined with tolerable accuracy. Finally, the substitution of these values of ϵ and x in the original equations will give a satisfactory clock-error if the observations are good and pretty numerous, even although the observer has not more than 50° of clear sky to work upon. The times of transit of other objects must be corrected by the quantities thus found, and in this way apparent right ascensions may be deduced with considerable certainty.

The clock correction should evidently come out the same in both positions of the instrument, and the differences from the mean fall within the ordinary errors of observation. If this is not the case, and there should be reason to fear any alteration in the position of the stand or the Y's in the process of reversing, the values of x cannot be assumed to be the same in both groups. If the time should be required with extreme accuracy from such imperfect observations, the observer may alter the quantity of collimation in his calculation till he does get the same clock-error, although with different deviations, from both sets. This may be done by one or two trials, but generally speaking the mean of the clock-errors from both sets will be near enough, and not differ sensibly from the more elaborate calculation. It is not however easy to get the time *very satisfactorily* without being able to see the pole, or at least the zenith.

In what precedes we have supposed the extreme case, that is, that nothing is to be seen north of the zenith, and that x therefore has always the same sign. The intelligent reader will be guided in practice, not by the directions here given, but by the *value of the coefficients of his unknown quantities*, a discretion which some astronomers cannot or will not use.

It is always desirable that the value of the three transit corrections should be small (indeed the formulæ are not exact, when the errors are large), to save unnecessary trouble in multiplying. The method of measuring the inclination implies that you can rely on the scale of the level for the quantity measured, which is scarcely true when the amount exceeds a few seconds of space. The collimation error is easily brought within reasonable limits, if the observer has a micrometer, or can see any fixed object distinctly while he alters the screws. The azimuthal adjustment requires either an object of reference, which is always the case in principal observatories, or adjusting-screws of which the thread and value are known, but this can only give correct results when the load upon the Y is inconsiderable. Portable instruments, which are really carried about and stuck at times out of a window, ought to have the spring to the azimuth-screw such as has been described.

It is convenient that the clock should be a little slow and have a small losing rate, the corrections for error and rate are then additive: if the west end of the axis be the higher and the deviation to the east of the south, the correction for these errors will also be *additive* to the observed transits of the greater part of the stars observed.

In most cases, the determination of the absolute time at the place is wanted, and this cannot be got without the level or some equivalent which tells how far the instrument swerves from the zenith. But where it is merely required to observe in a meridian, as in observing for a catalogue, it is more expeditious to change the form of the corrections. The two factors $\frac{\cos(\phi-\delta)}{\cos\delta} \times$ inclinat. $+ \frac{\sin(\phi-\delta)}{\cos\delta} \times$ deviation may be expressed by a correction of this form: $m + n \tan\delta$, where m and n are two constants to be determined by observation.* In this case the stars should be observed in zones, and when the sweeps are not near the pole, it is easier to destroy the error of collimation by adjustment very nearly than to allow for the error. The secant of declination varies very slowly, and may be considered as a constant for the whole sweep, within moderate limits, and for a small value of the collimation, which may easily be reduced to 0s·1 at once. Suppose an observer to have this purpose: he observes a large set of stars nearly at the same declination, taking care to have as many standard stars as possible above and below the limits of his sweep, and it is proper to have several with contrary declinations. Now calling the observed times of transit s, s', &c., he forms the following equations with standard stars:—

$$s + m + n \tan\delta = a$$
$$s' + m + n \tan\delta' = a'$$

and so on. From these he composed two equations, one formed of all those in which $\tan\delta$ is positive and another in which $\tan\delta$ is negative, and which therefore may be represented thus:

$$\Sigma + m + n\text{T} = \text{A}.$$
$$\Sigma' + m - n\text{T}' = \text{A}'.$$

from which n is found $= \frac{(\text{A} - \Sigma) - (\text{A}' - \Sigma')}{\text{T} + \text{T}'}$.

Substituting this value of n in the mean of the two equations, we

* If two known circumpolar stars, like δ Ursæ and Cephei 51 Hevelli, are observed, subtract one of these equations from the other, and you have an equation in which x has a large coefficient, and therefore a good determination; if Polaris is well observed, use it singly, and group the standard stars together which have not more than 30° or 40° declination.

† This was the case with Römer, and the transit instrument was invented precisely for such a situation. See 'Basis Astronomiæ,' cap. 8.

* If i be the inclination as given by the level and x the deviation, then expanding the numerators, the sum of the corrections

$$= \frac{i(\cos\varphi . \cos\delta + \sin\varphi . \sin\delta) + x(\sin\varphi . \cos\delta - \cos\varphi . \sin\delta)}{\cos\delta}$$
$$= i\cos\varphi + x\sin\varphi + (i\sin\varphi - x\cos\varphi)\tan\delta$$

which agrees with the formula given above, putting

$$m = \iota + i\cos\varphi + x\sin\varphi$$
$$n = i\sin\varphi - x\cos\varphi$$

The formula is easily deduced by drawing a figure and referring the transits to the meridian which cuts the equator at the same point as the circle described by the telescope.

have the value of m, and that with great exactness, if the stars have been well selected, are pretty numerous, and have been tolerably observed. To reduce the transits of the other objects observed to apparent R. A. nothing more is required than to add $m + n \tan \delta$ to the observed transit, which, besides being a good deal shorter than the method previously described, only requires a table of natural tangents for computing the corrections.

If the observations are made on or near the pole, where the sec δ varies almost as rapidly as the tangent, a sensible error of collimation would mix itself up in the value of tan δ. If the pivots of the instrument are exactly equal, two series might be observed in reversed positions of the axis, and as m and n would have the same value in each, while the sign of collimation changes, the determination of the latter would present no difficulty. We have used another plan, which in steady weather, when observations can be made on consecutive nights and in large masses, is perhaps the best for cataloguing. On the first night observe forty or fifty stars, consisting of all the standards which pass and those stars the places of which you wish to determine. These may now lie scattered all over the heavens, so far as the method is concerned. On the following evening reverse the instrument and observe the same stars. The first night, each observed star should be increased by $m + n \tan \delta + c \sec \delta$, while the second night the correction is $m' + n' \tan \delta - c \sec \delta$, the collimation being supposed (as is found to be the case) to be invariable in a well-made instrument, unless violence is used. Now if we add the observed transits of each star on the two nights together, and take a mean, the result requires a correction of $\frac{m + m'}{2} + \frac{n + n'}{2} \tan \delta$; and the collimation is eliminated. This new correction for the mean of the two nights is exactly of the same form as the original correction, call it $M + N \tan \delta$, and M and N are found by comparing the observed places of the standard stars with their known computed places, just as before. If the clock rate is sensible, the values of M, preceding and succeeding the mean of the standard stars, must receive a proportional correction, but it is easy to make the rate of a good clock so small that in ordinary circumstances this may be neglected. The rate may be determined near enough by observing the same high star both nights in the same position of the axis, and measuring the inclination by the level. From some trials of this method, we should strongly recommend it in a steady climate and where a large catalogue of stars is to be formed. An error of $0^s{\cdot}1$ would, we are convinced, be very rarely found in the R. A. of stars so determined within 40° of the equinoctial; the computations are very short and can scarcely be wrongly made, and there is only one computation of a mean place for two complete observations of an apparent place. Writing the separate results under each other, is an excellent check against those provoking small errors which, when they once get admittance, are so difficult of detection. It is a drawback that the computation does not furnish the absolute time or clock error, if that should be required for other purposes, without further calculation.

In this climate it frequently happens that the star is visible during only a portion of its passage over the wires, or the observer may lose some of the wires; hence it is necessary to have some means of completing the imperfect transits, and ascertaining so far as possible at what time the star would have passed the *mean* of the wires, if all could have been observed. For this purpose a sufficient number of complete and satisfactory observations is selected (suppose the illuminated end to be west), and the difference taken between each wire, and the mean of the wires. Multiplying these numbers respectively by the cosine of the corresponding star's declination, we have the differences, such as they would have been if the stars observed had been in the equinoctial. A mean of these is taken for each difference, and the proper sign affixed. If a second series be selected of observations made when the illuminated end is east, and be treated similarly, nearly the same values will be found as before, but in reversed order, and with different signs. A mean is taken when the number is sufficient to give a satisfactory result; and the logarithms of the intervals between each wire and the mean, for an equinoctial star, are set down for future use, discriminating whether the instrument is Illuminated end E. or W. Now suppose a broken set of wires is to be made up: take the logarithms with the proper sign corresponding to each wire, add to each logarithm the log. secant of the star's declination, and take the natural numbers corresponding to the logarithms thus found, and you have the number of seconds and decimals of a second which are to be *added* (algebraically) to the observation of each wire to reduce it to the mean wire. Of these partial results, a final mean is taken. The numbers for reducing each wire to the *mean wire* are found in the introductions to all the modern observations.

The slow-moving stars, such as Polaris and δ Ursæ Minoris, are those best suited for determining the interval of the wires, and this is one of the first points to which an observer should direct his attention, for he will observe a slow star as well at starting as afterwards, and as he will probably make a good many broken transits, the sooner he acquires the means of reducing them the better. The declination of these stars is perfectly known for every day from the Nautical Almanac, but there is a precaution to be taken here, which is unnecessary with quick-moving stars, as the path of the star being sensibly curved in moving

from the outer to the inner wires, the motion between the wires is not uniform. The exact formula is

sin distance of any wire from mean = sin time from mean × cos. declin. star ;

and the equatorial interval may be computed by taking the log sin of the intervals ÷ log sin 15″, instead of simply the log interval in seconds of time, as in other stars. Or if the following quantities be first subtracted from the intervals observed, the ordinary rule may be followed :—

Interval Observed.	Correction.	Interval Observed.	Correction.
4^m	$0^s{\cdot}0$	21^m	$1^s{\cdot}8$
8	0 ·1	22	2 ·0
12	0 ·3	23	2 ·3
13	0 ·4	24	2 ·6
14	0 ·5	25	2 ·9
15	0 ·6	26	3 ·3
16	0 ·8	27	3 ·7
17	0 ·9	28	4 ·2
18	1 ·1	29	4 ·6
19	1 ·3	30	5 ·1
20	1 ·5		

This table may also be used when the broken wires of a close circumpolar are to be reduced. Compute the correction for each wire by the ordinary formula, and add to it the number from this table corresponding to the interval, before applying the correction to the observation of the wire.

As the stars *sub polo* pass the wires in a contrary direction, the numbers for reducing each star to the mean wire must be taken from the table corresponding to the reversed position of the instrument, or, what comes to the same thing, they must be reckoned backward with changed signs from the table which belongs to the existing position. When the interval between the mean wire and the other wires is well established, the collimation error must be referred to the *mean* wire after it has been measured for the *middle* wire. There is a way of measuring the collimation, when the distance of each wire from the mean is well determined, which is very useful in the absence of a meridian or collimating mark. Polaris or δ Ursæ Minoris, or any slow-moving star, is observed over the first four wires (the inclination error having been previously measured); the instrument is then reversed and the star is observed over the remaining three wires, and the inclination again measured. The first set of observations is reduced to the *mean* wire by the known intervals at the horizontal position of the axis. The second set is similarly reduced to the mean wire, at the horizontal position. The difference between the two results, if the Y's have not been altered by lifting the instrument and setting it down again, is the sum of the collimation in two positions; and when this is divided by twice the secant of the star's declination, the result is the collimation error required. If the pivots are perfectly equal, the levelling may be omitted except as a precaution against altering the Y's. When the time is wanted with great nicety, it is convenient to observe a series of stars before reversing upon Polaris or δ Ursæ Minoris, and a second series after. If the pole star has been properly observed and reduced, and the collimation rightly determined, the two series will give nearly the same clock-error, and be a check on each other. The instrument must always be used in reversed positions, for determining the time, when this is practicable.

There is a curious anomaly sometimes found in transit observations, namely, that two practised observers will make a notable and constant difference in observing the exact moment at which a star passes a wire. Maskelyne first noticed this singularity in his assistant Kinnebrook, who observed a star $0^s{\cdot}7$ later than the Astronomer Royal. Bessel and Argelander have a still larger difference; and we found, on determining the longitude of Bruxelles chronometrically, that M. Quetelet, the director of that observatory, noted a transit about $0^s{\cdot}8$ earlier than Mr. Henry, one of the transit observers at Greenwich: so that if the time at each place had been simply taken from their observations without any allowance, the longitude would have been erroneous on that account *alone* $0^s{\cdot}8$, which might have been either way. This shows how insecure all nice chronometrical longitudes are, unless the same observer determines the time at both ends of the arc, or unless the relative *personal equation* of the observers at each end is *carefully* determined. [EQUATION, PERSONAL.] It would be advisable perhaps, where the result is very important and the distance considerable, to *reverse* the observers, as it seems that fatigue will, in some *cases* at least, cause a variation in the personal equation, and that two observers may begin a night with one difference and end with another.

If it were not for this latter circumstance, it would *perhaps* be possible to train observers to observe alike, by exhibiting the same phenomena of sound and sight (the relation between which might be established mechanically) to a class, and habituating them, *like* an orchestra, to keep the same time; and such a piece of mechanism would be easily made, though there would be a difficulty in getting observers to submit to the drill. We have found the following practice a good exercise for making the eye and ear work together. The pointer of a clock, with dead-beat scapement, springs forward simultaneously with the sound of the beat. Where there is a *good deal of* noise, and the clock has a low beat, it is found necessary to have a second clock called a journeyman, which strikes loudly and speaks as it were for the transit clock. The observer makes them beat pretty nearly together, and then listening at the principal clock and noting the difference, he either pushes forward or delays the pendulum of the journeyman to make the coincidence perfect, and this ought to be continued until he cannot distinguish between the two beats when standing close to the transit clock. Let a person try to make this coincidence by *looking* at the transit clock and *listening* to the journeyman, and if he can, or can very nearly do this, it is evident that he notes an appearance at the time it happens. Perhaps by trying the same thing when fatigued, he might detect a change in his perceptions, for the coincidence of sounds, as judged of when equalised by standing near the weaker source, is one in which a tolerable ear can scarcely be more than $0^s{\cdot}01$ or $0^s{\cdot}02$ out at farthest.

The position of the horizontal axis has been all along supposed to be measured by the level, and this is certainly the most ready method. But the level may happen to be broken, or, unless it comes from a very careful maker, it may be sluggish, or unequally divided. The beautiful levels which accompany Ertel's instruments, which are covered at the ends with parchment and filled with ether, are very liable to leak, as we know by experience. In such a difficulty, our celebrated surveyor Captain W. F. Owen raised a tall pole, and having put thereupon a distinct mark, adjusted his instrument by moving the elevation screw until the wire passed through the mark seen directly and by reflexion. In another instance, where the level was broken, an observer of some name was unable to supply its place, and a projected set of observations failed in consequence. The simplest method is that pursued by Captain Owen, substituting the pole star or other slow-moving star at its culmination for the tall pole. When the axis is thus *nearly* corrected, which may easily be done when the star passes the first wire, it is better to observe the star over the rest of the wires half directly and half by reflexion, and to reduce each set to the mean wire. On drawing the figure it will be seen that any error of level will affect the transit of a star seen directly one way, just as much as it will affect the transit of the same star, seen by reflexion, the other way, or that the difference of the two transits, after each set has been reduced to the mean wire, is twice the error due to inclination: that is, the difference of the transits in the two positions is, when the star is above the pole $= \dfrac{2\cos(\phi-\delta)}{\cos\delta}\times i$, from which i is determined, and may be used for all the other observations. The observation will succeed very well with any slow-moving star, if the observer has time to shift from one position to the other without hurry; or he may use two high stars, each observed over all the wires, if they have the same altitude, or if he should happen to know the other errors of his instrument. Indeed, if he has no objection to solve simple equations with four unknown quantities, he may proceed exactly as we have shown in former instances, introducing another term with i and its coefficient, and changing the sign for the observations by reflexion.

Observations by reflexion of Polaris are well suited for another purpose, namely, for examining the value of the level scale by means proper to the instrument itself. Raise the west end until the bubble is nearly at the west end of the scale, and by a mean of half a dozen readings, reversing each time, ascertain the error of inclination. Now observe Polaris exactly as we have before mentioned, or, if the observer likes better, directly over the 1st, 2nd, 6th, and 7th wires, and by reflexion over the 3rd, 4th, and 5th; reduce each set to the mean wire, and calculate by the formula already given the true inclination of the axis. On a following night repeat the operation, the illuminated end being on the same pier, only lowering the west end of the axis until the bubble is nearly at the east end of the scale, and get as before two values for the inclination, one from the scale, and another by observation. Take a mean, and you will have the true value of the parts of the scale. If the result varies much in the two experiments, it shows either that the curvature of the level is unequal, or that one pivot is thicker than the other. This may be ascertained by the level alone, as we have shown above, or would be indicated by a difference between the direct and reflected observations when the axis is horizontal by the level, or by comparing the inclination obtained from reflexion in the manner last pointed out, in reversed positions of the instrument, supposing the Y's not to change during the experiment. Thus if the inclination be determined by observing Polaris over the first half of the wires directly and the second half by reflexion, a value of the inclination will be found. Reverse the instrument, and make the same observations upon another slow-moving star, and you will have a second value of the inclination, which should agree with the former if the pivots are equal; half the difference, if it exists, is the difference in the radii of the pivots. The level however affords a much easier, and, we believe, better measure of inequality; but it will not show if the pivots be elliptic, which the observations by reflexion would do if stars at different altitudes were observed. If the two tests agree, it is a reason for believing that the pivots are round within the limits of these very searching experiments. But as we believe these observations have never yet been made, it would be useless to expatiate further upon their possible advantages. The late astronomer royal, Mr. Pond, tested the transit at Greenwich by observing a set of stars directly and a second set by reflexion after the axis had been most carefully levelled, and found that on reversing his sets on a subsequent night he got the same mean interval, as he ought. Professor Woodhouse examined his level scale by observing Polaris over half the wires with one end high, and the other half with the other end high. This is less sensitive than the method we have pointed out, but will do for its purpose very well, if the instrument is examined and verified by a meridian mark between the first and second set of observations, otherwise we should be afraid a change in azimuth might be caused by turning the elevating screw, in spite of all the care of the artist to prevent it.

An eye-piece has been introduced into use within the last few years, which, by illuminating the wires in a particular manner, enables the observer, looking downwards into a basin of mercury, to see at the same time the wires and their reflected image: if these be made to coincide, the telescope is vertical, and therefore the axis horizontal. If the micrometer wire be used to measure the interval, the result will be found to be twice the inclination.

The transit may be levelled, as it was in older times, by a plumb-line, which, hanging from a frame placed close to the instrument and in front of it, is made to pass over two dots, placed at the eye and object end of the telescope. This is an accurate but intolerably troublesome method. In Groombridge's circle, Troughton used a plumb-line in a tube at right angles to the axis and to the telescope for the same object. The images of the opposite dots at top and bottom were thrown on the line by lenses, and viewed through microscopes, in the way in which he always applied the plumb-line. We do not know whether Mr. Groombridge adjusted the horizontal axis by means of this plumb-line or no, but the artist himself said that he introduced the tube principally to make the axis equally weak all round, finding that it was previously so much stronger in one direction than another as to give him trouble in dividing it. Finally, the axis may be adjusted, or the inclination measured micrometrically, by means of a vertical collimator, which is convenient enough, but, so far as our own experience goes, rather uncertain in its indications, and much inferior in *both respects* to a good level. A really good level carefully and frequently applied will show the position of the transit axis to about $0''{\cdot}2$ or $0''{\cdot}3$, or the inclination correction to $0^s{\cdot}02$, and this is a smaller quantity than a considerable number of careful observations will show.

From what we have already said, it is evident that where exact time is wanted, the collimation, inclination, and deviation factors are perpetually required. The collimation factor is merely a table of secants of declination, and may be taken from any table of natural secants. The inclination and deviation factors should be computed for each observatory to every 10′ of declination, and be tabulated for constant use. For the stars often observed, we find it most convenient to have a catalogue in which the log secants of declination, the natural secants and tangents of declination, and the factors for inclination and deviation, are entered in parallel columns with the proper signs. The astronomer royal employs a sliding-rule for these and similar computations. In computing this table for a given latitude, the formulæ will be advantageously transformed thus:—

$$\text{Inclination factor} = \frac{\cos(\phi-\delta)}{\cos\delta} = \cos\phi + \sin\phi\tan\delta;$$

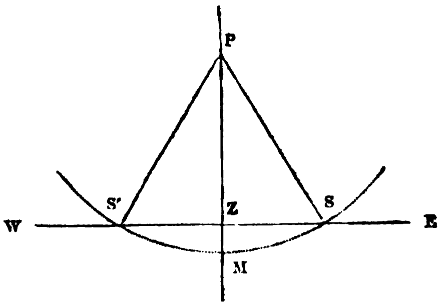
$$\text{Deviation factor} = \frac{\sin(\phi-\delta)}{\cos\delta} = \sin\phi - \cos\phi\tan\delta:$$

so that having the natural sine and cosine of latitude, and also the log sine and cosine, the computation reduces itself to adding the log tan. declination to these last. The necessary tables may be computed in a few hours as far as is advisable; for near the pole the change of declination has so large an effect, that it is necessary to use the exact declination.

Great service would be done to amateur practical astronomers by a judicious set of printed forms, in which to enter and reduce their observations; and by a set of tables sufficient for these small computations, and not containing anything further. This can only be obtained by repeated attempts, and after all most observers would probably prefer a modification of some form, to adopting it implicitly. We have tried to produce something in this way on which a better attempt may be founded. The astronomer royal published a portion of the forms used at Greenwich in the volume of the Observations for 1840, and we venture to recommend his practice to other observers, in order that their less able brethren may profit by their superior skill and experience.

While he was employed in the Royal Observatory of Paris, Römer proposed a method of determining the equinox by observing the azimuth of the sun at rising and setting near the time of the equinox, which method he illustrated by an example. ('Basis Astronomiæ,' p. 107.) He thus got rid of the effects of parallax and refraction, and deduced an accurate declination of the sun without an exact knowledge of the latitude. The method is a very good one, though undoubtedly inferior to that proposed and executed by Flamsteed. Many years after, Römer, on erecting a small observatory in his own country, placed a transit east and west, that is, in the prime vertical. Almost all his papers were destroyed by a great fire at Copenhagen, and it does not seem by Horrebow's account that any use was made of this prime vertical transit. He intended probably to observe the sun in the prime vertical for the purpose already explained; but as he had now a meridian transit circle, with which he could measure declinations with great accuracy, he seems not to have followed up this idea. Bessel, in the 'Astronomische Nachrichten,' vol. ii. p. 9, showed that the transits of stars over the prime vertical near the zenith might be employed for determining differences of latitude with great accuracy; and since that time several observatories abroad have had transits erected in this position. We shall here briefly show how terrestrial latitudes and differences of latitude may be determined by a transit in the prime vertical.

Let P be the pole, Z the zenith, EZW the prime vertical, which is also the line described in the heavens by the transit, and SMS' part of the daily parallel of a star which passes south of the zenith and near to it. Then if the time at which the star is on the wire at S and S' be noted, the angle SPS' is the difference of those times, and therefore known.



In the right-angled triangle ZPS,

$$\tan PZ = \tan PS \times \cos SPZ;$$
$$\text{or, } \cot \phi = \cot \delta \times \cos \tfrac{1}{2} \text{ time elapsed.}$$

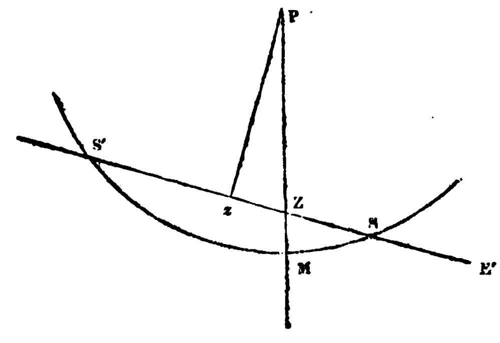
If then the declination of the star is known, the latitude is found; or if the same star be observed at two places, the difference of latitude may be found with only an approximate knowledge of its place.

Again, if the same star be observed regularly at the same place, as tan declination = tan latitude × cos ½ time elapsed, and as the time elapsed can be observed with the greatest nicety, the *variations* of declination can also be measured with great precision. Thus the constants of aberration and nutation may be determined by a transit in the prime vertical instead of a zenith sector; but the advantage appears to us questionable. The telescope in a zenith sector may be of almost any size, which gives it an immense advantage over the transit. The level may be applied just as well to one instrument as the other (the plumb-line much better to the zenith sector;) and though the division by time in the transit is more perfect than division by arc in the sector, the telescopes being of the same power, it is certain that the division is not the failing part of the sector. An error in the form of the pivots would be injurious to the transit, and is not readily to be detected: but of little consequence in the sector, and easily detected. It must, however, be admitted, in returning from this digression, that the zenith sector has not quite equalled the expectations which might be formed of it; and that the modern transit, as it comes from the best makers, is an almost perfect instrument.

In determining the latitude by the portable transit, it is easy to place the instrument with sufficient accuracy, for the error must be considerable to affect the result very sensibly. An object-glass may be inserted in one pivot, and wires and an eye-piece into the other, and the telescope be directed upon a mark placed in the meridian by the instrument used in the ordinary way. This would possibly suit most observers best. Ertel of Munich (and many other continental artists) makes an astronomical theodolet, which is particularly adapted to this observation: the divided horizontal circle enables you to set the transit axis in the prime vertical; and as the telescope has a prism at the centre of the axis, to reflect the rays down the transit axis itself, the observer looks horizontally wherever the stars may be. It may be necessary to warn the unpractised observer that in this problem he only gets the *exact* latitude at once if the telescope passes through the zenith, or if the axis is truly horizontal. If the north end is high, for instance, 5″, the circle described by his instrument will pass 5″ to the south of the true zenith, and he will get by the formula given above an apparent co-latitude too great by 5″.

If the axis is very incorrectly placed with respect to the meridian, the co-latitude will be sensibly too small. Let the axis point to the east of the north; then the telescope describes a vertical circle passing through E'z W, and Pz, which bisects SS', will be the co-latitude which results from the formula.

If the true sidereal time be known with moderate accuracy, find how much the middle of the times of the star's transit over the supposed prime vertical, corrected for clock-error, differs from the time at which it actually passes the meridian, that is, from its right ascension. This difference is the ∠ZPz, which is consequently known. Now from right-angled triangle PZz



$$\tan PZ. \cos. ZPz = \tan Pz = \tan PS \times \cos. \tfrac{1}{2} \text{ elapsed time};$$

$$\text{or, } \tan \phi = \frac{\tan \delta \times \cos. ZPz}{\cos. \tfrac{1}{2} \text{ time elapsed}}.$$

It would be better to deduce the angle ZPz, which is the same for all stars, from a star which does not pass very near to the zenith, as the passage is more easily observed, but the length of time which elapses between the two passages of such a star is inconvenient. If the time is well known, one such passage will do.

If the observer has any means of determining the error in azimuth by a reference to known objects in the horizon, the correct latitude may be easily deduced from the approximate.

$$\text{Sin } PZ = \frac{\sin Pz}{\sin PZz}, \text{ or cos lat} = \frac{\text{cos. approximate latitude.}}{\text{cos. of azimuthal error.}}$$

Lastly, as almost all transits have vertical circles, which are or may be tolerably adjusted, the observer may measure the apparent zenith distances, zS and zS', pretty nearly, and half the difference gives Zz.

Then cos PZ = cos Pz × cos Zz, or sin latitude = sin approximate latitude × cos of half difference in star's altitude east and west.

By reversing the instrument, any error of collimation or inequality of pivots will produce exactly a contrary effect on the latitude. Observations, therefore, of two stars on the same day in reversed positions, or of the same star on following days in reversed positions, will correct each other, and the mean will give the true latitude, that is, as nearly as the declination of the star is known. We have dwelt the longer and more minutely on this problem, because where great accuracy is required with but moderate means, it would seem that this is the best method of determining the latitude, and is, therefore, especially suited to coast surveying. It has been extensively used in the Russian navy, and by many travellers, German and Russian. There is one caution which the users of this method must not disregard, and that is, that the position of the instrument be so stable that no motion of theirs while observing can affect the horizontality of the axis. With this precaution, and such transits as are turned out of the best workshops here and abroad, a thirty-inch instrument will give, we conceive, the latitude within 1″ or 2″, without any particular skill on the part of the observer.

There is one word more to be said on the subject of pivots before concluding. By the mode in which they are turned and finished, they ought to be true cylinders, having their axes in the same right line; and so, no doubt, they are, very nearly, when the axis is strong and the pivots are turned in a good lathe, using a diamond for steel pivots. A little inequality of radius we have shown how to measure and correct for. But if the pivots are elliptical, the fault will not be shown by the level; and its effect will be to give the instrument a small variable error in azimuth, the period of which is 90°. There are several ways of trying whether the pivots have a correct form, but the error is so small as not to offer much hold to any direct method; and yet, if it does exist, no mass of observations will have any tendency to get rid of it. Reversion gives a chance of compensating the error in part; and we think the plan of rendering the object and eye end interchangeable is worth considering with a view to correcting such an error, at least in small instruments.

The right ascension of the standard fixed stars, as they are published by the principal observatories, do not in all instances agree as closely as might be expected from the mass of observations and the apparent accuracy of each. Whether this can be accounted for by supposing each catalogue to have a small variable error depending on the flexure of the axis of the instrument, or an error in the form of the pivots, is more than we can undertake to say; but it is a matter well worthy of investigation in the present state of practical astronomy.

We have deferred our account of the *Astronomical Observatory* until the principal instruments which form its furniture were described. We cannot attempt such a minute delineation as would suffice to guide any one who wished to erect such a building. It will be enough to state some of the properties which a well-contrived observatory should possess, and this may help an intelligent person to form a judgment after examining several of those which exist.

An observatory, as was well remarked by Römer, is nothing more than a covering for the instruments and a protection for the observer from the inclemencies of the weather. This should be steadily borne in mind by an architect who is called upon to furnish a plan for such a building, especially if he be limited in cost. The best situation is a gentle eminence which commands an uninterrupted view of the horizon, but which should not be abrupt or very high. The observatory at Cambridge is nearly perfect in this respect. The best foundation is undoubtedly rock; the foundation must be solid enough not to change rapidly. Absolute immoveability is not to be obtained. The supports of all instruments which are carefully watched show slow movements depending either on temperature or moisture, or some causes which are more obscure. No rule can be given as to the depth at which the foundations of the piers supporting the instruments should be laid, The deeper, broader, and more solid the better. The outer earth should not touch the base below the surface, and the outer walls should stand quite freely from it. The floor should be quite clear of a pier or its foundations. With these precautions the change of position in the instruments will be very slow, and when it is slow and uniform the effect is easily taken into account. In some of the earlier observatories, the instruments are placed high above the ground, and in several of the Italian and some Continental observatories they are at the summits of lofty towers. We need not say that any elevation beyond that which is required to command the horizon and keep the building dry and well ventilated is injurious. If distant meridian marks can be erected to the N. and S. it is of advantage, but this condition is not essential.

The instruments which are required for an observatory depend of course upon the class of observations which are to be pursued there. It has been too much the custom to build observatories nearly alike and to pursue exactly the same objects. We shall mention those instruments in order which may be considered important enough to give the name of observatory to their enveloping buildings.

The *transit* and its *clock*. These, on some scale or other, are required by almost every observer, as the time enters nearly into every observation, and a transit is the best instrument for getting it, and a good well-fixed clock is wanted for keeping the time when got. In principal observatories the transit is generally from five to ten feet focal length. We think the latter size unnecessarily large for the objects usually observed, and faint objects which require light, and consequently a telescope of large aperture, might be turned over to the large equatorial and micrometer. A 5-foot transit with an object-glass of the best quality will show everything that is usually observed, as well as the largest instrument, and is much more manageable. It can be levelled by one person with a hanging level and reversed by hand. The time can be got to the tenth of a second by a 45-inch or by a 30-inch transit, if they are of the *best* kind and well handled, so that these are sufficient for the most delicate determination of time. The larger transits are necessarily supported between two stone pillars, and we strongly recommend that the smaller transits should also be so mounted, when practicable, and on a sound and detached foundation. The clock is firmly fixed to its own insulated pier, or against a solid wall where there is not room or convenience for a separate pier. The best situation is with its face looking towards the observer when he is looking south, and so that the observing chair is not likely to strike it. The windows should be on the north side of the transit and circle rooms.

The *meridian circle*, which, in England at least, is always a mural circle, and, so far as we know, there has been hitherto no material improvement in the plan first followed by its inventor, Troughton. Perhaps if the circle were cast in one piece, the whole would be firmer. The standard size of the mural circle is six feet, but it has been made of eight, of five, and of four feet. The transit and circle require two observers, and consequently separate apartments, as the transit observer while counting the clock would be disturbed by any noise. Where two observers cannot be afforded, a *transit circle* may be made to answer both purposes, and such are used, in preference it would seem, in the German, Russian, and Italian observatories.

The transit, meridian circle, and clock are the instruments on which exact astronomy is founded, and they differ from other astronomical instruments in the observatory they require. This should be for each a square or oblong room, from 14 to 20 feet in its smallest direction, namely, north to south, and 10 or 14 feet high, with a slit of from 18 to 30 inches wide, cut in the direction of the meridian through the roof and side-walls, to about six inches below the height of the centre of the telescope. As this must be open during observation, it must be closed to exclude the weather by shutters easily removed. If the building is not very large, the vertical slits may be secured by a shutter in one or two pieces, and the top by one or more shutters turning on a hinge, pretty much like a box-lid, in a way that any good carpenter will understand. A specimen of what appears to us a very good fundamental observatory is the working part of that at Oxford, consisting of two square rooms like those described, separated by a small waiting-room between them and by an entrance. The slits in larger rooms may be closed by shutters which slide back and forwards by pulling the ropes attached to them. The shutters, where the opening is wide, are in halves, meeting in the middle. This is the Greenwich shutter: at Brussels the shutters are in one piece. At Cambridge the shutters are double, as at Greenwich, and the ropes connected with both sides are drawn simultaneously and either way by turning a winch. But whatever be the plan of the shutters, the opening must be wide enough to let the air within and without the building come to the same temperature very nearly. A telescope never performs well *optically* which peeps through a narrow slit, and the refraction must always be uncertain where the temperature of the air varies rapidly and irregularly.

The next instrument is the *equatorial*, which, when it is used for exact measurement depending upon the graduated circles, should scarcely have a larger telescope than one of five feet, with circles of from two to three feet diameter. Such an equatorial is intended at times to supply the place of the meridian instruments when the phenomenon observed is not visible on the meridian, and yet where the observations cannot be confined within the limits of the micrometer. The equatorial is necessarily an indifferent instrument, except used differentially; and in this case, the immoveability of the foundation is of less importance than the extent of the horizon. It is generally raised high enough to overlook the circle and transit rooms, and has a revolving roof with a slit on one side, which thus gives a command over the entire heavens. If an observer wishes for one instrument which will make good observations in any part of the heavens, he must confine himself to the *altitude* and *azimuth circle* under a revolving dome; but though everything may be done with this instrument, it must be admitted that it is with considerable expense of thought and calculation.

To be able to pursue some of the most interesting departments of modern astronomy, an observer must possess a telescope of large size, equatorially mounted, and carried by clock-work. This is especially designed for making all micrometrical observations, as those of double stars, diameters of planets, &c., and requires a graduated circle only for finding or identifying objects. Such an instrument is the superb telescope presented by the Duke of Northumberland to the Cambridge Observatory, which was mounted entirely on the plan of the astronomer royal. Instruments of this class are almost necessarily on the ground, and may be in an isolated building, if a better horizon can be thus commanded. It is not a simple thing to construct a rotatory roof of 25 or 30 feet diameter, light enough to be easily moved, and yet of sufficient strength, since it must necessarily have a slit on one side from top to bottom. The astronomer royal adopted at Cambridge a Chinese-looking form, namely, a flatter cone on the frustum of a sharper cone. There is a flattish channel on the top of the circular wall, in which half a dozen cannon-balls are laid at equal distances, and the roof rests on them, with another channel in its curb. This appears to be the cheapest, easiest, and most certain mode of getting a rotatory roof, but there is a good deal of rolling. The conical form is of much simpler construction than the spherical, and the shutters can be better applied to it; but in appearance the spherical form has greatly the advantage of any other form. For measuring objects which do not require a large field, the astronomer royal has applied a divided eye-piece, which answers very well. Both that and the usual micrometer are very limited as to the extent of angle they can measure; and where it is proposed to make most accurate measurements of angles, which may extend to 1°, the proper instrument is the *heliometer*, or equatorial with a divided object-glass. It is with this last-mentioned instrument that Bessel succeeded in establishing the existence of parallax, which had baffled astronomers ever since the existence of parallax was proposed as a test of the motion of the earth.

Lastly, if it is wished to cultivate that department of astronomy which we will call the *Herschelian*, an observatory must be furnished with gigantic reflectors, as it seems hopeless at present to expect that refractors can be made large enough to transmit sufficient light. These instruments however must almost of necessity be used in the open air.

A private astronomer would probably do most to advance the science by confining himself chiefly to extra-meridian observations, which may be taken up and left off at pleasure. A small transit for time, and as large an equatorial telescope as he can afford to set up, would be sufficient to employ his leisure very profitably.

An observatory is a very dull and uninteresting sight to any one who is not acquainted with the purposes to which it is applied; and we can scarcely conceive how Lalande could say, or others repeat after him, that a person would learn more of astronomy in one night in an observatory than in six months elsewhere. We should say there was no worse school; and that a person would learn astronomy far better from a celestial globe and a fine sky. It is probable, however, that Lalande supposed his learner to possess some elementary knowledge, and to be acquainted with the geometrical part of astronomy; in which case he would, no doubt, learn that in an observatory which is not to be learned or understood elsewhere.

There is no perfect model of an observatory, as respects the building, to which we can refer. Cambridge is, perhaps, the best, but on a larger scale than is necessary. We have already mentioned Oxford; Greenwich has nothing to recommend it as a building, but the goodness of the instruments, and the number and methodical arrangement of the observations and computations may be judged of from the printed Observations.

If an architect should have to construct a first-rate observatory, we should advise him, after learning what instruments are to be accommodated, to study each of these observatories, and arrange the rooms in the most convenient manner. The best appearance which the case admits of may be given afterwards, but he should not be very rigorous as to outside symmetry. It is scarcely possible to unite convenience as an observatory with a regular exterior, except at a considerable expense.

TRANSITS OF MERCURY AND VENUS. The inferior planets as they are called, whose orbits are within that of the earth, may sometimes appear to pass over the body of the sun, eclipsing, by their opacity, successive parts of the solar surface. The transits of Mercury and Venus are phenomena of this kind. They do not take place very often, as they can only be when the planet is in or very near to the node of its orbit, at the time when a line drawn through the sun's centre and that node passes through the earth. As the nodes of the planets alter their positions on the ecliptic very slowly, it will happen for many centuries together that these appearances can only take place at stated periods of the year in which they happen. A transit of Mercury is always either in May or November (according to the node of the orbit at which it takes place), and one of Venus in June or December. The first transit of Mercury which was observed took place in 1631, and of Venus in 1639, and the following are the dates of those which have occurred since, or will occur for a long time to come:—

Transits of Mercury.

Nov. 6, 1631.	Nov. 10, 1736.	Nov. 11, 1815.
Nov. 8, 1644.	Nov. 2, 1740.	Nov. 4, 1822.
Nov. 2, 1651.	Nov. 4, 1743.	May 5, 1832.
May 3, 1661.	May 5, 1753.	Nov. 7, 1835.
Nov. 4, 1664.	Nov. 6, 1756.	May 8, 1845.
May 6, 1674.	Nov. 9, 1769.	Nov. 9, 1848.
Nov. 7, 1677.	Nov. 2, 1776.	Nov. 11, 1861.
Nov. 9, 1690.	Nov. 12, 1782.	Nov. 4, 1868.
Nov. 2, 1697.	May 3, 1786.	May 6, 1878.
May 5, 1707.	Nov. 5, 1789.	Nov. 7, 1881.
Nov. 6, 1710.	May 7, 1799.	May 9, 1891.
Nov. 9, 1723.	Nov. 8, 1802.	Nov. 10, 1894.

Of these the transits yet to come in 1861, 1868, 1878, will be visible (weather permitting) in this country.

Transits of Venus.

Dec. 4, 1639.	Dec. 8, 1874.	June 7, 2004.
June 5, 1761.	Dec. 6, 1882.	June 5, 2012.
June 3, 1769.		

Of these the transits of 1882 and 2004 may be visible in this country.

The use of these transits is threefold. First, they may be employed in correcting the tables of the planet in question; secondly, in computing the longitude of the place of observation; thirdly, in finding the actual distances of the planet and of the sun from the earth. The first of the uses is shared by the transits with many other kinds of observations, and as they occur so seldom, it is fortunate that in this respect they are by no means indispensable; and the same may be said of the second use. As to the third, the transits of Mercury, which occur with tolerable frequency, are comparatively useless, from the difficulty of the observation; but the transits of Venus are more available, and furnish our most precise mode of ascertaining the distance of the earth from the sun.

It cannot be shown *precisely* to any but a mathematician, how it is that the observation of a transit of Venus at several different places on the earth's surface is made to answer the above purpose. The phenomenon itself obviously resembles an eclipse of the sun, as distinguished from one of the moon; and is affected in its progress by the rotation of the earth. If a spectator were placed at the earth's centre, he would see Venus pass over a certain line on the sun's disc, traced out by a moving line the end of which is in his own eye, and which passes through the centre of Venus. Whenever this line passes through the sun's surface, Venus will appear to be projected on that surface as a dark spot. At the same time a spectator on the surface of the earth will refer the spot to a different point of the sun's surface, and the thing to be noted is, that the difference of the lines which Venus appears to pass over on the sun's surface depends jointly on the spectator's place and the positions of Venus and the sun. The formula by which the time of transit is connected with these two things—the spectator's place, and the position of Venus and the sun—points out that the difference of the apparent beginnings and endings of the transit at different places on the earth's surface depends entirely on the difference of the distances of the sun and Venus from the earth (as is sufficiently evident without the formula; for if the planet were at the same distance from us as the sun, that is, if it really passed over the body of the sun, the phenomena would not be sensibly different at any two parts of the earth). The distances of the sun and planet enter into the formulæ by means of their parallaxes [PARALLAX]; and if the difference of the parallaxes is once known, the parallaxes themselves are known, for the proportion of the distances of the earth and Venus from the sun is sufficiently well ascertained from Kepler's laws. At a place of known longitude, if only the ingress or egress of the planet be observed, either of the two, and if the phenomenon can be calculated as it would be seen from the centre of the earth, then the difference of the parallaxes can be found; but this supposes, first, that the longitude of the place is very well known; secondly, that the errors of the tables of the sun and Venus are insensibly small. If both the beginning and ending of the transit can be observed at one place, it is no longer of any consequence that the longitude of the place should be so accurately known; an approximate determination of it will be sufficient. Still the errors of the planetary tables remain. But if both beginning and ending of the transit can be observed at two different places (and the greater their difference of longitude the better), then the differences of the parallaxes can be computed from the two observed durations of the transit, independently both of the longitudes of the places and of the planetary tables, that is, so as not to be rendered sensibly inaccurate by any moderate inaccuracy in either. The fact is, that when the transit is observed at one place only, the formulæ suppose it to be known at some other, either the centre of the earth, or Greenwich or some other observatory. When the transit is observed at two places, the second observation is inserted instead of the computed substitute for observation. This explains why it was that expeditions were sent by different governments to different parts of the globe to observe the transits of 1761 and 1769. If the transit should be seen both at its beginning and ending at six different places, every pair of them (and there are 15 pairs) would give a determination of the difference of parallaxes, and the mean of all the results would be entitled to a high degree of confidence.

The first transit of Mercury that was ever observed was seen by Gassendi, November 6, 1631; the first transit of Venus by Horrocks, December 4, 1639. Halley pointed out the use of such transits, and preparation was made to observe that of 1761. Legentil was sent to India, Chappe to Tobolsk, and Pingré to the island of Rodriguez, by the French government; Maskelyne went to St. Helena, and Mason to the Cape of Good Hope (he intended, but was prevented, to go on to Sumatra). The weather hindered or injured most of the observations; the most fortunate was that of Mason, who made the sun's parallax eight seconds and a half. The transit of 1769 was still better attended to. The complete duration of the transit was observed at Cape Wardhus, Kola, Cajaneburg, O-taiti, Fort Prince of Wales on the north-west coast of Hudson's Bay, St. Joseph, and Santa Anna in California. The ingress of the planet was seen at almost all the observatories of Europe; the egress at Petersburg, Yakutsk, Manilla, Batavia, Pekin, Gurief, Orska, and Orenburg. The value of the parallax was variously deduced, different astronomers preferring different values, from 8"·5 to 8"·8: Laplace used 8"·66; M. Encke deduced 8"·5776 from all the observations. De Ferrer ('Mém. Astron. Soc.,' vol. v., p. 258), from a re-examination of the whole observations, deduces 8"·58, and thinks this cannot be wrong by so much as $\frac{1}{100}$ths of a second.

Most of the observers who saw the ingress of the planet unite in stating that after the planet had entered on the sun, it continued for a short time to appear as if it were joined to the limb or border of the sun by a dark protuberance or ligament (some call it a thread). This phenomenon appears to be of the same sort as that noticed in SUN with respect to the annular eclipse. A full account of what was seen with respect to Venus will be found in Mr. Baily's paper there referred to. ('Mém. Astron. Soc.,' vol. x., p. 1.)

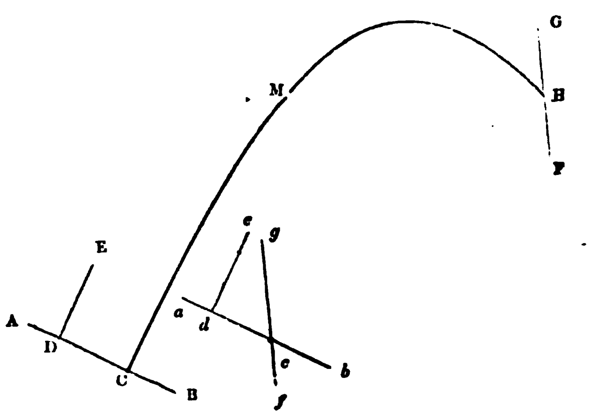
TRANSLATION. This word is used in mechanics, as distinguished from ROTATION, in the following manner:—A body has motion of translation when all its points move in parallel straight lines; when, in fact, all its points have the same motion. If all have not the same motion, there is either simple rotation, that is, about one permanent axis; or rotation about a varying axis; or else a compound of translation and rotation.

The point which is called the centre of gravity of a system, and which is of no small importance in the theory of equilibrium, has yet more in that of motion. The motion of any free system is compounded of the translation of its centre of gravity, and the rotation about an axis (whether always in one direction or not) passing through its centre of gravity. Now whatever the forces may be by which such a system is either set in motion, or acted on while in motion, the translation of its centre of gravity may always be made a distinct problem from the rotation about its centre of gravity, by the following simple rules:—

1. The centre of gravity moves just as it would do if the whole system were there collected, and all the forces were there applied.

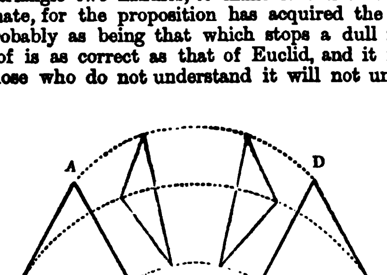
2. The rotation of a system about its centre of gravity is no other than what it would be if that centre were made a fixed point, and all the forces applied in their proper places.

Suppose, for instance, a bar A B, whose centre of gravity is at C, is sent spinning into void space by a certain blow in the direction D E, communicated at D. Let there be another similar bar *ab*, whose centre of gravity *c* moves on a fixed pivot without friction, and which, being parallel to A B, is struck at the same instant with a similar blow in the direction *de*. To find the position of the bar at the end of any given time, say three seconds, is a twofold problem, as follows:—First suppose all the mass of the bar concentrated at C, and let the blow be struck, with the same force and direction, at the point C. This point C will then describe a certain parabola C M H; say that in



three seconds it is at H. Next turn to the bar which moves on a fixed pivot, and let fg be its position in three seconds. Draw F G, a position of the bar parallel to fg, H being its centre of gravity, and F G will be the real position of the bar at the end of the given time, three seconds; and similarly for any other given time.

Thus much of translation, mechanically considered: we now speak of the wider use which the word has, or might have, in geometry; at any rate we have the thing to consider, and perhaps *transference* might be preferable to translation, as applied to the motion of a figure from one part of space to another. The conception of the possibility of figures differing only in position, and composed of perfectly equal and similar parts of space, similarly bounded, is one which is demanded of the beginner in geometry. Euclid requires this when he speaks of equal figures; and his test of equality, namely, the possibility of creating a perfect coincidence, requires the notion of one figure being transferred in any requisite manner, whether by what is called in mechanics translation, or by rotation, or both. It must be a sort of copy, or facsimile, of one part of space which is thus moved into and made to occupy another: for it is impossible to imagine *space removed*, or any part of *space* made to change place. And this copy, or whatever it may be, must have rigidity, that it may not change form by the way: it must be rigid in our thoughts, at least. We are thus required to imagine space endowed with some of the essential qualities of matter, before we can prove the fourth proposition of Euclid's first book: there must be the consistence of matter without its impenetrability, but whether it require force and time to change place, or not, is of no consequence. Even a plane figure must be a sort of rigid consistence with two sides to it, for it is necessary to imagine it turned round, so as to present a different face to the spectator. In the fifth proposition of the first book, the very first step is the application of the fourth proposition to prove the equality of two triangles. Now the fourth proposition requires one triangle to be placed upon the other, which cannot be done in the figure of the fifth, unless one of the triangles be turned round, so as to show the other front to the spectator. If Euclid meant, by giving the triangle two handles, to make it easier to turn, he has been unfortunate, for the proposition has acquired the name of the *ass's bridge*, probably as being that which stops a dull reader. The following proof is as correct as that of Euclid, and it is not much to say that those who do not understand it will not understand the one he gave.



Let A B C be an isosceles triangle, having A B = A C. Let it be turned round (for illustration, the dotted lines show the tracks of the three points, and two intermediate positions are shown) into the position D E F. Then in the two triangles A B C, D E F, we have A B = D E, for D E is A C (= A B by hypothesis) removed. Also A C = D F, for a similar reason. And the angle B A C = the angle E D F, the second being only the removal of the first. Hence we have A B = D E, A C = D F, and $\angle$ B A C = $\angle$ E D F, and now by the fourth proposition it follows that $\angle$ A B C = $\angle$ D E F. But $\angle$ D E F is only another position of $\angle$ A C B; whence $\angle$ A B C = $\angle$ A C B, which was to be shown. If preferred, the triangle A B C might be turned round upon itself, and the reasoning of the fourth proposition applied at once.

It is not to be supposed that Euclid did not see the preceding: but he is a writer who very rarely goes out of the most obvious path without some cogent reason connected with his system. The proof given above would not serve to demonstrate the equality of the external angles without the previous introduction of the properties of adjacent angles; and it happens that the knowledge of the equality of the external angles is immediately wanted.

TRANSLATION. [VERSION.]

TRANSMUTATION OF METALS. [ALCHEMY.]

TRANSOM. [MULLION.]

TRANSPARENCY is that quality of certain substances or media by which rays of light are allowed to pass freely through them. It is doubtful whether any substance exists which is perfectly transparent; for even water and air stop more or less of the light passing through them when the length of its path is very great. It is, however, exceedingly difficult in such cases to say whether the observed stoppage be due to the pure substance, or to foreign bodies present in proportions otherwise perhaps inappreciable. On the other hand we have reason to believe that all bodies possess the property of transparency in a certain degree. Thus many metals have been obtained by mechanical or chemical means in such a state of thinness as to transmit a certain amount of light; for example, gold, which in the state of gold-leaf transmits a greenish light.

There are two distinct obstacles to transparency, one a defect of homogeneity, whereby a portion of the light in its onward progress is continually reflected in another direction, at the surface of separation of adjacent portions of the body having different refractive powers; the other the power which a very great number of substances possess of *absorbing* light. [ABSORPTION OF LIGHT.] A good example of the former is afforded by snow, which in sufficient thickness prevents the transmission of light, but simply in consequence of its reflecting the light backwards at the various surfaces of the icy crystals; and accordingly snow is brilliantly white by reflection, whereas the single reflection from a sheet of water or ice is comparatively feeble. Other examples are afforded by a mixture of water and oil, or water and bisulphide of carbon, shaken up together; or better still, an alcoholic solution of bisulphide of carbon precipitated by the addition of water. In these cases mixtures are obtained which, from the multiplied reflections, have a milky appearance, and in sufficient thickness stop transmitted light, though the mixed fluids (bisulphide of carbon and watery alcohol in the last example) are separately transparent. The transparency of white paper is greatly increased by oiling the paper, the reason of which is that the quantity of light reflected at the common surface of the fibres and oil, which do not very greatly differ in refractive power, is very much less than that reflected at the common surface of the fibres and air. The mineral hydrophane derives its name from becoming more transparent after being placed in water, which is in consequence of its imbibing water in the pores with which it is filled.

Examples of the second obstacle to transparency are sufficiently familiar, as may be gathered from the article on ABSORPTION. Thus the common blue glass cuts off a large quantity of the light incident upon it, and when in tolerable thickness may for most purposes be regarded as opaque. Most commonly both obstacles to transparency exist together, as in the case of wood, cork, brick, dyed cloths, &c.

That homogeneity should be one requisite for transparency, follows from the existence of reflection at the common surface of media of unequal refractive power; and therefore in considering the cause of transparency it will be sufficient to confine our attention to homogeneous media. In such media transparency is to be contrasted with the power of absorbing light; the former in the absence of the latter. The speculations at one time entertained respecting the cause of absorption on the supposition that light consists in particles darted forth by the luminous body can now only be matter of history; we shall confine ourselves to a consideration of the probable cause of absorption, on the supposition that light consists in the tremors of an elastic medium.

In the case of gaseous media especially, the rate of absorption of light passing through them changes, in many instances, in a very remarkable manner with the refrangibility of the light. Hence the spectrum of white light subjected to prismatic absorption on the part of such media, presents fluctuations of intensity, simulating more or less completely effects due to interference. Accordingly attempts have been made to refer absorption to ordinary interference. But such explanations labour under one fatal defect; they suppose the annihilation of *vis viva*. The effect of ordinary interference is not to *destroy* light, but merely to alter the distribution of illumination. Thus, when the light of a rather distant candle is reflected from a thin plate of mica bent into a cylindrical form, and the linear image of the flame is analysed by a prism, it is true that dark bands are seen which remind one of the bands produced by the absorption of light by the vapour of iodine, and were applied by the Baron von Wrede to the explanation of the latter phenomenon, and of absorption in general. (Poggendorff's 'Annalen,' vol. xxxiii. (1834), p. 353, and Taylor's 'Scientific Memoirs,' vol. i., p. 477.) But there is this difference between the two cases, that in the experiment with mica, the light which is defective in the reflected beam is found in excess in the transmitted beam, which would yield a spectrum having bands complementary to those of the former; whereas in the case of absorption the missing light actually disappears *as such*. It is not however annihilated; an effect is produced on the medium, whether it be that the temperature is raised, or that chemical changes are produced, or that the medium is made to emit light of a different kind, as in the phenomena of phosphorescence and fluorescence. [FLUORESCENCE.] These phenomena, and especially perhaps the last, indicate that the molecules of the medium are thrown into a state of agitation; and thus we are led to suppose that the undulations of the luminiferous ether are spent in producing agitations among the ultimate molecules of the absorbing body, the consideration of which therefore must form an *essential* part of a complete explanation of absorption. That the period of the incident undulations should play such an important part in the phenomena, may be illustrated to a certain extent by considering the effect of a series of slight pushes, periodically applied to a body capable of swinging as a pendulum, which will throw it into a state of considerable vibration, provided the period of the pushes nearly agrees with that of the natural vibrations of the body. If the cause of absorption be that just explained, we must attribute transparency to the existence of such a constitution in the body, that the ether, or a portion of it at least, can in its undulations glide freely among the molecules of the body, without throwing them into a state of agitation.

TRANSPIRATION, a term applied by Mr. Graham to a peculiar and fundamental property of the gaseous form of matter in passing through capillary tubes. It differs from EFFUSION by which gases pass through a small aperture about $\frac{1}{500}$th of an inch in diameter, into a vacuum; but some of the results of transpiration correspond with the flow of liquids through capillary tubes referred to under DIFFUSION.

The results obtained by Dr. Poiseuille, and confirmed by Regnault, were obtained by sending a liquid under examination through a capillary tube under the influence of condensed air of known pressure. For a minute account of these experiments we must refer to the 'Annales de Chimie,' 3e serie, xxi.; an abstract of them is also given in Professor Miller's 'Chemical Physics,' where the apparatus is also figured. Among the general results obtained, it appears that the rate of efflux of the liquid when the tube exceeds a certain length (which is greater as the diameter increases) increases directly as the pressure, so that by doubling the pressure, the amount of liquid discharged is double, the times being equal. With tubes of equal diameter the quantities discharged in equal times are inversely as the length of the tube, so that a tube two inches long discharging 100 grains of liquid in five minutes, a similar tube four inches long would discharge only 50 grains in the same time. In tubes of equal lengths but of different diameters, the flow is as the fourth power of the diameters, so that the flow from a tube $\frac{1}{50}$th of an inch in diameter would be 16 times as great as from a tube $\frac{1}{100}$th of an inch in diameter, or as $1^4 : 2^4$. The material of the tube does not appear to influence the result; but the nature of the liquid does so greatly. In most cases the flow of saline solutions was found to be slower than that of distilled water: the alkalies produced this effect. Certain substances appeared to exert no influence, such as nitrate of silver, corrosive sublimate, iodide of sodium, iodide of iron, nitric, hydriodic, bromic, and hydro-bromic acids. The presence of some other substances increased the rapidity of the flow, such as hydro-sulphuric acid and hydro-cyanic acid; the nitrates of potash and ammonia, the chlorides of potassium and ammonium; the iodide, bromide, and cyanide of potassium. A slight increase in temperature generally augments the flow; water at 113° escaping $2\frac{1}{2}$ times quicker through the same tube than it did at 41°. But it is remarkable that concentrated solutions of iodide of potassium above 140° Fahr., and of nitrate of potash above 104° flow more slowly than distilled water. In general, however, the solutions contained only 1 per cent. of the substances; and they were exposed to a pressure equal to that of a column of water 1 mètre (39·37 inches) high, at the temperature of 52°·16, and escaped through a tube 64 millimetres (2·519 inches) in length, and 0·24946 millimetres (0·0108 inch, in diameter. No connection has been traced between the rate of efflux of the liquid and its density, capillarity or fluidity. The dilution of alcohol retards its efflux, up to a certain point, beyond which it increases it, the minimum efflux corresponding with that mixture of alcohol and water which is attended with the maximum contraction. The solubility of a substance in water exerts only a secondary influence on the efflux. Dr. Poiseuille has shown that various solutions introduced into the blood of a living animal apparently produce effects of acceleration or retardation on the capillary circulation corresponding with those noticed with the same liquids in glass capillary tubes.

Substituting gases for liquids, it appears that the rate of efflux, or the velocity of transpiration for each gas, is independent of its rate of diffusion. In Graham's experiments on this subject, ('Phil. Trans.' 1846 and 1849) the gas was contained in a graduated jar, standing over water, and suspended so that the water on the inside should be kept on the same level as that on the outside. On allowing the jar to sink, the gas was expelled by a flexible tube into a bent tube containing chloride of calcium, and being thus dried, it passed through a long capillary tube, and thus entered the exhausted receiver of an air pump, which was either kept exhausted, or the amount of exhaustion was noted by means of the gauge, the quantity of gas that entered the receiver in a given time being carefully noted.

By employing a certain length of tube increasing with the diameter, not the same for all gases, it appears that the rate of transpiration increases directly as the pressure, so that equal volumes of air at different densities require times inversely proportioned to the densities: —thus a pint of air double the density of the atmosphere will pass through the capillary tube into vacuum in half the time required for a pint of air of ordinary density. With tubes of equal bore the volume transpired in equal times is inversely as the length of the tube; thus, if 30 cubic inches of gas were transpired through a tube 10 feet long in 5 minutes, a similar tube 20 feet long would only allow the passage of 15 cubic inches in the same time. It was also found that the transpiration of equal volumes becomes slower as the temperature rises. Uniform results were also obtained, whether the tubes were of copper or of glass, or a porous mass of stucco were employed. Transpiration was found to vary with the chemical nature of the gases. The velocities of transpiration of different gases bore a constant relation to each other, independently of their densities, and it was thought probable that the rate of transpiration is the resultant of a kind of elasticity depending on the absolute quantity of heat, latent as well as sensible, which different gases contain under the same volume, so that transpiration seems to be intimately connected with the specific heat of gases.

Oxygen has apparently the slowest rate of transpiration, and is taken as the unit in the following table. It is found that a mixture of equal volumes of two gases does not always give the mean transpirability. Thus the time for the transpiration of hydrogen is much prolonged by admixture of oxygen, the rate being 0·9008 instead of the mean 0·72.

Gases.	Times for Transpiration of equal volumes.	Velocity of Transpiration.
Oxygen	1·0000	1·0000
Air	0·9030	1·1074
Nitrogen	0·8768	1·141
Binoxide of nitrogen	0·8764	1·141
Carbonic oxide	0·8737	1·144
Protoxide of nitrogen	0·7493	1·334
Hydrochloric acid	0·7363	1·361
Carbonic acid	0·7300	1·369
Chlorine	0·6664	1·500
Sulphurous acid	0·6500	1·538
Sulphuretted hydrogen	0·6195	1·614
Light carburetted hydrogen	0·5510	1·815
Ammonia	0·5115	1·935
Cyanogen	0·5060	1·976
Olefiant gas	0·5051	1·980
Hydrogen	0·4370	2·288
Vapours.		
Bromine, about	1·0000	
Sulphuric acid, anhydrous	1·0000	
Bisulphide of carbon	0·6195	
Chloride of methyl	0·5475	
Chloride of ethyl	0·4988	
Oxide of methyl	0·4826	
Hydrocyanic acid	0·4600	
Ether	0·4400	

In these experiments capillary glass tubes, varying from 20 feet to 2 inches in length, gave similar results, where a sufficient resistance was offered to the passage of the gas. The effusion of gases, or the discharge by an aperture in a thin plate, is dependent in all gases upon a constant function of their specific gravity; but the discharge of the same gases from tubes has no uniform relation to the density of the gases. Both hydrogen and carbonic acid, for example, pass more quickly through a tube than oxygen, although the one is lighter and the other heavier than that gas.

One of the capillary tubes used by Graham was as much as 22 feet in length; it was made up of several portions of capillary tube as nearly equal in bore as could be judged of by the eye, cemented together by the blow-pipe so as to form a continuous length, but bent up into coils for the convenience of using. Its extremities were connected with block-tin tubes, proceeding from the drying-tube and air-pump jar by means of thick caoutchouc adopters. This long capillary tube allowed one cubic inch of air to pass into a vacuum in 15·64 seconds; two inches of the tube held 2·65 grains of mercury, which gives a diameter of 0·0222 inch, or $\frac{1}{45}$th of an inch.

It was found possible to form a capillary tube of copper of less diameter than one of glass, by the following means:—a cylindrical hole was first drilled in the axis of a solid copper rod, four or five inches long, which rod was then extended by passing it through a wire drawplate. An iron wire, or triplet, was placed within the copper tube, and drawn through the plate at the same time, in order to keep the surface of the copper tube smooth and uniform. It was found necessary to pull out the iron wire every time the copper was drawn, to prevent its becoming fixed. The iron wire was then extended separately, and again introduced into the copper tube, and the operation of drawing out was repeated. In this way the copper tube was extended 11 feet 8 inches, and it remained perfectly sound and air-tight. One cubic inch of air passed through it into a vacuum in 22·12 seconds. Its diameter was thus found:—Of the iron wire on which the copper was last drawn, 92·7 inches weighed 18·30 grains, or one inch weighed 0·1974 grains. Taking the specific gravity of iron at 7·7, this gives the diameter of the copper tube 0·0114 inch, or $\frac{1}{88}$th of an inch. In using this tube for transpiration experiments, it was coiled up into circles about 10 inches in diameter.

Mr. Graham's experiments, which are exceedingly numerous, are very neat and precise in their results: the experiments of Dr. Poiseuille have also an equal constancy and precision of result in the passage of liquids through capillary tubes which is quite remarkable. To take, for example, a few of Mr. Graham's results: the transpiration velocity of hydrogen is exactly double that of nitrogen, although the relation in density is as 1 : 14. The transpiration of carbonic oxide, like the sp. gr., is also identical with that of nitrogen. The transpiration velocity of oxygen is related to that of nitrogen in the inverse ratio of the densities of these gases, that is, as 14 : 16. In equal times, and with equal weights (not equal volumes) of these two gases, the more heavy gas was more slowly transpired in proportion to its greater density. Mixtures of oxygen and nitrogen have the mean velocity of these two gases, and hence the time of air is also found to be proportional to its density when compared to the time of oxygen. Indeed, the velocity of different gases through capillary tubes, bears a constant relation to each other. The constancy of these relations, or of the transpiration times, has been observed for several of the gases for tube resistances, varying in amount from 1 to 1000. These relations are more simple in their expression than the densities of the gases. It is, indeed, very remarkable to find the velocity of hydrogen to be exactly double that of nitrogen and carbonic oxide; the velocity of nitrogen and oxygen to be inversely as the specific gravity of these gases; the velocity of binoxide of nitrogen to be the same as nitrogen and carbonic oxide; the velocity of carbonic acid and nitrous oxide to be equal and directly proportional to their specific gravities when compared with oxygen. In like manner, it is found that the velocity of proto-carburetted hydrogen is 0·8, hydrogen being = 1, the velocity of chlorine is $1\frac{1}{2}$ that of oxygen, of bromine vapour and sulphuric acid vapour the same as oxygen, while that of ether vapour is the same as hydrogen. Olefiant gas, ammonia, and cyanogen are equal, or nearly equal, in velocity which approaches closely to double that of oxygen. Hydrosulphuric acid gas and the vapour of bi-sulphide of carbon have an equal transpiration time. The compounds of methyl have a less velocity than the corresponding compounds of ethyl, but are connected by a certain constant relation.

Among the general results obtained by Mr. Graham are the following:—2. That the resistance of capillary tubes of uniform bore to the passage of any gas is directly proportional to the length of the tube. 3. That the velocity of the passage of equal volumes of air of the same temperature, but of different densities or elasticities, is directly proportional. 4. That rarefaction by heat has a precisely equal effect in diminishing the velocity of the transpiration of equal volumes of air, as the loss of density and elasticity by diminished pressure has. 5. That a greater resistance in the capillary tube is required to bring out the third result, or law of densities, than is apparently necessary for the first or second result, and a resistance still further increased, and the highest of all, to bring out the fourth result, or the law of temperatures. 6. That transpiration is promoted by density, whether due to compression, to cold, or to the addition of an element in combination, as the velocity of oxygen is increased by combining with carbon, without change of volume in carbonic acid.

With respect to the influence of transpiration on the distribution of coal-gas by means of pipes, the results are similar with truly elastic gases whether the tubes be capillary or many inches in diameter, provided the length of the tube be not less than 4000 times its diameter. The small propulsive pressure applied to coal-gas is favourable to transpiration as well as the great length of the mains. The velocity of coal-gas should be 1·575, air being 1 under the same pressure. With a constant propulsive force in the gasometer, the flow of gas should increase in volume with a rise of the barometer or with a fall in temperature directly in proportion to the increase of its density from either of these causes.

TRANSPORTATION (*trans* and *porto*), removal, banishment to some fixed place. Transportation, as a punishment for crime in England, having been practically abolished, it is only in its historical point of view that it will be here considered. Under CRIMES AND PUNISHMENTS; LAW, CRIMINAL; and PENAL SERVITUDE, will be found the present state of the law with regard to the punishment of crime, and the nature of the system of imprisonment.

The statute of 39 Elizabeth, c. 4, for the banishment of dangerous rogues and vagabonds, was virtually converted by James I. into an act for transportation to America by a letter to the treasurer and council of the colony of Virginia, in the year 1619, commanding them "to send a hundred dissolute persons to Virginia, which the knight-marshal would deliver to them for that purpose." Transportation is not distinctly mentioned in any English statute prior to the stat. 18 Car. II., c. 3, which gives a power to the judges at their discretion either to execute or transport to America for life the moss-troopers of Cumberland and Northumberland. Until after the passing of the stat. 4 Geo. I., c. 2, continued by stat. 6 Geo. I., c. 23, this mode of punishment was not brought into common operation. By these statutes the courts were allowed a discretionary power to order felons who were by law entitled to benefit of clergy to be transported to the American plantations. Transportation to America under the statutes of George I. lasted from 1718 till the commencement of the War of Independence in 1775.

A plan for the establishment of penitentiaries, which was strongly recommended by Judge Blackstone, Mr. Eden (afterwards Lord Auckland), and Mr. Howard, was taken into consideration by parliament, and the act 19 Geo. III., c. 74, for the erection of penitentiaries, passed. The government failed, however, to adopt the necessary measures for its execution; and transportation was resumed by an act passed in the 24th year of George III., which empowered his majesty in council to appoint to what place beyond the seas, either within or without his majesty's dominions, offenders should be transported; and by two orders in council, dated December 6th, 1786, the eastern coast of Australia and the adjacent islands were fixed upon. In the month of May, 1787, the first band of convicts left England, which in the succeeding year founded the colony of New South Wales.

By statute 5 Geo. IV., c. 84 (amended by the 11 Geo. IV., and 1 Will. IV., c. 39) the crown was empowered to appoint places beyond the seas to which persons under sentence or order of transportation or banishment should be conveyed, the governor of the colony, or his assignee, having the property in the service of the convicts. The crown was also empowered to appoint places of confinement at home, either on land or on board vessels in the Thames, or other rivers or harbours, for the removal and confinement of male offenders (extended by the stat. 16 & 17 Vict. to females) under sentence of death, but reprieved or respited, or under sentence of transportation, there to remain under order of the Secretary of State until entitled to their liberty, or removed, or otherwise dealt with. The capital punishment for offenders found unduly at large before the expiration of their sentence, was still retained, but was subsequently abolished by the stat. 4 & 5 Will. IV. c. 67, which substituted transportation for life, with previous imprisonment not exceeding four years.

New South Wales, Van Diemen's Land, and Norfolk Island became, under these statutes and an earlier statute of George III., the principal receptacles for convicts. The power of the colonial governors to remit sentences was next restrained by the stat. 2 & 3 Will. IV., c. 62, they being only empowered to pardon or remit labour after the convicts had undergone a certain portion of their sentence; but this statute was repealed by the 6 & 7 Vict. c. 7, which provides that, instead of governors of colonies remitting either absolutely or conditionally the period of transportation, the governors shall recommend felons to government at home for pardon, and they are to be pardoned according to the instructions received thereupon, such pardons having the same effect as a pardon under the great seal.

Although, as already stated, the property in the services of convicts was vested in the colonial governor, a practice prevailed in those places to which offenders were transported, of granting them in certain cases permission to employ themselves for their own benefit. These permissions were usually called "tickets of leave." By the stat. 6 & 7 Vict. c. 7, the legislature, thinking it just that such convicts should be protected in their persons and in the possession of such property as they might acquire by their industry, empowered them to hold personal property, and to maintain actions in respect thereof while their tickets remained unrevoked.

The reception of convicts having, however, become distasteful to the colonies, the stat. 10 & 11 Vict. c. 67, was passed, permitting offenders under sentence of transportation to be removed to any prison or penitentiary in Great Britain; directors of the principal convict prisons being appointed afterwards under the stat. 13 & 14 Vict. c. 39. The difficulty attending the reception by the colonies of transported convicts having increased, the stat. 16 & 17 Vict. c. 99, next abolished the punishment of transportation for any term less than fourteen years, and substituted penal servitude, giving the courts power in all cases to award that punishment in lieu of transportation.

Finally, the stat. 20 & 21 Vict. c. 3, abolished transportation altogether as a punishment, substituting PENAL SERVITUDE; but convicts under sentence of penal servitude may still be sent beyond seas by order of the Secretary of State.

Transportation was of great value to our early colonists, as it supplied what was so essential to their well-being—cheap labour. From Australia it was subsequently extended to the settlements of the Cape of Good Hope, to Bermuda, and Gibraltar, but the last two were (and are) more of the nature of places of penal imprisonment abroad; and with respect to Bermuda, it has been recently (1861) announced by the Secretary of the Colonies that the government have adopted measures for diminishing the number of convicts at Bermuda, with a view to the early abolishing of transportation to that colony.

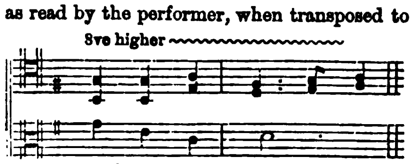
All convicts sent to Bermuda or Gibraltar are employed by the government on public works in the dockyards and fortifications. The system of punishment pursued is essentially different from that which has been in force in the Australian penal colonies. The convicts sent to Bermuda are kept apart from the free population; they are shut up in hulks by night, and are worked in gangs by day under the superintendence of free overseers. A small amount of wages is paid to them for their labour, a portion of which they are allowed to spend, and the remainder forms a fund, which they receive on becoming free. At the expiration of their sentences they do not remain in Bermuda, but are sent back at the expense of the government of this country.

Mr. Bentham, Dr. Whately, the present archbishop of Dublin, and other writers on the theory of punishment, have condemned the general principle of transportation; and comparatively little has been urged in opposition to their arguments. Mr. Bentham's objections will be found in a chapter on Transportation, in his 'Theory of Punishments;' the archbishop of Dublin's, in his two 'Letters to Earl Grey.' These arguments, but still more the resolutions of the colonies not to receive any more convicts, led to the abandonment of the system. The colonists were no doubt right in refusing to let their society continue to be the receptacle of the crime and profligacy of the parent state; but it is not so clear from doubt that in an early stage of settlement the system of transportation may not be adopted with advantage; indeed the remarkable prosperity of Australia, if not its very existence as a settlement, is owing to this system. Where the population is small, and labour scarce, the criminal is removed from much temptation, and placed in the very best position for retrieving his character; while the settler has the benefit of cheap and constant labour. The expense, however, to the parent state is large; it was estimated that in transporting to Australia each convict cost the state 82*l*.

TRANSPOSITION, the name given in Algebra to the process of removing a term from one side of an equation to another, changing its sign. Thus, if $a=b+c$, by transposition, $a-c=b$. On this we have only to remark, that in this instance the rule is not much of an abbreviation. If we say "transpose *c*," instead of "take *c* from both sides," so little is gained, that it may be doubted whether it would not be better to follow the Continental writers in the use of the latter form of expression: a process which would have the advantage of being a perpetual appeal to reason instead of rule.

TRANSPOSITION, in Music, is a change of the original key to one higher or lower. This is generally performed at a moment's notice by the accompanist to suit the convenience of the singer. To the latter, transposition is not attended with any difficulty: the change is little more than imaginary, except so far as relates to the compass of the voice. To the accompanist it is far otherwise; unless playing from memory, he must assign to all the notes as regards their pitch or their situations on his instrument, names wholly different from those in the copy placed before him. To accomplish this he has to *suppose* a change of clef, or clefs, and thus give new designations to all the lines and spaces. For instance—and without going into the extreme case of transposing from a score—a pianoforte player is required to transpose an air a whole tone lower,—from A to G. For this purpose he must assume a change in both clefs, the treble into the tenor, and each note to be played an octave higher than it is written; the bass into the alto, and each note to be played an octave lower than it is written. Example in A.

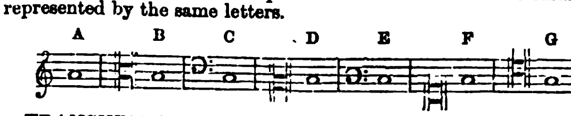
The same as read by the performer, when transposed to G:—



The difficulty attending this process is so great, that no amateur, and few discreet musicians, unless professed accompanists, or well acquainted with the composition to be transposed, will undertake the task; for to perform it in an artist-like manner, at first sight, requires a degree of practical skill only to be gained at the expense of much time that might be employed to far greater advantage in studying those higher branches of the art in which the most experienced will always find something to learn. Our remarks, it will be understood, relate to performers on the pianoforte and organ. To those who read from a single staff, and play single notes only, as violinists, flutists, &c., the task of transposing is comparatively easy.

To meet all the demands of transposition, a familiar knowledge of no less than seven clefs is necessary, and two of these—the mezzo-soprano, and baritone, or bass clef on the 3rd line [CLEF]—may be said to have become obsolete.

The annexed table will exemplify the use of clefs in transposition. It shows how to transpose a given key-note—A for instance—into any other note of the scale, and, consequently, how to transpose the whole of any composition. It is hardly necessary to add, that the semitonic scale, as concerns line and space, is governed by the diatonic; that A♯, A♭, &c., have the same places in the staff as the natural notes represented by the same letters.



TRANSUBSTANTIATION. [SACRAMENTS].

TRANSVERSAL, a name lately given to a line which is drawn across several others, so as to cut them all. The word is used in this sense in the writings of Carnot, Poncelet, Chasles, &c.

Let there be a triangle ABC (the reader may easily draw the figures of this article for himself) and let a transversal cut its three sides internally or externally; namely, let AB cut the transversal in c, BC in a, and CA in b. Then will either one or three of a, b, c, be in sides produced, and

$$Ac \times Ba \times Cb = Bc \times Ca \times Ab;$$

and the converse, namely, if a, b, c, be points taken on the three sides, having either one or three external, for which the above relation is true, then those three points are in the same straight line. In the language of Euclid, the ratio compounded of the three ratios of Ac to Bb, Ba to Ca, and Cb to Ab, is the ratio of a line to its equal.

This proposition is now frequently demonstrated in elementary works on geometry as follows:—From any one of the vertical points, A, B, C, draw a parallel to the side of the triangle which does not pass through that point; from C, for instance, draw CM parallel to AB, cutting the transversal in M. Then we have two pairs of similar triangles, MCb, cAb, and aBc, aCM, which give

$$aC : CM :: aB : Bc$$
$$CM : Cb :: Ac : Ab$$
$$\text{or } Ca : Cb :: Ac \times Ba : Ab \times Bc;$$

whence the proposition required is obvious. The converse readily follows by indirect demonstration.

Let any point P be taken inside or outside of the triangle ABC, and let AP, BP, CP, cut BC, CA, AB in a, b, c. Then either one or three of the points as a, b, c, are internal.

$$Ac \times Ba \times Cb = Ba \times Cb \times Ac,$$

which is proved by using the former property in the triangle ABa with the transversal CPc, and the triangle AaC with the transversal BPb. The converse is also easily proved, namely, that if a, b, c be so taken on the sides with one or three internal as to satisfy the above relation, then Aa, Bb, Cc all meet in one point.

The same proposition as the first is true of any polygon whatsoever: thus, let ABCDE be a pentagon, the sides of which are cut externally or internally by a line, namely, AB in c, BC in d, CD in e, DE in a, EA in b; then

$$Ab.\ Bc.\ Cd.\ De.\ Ea = Ac.\ Bd.\ Ce.\ Da.\ Eb.$$

For let BD and BE meet the transversal in m and n: then the three triangles BDC, BED, BAE are cut by a transversal, giving

$$Bm . De . Cd = Dm . Ce . Bd$$
$$Dm . Ea . Bn = Bm . Da . En$$
$$En . Ab . Bc = Bn . Eb . Ac;$$

by multiplication of which the theorem follows.

If the transversal be parallel to either of the sides, the two segments, which are then infinite, are to be considered as equal, and removed from both sides of the equation.

In the article PROJECTION a test is given which, being satisfied, shows that a proposition is true of any figure, if it be true of any one of its projections. This test is satisfied in all the preceding cases, so that it is enough to prove any one case of these propositions, that is, for any one projection of the figure. Now there is no case in which they are obviously true, *à priori*, except for that projection in which the transversal becomes the vanishing line, or all the segments become infinite. If we put the first proposition of all in this form

$$\frac{Ac}{Ab} \cdot \frac{Ba}{Bc} \cdot \frac{Cb}{Ca} = 1,$$

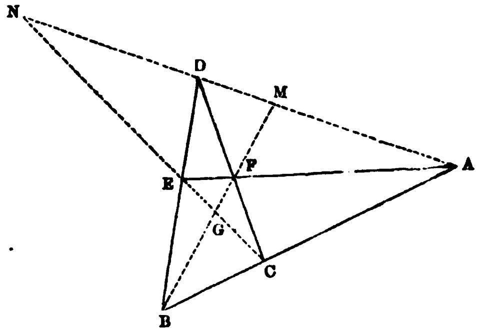
it is obviously true when the line abc is at an infinite distance, each of the ratios being then unity. It would not be safe, upon the proof given in the article cited, to allow this extreme case of projection to enter into the theorem: nevertheless, other proof might be given, which would make this very simple and perceptible instance, the truth of which is seen at once, sufficient evidence of all the others. We mention this only to show the very great power of the geometry of projections: our limits do not allow of our entering further into the subject.

The theory of transversals may be made useful in surveying, particularly in military surveying: as an instance take the following. There is an inaccessible point A, from which to B it is required to find the distance without any instruments except signal-poles and a measuring-line. At B set up a signal, and another, C, at a convenient distance between B and A. Choose another signal-point, D, and between D and B set up a signal at E, and another at F, between D and C, and also between E and A. All this must be done by trial. Then measure DE, EB, DF, FC, and BC. The triangle DBC, cut by the transversal EFA, gives the following relation:—

$$DE . BA . CF = EB . CA . FD$$
$$\text{or } DE . CF . BA = EB . FD\,(BA - BC)$$

$$\text{whence } BA = \frac{EB . FD . BC}{EB . FD - DE . CF}$$

The projection of figures may throw them into such different forms that lines which, in Euclid's mode of speaking, would be called sides, become diagonals, and *vice versâ*. The distinction of diagonal and side therefore becomes an incumbrance, and a new mode of viewing polygons is introduced, of which we shall now give an instance. A figure contained by four straight lines is, generally speaking, one which has six points: since four straight lines meet two and two in six points; thus, the four-sided figure E F B C has the six points E, F, B, C, D, A. If all these points be joined two and two, we have the additional lines B F, C E, D A, of which only the two first are commonly called diagonals: but all three have common properties. We shall prove the following by the extreme method of projection already alluded to, leaving the



reader to verify it by the theory of transversals: each of the diagonals is harmonically divided by the other two; that is,

AM : MD : : AN : ND
CG : GE : : CN : NE
BG : GF : : BM : MF

To show the first: project the figure so that N B shall be the vanishing line. Then D E C A will be projected into a parallelogram, and M G into a parallel to D E and A C passing through the intersection of the diagonals: consequently, in the projection, A M = M D, and we have, also in the projection,

$$\frac{AM}{MD} \cdot \frac{DN}{NA} = 1;$$

for D N and N A are both infinite, and D N ÷ N A is unity. Now by the test in PROJECTION, which is here satisfied, this proposition must be always true, whence in our figure we have A M : M D : : A N : N D. Similarly the other proportions may be proved.

Here then is the easiest way of dividing a line in harmonic proportion. Let A D be given, and M: it is required to complete the harmonic division by finding N. Take any point, B, and draw D B, M B, A B. Choose any point, F, in M B, and produce D F and A F to C and E. Then C E produced to meet A D will give the point N required. No instrument is wanted, except the ruler and pencil, and it is a good exercise in drawing to find out by repeated instances that, let B be taken where it may, there is but one position of N. It is also a good test of the straightness of a ruler.

TRANSVERSE, a name often given to one of the axes of a figure, usually that of greatest magnitude or which goes most directly across the figure. Thus the longer axis of an ellipse or hyperbola is called the transverse axis: but sometimes the shorter axis is so called. Properly speaking, it ought to be only a term of relative distinction: either axis is transverse to the other.

TRAPE'ZIUM, TRAPEZOID. The first word (*τραπέζιον*, a little table) is used by Euclid for, or at least defined to be, any four-sided figure which is not a parallelogram. The second word, formed from the first, has been used by various writers, and in different senses. A trapezoid, says Harris ('Lex. Tech.') is a solid irregular figure, having four sides not parallel to one another: Hutton repeats this, but says it sometimes means a trapezium, two (only) of whose sides are parallel to each other. What the *solid* figure with four *sides* means we do not know: but as the word is never used, we omit all inquiry about it. Words however are so scarce in mathematical language, that it is a pity when any become obsolete. If we were to suggest meanings for these terms, we should propose that *trapezium* should be the general word for *plane* four-sided figures, parallelograms and all; and that *trapezoid* should denote a four-sided figure whose sides are not in the same plane. Perhaps this is what was intended by the *solid* figure of four sides: if so, it was particularly unnecessary to state that the sides are not parallel.

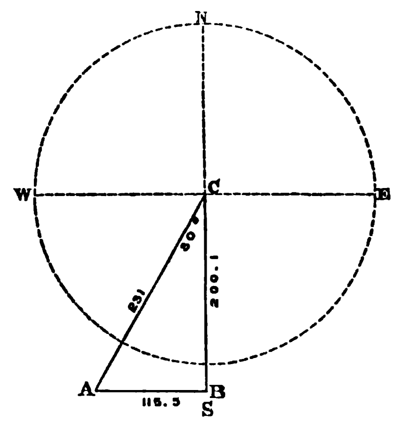
TRAVERSE, in Law, is a contradiction of some matter of fact alleged in pleading by the opposite party. Generally all matter of fact, that is material, ought to be either confessed and avoided, or traversed; and if a party justifies an act as to one particular time and place, or confesses and avoids in one respect, he ought to traverse it as to all other. Otherwise what is materially alleged will be taken to be admitted. Traverse of an immaterial fact, or of a mere supposition, or of inducement, is bad, for it is not an answer to the action. If a traverse is tendered as to a material point by one party, the other must accept it; he cannot waive it and tender another traverse.

In criminal pleading traverse of an indictment is the taking issue and denying some material point in it. Not guilty is a general traverse, which throws on the prosecutor the necessity of proving all the material facts.

TRAVERSE SAILING. [RECKONINGS AT SEA.]

TRAVERSE TABLE. In navigation two tables bear this name; the one is the list of courses, distances, northings, southings, eastings, and westings, in which they are arranged for the convenience of addition, so that difference of latitude and departure may be readily deduced in dead reckoning, when a ship cannot lay her course, but sails in various directions, or upon a traverse as it is called. [RECKONINGS AT SEA.] That which is more properly called a Traverse Table, is one from which the various northings, southings, &c. as above are gathered.

The following figure will explain its principles:—



Suppose a ship at C sails S. 30° W., a distance of 231 miles; according to the usual mode of construction, the side C B would represent the meridian of the ship, and, therefore, the distance C B would be the difference of latitude; while A B would be the departure from that meridian, and A C the distance sailed, the angle C being the course 30°, as marked. It will be seen that only four parts enter into consideration, because the angle A is known (as the complement) when C is known, and the ∠ B is a right angle: any two of these four parts being known, the others may be found by trigonometry. But to save the trouble of logarithmic calculation (which such involves), a large number of right-angled triangles have been purposely computed, and varied according to the magnitude of the course or ∠ C: being arranged in columns headed by the amount of such angles: the above example would appear in the table thus among the distances:—

Course 30°.

Dist.	Diff. Lat.	Dep.
231	200·1	115·5

Comparing this with the figure, the nature of the table will be evident, as each line represents three parts of a triangle, as taken in connection with whatever ∠ C heads the list or page.

The artisan and engineer would be greatly benefited if these tables were more in use. As it is, they are too generally considered as adapted to navigation principally, and the terms used favour this misapprehension. If, however, such tables were published with the substitution of ∠ C for "course;" *perpendicular* for "difference of latitude," and *base* for "departure," the difficulty would be at once removed. Such tables supersede calculation of right-angled triangles entirely, so far as application to practice demands. How far the facility thus offered would tend towards a superficial standard of mental attainment is another consideration: but such are the capabilities of the traverse table.

TRAVERSES, in Fortification, are usually masses of earth which are raised at intervals across the terreplein of a rampart or across the covered-way of a fortress: their positions in the covered way are indicated at *t*, *t*, &c. [FORTIFICATION.] On a rampart they serve to protect the guns and men against the effects of a ricocheting or enfilading fire, which might otherwise dismount the former, and compel the latter to abandon the parapet; and in the covered-way, besides serving for similar purposes, they constitute retrenchments behind which the defenders may keep up an annoying fire of musketry upon the enemy, should the latter attempt to force his way along the branches of that work. On this account they are provided with banquettes, or steps, on which the defenders may stand to fire over them. Such a work, when formed in a direction parallel to a rampart or parapet, on its interior side, for the purpose of securing the defenders against a fire from the ground in their rear, is called a parados.

Palisades are planted along the banquettes, in order to prevent the assailants from suddenly passing over the traverses; and at the passage between each traverse and the interior side of the glacis, is a strong gate, or barrier, which is closed in the event of the defenders being obliged to retire from one traverse to the next, or to abandon the covered-way entirely.

As, at the time of an assault being made at the salient part of a covered-way, the defenders might be bayoneted in attempting to retire along the passages between the traverses and the glacis (those passages being then commanded by the enemy), it has been recommended to form other passages about four feet wide between the opposite extremities of the traverses and the top of the counterscarp; and, in order that the retreat may be effected without molestation, a line of palisades is planted from each traverse to the next along the middle of the covered-way, in addition to the line which is always planted along the foot of the interior slope of the glacis.

The traverses, like other parapets, are usually above eighteen feet thick at the upper part, in order that they may not be immediately destroyed by the heavy artillery of the enemy; but the French engineers recommend that all the traverses in the covered-way, except those which are close to the re-entering places of arms, L, L [FORTIFICATION], should not exceed twelve feet in thickness, as it may be advantageous for the defenders to destroy them in the event of the enemy endeavouring to protect himself by them during the operation of cutting a trench across the covered-way for the purpose of making a descent into the ditch of the fortress.

TRAVESTY. [PARODY.]

TREACLE. [MOLASSES; SUGAR CULTURE AND MANUFACTURE.]

TREASON. This term, in its legal signification, is derived from the French *trahison*; and in conformity with this derivation, the offences designated by it in English law always contained the notion of treachery, or a breach of that allegiance supposed to be due from an inferior to a superior. Thus petit-treason was the murder of a husband by his wife, or a master by his servant, or a bishop by his subordinate in the church; and high treason consists in an attack upon the sovereign as the political head of the state. The former of these two kinds of treason was placed in another class of crimes by the statute of 9 Geo. IV., c. 31, s. 2, which made petit-treason murder only, and no greater offence. The only crime therefore now known to the law of England under this term is high treason, which, as it is composed of numerous acts and circumstances, constructively and remotely, as well as immediately, affecting the safety of the person of the sovereign, cannot be accurately described by any simple definition.

In early periods of the history of England, the law upon this subject was extremely vague and uncertain, in consequence of the great variety of acts which were held to constitute high treason as tending to diminish the power or dignity of the crown: killing the king's father or brother, or even his messenger, refusing to answer in the king's courts, and summoning an English subject to appear and defend himself in the court of a foreign prince, were deemed to be acts of treason. (3 'Inst.' 7; Hawkins's 'Pleas of the Crown,' b. 1, c. 17.) Indeed, immediately before the date of the statute of treasons, a knight was indicted for high treason in "usurping royal power within the king's realm," by assaulting another on the highway, taking his horse and detaining him until he paid 90*l.* (Hale's 'Pleas of the Crown,' vol. i., p. 80.) From these and many other instances which are to be found in law books, it appears that almost every act that could be in any way considered as a breach of the allegiance due to the king, or a constructive assumption of royal authority, was deemed to be high treason, as an "accroachment of royal power." This arbitrary state of the law became the cause of intolerable oppressions, and a petition to Edward III. from a parliament, which Mr. Hallam calls "one of the best that ever sat" ('Constitutional History,' vol. iii., p. 204), occasioned the statute 25 Edward III., commonly called the "Statute of Treasons." This enactment gave for the first time an intelligible definition of the crime of treason, and, notwithstanding the total change of national habits, still continues, after the lapse of five centuries, to be the governing law on the subject. Valuable as this law undoubtedly was in the comparatively rude times in which it was made, the inadequacy of its provisions to meet the complicated relations of a more refined state of society has frequently rendered supplemental statutes necessary, and has been the cause of those subtle and forced interpretations of its simple language, which have introduced scarcely less uncertainty and injustice into this department of the criminal law than prevailed before its enactment.

The several acts and circumstances constituting high treason by the "Statute of Treasons" are as follows:—1. Compassing or imagining the death of the king, the queen consort, or their eldest son and heir. 2. Violating the king's companion (by which is meant the queen consort), or the king's eldest daughter unmarried, or the wife of the king's eldest son and heir. 3. Levying war against the king within his realm. 4. Being adherent to the king's enemies in his realm, giving them aid and comfort in the realm or elsewhere. 5. Counterfeiting the king's great or privy seal. 6. Counterfeiting the king's money, or knowingly bringing false money into the realm counterfeit to the money of England, to merchandise and make payment withal in deceit of the king and his people. 7. Slaying the chancellor, treasurer, or the king's justices of either bench, justices in eyre, justices of assize, or any other justices assigned to hear and determine, being in their places, doing their offices. As several of the offences above enumerated are acts of the mind, and consist in intention, the statute declares that in such cases the intention, in order to come within the meaning of the law, must be manifested by some open or *overt* act done towards the accomplishment of the traitorous intention. This provision, although by its position in the statute it is apparently limited to the offence of adhering to the king's enemies, has been held to apply to all the treasons before mentioned. (Hale's 'Pleas of the Crown,' vol. i. p. 108.)

The word "king," used in the first clause of the statute describing the offence of compassing the king's death, comprehends the case of a queen regnant, as she is invested by the constitution with full royal authority, and is entitled to the allegiance of her subjects. But the husband of the queen regnant is not within the words or meaning of the statute. The precise meaning of the words "compass" and "imagine" in this clause of the statute has been the subject of some discussion. Mr. Luders has thrown much light upon their signification by collecting the instances in which the same language has been used in writings contemporaneous with the statute; and although attempts have been made to give them a more enlarged signification, it is clear that they mean nothing more than "attempt" and "contrive." ('Considerations on the Law of High Treason in the article of Levying War,' p. 137.) If this be so, the meaning of this clause is sufficiently obvious to an ordinary reader, and would be certainly limited in his apprehension to attempts or contrivances against the natural life of the king. But by means of legal construction, the words have received a much wider meaning. Thus, a conspiracy to imprison or depose the king, which by the statute of treasons is not declared to be a substantive treason, has been repeatedly held to be high treason in the article of compassing his death, because, according to a saying of Machiavelli, "There is but a short interval between the prisons and graves of princes." Mr. Hallam justly observes, that "it seems not very reasonable to found a capital conviction on this sententious remark." It appears indeed formerly to have been questionable law, for Chief Justice Brooke, who compiled his 'Abridgment of the Law' at the commencement of the 16th century, expresses a doubt whether a design to depose the king be within this clause of the statute; "for," says he, "one may deprive the king of his crown, without designing his death;" and in confirmation of his view of the matter, he refers to the statutes which had been passed from time to time to remedy this defect in the Statute of Treasons. (Brooke's 'Abridgment,' tit. 'Treason,' fol. 24.) And in fact experience shows that the adoption of this proposition would frequently lead to a false result, several instances of rebellion having occurred in English history, in which the designs of the rebels would have been wholly defeated by the death of the king, whose name they designed to employ. ('Constitutional History,' vol. iii., p. 208.) Nevertheless the doctrine that a design to depose is an overt act of compassing the death of the king, has been repeatedly confirmed by treatises of the highest authority, as well as by judicial decisions. (Foster's 'Discourse on High Treason,' p. 196; Howell's 'State Trials,' vol. xxiv., p. 1361; vol. xxv., p. 725.) A still more extensive signification has been given to these words of the statute by the forced interpretation that a conspiracy to levy war against the king and also consulting with a foreign enemy to invade the realm, were overt acts of treason in the article of compassing the king's death. (Hale's 'Pleas of the Crown,' vol. i., p. 120.) This mode of reading the plain words of a penal statute was obviously liable to serious objections and led to great oppression and injustice; "such a method," as Sir M. Hale says, "admitting of no limits or bounds, but running as far as the wit or invention of accusers, and the odiousness and detestation of persons accused, will carry men." ('Pleas of the Crown,' vol. i., p. 86–7.)

The doctrine of constructive treason having been brought into prominent notice and much discussed in the trials of Hardy, Horne Tooke, and others in 1794, the statute 36 Geo. III., c. 7, was passed with a view of superseding the necessity of resorting to any such modes of interpretation for the future. This statute, which, although originally in force only for the life of George III., was made perpetual by the stat. 57 Geo. III., c. 6, enacted that "if any person shall, within the realm or without, compass, imagine, invent, devise, or intend death or destruction, or any bodily harm tending to death or destruction, maim or wounding, imprisonment, or restraint of the person of the king, or to deprive or depose him from the style, honour, or kingly name of the imperial crown of this realm, or of any other of his majesty's dominions or countries, or to levy war against his majesty within this realm, in order by force or constraint to compel him to change his measures or councils, or in order to put any force or constraint upon, or to intimidate or overawe both Houses or either House of Parliament, or to move or stir any foreigner or stranger with force to invade this realm, or any other of his majesty's dominions or countries under the obeisance of his majesty; and such compassings, imaginations, inventions, devices, and intentions, or any of them, shall express, utter, or declare, by publishing any printing or writing, or by any overt act or deed, every such offender, being legally convicted upon the oath of two lawful and credible witnesses, shall be adjudged a traitor, and suffer as in cases of high treason." It was no doubt the intention of the legislature that this statute should put an end to all artificial constructions of the statute of Edward III.; nevertheless the practice of resorting to these forced interpretations has been continued, and sanctioned by the approbation of the judges in several subsequent prosecutions for high treason. ('Sixth Report of Commissioners on Criminal Law,' p. 16.)

The second kind of treason declared in the Statute of Treasons is the violation of females of the royal family, and was obviously intended to preserve the purity of the succession to the throne. With a view to this object, the law has been held to apply to a criminal connection by consent as well as to a forcible violation. It is worthy of remark, as one of the numerous circumstances showing the inapplicability of this ancient law to modern times, that a queen regnant, whether married or single, is not within this clause of the statute.

The third species of treason above mentioned is "levying war against the king in his realm." It amounts to treason under this clause of the statute to take arms against the king, not only with the object of destroying him, but where it is intended by open violence to reform religion or the laws, or to remove evil councillors, or other grievances, whether real or pretended. (Hawkins's 'Pleas of the Crown,' b. i., c. xvii., s. 25.) The plain words of this clause of the statute have been still more extravagantly extended by legal construction than those of the clause relating to compassing the king's death. Thus riotous assemblies, where the object has been to destroy *all* property of any particular class, such as to pull down all meeting-houses, or to destroy all inclosures, have been held to be treason in all who join them, by reason of the generality of the design. This doctrine has, however, been much questioned in recent times; and to the extent formerly contended for, would probably not be countenanced by the judges at the present day. (Luders, 'On Constructive Treasons;' 'Sixth Report of Commissioners on Criminal Law.') Indeed the necessity for constructive extensions of the words of this clause, which might have been plausibly argued from the omission in the Statute of Treasons to notice conspiracies or preparations to levy war against the king, has been entirely removed by the above-mentioned statute of the 36 Geo. III., c. 7.

The fourth kind of treason mentioned in the Statute of Treasons is adherence to the king's enemies. The enemies here mentioned are foreign powers and states with whom the king of England is at war, and who owe him no allegiance; and, therefore, an adherence to British subjects in a state of rebellion against the king will not constitute treason under this clause, although it may amount to treason in the article of levying war. This kind of treason must, like compassing the king's death, or levying war against him, be evidenced by some overt act, such as treacherously surrendering a fortified place, or supplying arms, or giving information to an enemy.

The fifth treason mentioned in the statute is counterfeiting the king's seals; and this offence would now be punishable as forgery only. The clause in the Statute of Treasons, which declares the offence of counterfeiting the king's coin to be high treason, has been repealed by the stat. 2 Will. IV., c. 34; and the crime itself has been by the same enactment divided into distinct classes, as felonies and misdemeanors, with a graduated scale of punishments.

The last species of treason above referred to is the offence of slaying the chancellor or the judges, which still continues to be high treason. This part of the law is, however, obviously imperfect, as it does not comprehend the barons of the exchequer, who at the present day are the king's superior justices as fully as the judges of the other courts of Westminster Hall; whereas it includes the justices in eyre, whose office has long since been abolished.

Besides the several treasons above enumerated, a large class of offences has been created by various statutes passed from time to time in the reigns of Elizabeth and James I., with the avowed object of protecting the Protestant religion from the designs of Roman Catholics. But as many of these statutes have not been the subject of prosecution for nearly three centuries, and many others have never been enforced at all, they may perhaps be considered as virtually obsolete, and do not require to be particularly noticed in this article. ('Sixth Report of Commissioners on Criminal Law,' p. 35.)

With a view to diminish the peculiar disadvantage under which a person charged with treason was supposed to labour in having to defend himself against a prosecution in which so powerful an adversary as the crown was interested, several privileges as to process, evidence, and trial have been given by statute to persons so accused. It is declared by the stat. 7 Will. III., c. iii., s. 2, that no person whatsoever shall be indicted, tried, or attainted of high treason or of misprision of treason, but upon the oaths of two lawful witnesses, unless the party indicted shall willingly, without violence, in open court confess the same. And by the third section of the same statute, it is declared that if two or more distinct treasons of divers heads or kinds shall be alleged in one indictment, one witness produced to prove one of the treasons, and another witness to another of the treasons, shall not be deemed to be two witnesses to the same treason within the meaning of the statute. The same statute of the 7 Will. III., c. 3, also enacted that no person should be tried for any treason (except an attempt to assassinate the king) unless the indictment be found within three years after the offence committed. Moreover, the prisoner is to be furnished with a copy of the indictment five days, and a copy of the panel of jurors two days, before the trial. He is to have the same compulsory process to enforce the attendance of his witnesses as was at the time of the statute exclusively applicable to the prosecutor's witnesses; and he is to have full defence by counsel selected by himself and expressly assigned to him by the court. The stat. 7 Anne, c. 21, materially extended these privileges by directing that all persons indicted for high treason, or misprision thereof, shall have not only a copy of the indictment, but also a list of all the witnesses to be produced, and of the jurors impanelled, with their professions and places of abode respectively, delivered to him ten days before the trial, and in the presence of two witnesses, the better to prepare him to make his challenges and defence.

It may perhaps be doubted whether these indulgences are founded upon any true principles of criminal jurisprudence. If justice requires them, they should be generally applied to all crimes; and at all events there seems to be no sufficient reason for giving a different measure of advantage to persons accused of high treason from that afforded to persons accused of many other offences. So obvious indeed was the inconsistency of giving greater privileges and advantages to a person charged with an attempt to kill the king than were permitted in the case of a similar attempt upon the life of a private person, that upon occasion of an attack upon George III., in the year 1800, an act of parliament was passed to remove it. The statute 39 & 40 Geo. III., c. 93, enacts that in all cases of high treason, in compassing or imagining the death of the king, and misprision of such treason, where the overt act alleged shall be the assassination or killing of the king, or any direct attempt against his life, or against his person, whereby his life may be endangered, or his person suffer bodily harm, the offender may be indicted, arraigned, tried, and attainted, in the same manner, and according to the same course and order of trial in every respect, and upon the like evidence, as if such person stood charged with murder; and none of the provisions contained in the above-mentioned acts of 7 Will. III., c. 3, and 7 Anne, c. 21, shall extend to any indictment for this species of treason. A clause in a subsequent statute (6 Geo. IV., c. 50, s. 21) provides that the list of the jury shall in all indictments for treason, or misprision of treason, in other courts than the King's Bench, be delivered at the same time with the copy of the indictment, and ten days *before* the arraignment; and in the court of King's Bench it may be delivered *after* the arraignment, but ten days before the trial. This statute does not extend to the case of attempts upon the life of the king mentioned in the stat. 39 & 40 Geo. III., c. 93. By the stat. 5 & 6 Vict., c. 51, the provisions of the stat. 39 & 40 Geo. III., c. 93, are extended to "all cases of high treason in compassing or imagining the death or destruction of the queen, or in compassing or imagining any bodily harm tending to the death or destruction, maiming, or wounding of the queen, and of misprision of such treason, when the overt act alleged shall be any attempt to injure in any manner whatsoever the person of the queen;" and such cases are expressly excepted from the operation of the above-mentioned statutes of 7 Will. III., c. 3; 7 Anne, c. 21; and 6 Geo. IV., c. 50, s. 21.

The judgment in high treason is that the offender shall be drawn on a hurdle to the place of execution, and there be hanged by the neck until he is dead; that afterwards his head shall be severed from his body; and his body, being divided into four quarters, shall be at the disposal of the crown. This punishment was substituted by the statute 54 Geo. III., c. 146 for the ancient and barbarous sentence which required that the person convicted should be hanged, but taken down alive, and then that his bowels should be taken out and burnt before his face. By the 2nd section of stat. 54 Geo. III., c. 146, authority is given to the crown by warrant under the sign manual, countersigned by a secretary of state, to alter this sentence, and to direct that, instead of the ignominious part of it, the party shall be beheaded whilst alive.

TREASURE-TROVE, in legal Latin called *thesaurus inventus*, is a branch of the revenue of the crown by the law of England. Where coin, plate, or precious metals are found hidden in the earth or any private place, and the owner or person who deposited them is unknown, the property becomes vested in the king by virtue of his prerogative. But if the owner is known, or is ascertained after the treasure is found, the property belongs to him, and not to the king. The civil law gave treasure found in general to the finder; but if found accidentally in another man's land, half was given to the finder, and half to the owner of the land. And so if it was found in the land of the emperor, it was to be equally divided between him and the finder. ('Inst.,' lib. ii., tit. i., § 39; 'Cod.,' lib. x., tit. 15.) Grotius says that the title of the prince to treasure-trove had in modern times been so generally established in Europe as to have become "jus commune et quasi gentium" ('De Jure Belli et Pacis,' lib. ii., c. viii., § 7). The law of England adopts the definition of treasure-trove from the civilians as "vetus depositio pecuniæ cujus dominus ignoratur' (Paulus, lib. xxxi., § 1); and to entitle the crown to the property, it must appear to have been hidden or deposited by some one who at the time had the intention of reclaiming it. Whenever, therefore, the intention to abandon appears from the circumstances—as for instance, where the property has been found in the sea, or in a pond or river, or even openly placed upon the surface of the earth—it belongs to the finder. In England, the concealment of treasure-trove from the king was formerly a capital offence; at the present day it is a misdemeanor only. Ancient coins or other valuable articles found, are now declared to be so far the property of the finders that they may have the value paid to them. This has been directed by an order in council in order to prevent the destruction of such objects for the mere value of the material.

TREASURY, a department of the British government which controls the management, collection, and expenditure of the public revenue. It is the business of another department, the Exchequer, to take care that no issues of public money are made by the Treasury without their being in conformity with the authority specially enacted by parliament. When money is to be paid on account of the public service, this is almost always done on the authority of a Treasury warrant; and in other cases the countersign of the Treasury is requisite. The Board of Treasury consists of the prime minister and the chancellor of the Exchequer. The real office which the premier holds is generally that of first lord of the Treasury. There are also four junior lords, who have usually seats in parliament, as have also the two joint secretaries of the Treasury. The departments immediately subordinate to the Treasury are the boards of Customs and of Trade, and the Post-Office, the various officers in which are to a great extent appointed by the lords of the Treasury; and this constitutes an important part of the patronage of the ministry. The duties of the Board of Treasury are heavy and multifarious, all exceptional cases in matters relating to the revenue being referred to it. The offices of the Treasury are in Whitehall. The first lord of the Treasury receives 5000*l.* a-year; two secretaries of the Treasury receive 2500*l.* a-year each, and the assistant-secretary 2000*l.* a-year; the solicitor of the Treasury receives 2850*l.* a-year; four commissioners of the Treasury receive 1200*l.* a-year each; and other officers receive sums varying from 1000*l.* to 1500*l.* each.

TREATIES, CHRONOLOGICAL TABLE OF. A treaty (immediately from the French *traité*) means literally that which has been drawn up, or, in other words, arranged and agreed upon, by two or more parties, who are accordingly called the contracting parties. It is in fact the same word with contract. The term in its several variations is now employed by most of the nations of Europe—by the Italians, the Spaniards, the Germans, the Dutch, &c., as well as by the English and the French—to designate the conventions or agreements which governments make with one another. By the Romans a treaty was commonly called *foedus*, a word of unknown or uncertain etymology. From *foedus* we have formed our federation, confederacy, &c.

Although a treaty is commonly defined to be an agreement made with one another by two or more governments, it is not necessary that the party to a treaty should always be an absolutely sovereign and independent power or political society. Communities, or even individuals, which are subjects in many or in all other respects, may be empowered to enter into treaties. Such engagements, however, are for the most part only to be depended upon so long as they are for the advantage of the one party as well as of the other. Hence the best and most durable treaty is always that which is the fairest and the most equal. But the main purpose and utility of a treaty, after all, is not that it may secure certain advantages to either party, but that it makes clear and fixes those relations between the two which would otherwise remain obscure, indeterminate, and subject to continual misconception or controversy.

We proceed to give a *Chronological Table* of the more important treaties between the principal civilised nations, beginning with that of 1217, the first formal treaty of England, and stating briefly the chief objects of each.

1217, Sept. 11. Treaty at Kingston between Louis of France and the Regent in the name of Henry III., by which Louis abandoned his attempt on the English crown.

1274. Treaty between Edward I. and Guy Earl of Flanders. This is the first recorded commercial treaty of England. There had been a petty quarrel with the Flemings, chiefly between the fishermen of the two countries; and England had prohibited the exportation of wool, to the great detriment of the manufactures of the Flemings. These differences were accommodated by this treaty; but fresh ones broke out apparently, as treaties of commerce with Flanders are frequent after this period.

1308. Commercial treaty with Portugal, and in the same year another with Spain. Ferdinand of Castile wishing for a "mutual free correspondence" between his subjects and England, and Dionysius of Portugal desiring to "strengthen the agreement and correspondence already on foot between the merchants of both nations."

1328. Treaty of Northampton with Robert Bruce, by which the independence of Scotland was recognised.

1356. The Golden Bull, a convention of the German sovereign princes, settled at Nürnberg, by which the mode of electing the Emperor was determined.

1360, May 8. Peace of Bretigny, near Chartres, between England and France, whereby England retained Gascony and Guienne, acquired Saintonge, Agenois, Perigord, Limosin, Bigorre, Angoumois, and Rovergne, and renounced her pretensions to Maine, Anjou, Touraine, and Normandy; England was also to receive 3,000,000 crowns, and to release King John, who had been long prisoner in London.

1381, Aug. 8. Treaty of Turin, between Venice and Genoa.

1390. Treaty between the Sultan Bajazet and the Greek Emperor, John Paleologus.

1420, May 21. Treaty of Troyes, between England, France, and Burgundy, stipulating that Henry V. should marry Catherine, daughter of Charles VI., be appointed Regent of France, and after the death of Charles should inherit the crown.

1423, April 17. Treaty at Amiens between England and Burgundy.

1435, Sept. 22. Treaty of Arras between France and Burgundy.

1438. The Pragmatic Sanction settled in France, regulating the election of bishops, and moderating the power of the pope.

1453. The first alliance entered into between the French and Swiss.

1464. A league, designated "For the public good," formed between the Dukes of Burgundy, Brittany, and Bourbon, and others, against Louis XI. of France.

1465. Treaty of Conflans, between Louis XI. and the chiefs of the above league.

1468. Treaty of Peronne, between Charles Duke of Burgundy and Louis XI., who was forced to confirm the stipulations of Arras and Conflans.

1475. The Peace of Picquini, concluded between Edward IV. of England and Louis XI. of France.

1475. Charles the Bold, of Burgundy, concluded a treaty with the French king, but speedily afterwards leagued against him with Edward IV. of England, and the Duke of Brittany. Louis XI., on the other hand, entered into a treaty with the Switzers, and succeeded ultimately in becoming an ally of England.

1482. The Treaty of Arras, between Maximilian of Austria, the husband of Mary of Burgundy, and Louis XI. of France, whereby Margaret, daughter of the former, was espoused to the dauphin, son of the latter, with Artois and Burgundy as a dowry.

1497. Treaty between England and Scotland, by which Perkin Warbeck was compelled to quit the latter kingdom.

1501. Treaty between Louis XII. of France and Ferdinand of Spain, for the division of the kingdom of Naples.

1508, December 10. The League of Cambray against the republic of Venice, comprising the Pope, the Emperor, and the kings of France and Spain.

1510. Holy League against Louis XII. of France.

1514. France obliged to sue for peace, which was obtained from the Pope, by promising to abolish the Pragmatic Sanction; from the King of Spain, by uniting his grandson, the Duke of Ferrara, to Renée, daughter of the King of France; and from England, by Louis XII. espousing Mary, sister of Henry VIII.

1516, August 16. The Treaty of Noyon.

1525. A Treaty concluded between France and England.

1526. Concord of Madrid. Francis I., to release himself from captivity, signed a treaty with Charles V., surrendering Burgundy, Artois, Flanders, &c., and renouncing all pretensions to Italy.

1527. A Treaty of mutual obligation entered into between France and England; and in the same year a fresh treaty, for the purpose of carrying war into Italy to restore the Pope to liberty.

1529, August 5. The Peace of Cambray.

1529, December 31. The League of Smalcald in Franconia, entered into between the Elector of Brandenburg and other princes of Germany, in defence of Protestantism.

1532, June 23. A new Treaty of Alliance ratified between the kings of England and France.

1532, August 2. The Treaty of Nürnberg ratified.

1538, June 18. Treaty of Nice, between Francis I. and Charles V.

1544. League between England and the Emperor Charles V. against France, shortly after which peace was concluded with France, and signed at Cressy in Valois.

1548, May 15. The Interim granted by the Emperor Charles V. to the Protestants of Germany.

1549. Peace ratified between France and England. Boulogne restored to France.

1551, October 5. Treaty of Friedwald, between France and the Protestant princes of Germany.

1552, January 15. Treaty of Chambord, confirming the league between France and the Protestant princes of Germany.

1552, August 12. Treaty of Passau, ratified between Charles V. and the Protestant princes of Germany. Freedom of religion established.

1555. Peace of Religion concluded at Augsburg,—a confirmation of the Treaty of Passau, establishing the free exercise of the Protestant religion.

1556. England entered into an alliance with Spain against France.

1559. Peace of Cateau Cambresis, between France, Spain and Piedmont. France ceded Savoy, Corsica, and nearly 200 forts in Italy and the Low Countries.

1560. Peace ratified between England, France, and Scotland.

1561. Treaty of Wilna, between the Northern Powers.

1564, April 29. Peace ratified between France and England.

1570. Peace of St. Germain.

1570, December 13. Peace of Stettin, between Sweden and Denmark.

1571. Spain, Venice, and the Pope combine against the Turks, who were endeavouring to subdue Cyprus.

1572. Peace concluded between England and France.

1576. November 8. Pacification of Ghent, by which foreign troops were expelled from the Netherlands and the Inquisition abolished.

1576. The League begins in France.

1579, January 22. The Union of Utrecht, formed by Holland, Utrecht, Zealand, Friesland, and Guelderland, by which the republic of Holland was constituted. Overyssel joined in 1580, and Groningen in 1594.

1598, May 2. Peace ratified at Vervins between France and Spain. Spain restores her conquests of Calais, Amiens, &c.

1603. A Treaty between James I. of England and Henry IV. of France, in order to support the States-General of Holland.

1604, August 18. Peace between England and Spain ratified.

1609, April 4. A Truce of twelve years between the Spaniards and Dutch.

1610. Treaty of Halle, between the Protestant princes of the empire.

1610. League of Würzburg, between the Roman Catholic princes of the empire.

1613. Peace of Siöröd, concluding a war of two years between Sweden and Denmark.

1619. Peace between France and Spain. Marriage of Louis XIII. with Anne of Austria, infanta of Spain.

1620, July 3. Peace of Ulm, by which Frederic V. lost Bohemia.

1626. League of the Swedes, Dutch, and the Protestant princes of Germany, against the Emperor.

1629, April 14. Peace ratified with France.

1629, May 22. Peace of Lubeck, between the Emperor and King of Denmark.

1630. League of France with the Protestant princes of Germany, Gustavus Adolphus of Sweden, and Holland, against the house of Austria, in Germany and Spain.

1630. England also acceded to the above alliance, with a view of procuring the restoration of the Elector Palatine.

1630, October 13. Peace of Ratisbon, between France and the Emperor, terminating the war for the Mantuan succession.

1630, November 27. Peace proclaimed between England and Spain.

1631, January 13. Subsidising alliance of France with Sweden.

1631, April. Alliance of Leipzig, between the Elector of Saxony and the Protestant princes.

1631. Treaty of Chierasco, by which the Duke of Nevers finally takes possession of his Mantuan territories.

1633, March. Treaty of Heilbron, between Sweden and the Northern Protestant states of Germany, after the death of Gustavus Adolphus.

1635, February 28. Alliance between France and Holland.

1635, May 30. Peace of Prague, between the Emperor and the Elector of Saxony.

1648, January 30. Peace of Münster, between Spain and the Dutch. Independence of Holland fully recognised.

1648, October 24. The Peace of Westphalia signed at Münster and at Osnaburg, between France, the Emperor, and Sweden; Spain continuing the war against France. By this peace the principle of a balance of power in Europe was first recognised, and the independence of the republics of Switzerland and the United Provinces of the Netherlands recognised.

1654, April 5. Peace ratified between the Dutch and the Commonwealth of England.

1655, November 3. Articles of Peace signed between England and France.

1656, November 10. Treaty of Liebau, which annulled the feudal subjection of the duchy of Prussia to the crown of Sweden.

1657, March 23. Treaty of Alliance between England and France against Spain.

1657, May 27. Alliance of Vienna, between Poland, Denmark, and the Emperor, against Sweden.

1659, May 21. Treaty of the Hague, between England, France, and Holland, to maintain the equilibrium of the North.

1659, November 7. Peace concluded between France and Spain, by the Treaty of the Pyrenees.

1660, May 3. The Peace of Oliva ratified between Sweden, Poland, Prussia, and the Emperor. Esthonia and Livonia given up to Sweden.

1660, May 27. Peace of Copenhagen, between Sweden and Denmark.

1661, June 23. Treaty of Alliance between England and Portugal.

1663. France entered into a defensive alliance with Holland and Switzerland.

1664, September 7. The Truce of Temeswar concluded between Turkey and Germany.

1666, January 26. The Danes entered into a league with the Dutch against England.

1667, July 25. Peace of Breda concluded between England, France, Holland, and Denmark.

1668, January 28. A Treaty of Alliance ratified between the States-General and England against France, for the protection of the Spanish Netherlands; Sweden afterwards joining the league: it was known as the Triple Alliance.

1668, February 13. Peace of Lisbon concluded between Spain and Portugal through the mediation of England. Independence of Portugal acknowledged by Spain.

1668, May 2. Peace of Aix-la-Chapelle, between France and Spain, signed. France yields Franche Comté, but retains her conquests in the Netherlands.

1669, May 7. Treaty of the Hague, between Holland and Portugal: the Dutch allowed to retain their conquests in India.

1672. Treaty between France and England (February 12), and Sweden (April 14), against Holland.

1672, August 30. An Alliance entered into between the Emperor, Spain, and Holland, against France.

1673, June 16. Peace of Vossem, between the Elector of Brandenburg and France; the former engaging not to assist the Dutch.

1674, February 19. Peace of Westminster, between England and Holland.

1678, January 10. Treaty concluded between England and Holland, by which Holland detached Charles II. from the interests of France.

1678, August 10. Peace of Nimeguen concluded between France and Holland. Spain accedes to the peace September 17, giving up Franche Comté, &c.; the Emperor on February 5 following; and Sweden on March 29.

1679, June 29. Peace of St. Germain en Laye concluded between France, Sweden, and the Elector of Brandenburg.

1679, September 2. Peace of Fontainebleau, between France and Denmark.

1683, March 31. Alliance of Warsaw, between Austria and Poland, against Turkey, in pursuance of which John Sobieski assisted in raising the siege of Vienna, on Sept. 12.

1684, August 15. Truce of Ratisbon concluded by France with Spain and the empire, terminating the war of the previous year.

1686. League of Augsburg entered into by Holland and other European powers for the purpose of causing the treaties of Münster and Nimeguen to be fulfilled on the part of France.

1689, May 12. The Grand Alliance signed at Vienna between England, the Emperor, and the States-General; to which Spain and the Duke of Savoy afterwards acceded.

1696, August 29. The Duke of Savoy quitted the coalition, and entered into a treaty with France.

1697, September 20. Peace of Ryswick, between France, England, Spain, and Holland; signed by Germany October 30.

1698, October 11. First Treaty of Partition signed between France, England, and Holland, for the purpose of regulating the succession of the territories of the King of Spain.

1699, January 26. Peace of Carlowitz, between Turkey and Germany, Poland, Russia, and Venice.

1700, March 13. Second Treaty of Partition between France, England, and Holland, declaring the Archduke Charles presumptive heir of the Spanish monarchy.

1701, September 7. England and Holland conclude a formal alliance at the Hague, to resist the claim of Philip of Anjou, to which almost all the European states successively accede.

1703. The Methuen Treaty, between England and Portugal, principally for the regulation of commerce.

1706, September 24. Peace of Alt Radstadt, between Charles XII. of Sweden and Augustus of Poland.

1711, July 2. Peace of Falczi concluded between Russia and Turkey, the Russians giving up Azof and all their possessions on the Black Sea to the Turks; in the following year the war was renewed, and terminated by the Peace of Constantinople, April 16, 1712.

1713, April 11. Peace of Utrecht, signed by the ministers of Great Britain and France, as well as of all the other allies, except the ministers of the empire. The most important stipulations of this treaty were the security of the Protestant succession in England, the disuniting the French and Spanish crowns, the destruction of Dunkirk, the enlargement of the British colonies and plantations in America, and a full satisfaction for the claims of the allies. Spain also granted to Great Britain the privilege of supplying Spanish America with negro slaves. This is the Assiento treaty.

1713, April 17. The Emperor Charles VI. published the Pragmatic Sanction, whereby, in default of male issue, his daughters should succeed in preference to the sons of his brother Joseph I.

1713, July 13. The Treaty of Utrecht signed by Spain, which included the Assiento contract.

1714, March 6. Peace of Radstadt, between France and the Emperor of Germany.

1714, September 7. Peace of Baden, between France and the Emperor of Germany. Landau ceded to France.

1715, November 15. The Barrier Treaty signed at Antwerp, by the British, the Imperial, and Dutch ministers. Low countries ceded to the Emperor of Germany.

1717, January 4. The Triple Alliance of the Hague, between France, England, and Holland, to oppose the designs of Cardinal Alberoni, the Spanish minister.

1718, July 21. Peace of Passarowitz, between the Emperor, Venice, and Turkey.

1718, August 2. The Treaty of Alliance between Great Britain, France, and the Emperor, signed at London. This alliance, on the accession of the states of Holland, obtained the name of the Quadruple Alliance, and was entered into to force the King of Spain to observe the stipulations of the treaty of Utrecht.

1718, November 18. The Duke of Savoy joined the Quadruple Alliance, signing the treaty by his envoys at Whitehall.

1719, November 20. Peace of Stockholm, between the King of

Great Britain and the Queen of Sweden, by which the former acquired the duchies of Bremen and Verden as Elector and Duke of Brunswick.

1720, January 26. The King of Spain accepts and signs the Quadruple Alliance.

1721, August 30. Peace of Nystett, in Finland, between Sweden and Russia, whereby Livonia and Ingria were ceded to Russia.

1724, March 24. Treaty of Stockholm, between Russia and Sweden, in favour of the Duke of Holstein Gottorp.

1725, April 30. The Vienna Treaty, signed between the Emperor of Germany and the King of Spain, by which they confirmed to each other such parts of the Spanish dominions as they were respectively possessed of.

1725, September 3. The Hanover Treaty concluded between the Kings of England, France, and Prussia, as an act of self-defence against the provisions of the Vienna Treaty.

1726, August 6. Treaty of Alliance between Russia and the Emperor of Germany.

1727, May 31. Preliminary articles for a general pacification, signed at Paris by the ministers of Great Britain, the Emperor of Germany, the King of France, and the States-General.

1727, October 21. Treaty of Nipchoo (Nerchinsk), between Russia and China, by which the boundaries of the two empires were settled, and a Russian resident at Pekin allowed. Not ratified until June 14, 1728, in consequence of the death of Catherine.

1729, November 9. The Peace of Seville, between Great Britain, France, and Spain: and a defensive alliance entered into: to this treaty the states of Holland afterwards acceded, November 21.

1731, March 16. The Treaty of Alliance of Vienna, between the Emperor of Germany, Great Britain, and Holland, by which the Pragmatic Sanction was guaranteed, and the disputes as to the Spanish succession terminated; Spain acceded to the treaty on the 22nd of July.

1732, October 7. Peace between Sweden and Poland.

1735, October 3. Preliminaries of peace signed at Vienna, between France and the Emperor of Germany. Spain acceded April 15, 1736.

1738, November 18. The Definitive Peace of Vienna, between the Emperor of Germany and the King of France, the latter power agreeing to guarantee the Pragmatic Sanction. Lorraine ceded to France, who acknowledged Augustus III. as King of Poland, abandoning the claim of Stanislaus, who resigned.

1739, September 18. Peace of Belgrade, between the Emperor of Germany and the Turks, the Emperor giving up Belgrade and Servia; this was speedily followed by a peace between Russia and Turkey, Russia surrendering Azof and all her conquests on the Black Sea.

1740, August. A Subsidy Treaty concluded between Great Britain and Hesse.

1741. Alliance between Great Britain, Russia, and Poland, with the Queen of Hungary (the Empress Maria Theresa), for the purpose of supporting the interests of the house of Austria; France, Spain, and Sardinia uniting about the same time in the interest of the Elector of Bavaria.

1742, June 28. Peace of Berlin, between the King of Poland and the Queen of Hungary. Silesia given up to Prussia.

1742, November 18. A Treaty for mutual defence and guarantee signed at Whitehall, between Great Britain and Prussia.

1743, June 24. A defensive Treaty concluded between Great Britain and Russia for fifteen years.

1743, August 7. Peace of Abo, between Russia and Sweden.

1745, April 23. Peace of Fuessen, between the Queen of Hungary and Elector of Bavaria.

1745, December 25. Peace of Dresden, between Saxony, Prussia, and the Queen of Hungary, confirming the treaties of Berlin and Breslau.

1748, April 30. Preliminary articles for the Peace of Aix-la-Chapelle signed by the ministers of Great Britain, France, and Holland, to which the Queen of Hungary, the King of Sardinia, and the Duke of Modena shortly after acceded, and Spain and Genoa before the end of June; in September and October the definitive treaty was concluded and signed by the respective powers. By this peace the treaties of Westphalia in 1648, of Nimeguen in 1678 and 1679, of Ryswick in 1697, of Utrecht in 1713, of Baden in 1714, of the Triple Alliance in 1717, of the Quadruple Alliance in 1718, and of Vienna in 1738, were renewed and confirmed; the Hanoverian succession in Great Britain recognised; the Pretender to be expelled from France, and Dunkirk to be demolished.

1750, October 5. Treaty between England and Spain, by which England renounced the Assiento Contract for the supply of slaves, included in the peace of Utrecht, in 1713.

1756, January 16. Treaty of Alliance between Prussia and England. Hanover put under the safeguard of the King of Prussia.

1756, May 1. Alliance between Austria and France concluded at Versailles.

1757, September 10. Convention of Closterseven.

1761, August 15. The Family Compact between the different branches of the House of Bourbon, signed at Paris.

1762, May 5. Peace of Petersburg, between Russia and Prussia. Russia restored all her conquests to Prussia.

1762, May 22. Peace of Hamburg, between Sweden and Prussia.

1762, November 3. Preliminaries of peace signed at Fontainebleau, between France and England.

1763, February 10. Peace of Paris concluded between France, Spain, Portugal, and Great Britain. Cession of Canada by France, and of Florida by Spain.

1763, February 15. Peace of Hubertsberg, between Prussia, Austria, and Saxony. End of the Seven Years' War.

1768, February 24. Treaty of Warsaw, between Russia and Poland.

1771, January 22. Treaty between Great Britain and Spain, confirming the possession of the Falkland Islands to the former.

1772, February 17. Secret Convention for the Partition of Poland by Russia and Prussia.

1772, August 5. Treaty of Petersburg for the same object, between Austria, Russia, and Prussia.

1774, July 21. Peace of Kutchuk Kainarji, between Russia and Turkey. Crimea declared independent, Azof ceded to Russia, and freedom of commerce and navigation of the Black Sea granted.

1775, May 20. The American Provinces sign Articles of Union and Alliance.

1778, February 6. A Treaty ratified with the States of America, by France, who acknowledged their independence.

1779, May 13. Peace of Teschen ratified between Austria, Saxony, and Prussia.

1780, July 9 and August 1. First Conventions for the Armed Neutrality, between Russia, Denmark, and Sweden. December 24, the States-General acceded.

1781, May 8. King of Prussia accedes to the Armed Neutrality.

1781, October 9. The Emperor of Germany joins the Armed Neutrality.

1782, November 30. The Independence of America acknowledged by England, and preliminaries of peace signed at Paris between the British and American Commissioners.

1783, January 20. Preliminary articles of peace signed at Versailles, between Great Britain, Spain, and France.

1783, September 2. Preliminaries of peace between Great Britain and Holland, signed at Paris.

1783, September 3. Definitive Treaty of Peace between Great Britain and the United States of America, signed at Paris; when the latter was admitted to be a sovereign and independent Power. On the same day, the definitive treaty was signed at Versailles between Great Britain, France, and Spain.

1784, June 20. Definitive Treaty of Peace between Great Britain and Holland, signed at Paris.

1785, July 23. Germanic Confederation between Saxony, Brandenburg, and Hanover.

1785, November 8. The Treaty of Fontainebleau, between the Emperor and Holland.

1790, September 27. The preliminary treaty ratified with Spain, relative to Nootka Sound; and the definitive treaty signed October 28th following.

1791, July 20. Convention of Pilnitz, between the Emperor Leopold and the King of Prussia.

1792, June 26. The First Coalition against France took place, and the King of Prussia issued his manifesto.

1793, February 9. The Duke of Tuscany acknowledged the French Republic.

1793, May 25. Spain engaged to assist Great Britain.

1793. Great Britain concluded treaties, July 14, with Prussia; August 30, with Austria; and September 26, with Portugal.

1795, February 15. The first Pacification between the National Assembly of France and the Vendeans, concluded.

1795, February 18. A defensive Alliance entered into with Russia, by Great Britain.

1795, April 5. Peace of Basel, between the King of Prussia and the French Republic.

1795, May 16. Treaty of Alliance signed at Paris, between France and the United Provinces, against England. Dutch Flanders ceded to France.

1795, July 22. Peace ratified at Basel between France and Spain. Spanish St. Domingo ceded to France.

1795, November 25. The Partition of Poland took place between Russia, Austria, and Prussia.

1796, May 15. Treaty of Paris, between the French Republic and the King of Sardinia, the latter ceding Savoy, Nice, the territory of Tende, and Beuil, and granting a free passage for troops through his states.

1796, August 5. The Treaty of Berlin ratified between Prussia and France, whereby the neutrality of the north of Germany was guaranteed.

1796, August 19. An Alliance offensive and defensive concluded at St. Ildefonso, between France and Spain.

1797, February 19. Treaty of Tolentino, between the French Republic and the Pope.

1797, April 18. Preliminaries of the Peace of Leoben signed between Austria and France.

1797, October 17. Treaty of Campo Formio, between France and Austria, the latter power yielding the Low Countries and the Ionian Islands to France; and Milan, Mantua, and Modena, to the Cisalpine republic.

1797, December 9. Congress of Radstadt commenced its labours to treat concerning a general peace with the Germanic powers.

1798, December 29. A Treaty of Alliance and Subsidies, agreed upon between Great Britain and Russia, against France.

1799, June 22. The Second Coalition against France, by Great Britain, the Emperors of Germany and Russia, part of the German empire, the Kings of Naples and Portugal, Turkey, and the Barbary States. Conference of Radstadt broken up.

1800, June 20. A Treaty of Subsidies ratified at Vienna, between Austria and England, stipulating that the war should be vigorously prosecuted against France, and that neither of the contracting powers should enter into a separate peace.

1800, September 30. A Treaty of Amity and Commerce ratified between France and the United States of America. Stipulated in the treaty that the flag should protect the cargo.

1800, December 16. A Treaty of Armed Neutrality ratified between Russia, Denmark, and Sweden, at Petersburg, in order to cause their flags to be respected by the belligerent powers. Prussia afterwards acceded to this treaty.

1801, February 9. Peace of Luneville, between the French Republic and the Emperor of Germany, confirming the cessions made by the treaty of Campo Formio, stipulating that the Rhine, to the Dutch territories, should form the boundary of France, and recognising the independence of the Batavian, Helvetic, Ligurian, and Cisalpine republics.

1801, March 21. A Treaty signed at Madrid, between France and Spain, whereby the estates of Parma were yielded to France, who in return ceded Tuscany to the Infanta Prince of Parma, with the title of King of Etruria.

1801, March 28. A Treaty of Peace between France and the King of Naples, signed at Florence, by which France acquired the isles of Elba, Piombino, and Presides.

1801, June 17. A Treaty concluded between Great Britain and Russia at Petersburg.

1801, July 15. The Concordat between Bonaparte and Pius VII., signed at Paris.

1801, August 8. A Treaty of Peace concluded between Spain and Portugal.

1801, September 29. A Treaty of Peace signed at Madrid, between France and Portugal.

1801, October 1. Preliminary articles of peace between France and England, signed at London by Lord Hawkesbury and M. Otto.

1801, October 8. A Treaty of Peace ratified at Paris between the Emperor of Russia and the French government.

1802, March 25. Peace of Amiens, between Great Britain, France, Spain, and Holland.

1802, June 25. Definitive Treaty between France and the Ottoman Porte.

1803, August 1. A Treaty ratified between Great Britain and Sweden.

1805, April 8. The Treaty of Petersburg entered into for a Third Coalition against France; England and Russia being the contracting parties.

1805, August 9. The Emperor of Austria acceded to the Treaty of Petersburg.

1805, August 31. An Alliance offensive and defensive entered into at Beekaskog, between Great Britain and Sweden.

1805, September 8. Third Coalition against France, the parties being Great Britain, Russia, Austria, Sweden, and Naples.

1805, September 21. A Treaty of Neutrality signed between France and Naples.

1805, December 26. Peace of Presburg, between France and Austria, by which the ancient states of Venice were ceded to Italy; the principality of Eichstett, part of the bishopric of Passau, the city of Augsburg, the Tyrol, all the possessions of Austria in Suabia, in Brisgau, and Ortenau, were transferred to the Elector of Bavaria and the Duke of Wirtemberg, who, as well as the Duke of Baden, were then created kings by Napoleon; the independence of the Helvetic Republic was also stipulated.

1806, July 12. The Germanic Confederation of the Rhine formed under the auspices of Napoleon.

1806, July 20. Peace of Paris, between France and Russia, which Alexander subsequently refused to ratify.

1806, August 1. The Treaty of July 12 notified to the Diet at Ratisbon, when the German princes seceded from the Germanic empire, and placed themselves under the protection of Napoleon.

1806, October 6. The Fourth Coalition formed against France, by Great Britain, Russia, Prussia, and Saxony.

1806, November 21. The Berlin Decree, issued by Bonaparte after the battle of Jena, declaring the British Islands in a state of blockade, and interdicting the whole world from any communication with them.

1806, December 11. A Treaty of Peace and Alliance signed at Cosen, between Napoleon and the Elector of Saxony, who then assumed the title of king.

1806, December 31. A Treaty of Commerce entered into between Great Britain and the United States of North America, which the latter Power afterwards refused to ratify.

1807, July 7. Peace of Tilsit concluded between France and Russia, when Napoleon restored to the Prussian monarch one-half of his territories, and Russia recognised the Confederation of the Rhine, and the elevation of Napoleon's three brothers, Joseph, Louis, and Jerome, to the thrones of Naples, Holland, and Westphalia; this treaty was ratified on the 19th.

1807, October 31. A Treaty of Alliance entered into between France and Denmark.

1807, November 10. A Treaty ratified at Paris between France and Holland, whereby Flushing was ceded to the French.

1807, December 17. Milan Decree issued by Napoleon; England declared in a state of blockade.

1808, February 8. Treaty of Peace between Great Britain and Sweden.

1808, March 30. A Treaty of Alliance and Subsidy entered into between England and Sicily, whereby the latter was to be garrisoned by 10,000 British troops, and to receive an annual subsidy of 300,000*l*.

1808, May 5. Treaty of Bayonne, whereby Charles IV. ceded all his titles to Spain and its dependencies to Napoleon, expressly resigning to him the right of transmitting the crown to whomsoever he should think fitting.

1808, June 25. A Spanish Proclamation of Peace with England, and Sweden, her ally, published at Oviedo.

1808, August 30. The Convention of Cintra signed, the French agreeing to evacuate Portugal.

1808, November 5. The Convention of Berlin entered into, whereby Napoleon remitted to Prussia the sum due on the war-debt, and withdrew his troops from many of the fortresses in order to reinforce his armies in Spain.

1809, January 5. Peace ratified between Great Britain and the Ottoman Porte.

1809, January 14. A Treaty of Alliance ratified between England and the Spanish insurgents.

1809, April 9. The Fifth Coalition against France, by Great Britain and Austria.

1809, July 25. Armistice between Sweden and Norway.

1809, September 17. A Treaty of Peace signed between Russia and Sweden.

1809, October 14. Peace of Vienna, between France and Austria; Austria ceding to France the Tyrol, Dalmatia, and other territories, which were shortly afterwards declared to be united to France under the title of the Illyrian provinces, and engaging to adhere to the prohibitory system adopted towards England by France and Russia.

1810, January 6. Peace of Paris, between France and Sweden, whereby Swedish Pomerania and the island of Rugen were given up to the Swedes, who agreed to adopt the French prohibitory system against Great Britain.

1810, February 19. Treaties of Alliance and Commerce signed between Great Britain and the Brazils.

1810, April 19. The South American provinces of Caraccas, &c., form a federative government, under the title of the Federation of Venezuela.

1812, March 14. Treaty of Alliance signed at Paris between France and Austria.

1812, March 24. Treaty of Alliance, signed at St. Petersburg, between Bernadotte, Prince Royal of Sweden, and the Emperor Alexander; the former agreeing to join in the campaign against France, in return for which Sweden was to receive Norway.

1812, April 1. The Berlin Decree revoked as far as respected America.

1812, May 28. Preliminaries of peace ratified at Bucharest between Russia and Turkey, it being stipulated that the Pruth should form the limits of those empires.

1812, July 6. A Treaty of Peace between Great Britain and Sweden ratified at Orebo.

1812, July 20. Treaty signed between the Emperor Alexander and the Regency of Cadiz, in the name of Ferdinand the Seventh of Spain.

1812, August 1. Treaty of Peace and Union ratified at St. Petersburg between Great Britain and Russia, renewing their ancient relations of friendship and commerce.

1813, January 25. Concordat at Fontainebleau, between Napoleon and Pius VII.

1813, March 1. The Sixth Coalition entered into between Russia and Prussia against France, the treaty being ratified at Kalisch.

1813, March 3. The Treaty of Stockholm entered into between England and Sweden.

1813, June 14. A Treaty of Alliance concluded between Great Britain, Russia, and Prussia.

1813, July 8. The Convention of Peterswalden, between Great Britain and Russia.

1813, July 10. A reciprocal Treaty of Alliance and Guarantee between France and Denmark, ratified at Copenhagen.

1813, September 9. A Triple Treaty of Alliance ratified at Toplitz between Russia, Austria, and Prussia.

1813, October 3. A preliminary Treaty of Alliance signed at Toplitz between Austria and Great Britain.

1813, December 8. Treaty of Valençay, between Napoleon and Ferdinand the Seventh of Spain, whereby the latter was to be put in full possession of that kingdom, on agreeing to maintain its integrity.

1814, January 14. Treaty of Kiel, between Great Britain, Sweden, and Denmark. Norway ceded to Sweden.

1814, February 5. The Cortes of Spain renounce the treaty ratified at Valençay.

1814, February 5. Congress of Chatillon, between the four great powers allied against France, at which Caulaincourt attended on the part of France; the Congress broke up on the 19th of March.

1814, March 1. Treaty of Chaumont, between Great Britain, Austria, Russia, and Prussia.

1814, April 11. The Treaty of Paris ratified on the part of Napoleon and the Allies, by which Napoleon renounced his sovereignty over France, &c., stipulating that the island of Elba should be his domain and residence for life, with a suitable provision for himself and Maria Louisa, who was to have vested in her the duchies of Parma and Placentia, the same to descend to her son.

1814, April 23. A Convention signed at Paris between the Count d'Artois on the one part, and the Allied Powers on the other, stipulating that all hostilities should cease by land and sea; that the confederated armies should evacuate the French territory, leaving its boundaries the same as they were on the 1st of January, 1792.

1814, May 30. Peace of Paris ratified between France and the Allied Powers, in a supplemental article of which Louis XVIII. stipulated that he would exert his endeavours with the continental powers to ensure the abolition of the slave-trade, in conjunction with Great Britain.

1814, July 20. A Treaty of Peace signed between France and Spain at Paris, confirming the stipulations of previous treaties which had existed on the 1st of January, 1792.

1814, August 13. Convention between Great Britain and the Sovereign Prince of the Low Countries respecting the Dutch colonies.

1814, September 28. A Convention ratified at Vienna, whereby Saxony was placed under the control of Prussia.

1814, December 24. Peace of Ghent, between Great Britain and the United States of America.

1815, March 23. Treaty of Vienna, between Great Britain, Austria, Russia, and Prussia, confirming the principles of the treaty of Chaumont, March 1, 1814, on which they had acted; and uniting Belgium to the Netherlands under the sovereignty of the king of the Netherlands.

1815, May 18. Peace ratified between Saxony and Prussia.

1815, May 20. A Convention signed at Zurich between the Swiss Diet and the plenipotentiaries of Great Britain, Austria, Russia, and Prussia.

1815, May 31. Treaty of Vienna, between the King of the Low Countries on the one part, and Great Britain, Russia, Austria, and Prussia on the other, agreeing to the enlargement of the Dutch territories, and vesting the sovereignty in the House of Orange.

1815, June 4. Treaty of Vienna. Denmark cedes Swedish Pomerania and Rugen to Prussia, in exchange for Lauenburg.

1815, June 8. Federative Constitution of Germany signed at Vienna.

1815, July 3. Convention of St. Cloud, between Marshal Davoust on the one part, and Wellington and Blücher on the other, by which Paris was surrendered to the Allies, who entered it on the 6th.

1815, August 2. A Convention signed at Paris between Great Britain, Austria, Russia, and Prussia, styling Napoleon the prisoner of those powers, and confiding his safeguard particularly to the British government.

1815, September 14. A Convention entered into at Vienna, whereby the duchies of Parma, &c., were secured to the Empress Maria Louisa, and on her demise to her son, by Napoleon.

1815, September 26. The Treaty denominated of the Holy Alliance, ratified at Paris by the Emperors of Austria and Russia, and the King of Prussia.

1815, November 5. A Treaty ratified at Paris between Great Britain and Russia respecting the Ionian Islands, which were declared to form a united state under the sole protection of the former power.

1815, November 20. Peace of Paris, between France on the one part, and Great Britain, Austria, Russia, and Prussia on the other, establishing the boundaries of France, and stipulating for the garrisoning of several of the fortresses in France by foreign troops for three years.

1815, November 20. The Treaty of Paris executed between Great Britain, Russia, Austria, and Prussia, confirming the treaties of Chaumont as well as those of Vienna.

1816, March 13. A Treaty entered into between France and the Swiss Cantons, whereby 12,000 Swiss troops were admitted into the French service.

1817, June 10. Treaty of Paris, between Great Britain, France, Spain, Russia, and Prussia, in order to fulfil the articles of the Congress of Vienna.

1818, April 25. A Convention signed at Paris between France and the Allied Powers, releasing France from all debts referred to in the treaties from the 30th May, 1814, to the 20th November, 1815.

1818, April 25. A Convention ratified at Paris between England and France, whereby the latter power undertook to liquidate all further demands on the part of British subjects.

1818, May 4. A Treaty ratified between Great Britain and the Netherlands for abolishing the slave-trade.

1818, October 9. A Convention entered into by the great powers of Europe, assembled at Aix-la-Chapelle, on the one part, and the Duke de Richelieu on the other, whereby it was stipulated that the army of occupation should quit the French territory on the 30th of November ensuing; it was also agreed that the remaining sum due from France to the Allies was 265,000,000 francs.

1819, August 1. Congress of Carlsbad.

1820, October 20. Congress of Troppau.

1820, October 24. Treaty between Spain and America: Florida ceded to the United States.

1821, May 6. The Congress of Laybach, which had been for some time attended by the sovereigns of Austria, Russia, and Prussia, finally broke up, having issued two circulars stating it to be their resolution to occupy Naples with Austrian troops, and proscribe popular insurrection.

1822, August 25. Congress of Verona.

1824, February 4. A Convention between Great Britain and Austria laid upon the table of the House of Commons, by which the former agreed to accept 2,500,000*l.* as a final compensation for her claims upon the latter power, amounting to 30,000,000*l.*

1824, June 16. Commercial Treaty between Great Britain and Denmark.

1825, February 2. Treaty of Commerce signed at Buenos Ayres between Great Britain and the United Province of Rio de la Plata.

1825, February 28. Convention between Great Britain and Russia; frontier of north-west coast of America settled.

1825, April 17. France recognises the independence of St. Domingo.

1825, April 18. Treaty of Amity between Great Britain and Columbia.

1825, September 20. Commercial Treaty between Great Britain and Hanse Towns.

1825, October 18. Treaty between Great Britain and Brazil for abolition of slave-trade.

1826, January 26. Treaty of Navigation between Great Britain and France.

1826, May 19. Treaty of Navigation between Great Britain and Sweden.

1826, September 4. Treaty of Akermann, between Russia and Turkey, respecting the Principalities of Moldavia and Wallachia.

1826, November 13. Convention concluded between Great Britain and the United States, concerning indemnities to American subjects injured by the war.

1828, February 22. Peace of Turkmanchay, between Russia and Persia. Erivan and the country to the Araxes ceded to Russia.

1828, June 26. Convention between Great Britain and Spain for satisfying claims of British merchants.

1828, August 29. Treaty of Peace between Brazil and Buenos Ayres, at Rio Janeiro.

1828, October 28. Peace between Naples and Tripoli.

1829, July 6. Treaty of London, between Russia, France, and Great Britain, for the settlement of the affairs of Greece.

1829, September 14. Peace of Adrianople, between Russia and Turkey, by which Russia acquires the protectorate of Moldavia and Wallachia.

1830, May 7. Treaty between Turkey and the United States. American vessels allowed to pass to and from the Black Sea.

1830, November 2. The independence of Belgium recognised by England and France.

1831. The commercial union of the northern states of Germany, known as the Zollverein, commenced under the auspices of Prussia.

1831, November 15. A Treaty signed between Great Britain and France, for a settlement of the points of dispute between Holland and Belgium, to which Holland acceded March 13, 1838.

1833, July 8. Treaty at Constantinople between Turkey and Russia, by which it was stipulated that the Dardanelles should be shut to all foreign vessels of war.

1834, April 22. Quadruple Treaty between Great Britain, France Spain, and Portugal, in support of the two queens, Isabella and Maria.

1835. Supplementary Treaties with Portugal and Spain, by the former of which the Methuen Treaty with Portugal was annulled.

1837, November 16. Treaty at the Hague with Holland, by which discriminatory duties on the ships and cargoes of Great Britain and Holland are respectively abolished.

1838, July 3. A Commercial Treaty between Great Britain and Austria, signed at Vienna.

1838, November 16. A Commercial Treaty concluded in London between Turkey and Great Britain.

1840, July 15. Treaty signed in London between Great Britain, France, Austria, Russia, Prussia, and Turkey, for the settlement of the dispute between Turkey and Mehemet Ali.

1841, June 15. Treaty between Great Britain and Denmark relative to the passage of the Sound.

1841, July 13. Convention at London, between the European Powers and Turkey, by which the closing of the Dardanelles against ships of war is made general to them all while Turkey is at peace.

1842, August 29. Treaty of Nankin with China, by which several ports were opened to the British trade, Hong-Kong ceded, and an indemnification of 21,000,000 dollars paid.

1844, July 22. Treaty between Great Britain and Hanover for the regulation of the Stade Duties.

1844, September 2. Treaty between Belgium and the German States parties to the Zollverein.

1845, May 29. A Convention signed in London between Great Britain and France for the suppression of the Slave Trade.

1845, June 25. Treaty of Commerce for ten years ratified between Great Britain and the Two Sicilies.

1846, November 16. Austria, Russia, and Prussia revoke the treaty of 1815, constituting Cracow a free republic, and restore the territory to Austria. Soon after the kingdom of Poland is incorporated with Russia. Great Britain, France, Sweden, and Turkey unite in a protest against these proceedings.

1849, August 6. Treaty of Milan, between Austria and Sardinia.

1850, February 27. Treaty at Munich between Austria, Bavaria, Saxony, and Würtemberg, to form a Southern German Union against the pretensions of Prussia.

1850, April 19. Treaty at Washington between Great Britain and the United States, respecting a ship-canal through the state of Nicaragua, to connect the Atlantic and Pacific Oceans.

1850, July 2. Treaty of Peace between Prussia and Denmark, Prussia withdrawing from the support of the duchies of Holstein and Schleswig; and on July 4 a protocol was signed in London between Great Britain, France, Prussia, and Sweden, guaranteeing the integrity of the Danish territories.

1852, April 6. Coalition at Darmstadt between Saxony, Bavaria, Würtemberg, Baden, Nassau, and the two Hesses, against the renewal of the Zollverein, except Austria be admitted into the Union.

1853, February 18. Treaty at Washington between Great Britain and the United States, for an international copyright.

1853 February 19. Commercial Treaty signed at Berlin between Austria and Prussia, for twelve years.

1853, December 3. Protocol signed at Vienna by Great Britain, France, Austria, and Prussia, for the maintenance of the integrity of the Ottoman empire, and for the restoration of peace between her and Russia.

1854, March 12. Alliance of Constantinople, between Great Britain, France, and Turkey, against the hostilities of Russia.

1854, April 20. Treaty of Berlin, between Austria and Prussia, for the mutual defence of their respective territories, and of Germany; and against Russia, should that power cross the Balkan.

1854, June 7. Treaty at Washington between the United States and Canada, by which the British-American coast-fisheries are thrown open to the United States fishermen, the navigation of the St. Lawrence and the Canadian lakes declared free, and the products of the two countries (except sugar and tobacco) reciprocally exempted from duty.

1854, December 2. Treaty of Alliance signed at Vienna between Great Britain, France, and Austria.

1855, January 10. Sardinia joins the Alliance of Great Britain and France against Russia, agreeing to send a contingent force to the Crimea.

1855, November 9. An international copyright treaty concluded with Prussia.

1856, February 1. Protocol signed at Paris by the plenipotentiaries of Russia, and those of Great Britain, France, Austria, and Turkey, for a peace between those powers.

1857, March 3. Treaty of Peace signed at Paris between Great Britain and Persia.

1857, March 14. Treaty between Denmark and the principal states of Europe, for the abolition of the Sound dues; signed at Copenhagen.

1857, May 26. Treaty signed at Paris by the great European Powers, for the settlement of the dispute between Prussia and Switzerland relative to Neufchâtel.

1858, June 26. Treaty of Tien-tsin with China, by which intercourse with the interior of China was stipulated for, several additional ports were opened to British commerce, and a British ambassador admitted to reside at Pekin.

1858, August 20. Convention signed at Paris, constituting Moldavia and Wallachia independent principalities, under the suzerainty of Turkey.

1858, August 26. Commercial Treaty between Great Britain and Japan, signed at Jeddo.

1860, February 11. Commercial Treaty between Great Britain and France, published in the 'Moniteur.'

1860, March 24. Treaty between France and Sardinia, signed at Turin, by which Savoy and Nice are ceded to France.

1860, July 11. Peace of Villa Franca, between France and Austria, by which Lombardy is transferred to Sardinia, and a confederation of Italian States, under the protection of Austria, stipulated for. This treaty was formally ratified at Zurich on Nov. 11.

1860, October 24. Ratification of the Treaty of Tien-tsin, and a new peace with China, signed at Pekin; China paying an indemnity for the expenses of the allies and the losses of the British merchants.

1861, May 1. Commercial Treaty between France and Belgium.

1861, May 15. Commercial Treaty between Great Britain and Turkey, signed at Constantinople.

There are several voluminous collections of treaties, of which one of the most complete is that of G. F. von Martens, who continued the works of Du Mont and Rousset, of which the first volume was published in 1790. A preliminary account of all preceding printed collections was published by him in 1802. Successive supplements, by different editors, have brought down the account of the various treaties to a very recent period. The collection of C. W. Koch, in 15 vols. 8vo, is a useful one, but does not come down so late.

TREES, LAWS RELATING TO. [TIMBER.]

TRENCH, in military works, is an excavation in the ground from twelve to eighteen feet wide, and three feet deep, and generally of considerable length, the earth being thrown up on one side in order to form a sort of parapet by which the soldiers in the trench may be covered from the view, or protected from the fire of the enemy. [SAP; SIEGE.]

TRENT, COUNCIL OF (*Concilium Tridentinum*), was first convoked by a bull of Pope Paul III., dated May, 1542, but the war between the Emperor Charles V. and Francis I. of France, together with the negotiations then being carried on between the emperor and the German princes who had embraced the Protestant faith, prevented its installation until December 13, 1545: even then only four archbishops, twenty bishops, five heads of monastic orders, three papal legates, and an auditor, besides the imperial orators or envoys, were present; but other prelates afterwards gradually joined the assembly. After arranging some preliminary difficulties, the council proceeded to consider the two great objects for which it had been convoked—the definition of the dogmas of faith and the condemnation of heresies, and the reform of the church in matters of discipline and jurisdiction. The German bishops, supported by the envoys of the emperor, urged that the labours of the council should begin with the business of reform, as it was the relaxation of discipline that had first occasioned the present schism in the church, and that the only chance of reclaiming the seceders was to manifest an earnest will to reform abuses before proceeding to condemn them and their tenets; that if the council did not take in hand speedily the work of church reform, the lay powers would take it up themselves, to the manifest injury of the ecclesiastical authority. The bishop prince of Trent spoke at length on this side, as, being on the threshold of Germany, he was acquainted with the state of opinions in that country; and the majority of the prelates seemed to incline to his opinion. The papal legates, however, supported by the Italian prelates, were of opinion that the council should begin with defining the dogmas, as that was the highest task, and ought to be first attended to, because faith is the foundation of all moral virtues; that the outcry about reform was well known to be mainly directed against the court of Rome and its jurisdiction, and was an indirect attack upon the authority of the sovereign pontiff, towards whom it would be more reverent to leave him the initiative in correcting the abuses of his own court, while the council was attending to the graver questions of religion, otherwise dissensions would arise between the head and body of the church, only to the advantage and satisfaction of heretics. At last, in order to conciliate all parties, it was resolved that the two departments of doctrine and discipline should be proceeded with simultaneously; that for every sitting congregation engaged in discussions on dogma, there should be another concerning the reform of discipline; and this resolution was at last agreed to by the pope.

The council, at the beginning of its regular session, undertook to define first of all what were the sources of authority in matters of faith. It declared that the Catholic doctrines are contained in the authentic books of the Old and New Testaments, and also in the traditions concerning faith and morals which are preserved in the Catholic Church. This was a condemnation of Luther's assertion that all the doctrine of the Christian faith is contained in the Scriptures, and that unwritten tradition is not to be held as authority.

The council next proceeded to define the dogmas of faith, such as those of original sin, predestination, grace, and free will, the definition of which may be seen in the catechism published by the name of 'Catechismus ad Parochos,' or 'Catechism of the Council of Trent,' which is translated into most languages.

The council next propounded the doctrine of the church concerning the sacraments, which they stated to be seven in number, namely, baptism, confirmation, the eucharist, confession or penitence, extreme unction, ordination, and matrimony; and afterwards they proceeded to treat of each of them seriatim, laying down the orthodox doctrine and anathematising the discordant tenets of the Lutherans, Zwinglians, and other heretics. At the same time the council proceeded with discussions on subjects of discipline and reform. The question of pluralities proved a most difficult one to settle. The Spanish bishops made a strong remonstrance against the abuses of pluralities and non-residence, and wished the council to pass at once severe decrees against both. The legates proposed that the pope should take into his own hands the task of reform, and they wrote to Rome accordingly, and the pope directed a bull to the council by which he referred the matter to himself. This bull met with great opposition, and was a source of misunderstanding between Rome and the council. At last, in March, 1547, the legates suddenly closed the session, which was reckoned the seventh since the opening of the council, and in virtue of the authority they held from the pope they transferred the council to Bologna, under the plea that a contagious disorder had broken out in the city of Trent. The majority of the prelates assented; but there were eighteen bishops, chiefly of the dominions of the emperor, who refused to leave Trent. The others followed the legates to Bologna, where, after opening the session, the council was adjourned *sine die*. Charles V. protested against the meeting of Bologna, which he did not acknowledge as a council, and insisted upon the council being restored to Trent.

In 1549 Pope Paul III. died, and his successor Julius III. again convoked the council at Trent, in May, 1551. Not many prelates attended. The council of Trent proceeded to define the doctrine of transubstantiation, the Lord's Supper, and the mass, and afterwards that of confession and the other sacraments. At the same time decrees were made concerning points of discipline, touching the episcopal jurisdiction, the appeals to Rome, and other such matters. In 1552 the pope prorogued the council, and this prorogation was continued for ten years, during which period three popes died in succession,—Julius III., Marcellus II., and Paul IV. At last Pius IV. being elected, began to think seriously of re-opening the general council, of which the church seemed to stand more in need than ever.

In 1561 the Fathers gathered again at Trent, and on the 18th of January, 1562, the session was solemnly opened. One hundred and twelve, consisting of archbishops, bishops, and mitred abbots, were present, besides the cardinals. The orators of the various states were also present. After very lengthened discussions on various subjects, and some interruptions from political causes, the council, in July, 1563, issued its canon on the subject of residence. Without entering into the question of divine right, it enjoined all bishops, archbishops, and cardinals having the charge of a see or cathedral church, to reside personally in their respective cathedrals throughout the year, and more especially during the Lent, Advent, Christmas, Easter, and other solemn festivals, except in cases of urgent necessity, through motives of Christian charity, or "for the evident advantage of the church or commonwealth," and then not without the written approbation of the pope or of the metropolitan. The same decree was extended to incumbents of parishes.

The council issued a canon concerning the doctrine of the institution of bishops. It stated that there is a hierarchy in the church, instituted by divine ordination, and consisting of bishops and presbyters and other ministers; that bishops are superior to presbyters, and have the power of ordaining and confirming, which is not given to the others; that the only legitimate bishops are those ordained by the pope or by other ecclesiastical and canonical authority.

The council next laid down the doctrine of the Catholic Church concerning marriage, which it reckons as one of the sacraments. Among other articles on this subject, it condemns polygamy as contrary to divine law; it forbids persons in holy orders contracting marriage; and it states marriage to be indissoluble, even after the adultery of one or both of the parties.

On the important question of clandestine marriages,—that is to say, marriages contracted before witnesses without the intervention of the parish priest,—the council decreed that in future no marriage should be considered valid which was not contracted before the parish incumbent or before another clergyman duly deputed by the incumbent, or by the ordinary, and in presence of at least two witnesses besides, and that their names, as well as the names of the married parties, and the date of the celebration of the marriage, should be entered into a register to be kept by every parish incumbent. The council explained also what were the cases of relationship and other canonical impediments to the contracting of marriages; and although it did not condemn altogether the practice of dispensations being granted by the pope in particular instances, it recommended that such dispensations should be granted rarely, gratuitously, and on proper and sufficient grounds.

Hitherto the secular princes had insisted upon reforms of the church and clergy; now the pope and court of Rome urged the council to make reforms affecting the princes and their courts. According to instructions received from Cardinal Borromeo, the pope's minister at Rome, the legates laid before the assembly several motions, chiefly in support of the ecclesiastical immunities. The following were among the principal heads:—That churchmen should not be summoned before the lay courts. That the lay courts and magistrates should not interfere in cases of matrimony, heresy, tithes, patronage, patrimonial benefices, ecclesiastical fiefs, the temporal jurisdiction of churches, nor in any cause, civil, criminal, or mixed, pertaining to the ecclesiastical courts. That churchmen should not be liable to pay taxes, tenths, forage, or subsidies of any sort, either on the property of the church or on their own patrimonial property. That the property of the church, moveable and immoveable, of every sort, tithes and other rights, should be held as sacred from the hands of the lay powers. That all letters, citations, sentences, and excommunications, from the ecclesiastical courts, or from Rome, should be promulgated and executed without requiring any exequatur or permission from the civil power. That neither emperor nor king, nor any other prince, should interfere with the said courts or with the tribunal of the Inquisition, but should, when required, give them the assistance of the secular arm.

The above demands put forth by the legates raised a storm on the head of the council. The Emperor Ferdinand and Charles IX. of France protested against any such proceedings, and the pope directed his legates to withdraw the obnoxious motions, and to content themselves with a general admonition to all Christian princes, which was adopted by the council, exhorting them to respect and cause to be respected the rights and immunities of the church, and the constitutions of the popes and councils in favour of ecclesiastical persons and ecclesiastical liberties. But the obnoxious principles started by the legates of Pius IV. were revived by his successor Pius V., and promulgated by him in the famous bull "In Cœna Domini."

The council now drew to its conclusion. A number of canons concerning doctrine as well as discipline were passed; other minor points were referred to the decision of the pope. The doctrine of purgatory and indulgences, and of the benefit derived to the departed souls from the prayers of the living, were confirmed. The invocation of the saints who intercede with God on behalf of men, and the veneration for their relics, were likewise adopted. The images of Christ and the saints were to be retained and venerated in the churches for the sake of those whom they represent, at the same time that no meretricious ornament or other sensual enticement was to be mixed with the devotional practices. Severe penalties were decreed against churchmen having concubines, against simony, against pluralists of livings with cure of souls, and against duellists. Several regulations were made for the proper examination and selection of candidates to vacant sees, or to livings with cure of souls. The bishops were enjoined to make a visitation of their dioceses once every year with a modest train and retinue, and they, as well as the parish incumbent, to preach every Sunday and other solemn festivals. No one was to be appointed to a benefice with cure of souls under twenty-five years of age. Criminal charges against a bishop to be judged by the Roman pontiff. Provincial synods to meet once every three years, and diocesan synods every year.

These and other canons being passed, in the beginning of December, 1563, it was agreed that the council should be closed. The acts of the council were then authenticated by the notaries, and by the secretary of the council, and signed by the fathers to the number of 255, namely, 4 legates and 2 other cardinals, 3 patriarchs, 25 archbishops, 168 bishops, present; 39 proxies, 7 abbots and 7 generals of monastic orders. The acceptation of the ambassadors was then requested and given, except the ambassador of Philip of Spain, who by order of his king opposed the closing of the council, and the ambassadors of France, who had left Trent in dudgeon.

Pope Pius IV., in solemn consistory, on the 26th of January, 1564, confirmed the acts of the council by a bull countersigned by the cardinals. All the Roman Catholic states accepted the council, and promulgated it in their states, with the exception of France, which persisted in those assertions of jurisdictional independence of its church and king, which were afterwards embodied in a regular form by the assembled French clergy in 1682.

Two distinguished Roman Catholic writers have written professedly the history of the council of Trent, its proceedings and acts: one, the famous Frà Paolo Sarpi, displays at times a feeling hostile to the court of Rome; the other, Cardinal Sforza Pallavicino, on the contrary, writes in a tone of perfect submission to the Roman see. By comparing the two works, readers are enabled to come to something like a fair understanding of the labours and the merits of that memorable assembly.

TREPAN. [TREPHINE.]

TREPHINE is a kind of saw employed in surgery for the removal of a circular portion of bone. For this purpose it is used in various cases, such as diseases requiring perforation of the antrum, necrosis with loose enclosed sequestra, abscesses in bone or under bones, &c.; but especially in injuries of the head and their various consequences, for which the removal of a portion of the skull is deemed necessary.

The trephine is now commonly employed in this country instead of a somewhat similar instrument, the trepan, which was formerly used by all surgeons, and is still frequently used on the Continent. The trepan is very like the tool called a wimble, which is used by coopers for boring holes for large corks, and is worked in the same way, with a curved rotating lever under the handle; but instead of the share-like cutting edge of the wimble, the trepan has a circular saw, which, being rotated with the lever, cuts its way through the bone.

The trephine is a smaller and more simple, but, in other respects, not more convenient instrument. Its handle is like that of a gimlet, but stronger. The shaft is terminated below by a sharp steel point, called the centre-pin, which may be fixed and removed at pleasure, and which stands in the centre of the circle formed by the saw. The purpose of the centre-pin, which projects a little below the edge of the saw, is to fix the trephine before the working of the saw; and it is kept in its place till the saw has cut a groove sufficiently deep to steady it in its further working. After this the centre-pin should be removed, for it hinders the action of the saw, and (in trephining the skull) would perforate the dura mater before the saw had cut through the bone. Around the handle of the trephine, at a short distance above the part to which the centre-pin is fixed, there is attached a hollow steel cylinder, the lower margin of which is a saw. This is called the crown of the trephine, and, for various purposes is of different sizes.

In using the trephine, the saw is made to cut through the bone, not by a series of complete rotations, such as are made by the trepan, but by rapid half-rotations alternately to the right and to the left, as in boring with an awl. In trephining the skull various cautions are necessary, according to the form of the bone to be cut through, and the nature of the parts immediately beneath it; but the most comprehensive rule is to examine frequently what progress the saw makes, and, if it have cut through one part of the circle much sooner than the rest, to apply it somewhat obliquely, taking off the pressure of its edge from that part. The most dangerous part of the operation is when the bone is nearly cut through; for it is necessary to avoid wounding the dura mater, injuries of which are often followed by severe disease. To escape these, it is advisable when a part of the circle is cut through, and but a thin plate of bone remains in the rest of its extent, to break through this by an elevator or proper forceps. And if, after using either of these instruments, sharp points of bone are left projecting from the margin of the circular aperture, these must be carefully cut or broken off.

The use of the trephine is now much more rarely required than in former times; and this, not only because, since the time of Mr. Pott, surgeons have learned that it is beneficial in few injuries of the head beyond those in which there are distinct signs of compression of the brain, but also because, in many of the cases in which it is necessary to remove portions of bone, the instrument called Hey's saw is far more convenient. This consists of a handle and a shaft, much like those of a common fork, of which the latter has fixed to its end a transverse broad plate of steel, one end of which is a straight, the other a convex saw. With this, portions of bone of almost any form and size can be cut out both more easily and more rapidly than is possible with the trephine. It is especially useful in those cases of fracture of the skull in which angles of the broken bone are depressed, and for which the trephine used to be applied chiefly for the purpose of introducing the elevator; for in these the depressed portion itself may be cut off, and the elevator may, if necessary, be introduced at the aperture which is thus made.

TRESPASS is a wrong directly done to the person, to the goods and chattels, or to the lands and tenements of any man.

To the person it may be by menace, assault, battery, or maiming. [ASSAULT.] To either dead or live chattels, by taking them away or by injuring them. To land and tenements, by entering upon them and injuring them. Trespass is the action by which a person in the actual and exclusive possession of property is protected against the forcible interference with it by those who are not entitled to it. By this action also he may recover damages for the injury done to his possessions.

To constitute trespass, the act done must be wilful, not the result of negligence, and have something of force in it, so as to be, according to the construction of the law, against the peace; and the injury must be the immediate, not the consequential result of the act. This is rendered very intelligible by the instance given (1 Strange, 636): "If a man throw a log into the highway, and in that act it hits me, I may maintain trespass, because it is an immediate wrong; but if, as it lies there, I tumble over it, and receive an injury, I must bring an action on the case." But it is not necessary that it should be done with the design to cause the injury complained of, it may be done in mistake or ignorance. Thus where one shooting at a mark hits a bystander, he is guilty of trespass. A sheriff commits an act of trespass if he takes the goods or arrests the person of B, mistaking him for A. A man is liable in trespass for the injury done by his cattle to the land of another, whether he knew of their doing it or not. In trespass, all persons who assist in the act done, or cause it to be done, or, if it is for their use, assent to it afterwards, are considered as principals, although not actually present at the doing of the act. Where an act is done by a servant while in the discharge of his business as servant, the master is liable for the act in trespass. But if it be wilful on the part of the servant, and not in discharge of his master's business, the master is not liable.

Where a person has an authority or licence given him *by law*, and he takes advantage of that to commit an act of trespass, he is held to have been a trespasser from the very commencement of the proceedings: as where a landlord lawfully distrains a beast and afterwards works or kills it, or an officer of the customs entitled to search "unpacks stuffs and puts them in the dirt." If, however, the licence or authority has proceeded from a private party, the trespass does not relate back, but is confined to the mere act itself: as where parties enter a tavern, drink and pay for wine, and afterwards commit a trespass—that will not make their entry a trespass. In cases where a trust is reposed, trespass will lie for an act which is at variance with the trust, as where a lessee at will cuts down the timber.

Various circumstances may exist which afford a justification for an act which otherwise would amount to trespass. Thus a man is not liable in trespass though his cattle have entered the field of another, if they have done so in consequence of the neglect of the party into whose lands they enter to repair the fences between the lands of the parties; though it is no justification that the cattle have entered because the land was open to the highway. Again, a man is justified in entering upon the lands of another to retake his goods which have been carried there by the occupier of those lands; or to carry away goods bought of the occupier, to repair a watercourse granted to him, &c. He is also justified in pulling down, for the safeguard of his own, his neighbour's house which is on fire. Where an act amounts to a felony it is not competent for the party injured to treat it as a trespass. (Comyn's 'Dig.,' 'Trespass.')

In the case of malicious injuries done to property by trespassers, a number of provisions have been enacted by 7 & 8 Geo. IV., c. 30. In many cases a jurisdiction is given to magistrates to inflict punishment on the offenders, to award compensation to the parties injured, &c.

TRET. [TARE.]

TRIADS. [WELSH LANGUAGE AND LITERATURE.]

TRIAL, the means adopted for the purpose of ascertaining facts in issue, whether civil or criminal. The kinds of trial in civil cases were formerly seven in number, according to Blackstone; and those which he enumerates are, by record, by inspection or examination (divided into two distinct kinds by Comyns), by certificate, by witnesses, by wager of battle, by wager of law, and by jury. In reality the six first might more properly be called modes of proof rather than kinds of trial, which in truth divide themselves into two classes only: 1. That where the court itself decides upon the evidence without the intervention of a jury: 2. That where the jury decides.

The first class contains the first six enumerated by Blackstone; that *by record* is where the existence of a certain record has been alleged in the pleadings of an action and is denied by the pleadings on the other side. The existence of it must be proved by the record itself. The court itself tries this issue, and decides accordingly as such a record is, or is not produced. [RECORD; RECORDS.]

Questions whether or not a party is a peer are thus proveable by the king's patent; whether an alien is friend or enemy, by production of the treaty between his country and Great Britain, &c.

By inspection was where it was supposed a matter might be clearly made manifest on view to the court. In error by an infant, to reverse a fine, if issue was taken as to his nonage, he might be brought into court and there inspected for the purpose of ascertaining the fact. If on his appearance it remained doubtful, the court might question him, or examine those likely to be informed. So where a defendant pleaded in abatement that the plaintiff was dead, and some one appeared and said that he was the plaintiff, &c. The court had at all times the power, if they felt doubt, to order a trial by jury. This mode of proceeding has now become obsolete.

By *examination* is upon inquiry by the court into, for instance, the customs and usages of a court.

By *certificates*. By certificate is where a fact is proved by the production of a certificate from a certain official person qualified to grant such certificate. Thus formerly the absence of a person from England during war might be tried by the court, and proved by a certificate of the "mareshal of the king's host." In the same manner the customs of the city of London are proved by the certificate of their recorder. A certificate of a bishop is proof respecting matters of ecclesiastical jurisdiction, &c.

By *witnesses*. In action of dower where the tenant pleads that the husband is alive, the court may inquire of the fact by witnesses called before themselves. Lord Coke mentions several other cases where the court itself decides upon the examination of witnesses; and he further states that in all such cases each fact must be proved by two witnesses at least. Although in the case of a trial by jury one witness, according to the English law, is sufficient.

By *wager of battle*. That is by single combat between the champions of the parties. [APPEAL.] This proceeding was abolished by 59 Geo. III. c. 46.

The proof by *wager of law* was employed in an action of debt upon simple contract, of detinue, account, and some others. It was effected by the defendant coming into court attended by eleven of his neighbours who were called compurgators. He then solemnly swore that he did not owe the sum with which he was sought to be charged, or detain the thing sought to be recovered, and the eleven compurgators swore that they believed him. The wager of law had already fallen into disuse when it was wholly abolished by 3 & 4 Will. IV., c. 42.

The mode of trial always the one most in use both in civil and criminal matters, was the trial by jury. [JURY.]

In criminal cases recourse was anciently had to the ordeal for the purpose of ascertaining the guilt or innocence of a party [ORDEAL], and also to the single combat. [APPEAL.] It appears doubtful whether the ordeal fell into disuse, or was abolished by statute. Appeals in criminal cases were done away with by 59 Geo. III., c. 46.

A peer of Great Britain indicted capitally is entitled to be tried by the peers of parliament assembled in the court of the Lord High Steward of Great Britain, who is a peer nominated to that office by the crown for the occasion. The proceedings of the trial are carried on in the same way as on a trial by jury, and judgment is pronounced according to the opinion of the majority, which must consist of at least twelve. Cases of impeachment by the Commons are also tried by the Lords.

A trial at bar resembles the ordinary cases of trials by jury, except that instead of its being presided over by a single judge, all the judges of the court in which the action is brought are in attendance. It is granted on application to the court, but only in cases of great difficulty and importance. In informations exhibited by the attorney-general, as law-officer of the crown, he is entitled to a trial at bar.

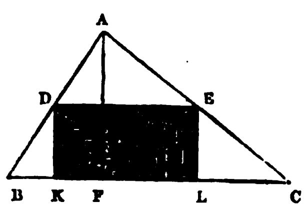
New Trial. After a trial has been already had, it is competent to the court in which the action is brought to grant a new trial on an application made, and grounds shown for supposing that justice has not been done between the parties; and that the case is of sufficient importance to warrant such a further expense. These grounds are various, such as a misdirection by the judge, a verdict against evidence, excessive damages, &c.

TRIAMYLAMINE. [ORGANIC BASES.]

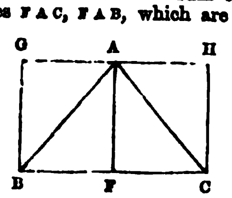
TRIANGLE, a figure having three angles, and consequently three sides: this consequence is usually made the definition; and the same thing occurs in Euclid, whose word is τρίγωνον in the Elements, though it is τρίπλευρον in the definitions prefixed.

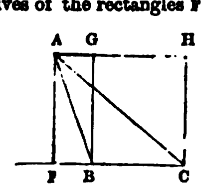
A triangle may be drawn upon any surface, and having any sort of lines for its sides: but it is not usual to consider any except *plane* triangles drawn on a plane with right-lined sides, and *spherical* triangles drawn on a sphere with arcs of great circles for the sides. The SPHERICAL triangle has been already considered; and the formulæ connected with the plane triangle have been given in MENSURATION. There is much connected with this article in ANGLE, PARALLEL, SIMILAR, TRANSLATION, TRANSVERSAL, TRIGONOMETRY, &c., so that we have no need to make this article of a length proportioned to the importance of its subject in geometry. In fact, triangles are as much the elements of all figures as the letters are of words, being the figures of the smallest possible number of sides, and into which all figures can be divided.

The two most important properties of the triangle are, that the sum of its angles is always two right angles, and that the area is half that of a rectangle of the same base and altitude. Both of these propositions admit of such practical verification as would make them perfectly intelligible to those who do not understand geometry. Take the greatest angle B A C of a triangle cut out in paper, and fold the paper so that A may rest on B C at F, the part A D E folding over D F E. Then it will be found that by further folding E C L can be brought over E F L, and B D K over F D K, so that the three angles of the triangle



K F D, D F E, and E F L are so placed that the first side of the first and the last side of the last, K F and F L, are in the same straight line, and the three make up the two right angles K F A, A F L. Again, the triangle B A C is either the sum or difference of the two right-angled triangles F A C, F A B, which are the halves of the rectangles F A C H,





F A B G, the sum or difference of which is the rectangle B G H C: whence the triangle is the half of the rectangle B G H C, of the same base and altitude as the triangle.

The three lines which bisect the angles of a triangle meet in one point, which is the centre of the inscribed circle; and the three perpendiculars which bisect the three sides also meet in one point, which is the centre of the circumscribed circle. Moreover, the three lines drawn from the vertices bisecting the sides meet in one point, which is the centre of gravity of the triangle: as also do the three perpendiculars drawn from the vertices to the sides. All these propositions, except the second, can be proved by the same process, namely, by showing that the segments of the sides satisfy the theorem given in TRANSVERSAL.

The number of isolated theorems which might be given on this subject is very large, but there is little unconnected with the trigonometrical formulæ which is of use in application.

TRIANGULA and TRIANGULUM AUSTRALE (constellations). The first (the Triangles) is a northern constellation, surrounded by Perseus, Andromeda, Aries, and Musca. It is one of the old constellations, but there is only one triangle in Aratus. Hevelius added the second. The second, or Southern Triangle, is a constellation of Bayer, lying between Ara, Centaurus, and the South Pole.

The principal stars are as follow:—

TRIANGULA.

TRIANGULAR COMPASSES. [COMPASSES.]

TRIANGULAR NUMBERS. [NUMBERS, APPELLATIONS OF.]

TRIANGULATION, a name given to the net-work of triangles with which the face of a country is covered in a TRIGONOMETRICAL SURVEY.

TRIARSENIO-METHYLAMINE. Synonymous with *trimethylarsine*. [ORGANOMETALLIC BODIES. *Arsenic Series.*]

TRIATOMIC ETHERS. [ETHERS.]

TRIBE (*tribus*, φυλή). All the states of antiquity of which we have any records were divided into a certain number of tribes, consisting of the great bodies of citizens of which the state was composed. These tribes, however, were of two different kinds, either genealogical (γενικαί) or local (τοπικαί). (Dionys. Hal., iv. 14.) The former, which must be considered as the more ancient of the two, were the different national elements of which a state was made up, that is, each was a distinct people, though akin to the others, and each traced its origin to some mythical ancestor; whence Dionysius calls such tribes genealogical. The other, or local tribes, to which a later origin must be assigned, and which in most cases superseded the old genealogical tribes, were artificial local divisions made for political and other purposes, and any one of them might contain people who, according to the genealogical division, would belong to different tribes. Thus we find in the history of Attica that the four original tribes were done away with after the institution of the ten local tribes by Cleisthenes; and at Rome the three ancient Romulian tribes which retained their political importance almost to the time of the decemviral laws, died away and ceased to be noticed in Roman history save as an archaic institution, the thirty local tribes established by the Servian constitution having gradually superseded them. At Sparta alone the three original Doric tribes, the Hylleans, Pamphylians, and Dymanians, were retained without any change. Genealogical tribes may, in many instances, as was originally the case at Rome, have inhabited different districts, so that they were at the same time local tribes; but this is merely an accidental circumstance.

The number of the genealogical tribes was different in the different states of antiquity, and depended upon various circumstances, such as the number of national elements brought together to form a state, or the partiality of a race of men for particular numbers which were used as typical. Thus we find that the Doric states were originally divided into three, the Ionic into four, and the Romans into three tribes, and, later on, into a multiple of these numbers. Although these tribes only contained freemen, they were not always on a footing of equality; but the most ancient one, to which the others had only been added at some time by treaty or contract, always retained, at least for a time, a superiority over the others, and reserved for itself rights and privileges which were denied to the others. Such was the case with the Hylleans at Sparta, the Eupatrids at Athens, and the Ramnes at Rome. Each tribe was usually subdivided into smaller bodies, as at Athens into φρατρίαι and γένη, at Sparta into ὠβαί and τριακάδες, and at Rome into curiæ and gentes. The number of senators and of the great officers of a state likewise bore a certain relation to the number of tribes or their subdivisions. The bond of union between such tribes was more or less loose according to circumstances; and the history of Attica gives us an instance of their being at war with one another. Each tribe had usually its separate religious observances and festivals, and the same was the case with its subdivisions.

All the tribes of which a state consisted formed the sovereign people (as at Rome the populus), which in many cases ruled over a subject population superior in numbers (περίοικοι, plebeians). When a Greek state sent out a colony to a foreign country, it appears to have been customary to divide the new state into the same number of tribes as that which existed in the mother-city, and the names also were retained; in some cases, as at Cydonia and Halicarnassus, both of which were Doric colonies, we only find mention of one tribe, which may have arisen from the fact that only members of one tribe of the mother-state took part in the establishment of the colony. (Wachsmuth, 'Hellenische Altherthumskunde,' ii. 1, p. 15, &c.)

In regard to the later or local tribes, it is clear from the name itself that each inhabited a distinct district, containing either one or more townships, which were called in Attica δῆμοι, and at Rome *vici* or *pagi*. Every citizen belonging to a tribe was obliged to have his name registered in a township of his tribe, though he was not bound to reside in the same in which he was registered and to which he belonged.

Each tribe, whether genealogical or local, managed its own affairs, and was headed by a tribune (φύλαρχος). The same was the case with the subdivisions of a tribe.

We have here only given a brief outline of the subject in general, as a more detailed account of the tribes in the different states of antiquity is given in the articles ATHENS; SPARTA; ROME, in GEOG. DIV.; CLEISTHENES; SERVIUS TULLIUS, in BIOG DIV.; DORIANS;

IONIANS; and others. Compare, also, Wachsmuth, 'Hellen. Alterthum.,' ii. 1, p. 15, &c.; Hermann, 'Political Antiquit.;' Schömann, 'De Jure Publico Græcorum,' p. 165, &c.; Niebuhr, 'Hist. of Rome,' i., p. 306, &c.

TRIBROMANILINE. [ANILINE.]

TRIBROMEUXANTHONE. [EUXANTHIC ACID.]

TRIBROMOBENZIN. Synonymous with *tribrombenzole*. [BENZOLE.]

TRIBROMO-PHENIC ACID. [PHENYLIC GROUP.]

TRIBROMO-SALICYLIC ACID. [SALICYLIC GROUP.]

TRIBUNUS (φύλαρχοι), according to the etymology of the word, signifies any officer who is at the head of a tribe [TRIBE], and conducts either the internal administration of a tribe, or represents it in its relations to other powers in the state. This signification applies indeed to some of the officers of this name who occur in the history of Rome, but in regard to others it must remain doubtful why they bore this name. The following is a list of all the Roman officers bearing the name of tribune.

1. *Tribunes of the Three Romulian Tribes.*—The existence of a tribune for the three ancient patrician tribes, the Ramnes, Tities, and Luceres, is attested by several passages of ancient writers. (Dionys. Hal., ii. 7; Servius, 'Ad Aen.,' v. 560; Pomponius, 'De Orig. Juris,' 'Digest,' i., 2, 2, 20.) As regards their functions we have no definite statements: they may have been intrusted with the management of the civil, religious, and military affairs of their respective tribes.

2. *Tribunus Celerum* is an officer who only occurs in the history of Rome during the period when it was governed by kings. He was the commander of the 300 equites (celeres) who formed the king's body-guard, 100 being taken from each of the three tribes. He was, next to the king, the first person in the state. (Dionys. Hal., ii., 64; Pomponius, 'De Orig. Juris;' 'Digest,' 1, 2, 2, 15.) In the absence of the king, the tribunus celerum acted as his representative, and convoked the senate, as well as the comitia of the curiæ, at which he presided.

3. *Tribunes of the Servian Tribes.*—When Servius Tullius organised the body of plebeians by dividing them into thirty local tribes, each of them was headed by a tribune, who had to keep a register of the inhabitants of his district and of the condition of every household in it. (Dionys. Hal., iv. 14; and Varro, 'De Vit. Pop. Rom.,' i. 240.) The scrutiny into every household appears to have gradually ceased, partly because it was repugnant to the spirit of liberty, which was rapidly developing, and partly because the state obtained sufficient information through the census. When subsequently the Roman people became exempt from taxes, the main functions of the tribunes ceased, but they themselves continued to exist, nor is it improbable that the tribuni ærarii, who are mentioned from the time that pay began to be given to the soldiers (B.C. 406) down to the end of the republic, are the same as the tribunes of the Servian tribes. (Niebuhr, 'Hist. of Rome,' i. p. 421.) The tribuni ærarii had to levy the tribute in their tribes and to pay the soldiers with it. (Varro, 'De Ling. Lat.,' v. § 181; Gellius, vii. 10.) After the institution of the quæstors, the tribuni ærarii had only to levy the tribute and hand it over to the quæstors, who distributed the pay among the soldiers. The Lex Aurelia, B.C. 70, gave to these tribunes judicial power along with the senators and equites; but they were deprived of it by J. Cæsar. (Sueton., 'Cæs.,' 41.)

4. *Tribuni Plebis.*—These were the most important among the many officers bearing the name of tribune; and whenever tribunes are mentioned without any further qualification, the tribuni plebis are meant. In the year B.C. 494, when the plebeians had been driven by the oppression of the patricians to secede to the Mons Sacer, peace was concluded between the two orders on condition that the plebeians should be allowed to have magistrates of their own, whose province it should be to protect the members of their order against the patrician magistrates, and whose persons should be sacred and inviolable. It was farther agreed, that whoever should maltreat, kill, or compel a tribune to anything by force, should be outlawed and his property should be forfeited to the temple of Ceres. (Liv., ii. 33 and iii. 55; Dionys. Hal. vi., pp. 89, and vii. 17.) These agreements, however, were insufficient to protect the tribunes against various annoyances of the patricians; hence it was found necessary, soon after the institution of the tribunate, to give still more security to the exercise of their power. A law was accordingly passed forbidding any one to interrupt or disturb the tribunes in their transactions with the plebs, and enacting that any one who should act contrary to this law should give bail to the tribunes for any fine inflicted upon him; those who refused to give bail forfeited their life and property. The inviolability of the tribunes was finally established after the time of the decemvirate by a law of M. Horatius.

With regard to the conflicting statements as to the number of the tribunes, the probability is in favour of the number five, so that one was taken from each of the five Servian classes. Thus much only is certain, that in the year B.C. 457 the number of tribunes was increased to ten; so that if they really bore any relation to the classes, each furnished two. This number remained unaltered to the end of the republic. The tribunes were attended by public servants, called viatores, who carried their commands into effect.

The accounts about the manner in which the tribunes were originally elected are as contradictory as the statements about their original number. The statement of Dionysius and Cicero, that they were elected by the curiæ, must either have arisen from a misunderstanding of the nature of the curiæ, or from a confusion of the election and the sanction of the election; for the latter was a right which the curiæ unquestionably possessed for a time. If, as Niebuhr thinks, they were intended to represent the classes, they were elected by the centuries; but it is much more probable that the college of tribunes, at the expiration of the year of office, appointed their successors, after a previous consultation with the plebs. The sanction of the curiæ ceased to be necessary shortly before the time of the Publilian law; and after that time we have express testimonies that the tribunes were elected by the comitia of the tribes, under the presidency of one of the tribunes whose office was expiring. (Livy, ii. 56, &c.; iii. 64; Dionys. Hal., ix. 2.) As it was necessary that all the tribunes should be elected on one day and before sunset, it often happened that when the business of election could not be completed within the lawful time, those who were elected had to fill up the number by co-optatio. This inconvenience was done away with in 448 by the tribune L. Trebonius, who got a law passed, ordaining that in future the elections should be continued the next day or days in cases where one day should be too short a time to complete them.

The field of action for the tribunes were the comitia of the tribes and other meetings of the plebeians; and they arraigned before the assembly of the plebs any one, whether private individuals or magistrates, who had violated the rights of the commonalty, and that without any fear of being interrupted in their proceedings. They themselves had no judicial power; they had only the right to drag the offender before the assembly of the people, and to propose a fine to be inflicted on him. In later times they sometimes deviated from this rule, and assumed the right of proposing capital punishment. Their lawful power was originally mere *auxilium*; that is, to afford protection, without any right directly to interfere in the affairs of the state. Their power, the Tribunicia Potestas, or Tribunicium Jus, was confined to the city and one mile beyond its walls. They were not allowed to spend a night outside the city, except during the Feriæ Latinæ, when all the people were assembled on the Alban Mount. The house of a tribune was regarded as a place of refuge for any one who thought himself wronged or oppressed, and the doors were left open by night as well as by day. From the first the plebeians regarded the tribunes not only as their protectors against patrician oppression, but as arbitrators in matters among themselves. (Walter, 'Geschichte des Röm. Rechts,' p. 85.) The power of the tribunes, after it was once established, rapidly increased in proportion as the commonalty itself increased in importance; indeed we may say that the growing importance of the commonalty was the work of the tribunes. Not quite forty years after the institution of the tribunate we find the members present at the deliberations of the senate; and in B.C. 454 the tribunes compelled the senate to meet, in opposition to the consuls, that they might lay before them a rogation and discuss its merits. Henceforth either the tribunes themselves, or the consuls at their request, proposed legislative measures to the senate, as we see in the instance when a new legislation was demanded by the tribunes. This demand of the tribunes, after some struggles on the part of the patricians, was at last complied with, and led to the appointment of the decemvirs, for the purpose of framing a new code of laws. During the second decemvirate the tribunate was suspended, like all other magistrates; but when the business of legislation was completed tribunes were again appointed, and it was on their proposition that the consulship also was restored. (Liv., iii. 54.)

The position of the tribunes after the decemviral legislation was very different from what it had been before. Henceforth we find the patricians and the clients contained in the tribes, and the tribunes now stand in the same relation to the whole nation as they had before stood to the commonalty only: they are now the protectors of the whole nation as assembled in the comitia of the tribes, and in opposition to the senate and the magistrates; they are the representatives of the democratical element in the state, in opposition to the aristocratical. This explains how it happened that their protection was sought by patricians as well as plebeians. (Liv., iii. 56; viii. 33, &c.) They henceforth also appear in the possession of the right of being present at all the deliberations of the senate; but their place was outside the opened doors, where they sat upon benches. They had at all times the right to propose measures to the assembly of the tribes, which might pass them. Such resolutions of the tribes were called plebiscita, and required the sanction of the senate or the curiæ before they became laws. But the Lex Valeria ordained that all plebiscita should be binding upon the whole nation without any further sanction. ('Dictionary of Greek and Rom. Ant.,' under "Plebiscitum.") This gave to the tribunes an extraordinary influence in all the affairs of the state, and the democratical element had now gained the superiority. But while the power of the tribunate was thus outwardly increasing, a change took place within the body, or collegium, as it was called, which, to some extent, paralysed its power. Down to the year B.C. 394 all matters had been decided in the college of the tribunes by a majority of the members, but in this year we meet with the first instance of the intercession (veto) of one tribune rendering the resolution of his colleagues void. (Liv., v. 25, 29.) It is uncertain what gave rise to this innovation; but it weakened the power of the college, inasmuch as the aristocratic party might easily gain over one of its members, and thus thwart the plans of the rest. In such a case nothing could be done, and the matter was dropped. C. Tiberius Gracchus was the first who pointed out the manner in which the college might get rid of an obstinate member: he proposed to the people to deprive such a tribune of his office—an expedient which was afterwards occasionally made use of. The same power, however, which a tribune had over the resolutions of his colleagues he also had upon the proceedings of a magistrate, whether a consul, a censor, or a prætor, and even over an ordinance of the senate. The right of the tribunes of merely appearing in the senate was gradually increased by the power of convoking the senate, and laying before it any measure relating to government or administration; and the senate had often recourse to the tribunes for the purpose of compelling magistrates to comply with its wishes. (Liv., iv. 26; v. 9; xxviii. 45.) At last it was established by the Plebiscitum Atinium that a tribune should be a member of the senate by virtue of his office. The time when this plebiscitum was passed is uncertain, though it is not improbable that it originated with C. Atinius, who was tribune in B.C. 130.

There was no power in the Roman republic that could be compared to that of the tribunes, and during the latter period of the republic they formed a real democratical senate. But whatever may have been the abuse that some tribunes made of their exorbitant power, and however much evil they may have produced, yet it is a point acknowledged on all hands that Rome owed her greatness, in no small degree, to the institution of the tribunate.

Sulla, in his attempt to remodel the constitution upon aristocratic principles, reduced the powers of the tribunes to what they had been originally. But this innovation, like all his constitutional changes, was a complete failure, and the full power of the tribunes was restored to them by Pompey. [SULLA, and POMPEY, in BIOG. DIV.]

During the empire the college of tribunes of the people continued to exist; and in the reign of Augustus comitia for the election of tribunes were still held, although the freedom of election gradually disappeared. (Sueton., 'Aug.,' 40; Vellei. Pat., ii. 111.) The political influence of the tribunes also sank rapidly, and even at an early period of the empire we find it almost confined to intercession in decrees of the senate and to protecting oppressed or injured individuals. (Tacit., 'Annal.,' xvi. 26; 'Histor.,' ii. 91; iv. 9; Plin., 'Epist.,' i. 23; ix. 13.) Tribunes, however, continued to exist down to the 5th century of our era; and though their power was much limited, they still continued to be looked upon as the protectors of the weak and the injured, which made their office one of great moral importance. For this reason, as well as for the purpose of having a check upon the college, the emperors, although patricians, found it necessary to be tribunes. In fact, the office of tribune, all the other magistracies being united in one person, was the only thing that was wanting to complete the sovereign power of an emperor. This tribunicia potestas of an emperor was conferred upon him by the senate, and was justly deemed equivalent to regal or dictatorial power with a popular name, so that the tribunicia potestas became an essential part of the imperial dignity, and was finally established as such by the Lex de Imperio Vespasiani. (Suet., 'Tiber.,' 23; 'Vespas.,' 12; 'Titus,' 6.)

5. *Tribuni Militum cum Consulari Potestate.*—In the year B.C. 445 the tribune C. Canuleius carried several rogations, one of which was, that the people should be at liberty to elect the consuls from the patricians and plebeians indiscriminately. In order to avoid the consequences of this law, the senate decreed that instead of consuls, tribuni militum with consular power should be elected promiscuously from both orders; and in order that the plebeians might not gain too much at once, the censorial power, which had hitherto been a part of the consular power, was separated from it and given to two new patrician officers, the censors. Accordingly in the year 444 B.C. three tribunes were elected instead of consuls, one of them being a plebeian. The people however were allowed for the following years to elect either tribunes or consuls, as they might think proper. The consequence was, that for a series of years sometimes consuls were elected according to the old custom, and sometimes tribunes. From the year B.C. 426 the number of tribunes varied between three and four, until in B.C. 405 it was increased to six, which remained unaltered down to the year B.C. 366, when the office of the military tribunes with consular power was abolished, and the consulship restored. These consular tribunes, as they are briefly called, had the same power as the consuls, with the exception of that part of it which had been detached from it and given to the censors. For this and other reasons the patricians did not so much object to its being shared with the plebeians, as they did in regard to the consulship, which was sanctified by solemn auspices.

6. *Tribuni Militares*, or *Militum*, or tribunes of the soldiers, were a class of officers in the Roman armies, of whom at first there were four in a legion. They appear originally to have been appointed by the consuls, but in the year B.C. 363 it was decreed that henceforth half of them should be elected by the people in the comitia of the centuries, while the appointment of the other half was left to the commanders of the legions as before (Liv. vii. 5); and as there were six in a consular army, three were elected by the people and three by the consul. The latter were, down to the latest time of the republic, called *ruffuli*, and the former *comitiati*. (Festus, s. v. 'Ruffuli.') In later times the number of tribunes for each legion was increased to six, and their appointment was sometimes left altogether to the consuls. But this seems to have been an exception to the rule, for subsequent to that time we again find that the people had the election of a part of the tribunes. (Liv., xliii. 14 and 31; xliv. 21.) The functions of these tribunes of the soldiers consisted in maintaining the discipline among the troops, superintending their exercises and their state of health, in inspecting the sentinels, settling disputes among the soldiers, in taking care that they received their necessary provisions, and the like.

TRICHI'ASIS (τριχίασις), is a disease in which one or more of the eyelashes are turned inwards, so as to be in contact with the front of the eyeball. The irritation thus excited produces all the pain and other symptoms of inflammation of the conjunctiva, and if long continued may terminate in opacity of the cornea and complete blindness.

The wrong direction of the eyelashes may depend on various causes. Sometimes it appears to be their natural mode of growth; one or more growing differently from the rest, and being reproduced with the same faults as often as they are extirpated. More frequently it is due to some disease of the eyelid, producing a cicatrix or induration of its inner surface, which, contracting, draws in the margin of the lid, and with it the lashes. By a similar process, trichiasis is the constant accompaniment of the cases of entropium, or inversion of the eyelids, which depend on induration or contraction of their cartilages.

A temporary remedy for trichiasis is the extraction of the offending eyelashes, which may be effected by plucking them with broad-pointed forceps; but they are generally quickly reproduced, and, growing in the same direction, renew the patient's suffering. For a permanent remedy, some of the operations for entropium must be performed, or the portion of the inner margin of the eyelid from which the inverted lashes grow must be removed with their bulbs.

TRICHLORACETIC ACID. [CHLORACETIC ACID.]

TRICHLORALDEHYDE. [CHLORAL.]

TRICHLOR-EUXANTHONE. [EUXANTHIC ACID.]

TRICHLOROKINONE. [KINIC ACID.]

TRICHLOROMETHYL-DITHIONIC ACID ($C_2Cl_3HS_2O_6 + 2aq.$). *Trichloromethyl-Sulphurous Acid.* An unimportant organic acid obtained by treating trichloromethyl-sulphurous chloride with potash or baryta. This acid has also been named *chlorocarbo-hyposulphuric acid.*

TRICHLOROMETHYL-SULPHUROUS ACID. [TRICHLOROMETHYL-DITHIONIC ACID.]

TRICHLORONAPHTHALIC ACID. [NAPHTHALIC GROUP, *Trichlorophthalic Acid.*

TRICHLOROPHENIC ACID. [PHENYLIC GROUP.]

TRICHLOROVALERISIC ACID. [VALERIANIC ACID.]

TRIDENT (*tridens*, *τρίαινα*) is any instrument of the form of a fork, with three prongs; instruments of this kind were used by the ancients, as among ourselves, for various purposes. In mythology the trident is the attribute of several marine divinities, such as Nereus (Virg., 'Æn.,' ii. 418) and the Tritons (Cicero, 'De Nat. Deor.,' ii. 35), but above all of POSEIDON. The trident in these cases is the same as the sceptre with other gods, the emblem of the power of these gods of the waters. The ancients regarded earthquakes as arising from the sea, or, as they expressed it, as the work of Poseidon, who effected them by his mighty trident, whence Homer frequently calls him the "shaker of the earth," and whenever the god is represented as producing any convulsion of the earth or the sea, the trident is always mentioned. (Hom., 'Odyss.,' iv. 506; Claudian, 'De Rapt. Pros.,' ii. 179.)

TRIETHYLAMINE. [ORGANIC BASES.]

TRIETHYLPHOSPHINE. [ORGANIC BASES.]

TRIFO'RIUM, an upper gallery formed by small open arches above those dividing the nave from the side-aisles of a church, and beneath the clerestory windows, this intermediate tier being within the sloping roof over the aisles. These galleries are, in this country, sometimes called "Nunneries," but in Germany "Männerchor." They are not confined to the nave, but continued in the transepts, so as to afford a passage almost entirely round the upper part of the building. In general the triforium is very shallow or narrow, and the arches in front of it are small and low; and of these last, there are two, three, or even six, over each of the larger arches separating the nave from the aisles. There are however very great differences in these respects even in buildings of the same period and style. In some instances the triforium is very lofty and open, as in the Abbaye aux Hommes, Caen, and in the choir of Bayeux Cathedral, although the nave of the same edifice offers an example directly the reverse, the triforium consisting there of a range of very low and small arches; while the clerestory windows are remarkably large and lofty, much larger in fact than the pier-arches between the nave and aisles. In the Norman naves of some of our cathedrals the triforium arches are as wide and nearly as high as those of the aisles; and the triforium itself is so spacious as to form an upper aisle, lighted, like the lower one, with windows. Norwich is an example of this kind, as is likewise Peterborough, except that in the latter the large triforium arches corresponding with those below are subdivided into two lesser ones with a column between them. At Gloucester, on the contrary (also Norman), the triforium arches are low and small, being divided at first into two, each of which is again similarly subdivided, so as to make four openings over each of the large arches below. In the nave of Wells Cathedral the triforium consists of an uninterrupted range of small arches of peculiar character, in which the openings are very narrow in proportion to the solid parts or moulded piers between them. In English churches triforia are, during the First Pointed period, very ornamental in character; in the Second and Third Pointed styles they are generally smaller and less important.

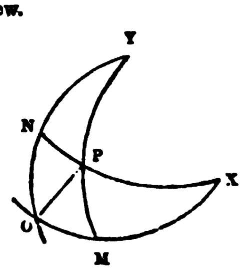
TRIGENIC ACID ($C_8H_7N_3O_4$). Aldehyde absorbs the vapour of cyanic acid with great avidity, producing a white crystalline mass, whilst carbonic acid is disengaged. Amongst other substances, trigenic acid is formed by the following reaction:—

$$\underbrace{C_4H_4O_2}_{\text{Aldehyde.}} + \underbrace{3CyHO_2}_{\text{Cyanic acid.}} = \underbrace{C_8H_7N_3O_4}_{\text{Trigenic acid.}} + 2CO_2$$

Trigenic acid crystallises in small prisms, very slightly soluble in water or alcohol. When submitted to destructive distillation, it appears to yield quinoleine and cyanuric acid. The trigenate of silver is insoluble in cold water, but soluble in hot water.

TRIGLYPH. [GRECIAN ARCHITECTURE.]

TRIGONOMETRICAL CO-ORDINATES. These co-ordinates were invented, independently of each other, by Professor Gudermann, of Cleves, and the Rev. Charles Graves, of Trinity College, Dublin. The latter called them *spherical co-ordinates*, a term which is liable to be confounded with the common astronomical co-ordinates described in SPHERE. This remarkable extension leads to a system of algebraic geometry for curves on a sphere, singularly resembling in its results the common system in a plane, many of the formulæ of the two being absolutely identical. We venture to predict that many difficulties of common algebra, arising from the entrance of the consideration of infinity, will find easy and natural explanations when the common system is considered to be, as it really is, an extreme particular case of this more general view.



Through any point O on a sphere, let arcs O X and O Y be drawn, which represent the axes of x and y. Let O X and O Y be each of them quadrants, and through any point P let arcs Y M, X N be drawn. Then the trigonometrical co-ordinates of the point P are the tangents of O M and O N, or of the angles subtended by them at the centre. These tangents are called x and y. If the whole system be projected, by lines drawn from the centre of the sphere, upon the tangent plane at O, then OM and ON will be projected into rectilinear co-ordinates to the projection of P. The equation of a great circle is of the first degree, or of the form $ax+by+c=0$, and an equation of the nth degree belongs to the intersection of the sphere with a cone of the nth degree whose vertex is at the centre. In the polar co-ordinates O P is the radius of the point, and the angle P O M its angle. This system of polar co-ordinates had been previously considered by Mr. T. S. Davies ('Trans. R. S. Edinb.,' vol. xii.), at great length, and with valuable results. Mr. Graves published his account of the trigonometrical co-ordinates in the appendix to his 'Two Geometrical Memoirs on the General Properties of Cones of the Second Degree,' &c.; Dublin, 1841.

The complete algebra [NEGATIVE, &c., QUANTITIES] may be easily applied to this system. If, in fact, the *tangent* of O P were called the radius vector, instead of O P, and denoted by r, the angle P O M being θ, we should have, for rectangular co-ordinates, exactly as in the plane system,

$$x=r\cos\theta,\ y=r\sin\theta,\quad x+y\sqrt{-1}=r\epsilon^{\theta\sqrt{-1}}$$

TRIGONOMETRICAL CURVES, a name given to curves having such equation as $y=\sin x$, $y=\cos x$, $y=a\cos x+b\cos 2x$, &c. To construct the forms of such curves from the knowledge of the fundamental properties of the sine, cosine, &c., should be an early exercise of the student in trigonometry, and will be of use in his subsequent reading.

TRIGONOMETRICAL SERIES. Infinite series which are of the form $a\sin x + b\sin 2x + c\sin 3x +$ &c., and $a\cos x + b\cos 2x + c\cos 3x +$ &c., are of important use in the higher parts of mathematics. The common mode of finding their equivalents, when $a+bz+cz^2+$&c., admits of representation in a finite form, is very easy. For instance, let it be required to find $1 + a\cos x + a^2\cos 2x +$, &c. Assume $2\cos x = z+z^{-1}$, then $2\cos nx = z^n + z^{-n}$, and substitution gives for the whole series,

$$\frac{1}{2(1-az)} + \frac{1}{2(1-az^{-1})} \text{ or } \frac{2-a(z+z^{-1})}{2(1-a(z+z^{-1})+a^2)}$$

$$\text{which is } \frac{1-a\cos x}{1-2a\cos x+a^2}$$

The most remarkable property of these series is that they are capable of representing discontinuous lines, so that an arc composed of arcs of different curves might have every one of its points made to satisfy an equation of either of the preceding forms. The whole of the discontinuous undulation, for instance, drawn in ACOUSTICS might be included under one equation. See the 'Differential Calculus' ('Library of Universal Knowledge'), p. 621. In the higher parts of physics, this property is of the greatest importance; and without doubt it is one of the most remarkable in the whole range of analysis. But it will not perhaps appear so singular if we remember that every curve made of arcs of different curves can have a continuous curve, represented even by a common algebraical equation, drawn as near as we please to any collection of its arcs. Lagrange showed the use of a finite trigonometrical series to be a very easy mode of actually representing the ordinate of this approximate curve: the infinite trigonometrical series is the limit which actually attains, algebraically speaking, the perfect representation of that to which a finite number of terms is only an approximation.

TRIGONOMETRICAL SURVEY. [GEODESY.]

TRIGONOMETRICAL TABLES. The chronological list given in TABLES will serve as a sketch of the history of these tables: we desire here to elucidate a point of their construction which, in the present state of transition from one system of definitions to another [TRIGONOMETRY], causes a great deal of confusion.

In the ordinary trigonometrical tables is set down the common or Brigg's logarithm of the sine, cosine, &c., of every angle which is an exact number of minutes (or seconds, or ten seconds, as the case may be) from 0° to 90°. Looking into a table we find for the logarithm of the sine of 35°, for instance, 9·7585913. This number is the logarithm of 5735764363, a number containing nearly six thousand millions of units. But the constructors of these tables used a radius of ten thousand millions of units, and their assertion consequently is, that if a right-angled triangle have ten thousand millions of units in its hypothenuse, and 35 degrees in one of its angles, the side opposite that angle will be 5735764363, which is correct within one unit. The logarithm of this radius is ten, and the earliest tables were constructed so as to give ten figures of the logarithms, from which ten significant figures of the sine, &c., might always be found: this radius was therefore convenient. Those who use the old system strictly, and employ the radius in every formula, find no difficulty: thus, if c be the hypothenuse of a spherical triangle, and a and b its sides, we have

$$\cos c = \frac{\cos a \cdot \cos b}{r}$$

$$\log\cos c = \log\cos a + \log\cos b - \log r \text{ (or 10).}$$

But those who use the old system, and have also dropped into the habit of making the radius always unity, or omitting it from the formulæ, and those who use the new system, in which the sines, &c., are numerical representations of ratios, will always find a difficulty, until they establish a new explanation of the characteristic of logarithms which they find in their tables. We speak of course of beginners, for practice will get over such a discrepancy, or will perhaps cause a sufficient explanation to suggest itself.

To either of the two last-mentioned classes of persons, the sine of 35° is ·5735764363, and its real logarithm is the negative quantity ·7585913−1, or −·2414087. To them therefore the simple explanation of the discrepancy between their logarithm and that of the tables is as follows:—The *tabular* logarithm is always 10 more than the *real* logarithm, and the real logarithm always 10 less than the tabular logarithm. There are two ways of proceeding: either to take out the real logarithm, which can always be done, using the characteristic −1 (or for distinction, $\bar{1}$) instead of 9, −8 or $\bar{8}$ instead of 2, −3 or $\bar{3}$ instead of 7, and so on; or to remember that each logarithm is 10 too great, and to make the correction, either mentally or at the end of each logarithm. We have always found the first mode the better of the two, and we should recommend no one to reject it without a sufficient trial.

For example, suppose it is required to calculate $\tan\theta=\sqrt{(\sin 1^\circ \sin 14^\circ \div \sin 3^\circ)^3}$. We have (not using the arithmetical complement)

$$\begin{array}{rr}
\log\sin 1^\circ & \bar{2}\cdot2418553 \\
\log\sin 14^\circ & \bar{1}\cdot3836752 \\
\hline
\text{add} & \bar{3}\cdot6255305 \\
\log\sin 3^\circ & \bar{2}\cdot7188002 \\
\hline
\text{subtract} & \bar{2}\cdot9067303 \\
\hline
 & 3 \\
\hline
\theta=1^\circ\ 19' \quad & 2)\bar{4}\cdot7201909 \\
\hline
 & \bar{2}\cdot3600955
\end{array}$$

In looking for the result, we remember that the tabular logarithm answering to $\bar{2}\cdot3600955$ is 8·3600955.

For the multiplication and division of negative characteristics, see LOGARITHMS, USE OF (col. 336).

TRIGONOMETRY. This word signifies the measurement of triangles, but we might as well attempt to confine geometry within etymological limits, as the science of which we are going to give some account in this article: the measurement of the earth is now only an isolated application of the former; and the measurement of triangles, of the latter.

In the modern division of the mathematical sciences, trigonometry, though still defined in books as the art of measuring triangles, really means the consideration of alternating or periodic magnitude; in which quantity is imagined to go through alterations of increase and diminution without end; that is ϕx, a function of x, is trigonometrical, when, as x varies through all stages of magnitude (or, in technical language, increases from $-\infty$ to $+\infty$), it takes an infinite number of alternate increases and diminutions. It is perfectly possible to contrive a common algebraic function which shall go through any given number of such changes—a thousand, a million, or more; but without recourse to infinite series, it is impossible to find one in which the number of alternations is unlimited. If the properties of algebraical series were as visible to the unassisted apprehension as those of figure in geometry, it would be seen that the two following series (afterwards known as those for the sine and cosine of x),

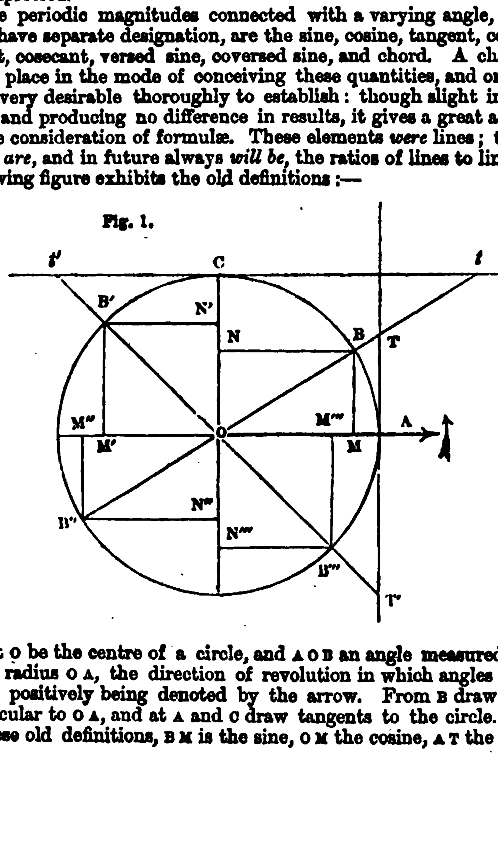
$$x - \frac{x^3}{2.3} + \frac{x^5}{2.3.4.5} - \&c., \text{ and } 1 - \frac{x^2}{2} + \frac{x^4}{2.3.4} - \&c.,$$

are periodic in value: and that, π being a certain incommensurable number (3·141592....), all the changes of magnitude that they can possibly take are only repetitions of what take place while x increases from 0 to 2π. We cannot form a more adequate idea of an intelligence superior to that of the human race, than by imagining one to which this truth should be, in consequence of sufficient rapidity of power of computation, a purely elementary one. We are obliged to come by this knowledge through our perceptions of space, and by the application of algebra to geometry; and the construction and use of our alphabet for the expression of periodic magnitude is contained in what are called the elements of trigonometry.

The most simple notion of periodic magnitude lies in supposing that the changes made are purely cyclical, or repetitions of the same for ever; as for instance, those which occur in turning a handle in a vertical plane. The number of revolutions traced out by the handle may be as great as we please, and the quantity of length of the circular arc described by its extremity may be as many times the circumference of the circle as we please, that is, as long as we please; but the distance of the handle from the ground is periodic, exhibiting perpetual increase and diminution as it rises and falls. Hence the circle naturally becomes a sort of standard of reference, and circular motion the primary idea, in all consideration of periodically changing magnitude. The arc, or the angle which it subtends at the centre, is the magnitude which increases without limit, all past revolutions being counted; and the lines which only depend on the position of the moving point in the circle, and not on the number of revolutions by which it has attained that position, are the periodic magnitudes in terms of which all others are expressed.

The periodic magnitudes connected with a varying angle, so far as they have separate designation, are the sine, cosine, tangent, cotangent, secant, cosecant, versed sine, coversed sine, and chord. A change has taken place in the mode of conceiving these quantities, and one which it is very desirable thoroughly to establish: though slight in appearance, and producing no difference in results, it gives a great advantage in the consideration of formulæ. These elements *were* lines; they now often *are*, and in future always *will be*, the ratios of lines to lines. The following figure exhibits the old definitions:—

Fig. 1.



Let O be the centre of a circle, and AOB an angle measured from a fixed radius OA, the direction of revolution in which angles are measured positively being denoted by the arrow. From B draw BM perpendicular to OA, and at A and C draw tangents to the circle. Then, in these old definitions, BM is the sine, OM the cosine, AT the tangent, Ct the cotangent, OT the secant, Ot the cosecant, AM the versed sine, CN the coversed sine, of the angle AOB. If AB should make a complete revolution, so as to come into the same position again, the angle under consideration would now be

$$\text{four right angles} + \angle AOB,$$

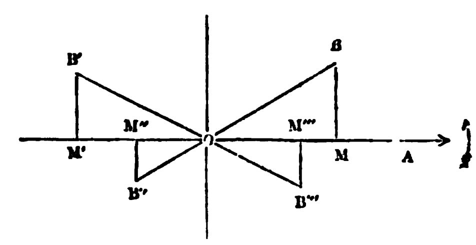
but the sine, cosine, &c. would all be the same as before.

As the line OB moves round, the signs of all these lines are to be taken positively when they are in the same directions as when AOB is less than a right angle. The following table will show them for the angles AOB, AOB′, AOB″, AOB‴, all measured in the same direction of revolution:—

Angle.	Sine.	Cosine.	Tangent.	Cotangent.	Secant.	Co-secant.	Versed Sine.	Co-versed Sine.
AOB, less than a right angle.	BM	OM	AT	Ct	OT	Ot	AM	CN
AOB′, between one and two right angles.	B′M′	−OM′	−AT′	−Ct′	−OT′	Ot′	AM′	CN′
AOB″, between two and three right angles.	−B″M″	−OM″	AT	Ct	−OT	−Ot	AM″	CN″
AOB‴, between three and four right angles.	−B‴M‴	OM‴	−AT′	−Ct′	OT′	−Ot′	AM‴	CN‴

In this system an angle has an infinite number of lines of each sort, one to every radius which can be taken. It is therefore necessary, either to introduce into the formulæ the value of the radius in every case, or to adhere to some one particular value of the radius, which is always understood. The plan usually adopted is first to embarrass the formulæ with the general value of the radius, then gradually to accustom the student to consider the radius as one unit, but to make an exception when trigonometrical tables are used, by considering the radius as ten thousand millions. These inconveniences are avoided in the new system of definitions, which is as follows:—

Fig. 2.



From any point in the line OB (or OB′, &c.) which is the variable boundary of the angle, draw BM (or B′M′, &c.) perpendicular to OA. Let OM and MB be positive, OM′ and M″B″, &c., negative, as in the usual method of reckoning co-ordinates. Call BM, B′M′, &c., opposite to the angles, OM, OM′, &c., adjacent; and let OB, OB′, &c., be called hypothenuses (and always considered positive). Then the sine of BOM is the fraction which BM is of OB, with its proper sign, in this case positive: but the sine of AOB″ is the fraction which M″B″ is of OB″, taken negatively, because M″B″ is negative. It is indifferent what hypothenuse is taken, by the property of similar triangles, and the following is the complete system of definitions, with the values written for the four angles. They give a slight degree more trouble at first, which is amply compensated in the superior ease with which all formulæ may be deduced, to say nothing of the advantage of avoiding the indefinite radius.

Definition.	AOB	AOB′	AOB″	AOB‴
Sine = $\frac{\text{Opp}^{\text{e}}\text{. side}}{\text{hypothen.}}$	$\frac{BM}{BO}$	$\frac{B'M'}{B'O}$	$-\frac{B''M''}{B''O}$	$-\frac{B'''M'''}{B'''O}$
Cosine = $\frac{\text{Adj}^{\text{t}}\text{. side}}{\text{hypothen.}}$	$\frac{OM}{OB}$	$-\frac{OM'}{OB'}$	$-\frac{OM''}{OB''}$	$\frac{OM'''}{OB'''}$
Tangent = $\frac{\text{Opp}^{\text{e}}\text{. side}}{\text{Adj}^{\text{t}}\text{. side}}$	$\frac{MB}{MO}$	$-\frac{M'B'}{M'O}$	$\frac{M''B''}{M''O}$	$-\frac{M'''B'''}{M'''O}$
Cotangent = $\frac{\text{Adj}^{\text{t}}\text{. side}}{\text{Opp}^{\text{e}}\text{. side}}$	$\frac{MO}{MB}$	$-\frac{M'O}{M'B'}$	$\frac{M''O}{M''B''}$	$-\frac{M'''O}{M'''B'''}$
Secant = $\frac{\text{Hypothen.}}{\text{Adj}^{\text{t}}\text{. side}}$	$\frac{QB}{OM}$	$-\frac{OB'}{OM'}$	$-\frac{OB''}{OM''}$	$\frac{OB'''}{OM'''}$
Cosecant = $\frac{\text{Hypothen.}}{\text{Opp}^{\text{e}}\text{. side}}$	$\frac{BO}{BM}$	$\frac{B'O}{B'M'}$	$-\frac{B''O}{B''M''}$	$-\frac{B'''O}{B'''M'''}$

Versed sine = unity − cosine
Coversed sine = unity − sine.

The chord has long ceased to be regarded as one of the trigonometrical functions, and is always used in its old sense, as the line joining the extremities of an arc.

We shall now make a collection of the principal trigonometrical formulæ, and properties of the fundamental functions, referring to ANGLE for the modes of measuring angles, to SINE for development of several of the most important points, to SERIES for the expansions of various functions, to MENSURATION and SPHERICAL for the formulæ particularly connected with triangles, and to ALGEBRA, ROOT, SUBSIDIARY ANGLE, &c., for various other usual applications.

1. No sine nor cosine exceeds unity; no secant nor cosecant is less than unity; a tangent or cotangent may have any value; versed sines and coversed sines are always contained between 0 and 2, both inclusive.

2. With the sines and cosecants must be remembered the succession + + − −; with cosines and secants, + − − +; with tangents and cotangents, + − + −. Thus when an angle is in the *third* right angle, or lies between two and three right angles, its cosine is negative, − being the third sign of the succession + − − +. Versed sines and coversed sines are always positive.

3. With the different functions must be remembered the following series of initial values, being those at the beginning of the several right angles: thus—

$$\sin 0=0,\ \sin(r^t\angle)=1,\ \sin(2r^t\angle^s)=0,\ \sin(3r^t\angle^s)=-1$$

sine	0	1	0	−1	cosine	1	0	−1	0	tangent	0	∞	0	∞
cosecant	∞	1	∞	−1	secant	1	∞	−1	∞	cotangent	∞	0	∞	0

4. To find a function of any number of right angles increased or diminished by a given angle, take the same function, if the number of right angles be even, its *cofunction* (sine for cosine, cosine for sine, &c.) if the number of right angles be odd: put that sign which belongs to the given function in the right angle to which the whole given angle belongs when the increment or decrement is less than a right angle. Thus we have

$$\sin\left(3\,\frac{\pi}{2}-\theta\right)=-\cos\theta,$$

which is thus obtained: the odd number of right angles ($\frac{1}{2}\pi$ representing a right angle) is a direction to put *cosine* instead of *sine* on the opposite side; now $\frac{3}{2}\pi-\theta$, θ being less than a right angle, falls in the third right angle, and the sine in that right angle is −, so that $-\cos\theta$ must be written. The following results should be remembered:—

$$\sin\left(\frac{\pi}{2}-\theta\right)=\cos\theta,\ \cos\left(\frac{\pi}{2}-\theta\right)=\sin\theta,\ \tan\left(\frac{\pi}{2}-\theta\right)=\cot\theta;$$
$$\sin\left(\frac{\pi}{2}+\theta\right)=\cos\theta,\ \cos\left(\frac{\pi}{2}+\theta\right)=-\sin\theta,\ \tan\left(\frac{\pi}{2}+\theta\right)=-\cot\theta;$$
$$\sin(\pi-\theta)=\sin\theta,\ \cos(\pi-\theta)=-\cos\theta,\ \tan(\pi-\theta)=-\tan\theta;$$
$$\sin(\pi+\theta)=-\sin\theta,\ \cos(\pi+\theta)=-\cos\theta,\ \tan(\pi+\theta)=\tan\theta;$$
$$\sin(2\pi-\theta)=-\sin\theta,\ \cos(2\pi-\theta)=\cos\theta,\ \tan(2\pi-\theta)=-\tan\theta;$$
$$\sin(-\theta)=-\sin\theta,\ \cos(-\theta)=\cos\theta,\ \tan(-\theta)=-\tan\theta.$$

5. In the first revolution, θ and $\pi-\theta$ have the same sines and cosecants, θ and $2\pi-\theta$ the same cosines and secants, θ and $\pi+\theta$ the same tangents and cotangents.

6. $\sin\theta\operatorname{cosec}\theta=1$, $\cos\theta\sec\theta=1$, $\tan\theta\cot\theta=1$,

$$\frac{\sin\theta}{\cos\theta}=\tan\theta,\ \frac{\cos\theta}{\sin\theta}=\cot\theta.$$

7. $\sin^2\theta+\cos^2\theta=1$, $1+\tan^2\theta=\sec^2\theta$, $1+\cot^2\theta=\operatorname{cosec}^2\theta$.

$$\sin\theta=\frac{\tan\theta}{\sqrt{(1+\tan^2\theta)}},\ \cos\theta=\frac{1}{\sqrt{(1+\tan^2\theta)}}.$$

8. If $\tan\theta=\frac{a}{b}$, then $\sin\theta=\frac{a}{\sqrt{(a^2+b^2)}}$, $\cos\theta=\frac{b}{\sqrt{(a^2+b^2)}}$.

9. $\sin(\theta+\phi)=\sin\theta\cos\phi+\cos\theta\sin\phi$
$\sin(\theta-\phi)=\sin\theta\cos\phi-\cos\theta\sin\phi$
$\cos(\theta+\phi)=\cos\theta\cos\phi-\sin\theta\sin\phi$
$\cos(\theta-\phi)=\cos\theta\cos\phi+\sin\theta\sin\phi$.

10. $\tan(\theta+\phi)=\dfrac{\tan\theta+\tan\phi}{1-\tan\theta\tan\phi}$, $\tan(\theta-\phi)=\dfrac{\tan\theta-\tan\phi}{1+\tan\theta\tan\phi}$

11. $\sin\theta+\sin\phi=2\sin\dfrac{\theta+\phi}{2}\cos\dfrac{\theta-\phi}{2}$

$$\sin\theta-\sin\phi=2\cos\frac{\theta+\phi}{2}\sin\frac{\theta-\phi}{2}$$
$$\cos\theta+\cos\phi=2\cos\frac{\theta+\phi}{2}\cos\frac{\theta-\phi}{2}$$
$$\cos\theta-\cos\phi=-2\sin\frac{\theta+\phi}{2}\sin\frac{\theta-\phi}{2}.$$

12. $\sin 2\theta=2\sin\theta\cos\theta$
$\cos 2\theta=\cos^2\theta-\sin^2\theta=2\cos^2\theta-1=1-2\sin^2\theta$,
$\tan 2\theta=2\tan\theta\div(1-\tan^2\theta)$.

13. $1+\cos\theta=2\cos^2\dfrac{\theta}{2}$, $1+\sin\theta=2\cos^2\left(\dfrac{\pi}{4}-\dfrac{\theta}{2}\right)$

$$1-\cos\theta=2\sin^2\frac{\theta}{2},\ 1-\sin\theta=2\sin^2\left(\frac{\pi}{4}-\frac{\theta}{2}\right)$$
$$\frac{1-\cos\theta}{1+\cos\theta}=\tan^2\frac{\theta}{2},\ \frac{1-\sin\theta}{1+\sin\theta}=\tan^2\left(\frac{\pi}{4}-\frac{\theta}{2}\right)$$

14. $\dfrac{\sin\phi-\sin\theta}{\sin\phi+\sin\theta}=\dfrac{\tan\frac{1}{2}(\phi-\theta)}{\tan\frac{1}{2}(\phi+\theta)}$, $\dfrac{\sin\phi\pm\sin\theta}{\cos\phi+\cos\theta}=\tan\frac{1}{2}(\phi\pm\theta)$

15. If θ be half a right angle, or less,

$$\cos\theta=\tfrac{1}{2}\sqrt{(1+\sin 2\theta)}+\tfrac{1}{2}\sqrt{(1-\sin 2\theta)}$$
$$\sin\theta=\tfrac{1}{2}\sqrt{(1+\sin 2\theta)}-\tfrac{1}{2}\sqrt{(1-\sin 2\theta)}.$$

16. If n be any integer, and if $(\cos\theta+\sin\theta)^n$ be developed by the binomial theorem into $P_0+P_1+P_2+$ &c., P_0 being $\cos^n\theta$, P_1 being $n\cos^{n-1}\theta\sin\theta$, &c., then $\cos n\theta$ is $P_0-P_2+P_4-$ &c., and $\sin n\theta$ is $P_1-P_3+P_5-\ldots$.

17. Let C_n and S_n stand for the cosine and sine of $n\theta$

$$2\cos^2\theta=C_2+1$$
$$4\cos^3\theta=C_3+3C_1$$
$$8\cos^4\theta=C_4+4C_2+3$$
$$16\cos^5\theta=C_5+5C_3+10C_1$$
$$32\cos^6\theta=C_6+6C_4+15C_2+10$$
$$64\cos^7\theta=C_7+7C_5+21C_3+35C_1$$
$$128\cos^8\theta=C_8+8C_6+28C_4+56C_2+35$$
$$256\cos^9\theta=C_9+9C_7+36C_5+84C_3+126C_1$$
$$512\cos^{10}\theta=C_{10}+10C_8+45C_6+120C_4+210C_2+126$$

To change these into corresponding formulæ for powers of $\sin\theta$,

For	C_1	C_2	C_3	C_4	C_5	C_6	C_7	C_8	&c.
Write	S_1	$-C_2$	$-S_3$	C_4	S_5	$-C_6$	$-S_7$	C_8	&c.

Thus $16\sin^5\theta=S_5-3S_3+10S_1$
$32\sin^6\theta=-C_6+6C_4-15C_2+10$.

18. *De Moivre's Theorem* and its consequences:—

$$(\cos\theta+\sin\theta.\sqrt{-1})^n=\cos n\theta+\sin n\theta.\sqrt{-1}$$
$$\epsilon^{\theta\sqrt{-1}}=\cos\theta+\sin\theta.\sqrt{-1}\qquad \epsilon^{-\theta\sqrt{-1}}=\cos\theta-\sin\theta.\sqrt{-1}$$
$$\cos\theta=\frac{\epsilon^{\theta\sqrt{-1}}+\epsilon^{-\theta\sqrt{-1}}}{2}\qquad \sin\theta=\frac{\epsilon^{\theta\sqrt{-1}}-\epsilon^{-\theta\sqrt{-1}}}{2\sqrt{-1}}$$
$$\text{If } 2\cos\theta=x+\frac{1}{x},\quad \text{then } 2\sqrt{-1}.\sin\theta=x-\frac{1}{x}$$
$$\text{and } 2\cos n\theta=x^n+\frac{1}{x^n},\quad \text{and } 2\sqrt{-1}.\sin\theta=x^n-\frac{1}{x^n}.$$

The versed sine is little used and rarely mentioned in formulæ; and the coversed sine is really only invented for analogy's sake.

The term *sine* (the Latin word *sinus*, meaning the bosom) has been the object of much discussion. It was at one time looked on as a barbarism from the Arabic; and some endeavoured to substitute *semissis inscriptæ*, the half of the chord, for it. Others again thought that it was a corruption of *S. Ins.*, the abbreviation of the above. Dr. Hutton asserts that the Arabic word *Jeib*, which is used for the trigonometrical sine in that language, also means the bosom in common language; and we have been told that this is correct; if so, the Latin *sinus* is only the literal translation of the Arabic. The arc representing a bow (from which it gets its name), half of the string, which represents the sine of half the arc, would come against the breast of the archer. The versed sine (*sinus versus*, or turned sine) was called the *sagitta*, or arrow. The terms tangent and secant are derived in an obvious manner from the old definitions.

There is little of the history of trigonometry which can be either usefully or intelligibly separated from that of mathematics in general. Up to the middle of the last century it belonged rather to geometry than to algebra; and even in our own day algebraical trigonometry is not fully established in England, though rapidly making its way. Those to whom trigonometry is only useful as an instrument in the solution of triangles may enjoy the advantage of that specific clearness which geometry gives to the individual proposition in hand, without needing to feel the want of a system which points out the direction of future progress. But those who are to be trained in mathematics for higher views and more difficult applications, must acquire trigonometry in its most algebraical form as a constituent part of the language of algebra, and an element in every step of their future progress. It is worse than useless to attempt, for them, to draw a distinction between algebraical and trigonometrical; the science will now allow that distinction to remain, and will rather demand new modes of expression than dispense with any of the old ones.

There are those who feel sensible of incongruity in combining the fundamental notions of space and number together, and would rather, at any expense of trouble, keep them separate, except when they are formally united for any particular application. This feeling has our sympathy; and if it were possible to present a complete algebra, both in definitions and processes, without recourse to trigonometrical language, we should willingly agree to the separation. But hitherto it is not so; the only view of algebra in which there is nothing *impossible* is [ALGEBRA] essentially joined to space, and particularly to angular magnitude; so that those who would have a perfectly pure algebra must buy it at the expense of unexplained and apparently contradictory symbols.

It would be easy to avoid the notion of space while using the terms of trigonometry and its powerful formulæ. The series at the beginning of this article might be made the definitions of the sine and cosine; or sin x might be only an abbreviation of $x - \frac{1}{2\cdot3} x^3 + \&c.$, and cos x of $1 - \frac{1}{2} x^2 + \&c.$ The fundamental properties of the sine and cosine might without much difficulty be proved to belong to these series, without reference to any geometrical reasoning.

TRIMETHYLAMINE. [ORGANIC BASES.]

TRIMETHYLPHOSPHINE. [ORGANIC BASES. *Organic phosphorous bases.*]

TRINITRANISOL ($C_{14}H_5[NO_4]_3O_2$). A nitro-derivative of the phenate of methyl. [ANISOL.]

TRINITROCRESIC ACID. ($C_{14}H_5[NO_4]_3O_2$). An organic acid prepared by adding cresylic alcohol, drop by drop, to strong nitric acid. Its potash salt crystallises in orange needles.

TRINITRONAPHTHALIN. [NAPHTHALIC GROUP.]

TRINITROPHENIC ACID. [PHENYLIC GROUP; CARBAZOTIC ACID.]

TRINITY HOUSE. As the general management of the lighthouses and buoys of the shores and rivers of England is entrusted to the Corporation of the Elder Brethren of the Holy and Undivided Trinity, generally known by the name of the Trinity House, it has been considered advisable to treat under the same head the special history of that corporation and the general discussion of the duties entrusted to their charge, as well as the discussion of the means usually adopted for lighting and buoying sea-coasts in general.

The objects it is desired to effect by those operations are, to indicate to mariners the precise position of sunken rocks, shoals, or sand-banks which may occur in the fair way of the navigation, and to mark the entrances of ports and harbours; and these objects must be effected in such a manner as that the more important indications should be visible by night as well as by day. Moreover, it is desired to indicate the navigable channel in passes or on shores during the daytime, when accumulations of alluvial matters, or sand-banks thrown up by tidal currents, or when bars at the mouths of rivers, render the navigation difficult or dangerous. The indications of the first class are usually given by light-houses, or by floating lights, visible from great distances; the indications of the second class are given by floating buoys, beacons, poles, or guides fixed in the beds of the channels. In all civilised countries the establishment of these indications is considered to be one of the most essential functions of the public authority; and the safety of commerce depends so greatly upon their perfection, that it is generally thought to be desirable to place them beyond the chances of irregularity attending private operations. Thus in England the Trinity House is charged with the performance of the necessary works for lighting and buoying the coast; in Scotland the Commissioners of the Northern Lights are so charged; and in Ireland the Ballast Board of Dublin has the control of the lights and buoys: all three being under the general superintendence of the Board of Trade. On the Continent, this branch of the public service forms part of the attributions of the minister of public works, and is usually centralised in his hands, in a far more distinct manner than it is in England.

The Trinity House appears to have been originally established in the reign of Henry VII., as an "association for piloting ships;" but it was only in 1680 that the Elder Brethren erected their first lighthouse, after several structures of that description had been built by private individuals under patents from the crown. The very irregular and unsatisfactory manner, and the very heavy charges entailed upon the commercial marine of England, by the unsystematic manner of lighting the coasts thus introduced, gave rise to so strong a spirit of opposition to its continuance, when the navigation of Europe had begun to revive after the peace of 1815, that numerous parliamentary inquiries have recently been made into the duties and functions of the Trinity House, and changes have been introduced in them from time to time. Thus the acts 3 Geo. IV. c. 3, 6 & 7 Will. IV. c. 79, 17 & 18 Vict. c. 104, have gradually led to the extinction of the private rights in light dues, and to the vesting of the whole of the duties of lighting and buoying the coasts in the authorities before described. The Trinity House in the meanwhile has maintained its original composition in all substantial matters; and it discharges at the present day the duties of superintending the pilotage of the English ports, concurrently with those of superintending the lighting and buoying, as well as of distributing the funds arising from certain light and pilotage dues, and from the sale of ballast (for which they have an exclusive patent in the port of London, with the exception of the Charlton pits), to certain charitable purposes specified in their original charter. The Trinity House consists of a master, a deputy master, nineteen acting elder brethren, eleven honorary elder brethren, and an unlimited number of younger brethren; in May, 1859, they numbered 178. The master and the honorary elder brethren have nothing to do with the practical operations of the House, and they are selected, solely on account of the eminence of their social positions, from the ministers of the crown or from amongst the higher aristocracy. The deputy master and the acting elder brethren are in fact self-elected from a list of the properly qualified younger brethren; and the qualifications for this purpose are,—that the candidates shall have attained the rank of commander in her majesty's navy for at least four years previously, or shall have served as master in the merchant service, on foreign voyages, for at least four years. The younger brethren are chosen from members of the royal navy, or from the commercial marine, and are admitted at the pleasure of the court of elder brethren upon the proposition of any one of those elder brothers. It may perhaps be as well to add, that subsequently to 1854 the Trinity House has abandoned its claim to the surplus of the light dues, which it had previously applied to charitable purposes. The act of parliament by means of which this expropriation of funds was effected also conferred upon the Trinity House general powers of supervision over the proceedings of the Commissioners of Northern Lights, and of the Irish Ballast Board, subject to the appellate jurisdiction of the Board of Trade.

The Board of the Trinity House discharges its duties by means of committees, and sub-committees for special purposes, whose proceedings, when necessary, are subject to confirmation by the general court. These committees are—1, the Treasury; 2, the Supervisors of the Ballast Department; 3, the Pilotage; 4, the Pilot Examination Committee; 5, the Lighthouse Committee; 6, the Pensioners; and 7, the House Affairs Committees. With the exception of the supervisors of the Ballasting Department, two in number, all these committees consist of four members; and the sub-committees named for special services may consist of any number of members at the option of the court, usually varying from two to four. The appointments are made annually, and the wardens are also elected annually, two going out every year; the master and the deputy master are usually elected during their lives, though they pass *pro forma* an annual election. The deputy master is *ex officio* chairman of all the committees. In scientific and technical matters the court is assisted by its engineer and an optician, those posts at the present day being occupied by Mr. J. Walker and Dr. Faraday. The members of the Trinity House divide among themselves the annual sum of 7000*l.*, and they employ a staff of clerks, messengers, &c., at their central office at an annual expense of about 6000*l.*; the salaries of the engineer and of the scientific adviser amount to 1700*l.*; so that the total cost of the central administration of the Trinity House is about 14,800*l.* per annum, for salaries, and for all miscellaneous expenses connected with the central board: it was, in 1857, about 17,285*l.* The gross income for the year 1857 was 268,646*l.* nearly, and the gross expenditure 204,013*l.*; for the year 1858 the gross income was 257,214*l.*, and the gross expenditure was 172,285*l.*: the surplus revenue is principally devoted to the extinction of the debt incurred, in pursuance of the act of 1846, for the purchase of the private interests in lighthouses.

The Commissioners for the Northern Lights were incorporated by act 38 Geo. III. c. 58, and they consist of 28 members, amongst whom are the lord advocate, the solicitor-general, the lords provosts and the elder bailies of the cities of Edinburgh and Glasgow, the provosts of Aberdeen, Inverness, Campbeltown, Dundee, and Greenock, and the sheriffs of the maritime counties of Scotland. The business of the commission is transacted in general meetings and in committee meetings; four of the former being held in the year, and of the latter there is usually one in every fortnight. The services of the members are gratuitous; in all technical and scientific matters they act under the advice of their engineers; and they have been fortunate enough to have secured for many years the services of the Messrs. Stevenson, who have done more to advance the science of lighthouse-building than any men since the days of Smeaton. The gross income of the commissioners for the years 1857 and 1858 was respectively 30,581*l.* and 26,865*l.*; whilst the gross expenditure was also respectively 62,204*l.* and 59,747*l.*, all in round numbers: from whence the deficiency was supplied does not distinctly appear in the published documents.

The Ballast Board of Dublin consists of 23 members, who are connected with the commerce of the country, but not necessarily, or even habitually, acquainted with the practical details of seamanship. The lord mayor of Dublin and the high sheriff of the city are annual *ex officio* members of the board. They manage their business by means of committees, thus arranged:—1, Library; 2, Lightship; 3, Inspection; 4, Accounts; 5, Lifeboat; 6, Harbour Bye-Laws; 7, Graving-Dock; 8, East Quay Wall Tax; 9, Pilotage Committees; and, whenever necessary, sub-committees for special purposes are appointed. The services of the members of the board are given gratuitously; the gross incomes for the years 1857 and 1858 being respectively 13,307*l.* and 15,710*l.* and the gross expenditure for the same years 58,768*l.* and 46,658*l.* It does not appear officially from whence the deficiency is supplied; but there can be little reason to doubt but that the money required for this purpose, as in the case of the deficiency of the Commissioners of the Northern Lights, is obtained from the Mercantile Marine Fund.

In addition to the lights and buoys maintained by the above enumerated public authorities, there are many others of perhaps a minor degree of importance, which are under the management of the local authorities, subject to the general control of the Trinity Board. Harbour lights, and the buoying of the entrances to docks, rivers, and navigable inland channels, are usually thus confided to the care of the local authorities interested in the navigation of the particular localities where those protections for shipping are placed.

It appears from the returns of the commissioners for inquiring into the subject of lighthouses, &c., published in 1861, that, at the end of 1859, there were the following numbers of lights, of the various kinds enumerated, around the coasts of Great Britain and Ireland :—

Country.	Lights on Shore.			Floating Lights.	Total.	Coast line in Miles.
	General.	Local.	Total.			
England	82	89	171	41	212	2405
Scotland	46	67	113	1	114	4469
Ireland	69	4	73	5	78	2518
Totals	197	160	357	47	404	9392

The Commissioners, however, observe that the immense number of islands, and deep bays, on the Scottish coast renders it difficult to make any accurate comparison between the efficiency of its mode of lighting, and that of other more regular coasts; but the table they insert of the distances apart of the lights in the United Kingdom and in France, has a considerable degree of interest. It seems that on the English coast there is 1 light on shore for 14 miles; on the Scottish coast, 1 for 39·5 miles; on the Irish coast, 1 for 34·5 miles; and on the French coast, 1 for 12·3 miles. The principle adopted by the French authorities in these matters is, that the lighthouses should be placed at such distances asunder as to allow their lights to cross one another, and to secure this condition with lighthouses of moderate elevation, it would appear to be necessary to adopt the average distance asunder of the French establishments. On a plain, easy shore, without rocks, or dangerous headlands, sunken reefs, or sand-banks, the distance apart, thus quoted, may be exceeded without inconvenience; but on dark nights it is difficult to distinguish a light at more than 15 miles distance, even when it is of the best construction, and at a great elevation above the sea level. In foggy weather, or during the fall of heavy rain, sleet, or snow, the range of visibility is, of course, considerably reduced. It is to be observed that if the English floating-lights be taken into account the distance asunder of the English lights does not exceed 11·37 miles.

The height to be given to a lighthouse must depend upon the distance to which its influence is required to extend. In order to keep the source of light on the level of the geometrical horizon at a distance of thirty miles, Mr. Airy says that a lighthouse ought to be 594 feet high, though the Cape St. Vincent light of 221 feet high, is stated in the report of the commissioners to be visible at that distance. It is seldom, however, that any necessity exists for so wide a range, and when light is diffused over so large an area, it can hardly be brilliant in any part thereof, unless at an immense cost. As a general rule, the horizon to be lighted is limited to about 15 or 20 miles, and the height of the lighthouses in such cases need not exceed from 110 to 220 feet above the sea level; as will be seen by an inspection of the table of lighthouses appended. The Eddystone lighthouse, which is built upon a solitary rock in the fairway of the British Channel, has a range of only nine miles, and the centre of the light is not more than 90 feet above low water line. In fact, the cost of erecting towers of this description in exposed situations is so great, that it is important to keep their height within the limits of the strict necessities of the respective localities. The average cost of a tower of about 110 or 120 feet high on the main land, or on rocky islands of comparatively easy access, is about from 4000*l.* to 10,000*l.*, including the illuminating apparatus; the cost of the more exposed towers is far greater, and some idea may be formed of the difficult and tedious nature of the works they involve from the outlay to which they give rise. Thus the Bell Rock lighthouse, on the east coast of Scotland, 117 feet high, cost 61,332*l.*, nearly; the Skerry Vore, on the west coast of Scotland, 158 feet high, cost 83,127*l.*; the Bishop's Rock, in the Scilly Isles, 145 feet high, cost 36,560*l.*; and the Phare de Bréhat, on the north-west coast of France, cost 38,800*l.*; but in this instance the expense of the engineer and the superintendents, and the cost of conveyance of materials, were not included. M. Reynaud, the engineer of this last-named tower, it may be added, dispensed with much of the complication of the joints of the courses of masonry introduced by Smeaton, and previously followed by other engineers; and he was thus enabled, not only to effect a considerable economy in the first outlay, but also to construct his tower more rapidly than his predecessors had done.

The floating lights are, as their name implies, fixed in vessels moored over or near to the danger it is desired to warn mariners to avoid. They are usually fixed at a height of from 20 to 45 feet above the sea level; and from that reason, as well as from the difficulty of introducing the best source of light (on account of the pitching and rolling of the ship in heavy seas), their range of visibility is not large. Practical authorities are still divided in opinion as to the best form of light vessels, and to the manner of mooring them; many persons, however, agree in recommending the adoption of a vessel built upon the principles of Herbert's circular buoys, moored from a central chain attached below the centre of gravity of the mass. Generally speaking, the light-vessels on the English shores are provided with gongs, which are sounded in foggy weather. The first cost of these vessels is, on the average, between 4000*l.* and 5000*l.*

Harbour lights are of every description, according to the importance of the harbour, and to the dangers of the navigable channel leading to it; sometimes they are exhibited from a small tower, sometimes from ordinary gas or oil lamps. It is rarely that the most expensive of these structures exceeds the cost of 400*l.* or 500*l.*; and the range of their illuminating powers is usually limited to two or three miles.

The sources of light used are of several descriptions. In the large shore lights, mechanical lamps with three concentric wicks, or pump lamps, with four concentric wicks, and argand burners, are used; in floating-lights, the argand burners are alone used. The rays are concentrated and directed as may be required, either by means of *dioptric* lenses, by *catoptric* reflectors, or by a mixture of the two systems in the *cato-dioptric* apparatus; Mr. Thomas Stevenson has also introduced an apparatus he calls the *holophotal* one, which is in fact, nothing but a modification of the cato-dioptric light. In France, the dioptric lights are exclusively used: in England both the dioptric and the catoptric lights are used for the great land-towers, whilst the catoptric lights are exclusively used for floating-lights; and the harbour lights are usually made upon the holophotal system in the more important ports. Mariners are divided in their opinions as to the relative merits of these systems; but the tendency of opinion amongst scientific opticians is decidedly in favour of the dioptric one, with a central pump lamp of four concentric wicks. As to the distribution of the light, it may be either *fixed*, or *by flashes*, or *by intervals*, or again, it may be *white* or *coloured*, though the loss of light by the passage through a colouring medium constitutes a serious objection to the adoption of that system. In all cases where the light is not required in any particular direction, it is advisable to prevent its passage, and to reflect the rays, which would otherwise be dispersed, in the direction to be illuminated. Floating-lights, however, are very frequently made to show a red light; and there seem to be reasons for believing that it would be desirable to confine that colour to them, in order to distinguish the land from the floating lights; in which case it would perhaps be also desirable to make the harbour lights green, the essential condition being that no confusion should occur between contiguous lights. In the table given in col. 374 the description of the apparatus used in the various lighthouses is given, wherever it can be ascertained from published documents; and it may here suffice to refer the student who would investigate their respective merits to the Reports of the Commissions of 1846 and 1858; to a recently published reply to the second of these reports, under the title of 'Lighthouse Management;' and to Alan Stevenson's 'Elementary Treatise on Lighthouses.' The distances at which the several lights are stated as being visible, are, it must be observed, affected by the quality and character of the light, the height of the observer above the level of the sea, and the atmospheric refraction.

It may be added, that the cost of a large source of light, on either the dioptric, or the catoptric systems, is usually about 2000*l.*; and that the annual expense of maintenance, including oil, wicks, salaries, repairs of buildings, and of apparatus, ranges between 300*l.* and 400*l.* for a dioptric light, and between 350*l.* and 400*l.* for a catoptric light: the cost of maintaining a floating-light varies between 1200*l.* and 1300*l.* per annum, the crew consisting of a master, mate, two lamplighters, and seven seamen, of whom one-third are on shore at a time.
